SEROUS HEPATOSIS: A PATHOGENESIS OF HEPATIC FIBROSIS IN JAMAICAN CHILDREN

PRELIMINARY REPORT*

BY

K. R. HILL, M.D. KATERINA RHODES,† M.B., Ch.B.

J. L. STAFFORD, M.B., Ch.B. AND R. AUB,† M.D.
(Department of Pathology, University College of the West Indies)

[WITH SPECIAL PLATE]

The object of this communication is to report upon a disease of the liver found in Jamaican children ; because of its clinico-pathological features we have proposed the term "serous hepatitis" (Hill, 1951 ; Hill *et al.*, 1951).

In all, 150 cases have been investigated. On clinical analysis it is apparent that they can be classified as conforming to certain different types which are, however, different phases of the same disease with the same underlying pathology. Histologically, this condition resembles that described by Roessle (1930) as "serous hepatitis," or that described by Keschner and Klemperer (1936) as "hepatic oedema."

Three methods of approach were used in the study of these Jamaican children. First, a dietary survey was made ; secondly, all children were subjected to a complete examination in which were included certain biochemical tests for liver function ; and, thirdly, needle-biopsy examination was carried out on approximately 50% of cases, from some of which serial biopsies were taken.

Dietary Survey

This has been previously described by Rhodes (1951). The common background of all these children was a poor dietary history starting in early infancy. Most of them were of good average weight when born, and they were breast-fed for a period varying from four to nine months. In Jamaica, however, complete breast-feeding is stopped early and complementary feeding adopted. This means that the baby receives breast milk about twice during the night, and during the day is fed on cereals such as cornmeal, or rolled oats with or without a little condensed milk.

From the neonatal period, except in a few cases, the babies are given "bush tea," which is an infusion of leaves, flowers, or seeds of various plants. When the babies are weaned they are put on a cornmeal diet, although rolled oats and Robinson's patent barley are also used. The diet is monotonous in the extreme, and one of these highly refined cereals is given meal after meal for months and years on end.

*Submitted in December, 1951.

†In receipt of research grants from the Josiah Macy Jr. Foundation.

For economic reasons, and also because of its poor keeping qualities in the Tropics, cows' milk is seldom used, and little, if any, meat, fish, and eggs is eaten. Often the children are given diluted condensed milk, one to two tins a week being shared by the whole family. Children 4 to 5 years and older live on root vegetables such as yams and sweet potatoes and, in addition, cornmeal and rice.

The dietary history as presented above implies a very low protein intake, particularly low in animal or so-called first-class protein, but an adequate calorie intake. Only a few cases of this series (7%) had a very low calorie intake in addition to a low protein consumption, and these, as shown later, presented a modified clinico-pathological picture.

Clinical Findings

The children were between the ages of 4 months and 16 years, the majority being from 1 to 3 years old. Nearly all were from poor homes, and the remainder came from lower middle-class homes in which the standard of intelligence or the knowledge of what comprises a nutritious diet is low ; possibly associated with this is the fact that the familial incidence of the disease is high. The children are predominantly of African extraction, with European, East Indian, and Chinese racial admixtures.

On examination about one-third of the cases were in the acute phase of the disease. About a half of these cases gave a recent history of acute illness such as tonsillitis, whooping-cough, and pneumonia before the onset of gross abdominal enlargement due to ascites and hepatomegaly. The acute illness usually preceded, or sometimes was concurrent with, the liver enlargement. These children were usually normal in physique, and in two or three weeks they recovered from the acute hepatic involvement, though often they had a residual asymptomatic enlargement of the liver. Liver-function tests showed an absolute rise in serum globulin with a reversed albumin/globulin ratio and a lowered serum cholinesterase. Recovery from the acute liver enlargement occurred whether or not treatment was given for this condition.

The other half of the patients in the acute phase had no previous history of infection so far as could be elicited. They had ascites and an enlarged firm liver. The liver-function tests generally showed a lowered serum albumin, often with a low total protein and also a low serum cholinesterase. On a high-protein diet it was two to three months

before they improved from the acute phase. A few apparently recovered completely, but frequently they tended to lapse into the subacute or chronic phase.

All the children in the series were very ill and fretful. The liver was hard, with a smooth outline and a sharp lower edge, and both the left and the right lobes were enlarged. Sometimes the liver was bulging and tender on pressure as if under tension. Occasionally the enlargement was great, up to 12 cm. below the costal margin; a varying degree of ascites was present, and on first paracentesis the protein content was sometimes as high as 2.1 to 2.8%. On subsequent tapping the protein content decreased.

Signs of vitamin deficiency were rare. The appearance of these children was in striking contrast to the usual picture of subnutrition found in the Tropics (Waterlow, 1951).

About one-third of the series were found to be in the subacute stage when first examined. They usually looked well developed, with rounded contours and adequate subcutaneous fat, although on closer examination some had flabby muscles, some were stunted, and many were underweight. The liver was often slightly or moderately enlarged and there was little or no ascites. Liver-function tests generally showed lowered serum albumin and serum cholinesterase. The results of the flocculation tests were not significant. Jaundice was absent, although not infrequently the total serum bilirubin was slightly raised. Many of these subacute cases were, however, asymptomatic, and were found only on routine examination at schools or on investigation of brothers and sisters of affected children. There was no complaint, and the child was usually happy and looked well, had no ascites, but had an enlarged liver. In a recent survey (not connected with this study) of 116 children from two villages, 55% were found to have symptomless liver enlargement.

About one-third of the series were seen in the chronic phase of the disease. They were usually older children with a long medical history. The picture was one of hepatic fibrosis with a large, nodular, or contracted liver, with sometimes an enlarged spleen and clubbing of the fingers and toes, an established collateral circulation, and occasionally jaundice. These children were retarded and of poor nutrition. Two cases have been followed from the subacute stage to the chronic stage over a period of a year.

Eleven cases in the whole series were starved babies with generalized oedema, loss of subcutaneous fat, and signs of vitamin deficiency such as angular stomatitis, depigmentation of the hair, and various dermatoses which have been described in the literature many times as part of the syndrome of kwashiorkor or fatty liver disease. These babies were on a low-calorie diet, and the usual history was loss of appetite for one to three months and subsequent feeding on sweetened "bush tea" as a home remedy. Oedema was always present and not necessarily associated with ascites, the oedema being presumably a starvation phenomenon. These cases had a high mortality, whilst in all the other cases the mortality was low, with a high and prolonged morbidity.

No case in the series showed severe anaemia, but some degree of slight or moderate iron-deficiency anaemia was often seen. Bleeding and coagulation times were normal. Sickling trait was found in 7% of the cases and 11% showed infection with *Ancylostoma duodenale*, *Trichuris trichiura*, or *Ascaris lumbricoides*. Malaria parasites in the blood were demonstrated in three cases.

Histology

Liver-needle biopsies were performed on 75 out of the 150 cases studied; in many cases serial biopsies were obtained. Specimens were fixed in various agents from time to time—for example, formalin, corrosive sublimate, alcohol, and Zenker's solution—but for the majority formal-sublimate solution was found to be the most suitable. Up to 80 serial sections of blocks were cut and sections were

stained routinely with H. and E., periodic acid Schiff (P.A.S.), picro-Mallory connective-tissue stain, and Foote-Wilder reticulin stain; special stains for amyloid, fibrin, glycogen, haemoglobin, and fat were done when indicated.

In 25% of cases an early exudative or transudative lesion was found; this consisted of out-pouring of serous fluid into the perisinusoidal spaces of Disse and around the centrilobular veins (Special Plate, Figs. 1, 2, and 3). In some cases the lesion occupied almost the whole of the liver biopsy section under examination, but in most cases the lesion was focal and multiple, each lesion involving up to one or two lobules. The unaffected liver tissue seemed to be quite healthy, but the liver-cell columns at the site of the actual lesions appeared to be flattened. Whether or not they were in fact compressed or whether they were atrophied or shrunken it is impossible to say at the present stage of this investigation. The Kupffer cells and other endothelial cells often seemed to be swollen, increased in number, and detached.

Generally in the liver sections the sinusoids were dilated and filled with blood; alternatively, the sinusoids were wide open and empty, but this was thought to be artifact due to draining out of the blood at the time of biopsy. In about 15% of cases there were focal areas of fresh haemorrhage at the sites of recent serous exudation. This haemorrhage was thought to be due to trauma at the time of biopsy of unduly fragile and congested capillaries; no focus of old haemorrhage was found, no iron-containing brown pigment or macrophagic reaction was ever observed to suggest haemorrhage as part of the disease process, and in only one or two cases was the haemorrhagic artifact found in serial biopsy after treatment.

In 80% of cases deposition of an eosinophilic coagulum was found in the spaces of Disse (Figs. 3, 4, 5, and 6) and "cuffing" the centrilobular veins. This was associated in about one-third of these cases with oedema of the space of Disse mentioned above, as if the coagulum had been precipitated out of the serous fluid or perhaps the fluid, a sol, had become a gel.

At this stage the study of the chemical nature of the serous fluid has not been established, although we are of the opinion that it is probably initially exudative in character; accordingly the term "exudate" will be used in this context.

Sometimes the serous exudate alternated with the coagulum around the centrilobular veins, giving the lesions a laminated appearance; this was interpreted as indicating repeated attacks of liver disease. Although, however, in about two-thirds of the cases the eosinophilic coagulum was found alone, it was probably secondary to the serous exudation.

The eosinophilic coagulum gave the tinctorial reactions of collagen, and was not digested by trypsin. In appearance it varied from a granular amorphous coagulum to waxy-looking blobs of material; on occasion it had a fibrillary appearance although almost acellular—that is, there were no fibroblasts (Fig. 3). Tinctorially it was not amyloid, paramyloid, or atypical amyloid (Teilum, 1948), or fibrin or haemoglobin; it was not birefringent with Congo-red stain and not metachromatic with toluidine blue.

Reticulin stains (Figs. 7 and 11) revealed a perisinusoidal reticulosis which showed swollen reticulin fibres in the perisinusoidal spaces (at the site of the coagulum), with condensation and possible proliferation, although this latter may be illusory. In places where the coagulum was abundant it could be seen as laminated yellow-coloured blobs adherent to black swollen reticulin fibres (Fig. 6).

In 50% of cases there was distension of the space of Mall in the portal triads by serous exudation (Fig. 8), and in some of these cases there was evidence of a recent deposition of eosinophilic coagulum within the exudate. Often there appeared to be a dilatation of the perivascular and periductal lymphatics.

The coagulum extended from the space of Mall, surrounding the intralobular and interlobular vessels arising from the vessels of the portal triads (Fig. 9).

In 75% of the cases fibrosis of the eosinophilic coagulum was seen. The youngest patient was aged 4 months. Fibroblasts could be seen invading the coagulum around the centrilobular vein and along the spaces of Disse (Fig. 10). In the former there were bands of perivascular fibrosis extending from lobule to lobule (reversed lobulation); in the latter there was perisinusoidal fibrosis distorting the lobule in all directions, and in some cases a vascular short-circuit was produced from portal triad to centrilobular vein. The fibrosis of the coagulum around the intralobular vessels contributed to the further intralobular distortion, whilst the fibrosis of the interlobular vessels produced the appearance of perilobular cirrhosis (Fig. 11).

Of the cases 30% showed extreme fibrosis with distortion, bile-duct proliferation, and nodular hyperplasia, an appearance generally associated with cirrhosis (Figs. 12 and 13).

In general, liver-cell damage was not observed except in cases with marked fibrosis; although at this stage of the investigation special histochemical stains have not been done. The liver cells were often slightly swollen or hydropic in appearance; generally, but not invariably, this was shown to be due to a high glycogen content. In five cases there was fatty metamorphosis, but in three cases this was associated with recent or old-standing serous exudation or deposition of eosinophilic coagulum. Cellular infiltration of portal triads was slight, and was associated with fibroblastic invasion of the eosinophilic coagulum; it was never observed to such an extent as to suggest infective hepatitis.

In summary, the histological picture appeared to show a train of events beginning with serous exudation followed by the deposition of an eosinophilic coagulum which was subsequently invaded by fibroblasts. Often the three processes were taking place concurrently in the same biopsy block of liver tissue but not necessarily at the same site. The end-result was extensive hepatic fibrosis.

A Pathogenesis of Hepatic Fibrosis: A Theory

The structure of the liver lobule is probably similar to that described by Elias (1949a, 1949b). Fig. A, I is a diagrammatic representation of part of a liver lobule (the centrilobular vein, sinusoid, liver cells, and the portal triad). The sinusoid lies in a lacuna which is lined by the liver cells making up the hepatic laminae (hepatic cell columns). The lacunar space between the hepatic laminae and the sinusoid is the perisinusoidal space of Disse. The hepatic laminae are continuous interconnecting sheets of cells and the lacunar spaces formed by them are also interconnecting to form a labyrinth. The capsule of the portal triad is circumscribed by a potential space—the space of Mall—which connects with the space of Disse. Branches of the portal vessels are the interlobular and intralobular vessels. These all pass through the space of Mall to enter the parenchyma, and in so doing carry with them an enveloping potential space which connects with the space of Mall. Structurally the spaces of Mall and Disse may well be a part of the "lymphatic" drainage of the liver.

The first stage of the pathogenesis of hepatic fibrosis is serous exudation into the space of Disse and around the centrilobular vein (Fig. A, II). Subsequently there is a deposition of eosinophilic coagulum in these areas (Fig. A, III).

Serous exudate and coagulum may be deposited in many areas as a result of repeated attacks; the lesions are focal and circumscribed. At the site of an initial lesion the serous exudation spreads out in all planes as the different lacunae interconnect to make up the hepatic labyrinth. The confinement of the exudation to focal areas may be due to the deposition of eosinophilic coagulum restricting the further spread of serous fluid. Thus any newly formed serous exudate will be prevented from flowing in the direction of the centrilobular vein or laterally into adjoining

FIG. A.—Diagram showing the various stages of the pathogenesis of hepatic fibrosis. (I) Normal liver lobule with hepatic lacuna between the hepatic laminae; within the lacuna lies the centrilobular vein and sinusoid; the portal triad is shown with peripheral space of Mall which connects with the perisinusoidal space of Disse (lacuna). (II) Serous exudation in perisinusoidal space of Disse. (III) Deposition of coagulum around centrilobular vein and also within the space of Disse. (IV) Distension of space of Mall, following further serous exudation subsequent to the deposition of coagulum. (V) Deposition of coagulum from the serous exudate present in the space of Mall and in the sheaths of the intralobular and interlobular vessels. (VI) Late stage of deposition of coagulum which becomes fibrosed by the invasion of fibroblasts.

lacunae, but rather will be directed into what is probably the natural flow of the liver-tissue fluid, in the direction of the space of Mall in the portal triad. The space of Mall will thus become distended with serous exudate (Fig. A, IV). Subsequently, an eosinophilic coagulum will be deposited around the portal triad and also along the sheath-like spaces enveloping the intralobular and interlobular vessels (Fig. A, V). The sheaths are extensions of the space of Mall.

The next stage is the invasion of the coagulum by fibroblasts; thus there is established a fibrotic cuffing of the centrilobular vein and an intralobular extension of fibrous bands along the space of Disse. At the same time fibroblastic proliferation from the periphery of the portal triads spreads along the interlobular and intralobular vessels (Fig. A, VI).

Subsequent contraction of this fibrous tissue causes lobular distortion and disorganization, which, together with reactive nodular hyperplasia, produce the final picture of diffuse hepatic fibrosis.

Discussion

The series of cases under study illustrate a development of gross hepatic fibrosis beginning as a serous exudation (or oedema), followed by deposition of an eosinophilic coagulum, followed in turn by invasion by fibroblasts.

One outstanding feature of the study was the finding of a serous exudate or transudate and coagulum in the perisinusoidal spaces of Disse and around the centrilobular vein. The source of the serous fluid is, at this moment, undetermined; there are three possibilities: (1) from the sinusoid through the capillary wall; (2) from the liver cells; and (3) from blockage of the normal tissue-fluid drainage—that is, "hepatic lymph" in the spaces of Disse and Mall.

Increase of capillary permeability in the liver due to toxic causes, resulting in serous exudation, is not a new

concept. Roessle (1907, 1930, 1933, 1943) was of the opinion that the escape of serum from damaged capillaries is in the acute stage a serous inflammation. The acute serous inflammation may be followed by a sclerosing lesion; thus the initial stage of cirrhosis is a "serous hepatitis."

This point of view was further elaborated by Eppinger *et al.* (1935), who extended their studies on the escape of serum from capillaries in shock to the general concept of serous inflammation. Eppinger (1949) has lately referred to this condition as "albuminuria into the tissues."

Keschner and Klemperer (1936) have described findings similar to those of Roessle in the perisinusoidal space in 15% of a large series of necropsies; although not agreeing with all Roessle's conclusions, and while preferring the term "hepatic edema" to "serous hepatitis," they concluded that in many cases the hepatic oedema is primarily from toxic causes. They base their conclusion on the association of hepatic oedema with diabetic coma, uraemia, exophthalmic goitre, and thermal burns.

As far back as 1909, Helly had observed the focal flecking of the liver in sepsis, and Keschner and Klemperer (1936) were of the opinion that this was focal hepatic oedema due to generalized toxæmia.

It is interesting to note that Popper (1936b) mentions that Henschen regarded hepatic oedema as a kind of "glaucoma of the liver," and he relieved it in practice by an operation in which he injured the liver surface, thus facilitating the escape of oedematous fluid, with immediate decrease in the size of the liver. Biopsy specimens taken from such a liver with oedema visibly shrank within a few minutes of the operation.

Serous hepatitis has been produced experimentally in dogs by Popper (1936a, 1937), using allyl formate. The lesions produced were similar to those found in serous hepatitis in humans, although there was no certainty in production of the lesions. It would be interesting to note whether the lesions could be produced with 100% certainty if the animals were on low protein diet. Furthermore, the lesions of serous hepatitis have also been produced experimentally by Eppinger and Leuchtenberger (1932) by the intravenous injection of histamine.

Another cause of the escape of serous fluid from the capillaries may be congestion, which probably acts by a hydromechanical effect and/or by increasing capillary permeability due to anoxia. Popper (1948) has reported the agonal changes in human livers following acute heart failure, drowning, and suffocation, in which there is a dilatation of the perisinusoidal spaces usually associated with accumulation of "albuminoid" material. In a series of cases of instantaneous death no such dilatation of the perisinusoidal spaces was seen. Keschner and Klemperer (1936) record a similar finding in 36% of cases after cardiac failure and describe it as a "mechanical oedema." They were of the opinion that the term "serous hepatitis" for such conditions was inappropriate; after all, if the agonal changes are due only to congestion, the so-called exudate is in fact "transudate."

We have in our laboratory a section from a patient dying from acute right-sided heart failure which shows an eosinophilic coagulum around the centrilobular vein. The fact that these changes can occur agonally in acute right-sided heart failure, whether they be from exudates or transudates, none the less supports the theory that the material in the perisinusoidal spaces occurring in the series of biopsies under study may be derived from vascular sources.

Many of our sections show hepatic congestion—so much so that some of the sinusoids are grossly distended and filled with blood or, alternatively, probably owing to artifact, are wide open and empty. This latter condition was described by Roessle (1930). Further, in 15% of our cases there was fresh haemorrhage, interpreted as being due to capillary fragility, associated with trauma at the time of the biopsy. Our reason for this opinion was that we never at any time saw evidence of old haemorrhage such as iron-

containing brown pigment or a macrophagic reaction; further, in only one or two cases, after treatment on a high-protein diet, did we obtain such an artifact, our assumption being that treatment had corrected the abnormal fragility of the capillary wall.

Cardiac failure was not the cause of liver (sinusoidal) congestion in our series of cases. Of the criteria for heart failure laid down by Sherlock (1951), such as crepitations of the lung bases, increased jugular pressure, peripheral oedema, and hepatic tenderness, only the last-mentioned was found clinically; histologically no centrilobular necrosis with graded histological change towards the periphery was found.

Maegraith *et al.* (1949, 1951) have shown that hepatic congestion can be produced in animals by hypersensitivity: this congestion is probably due to constriction within the hepatic venous tree. Essex and Thomas (1950) state that they have produced occlusive spasm of the hepatic veins in dogs and cats following intravenous injection of an extract of *Ascaris suis*, hydatid cyst fluid, and histamine.

Another source of the exudate may be from the liver cells themselves. This view has been put forward by Egér (1950), who suggests that there is a release of fluid from the liver cells into the space of Disse, with subsequent retraction of the liver cells. This gains a little support from the present study by the fact that in the foci of exudation the cells sometimes look flattened as though retracted; however, the cells are often swollen with glycogen or are hydropic, changes which are against the opening of the tissue spaces by the mechanical means of retraction.

Further, it is stated by Selye (1950) that the liver parenchymal cells in such conditions of serous inflammation imbibe serum from the tissue spaces with a rise in their sodium chloride, calcium, and water content, and a decrease in their phosphate and potassium content; this imbibition is a possible explanation of the hydropic appearance of liver cells in some of our cases.

The flattened appearance of the cells may be due to atrophy, but, in general, we have observed it only during the acute phase of serous exudation at the site of the exudation; further proof of this theory that the liver cell is the primary site of the liver lesion must await further investigation along the lines of histochemistry and cell and nuclear counts.

Dilatation of the space of Disse may be caused by blockage of the normal tissue-fluid drainage channels of the liver. Popper (1936b) describes the following morphological triad in serous hepatitis: (a) dilatation of the perisinusoidal space of Disse; (b) oedema of the portal canals; and (c) gall-bladder-bed oedema. In cases under study, dilatation of the perivascular and periductal (bile) lymphatics has been noted in association with the distension of the space of Mall. This, of course, as well as suggesting a block in the lymph drainage, may also indicate an increased production of the tissue fluid.

It is interesting to speculate at this stage whether or not the exudate in the perisinusoidal space flows into the perivascular lymphatics of the portal triads and then finally, as a back-pressure effect, into the peritoneal cavity to produce ascites. It is noteworthy that the ascitic fluid on first paracentesis has often a high protein content (2.1 to 2.8 g.%). Gray (1951) has indicated that the source of the ascitic fluid is an excess of hepatic lymph. The hepatic sinusoids are said to be unusually permeable to albumin both in experimental animals (McKee *et al.*, 1949) and in man (Patek *et al.*, 1948).

Experimentally, support for the theory of the drainage of tissue fluid from the perisinusoidal spaces into the lymphatics of the portal triad is given by the work of Koch-Weser (Popper, 1951), who ligated the common bile duct near the liver in rats and produced lesions resembling serous hepatitis. Several authors, including Bollman (1950) have stated that the bile ducts are surrounded by a plexus

of vessels in which the lymphatics are included. Hence ligation of the common duct will exert a block, producing back-pressure distension of the space of Disse.

In the cases under study no evidence of lymph-duct blockage, either inflammatory or mechanical, has been detected, and the evidence points to overproduction of tissue fluid to explain the dilatation of lymph and tissue spaces.

In summary, the evidence available in this preliminary report is that the serous exudation and the coagulum are produced from vascular sources. Whether this is due to an increase in capillary permeability *per se*, or to congestion producing its anoxic and hydromechanical effects, it is impossible to say at this stage of the investigation.

The possibility that toxic factors are a cause of the increase in capillary permeability *per se* has some support. It is significant that the left lobe appears to be enlarged as much as the right. This lobe may drain the blood of the large gut, and if the latter is a source of bacterial or other toxins then the involvement of the left lobe may be thus explained.

It is to be noted that McFarlane and Branday (1945) and Royes (1948), in their articles on liver disease of Jamaican children, suggest toxins in association with low-protein diet as the aetiological agents. The possible toxicity of the various Jamaican "bush teas" is now being investigated. Further, Watson (1951) has pointed out the efficacy of aureomycin and also of enemata on patients suffering from hepatic coma, and he suggests that the action may be to reduce the toxicity by altering the bacterial flora of the gut.

One constant feature is that the serous exudate and the coagulum are never associated with a cellular infiltrate, which is the usual accompaniment of inflammation. However, according to Selye (1950), the emigration of leucocytes can be inhibited by systemic intoxication with bacterial endotoxins and by anaphylactoid, traumatic, and "toxic" shock.

Increased capillary permeability producing hepatic oedema was found by Keschner and Klemperer (1936) in association with asthma; it has also been produced by Eppinger and Leuchtenberger (1932) by the intravenous injection of histamine. These examples would point to the circulation of a toxic histamine-like substance, and may well suggest further experimental work on the lines of hypersensitivity. It is to be noted that two of our cases with primary tuberculous lesions showed acute hepatic enlargement immediately after the tuberculin test, which, as was expected, was positive. Biopsy of the cases showed the histological picture which we have found associated with acute serous hepatitis.

Whatever the source of the exudate, the fact remains that an exudate and/or coagulum are constantly found, and the question may be asked, "What is the coagulum?" The coagulum gives all the tinctorial reactions of collagen and is not digested by trypsin. Is it in fact collagen, or a precursor of collagen? In many cases the coagulum has the waxy appearance of amyloid with H. and E. stain, and in some cases it has a fibrillary appearance although acellular. Reticulin staining shows the reticulin fibres black and swollen, and adherent to them are blobs of laminated material staining yellow. These blobs are in fact the coagulum. Are they blobs of protein from the serous exudate forming on the side of the swollen reticulin fibres or are they swollen reticulin fibres which are blowing up to bursting point at various places along their lengths owing to imbibition of serous fluid?

The fact that the coagulum is acellular does not preclude the possibility of its being collagen or pre-collagen protein material. Porter and Vanamee (1949) have shown in tissue culture, by studies using the electron microscope, that unit fibrils may combine to form protofibrils of collagen without the intermediary of fibroblasts. Further, Porter (1951), in an extension of these studies, has shown that after being shed from the fibroblasts the collagen fibrils increase in

size by the accretion of a material from the ground substance. This method of accretion may explain the deposition of protein of serous origin on pre-existing connective-tissue fibres in the liver of the cases under study. The possibility of collagen-fibre formation by precipitation in a protein-rich exudate has also been advanced by Klemperer (1951), and Day and Armstrong (1940) have commented on the curious absence of fibroblastic activity in the genesis of cardiac cirrhosis.

Roessle (1930) explains the sclerosis following serous hepatitis due to the intermediation of endothelial proliferation. The endothelial cells (including the Kupffer cells) increase in number and become detached to form a connective-tissue reticulum—"the endothelialite." In the present study some endothelial swelling and proliferation have been noted, and the few cells seen in the perisinusoidal spaces are often endothelial or Kupffer-cell types.

The coagulum, whatever its derivation, is a precursor of fibrosis. Sections have been studied which show what is interpreted to be the fibroblastic invasion of the coagulum—that is, the coagulum is there first and at a later stage it is invaded by fibroblasts. It is tempting at this stage, therefore, to consider the coagulum as collagen protein or pre-collagen and the process of the laying down of the eosinophilic coagulum as a "collagenosis."

So far, the aetiology of the process of events occurring in the liver has not been determined. One salient fact elucidated has been the woefully deficient protein in the diets; this deficiency was not only in total protein but also in first-class protein of animal origin. It is not known whether the lack of single or multiple amino-acids, or the disproportion of protein to carbohydrates, or perhaps a combination of these factors, contributes to the development of liver disease. At this stage it is pertinent to mention that the cases of serous hepatitis differ, both clinically and histologically from those cases of subnutrition with fatty liver disease in the Tropics described as kwashiorkor (Williams, 1933; Trowell, 1949; Davies, 1950; Waterlow, 1951).

It is true that about 7% of the cases conform to the classical description of kwashiorkor. It is of interest that these cases were on a low-calorie as well as a low-protein diet, in contradistinction to the main type of case, which had a low protein but normal calorie intake. Notwithstanding the clinical appearance of starvation and fatty metamorphosis of the liver, evidence of an underlying pathological condition similar to the main group of the cases was found. It is tempting, therefore, to assume that the fatty metamorphosis in these few cases was a side-effect to starvation—that is, deficient calories in the diet.

Mottram (1909) drew attention to the fact that fatty metamorphosis of the liver may be encountered in some cases of starvation, a feature now well recognized in severe deficiency states. Dible (1951) suggests that in such cases the liver cells receive more fat than they are capable of dealing with, and he strongly asserts that there is little evidence that fatty metamorphosis is a precursor of human cirrhosis, as, for example, accepted by Moschowitz (1948), pointing out that the dietary evidence from experimental work cannot be directly applied to man. Hartz (1949) has described a fatty metamorphosis occurring in children in Curaçao which he claims never goes on to cirrhosis.

Liver-cell damage has been noted (using the usual routine staining methods) only in association with marked hepatic fibrosis. Further study is needed to decide whether or not liver-cell damage is an important feature of the disease under investigation. The results of liver-function tests are, except for a persistent lowered serum albumin and serum cholinesterase, equivocal, and do not conform to any set pattern. None the less, functionally the liver cells would be expected to be defective because the exudate and coagulum in the perisinusoidal spaces (haematoparenchymal barrier) must impair the diffusion of nutrients from the blood stream to the cells. Further, the removal of waste products from the cells to the capillaries will also be

impaired, and therefore local intoxication and malnutrition of the parenchymal elements must follow the initial stage of disturbed capillary permeability. This has been pointed out by Eppinger *et al.* (1935), as well as the fact that excessive amounts of serum proteins in the perisinusoidal spaces may well lead to the invasion of the parenchymal cells by serum proteins and by serum enzymes, resulting in damage to the cell (Böck and Popper, 1937).

The final picture of serous hepatitis is diffuse hepatic fibrosis. This has been arrived at by a slowly progressive fibrosis, intralobular and also perilobular in distribution, which occurs in the coagulum deposited in these positions. A theory has been postulated which attempts to explain the pathogenesis of this fibrosis.

Serous hepatitis, then, may well be one of the causes of polylobular cirrhosis, which Dible (1951) refers to as "cryptogenic."

Summary

A liver disease occurring in Jamaican children has been described; because of its clinico-pathological aspects it has been named "serous hepatitis." To date the only aetiological factor which has been ascertained is a low dietary protein intake. It is suggested that toxic factors may also play a part.

Clinically, the condition occurs in children, usually between the ages of 1 and 3 years, who have an enlarged firm liver and ascites; ultimately the appearance may be one of classical hepatic cirrhosis.

Histologically, the disease is a progressive one, passing from an initial exudation or oedema to the deposition of an eosinophilic coagulum which is finally invaded by fibroblasts.

The condition is similar to that described by Roessle (1930) as "serous hepatitis."

A theory of the pathogenesis of liver fibrosis has been postulated.

TREATMENT AND PROGNOSIS OF ACUTE PERFORATED PEPTIC ULCER

BY

F. AVERY JONES, M.D., F.R.C.P.*

Physician in Charge of Gastro-enterological Department,
Central Middlesex Hospital

AND

R. DOLL, M.D., M.R.C.P.

Associate Physician, Gastro-enterological Department,
Central Middlesex Hospital; Member of the Statistical
Research Unit, Medical Research Council

With the assistance of

KEENA JONES, M.A., and BARBARA WHITE, B.Sc.

During the last decade there has been a striking fall in the fatality of acute perforated peptic ulcer. Whereas before 1942 the operation mortality was commonly 20%, the figure to-day is not more than a quarter of that level. This fall can mainly be attributed to improvements in anaesthesia with the introduction of muscle relaxants and to the use of antibiotics. Deaths from peritonitis in the first week have almost ceased to occur, and fatal cases are now mainly due to concomitant bleeding, intestinal obstruction, and associated diseases. This was demonstrated in the series reported by Avery Jones, Parsons, and White (1950). With the reduction in fatality, interest has been aroused in new methods of management.

Three methods are currently recommended—medical management with gastric aspiration, simple surgical closure, and immediate partial gastrectomy. The choice, in the individual case, must depend on the facilities available, but it will be influenced by knowledge of the immediate and late prognosis in similar cases treated by each method, and it will not necessarily be the same for all patients. It is difficult, on the existing evidence, to assess the relative merits of the three methods, partly because the fatality associated with each method has been rapidly decreasing, and partly because insufficient attention has been paid to the end-results, after the patients have left hospital.

The series reported by Avery Jones, Parsons, and White included 490 patients treated at the Central Middlesex Hospital during 1938–48, the great majority of them by simple surgical closure of the perforation. Since 1948 patients at the hospital have, in the main, continued to be treated by the same method, and the results have been analysed for a further period of three years to see, first, whether the fatality has continued

*With a grant from the Medical Research Council.

to fall; secondly, whether a figure can be obtained for the fatality from surgical closure for comparison with the results obtained by other methods; and, thirdly, whether indications can be defined for the choice of patient to be treated medically with gastric aspiration or by immediate partial gastrectomy.

Immediate Prognosis

Table I shows the number of patients, operated and unoperated, with the corresponding number of deaths each year from 1938 to 1951. Patients diagnosed as having "leaking ulcers" are not included. The table shows that there has been no recognizable change in fatality since the beginning of 1947, when the standard

interest that the sole patient who recovered without operation prior to 1947 was shown radiographically to have a gastric ulcer after recovery from the perforation and died five years later from a slowly growing carcinoma originating in the same part of the stomach.

Surgical Closure of the Perforation

The crude fatality rate is of limited value for comparative purposes, since fatality also depends on a number of factors other than treatment, and these are not always constant. Factors usually considered to influence the fatality of perforated ulcers are the sex and age of the patient, the site of the ulcer, and the duration of the delay between onset and institution of treatment. From the experience of the results in the whole series of surgically treated cases,

TABLE I.—Prevalence and Fatality of Perforated Peptic Ulcers, 1938–51; Operated and Unoperated Cases

Year:	1938	1939	1940	1941	1942	1943	1944	1945	1946	1938–46	1947	1948	1949	1950	1951	1947–51	1938–51
Patients operated on	39	35	32	38	33	44	41	41	46	349	52	54	64	67	83	320	669
No. of deaths	12	8	7	7	11	3	4	5	3	60	3	1	0	3	3	10	70
Patients not operated on*	0	1	0	2	2	3	7	4	7	26	6	3	5	2	4	20	46
No. of deaths	0	1	0	2	2	3	6	4	7	25	5	2	5	2	3	17	42
Total perforations	39	36	32	40	35	47	48	45	53	375	58	57	69	69	87	340	715
No. of deaths	12	9	7	9	13	6	10	9	10	85	8	3	5	5	6	27	112

* Necropsy examinations were performed more frequently in the later years, and it is possible that some fatal perforations were missed in the period 1938–42.

treatment described by Avery Jones, Parsons, and White was adopted. In the five years 1947–51 the total fatality in 340 cases, including those undiagnosed till after death, was 7.9%. The operative mortality in 320 cases was 3.1%. Nineteen patients were treated by immediate partial gastrectomy without a death and 301 were treated by surgical closure of the perforation with 10 deaths, giving a mortality of 3.3%.

Unoperated Cases

Forty-six patients were not operated on. Medical treatment did not include the use of gastric aspiration until after 1946; since then it has been used routinely in cases diagnosed in life. The reasons for which operation was withheld and the results of treatment are given in Table II.

TABLE II

	1938–46		1947–51	
	Cases	Deaths	Cases	Deaths
Perforation undiagnosed	12	12	5	5
Patient too ill	13	12	9	9
Medical treatment preferred	1	1	5	3
Operation refused	—	—	1	0

One diagnostic error was failure to recognize perforation in patients who had recently had a severe haematemesis or melaena; the diagnosis in this group was sometimes particularly difficult because of the presence of peripheral circulatory failure and the lack of abdominal tenderness and rigidity. The double complication was unrecognized in six instances, all during the period 1938–46. Other patients were thought to have coronary thrombosis, mesenteric thrombosis, or carcinoma; others came into hospital unconscious and no diagnosis was made.

The majority of the patients in whom perforation was diagnosed and who were not operated on had peripheral circulatory failure and could not be resuscitated sufficiently for operation; they cannot be used for assessing the results of medical treatment. It is, however, of

it can be shown that differences in the fatality rate in men and women can be adequately explained by the greater proportion of women among patients with gastric perforations and among those in whom operation is delayed more than 12 hours. On the other hand, the age of the patient, the site of the ulcer, and the duration of delay all affected the fatality independently of one another. The results are shown in Table III. The expected numbers of deaths have

TABLE III.—Fatality of Perforated Gastric and Duodenal Ulcers Treated Surgically, 1938–51. Subdivided by Sex and Age of Patient, Site of Ulcer, and Duration of Delay Before Treatment*

Factor Affecting Fatality	No. of Cases	No. of Deaths		Factor Affecting Fatality	No. of Cases	No. of Deaths	
		Obs.	Exp.			Obs.	Exp.
Sex:				Site:			
Male	598	62	62.5	Stomach	122	27	16.4
Female	53	7	6.5	Duodenum	529	42	52.6
Age:				Duration of delay:			
Under 35	146	7	13.1	Less than 6 hr.	370	25	33.6
35–44	155	5	13.6	6–11 hr.	197	15	23.1
45–54	161	19	15.6	12–17 hr.	43	11	7.1
55–64	118	24	16.4	18 hr. and over	41	18	5.2
65 and over	71	14	10.3				

* Eight cases with one death have been omitted because the case records were incomplete, and 10 cases of perforated jejunal ulcer with no deaths have been excluded as being too few for separate analysis.

been calculated by allowing for the effects of all the other factors under consideration. For example, to obtain the expected numbers of deaths in men and in women, the numbers of men and of women with perforations in each age, site, and duration of delay subgroup were multiplied by the fatality rate for persons in that subgroup and the resulting products for each subgroup were added.

The excess mortality from perforated gastric ulcers is striking; it occurred in each age group, but to a significant extent only when the duration of delay was less than six hours (Table IV). The reason for the excess mortality

TABLE IV.—Duration of Delay

Hours:	Less than 6	6–11	12–17	18+
Duodenal perforations:				
Observed deaths	11	9	7	15
Expected	20.5	9.9	7.0	14.2
Gastric perforations:				
Observed deaths	14	6	4	3
Expected	4.5	4.1	4.0	3.8

give much indication of the subsequent course of the disease, but the number of cases in women was small, and it is possible that a sex difference would be revealed by larger numbers. Looked at from the point of view of freedom from symptoms, similar results are obtained. The sex and age of the patient seem to be unimportant, but 32% (12/38) of the patients with histories of one year or less remained symptom-free against 20% (14/71) of those with longer histories, and 30% (20/67) of those who had not had an ulcer diagnosed previously remained symptom-free, against 14% (6/42) of those who had. It can be concluded that symptoms which had lasted for more than a year or which had been severe enough to result in an ulcer having been already diagnosed before the perforation occurred are indications that the course of the ulcer disease will be unsatisfactory if the perforation is treated by simple closure.

Discussion

In recent years immediately good results have been reported with each of the three main methods of treatment; examples are shown in Table XI. The two series

TABLE XI.—Immediate Results of Different Methods of Treatment: Recent Series

Authors	Period of Admission	No. of Cases	No. of Cases Treated by:			General Fatality Rate
			Gastric Aspiration	Surgical Closure	Immediate Partial Gastrectomy	
Taylor (1951)	1946-50	73	72	1	0	9.6%
Heslop, Bullough, and Brun (1952)	1947-51	110	104	6	0	8.2%*
	1946-50	124	20	104	0	9.7%*
Present authors	1947-51	340	20	301	19	7.9%*
Nubser (1951)	1947-50	65	3	0	62	6.2%*
Lowdon (1952)	1951	65	1	13	51	6.2%*

* Including one death from haematemesis a few days after suture of the perforation, excluded from the fatality rate reported by the authors.

reported by Heslop, Bullough, and Brun are of particular interest for comparative purposes, as the patients were treated in neighbouring hospitals. The authors commented that "the two surgical departments of the hospitals concerned are both engaged in general surgery, are roughly the same size, they receive their patients from the same general practitioners of the area, and one of us is the connecting link between the two hospitals in that he is on the staff of both." The separate fatality rates for the groups of patients selected for the different forms of treatment differ greatly—for example, only one death occurred among the 132 patients treated by immediate partial gastrectomy—but the immediate overall fatality rates are strikingly similar.

In these circumstances conclusive evidence of the superiority of one or other method is likely to be obtained only by means of a controlled trial which, because of the low fatality rate now associated with all forms of treatment, would need to be very extensive. In the published reports the low fatality with immediate partial gastrectomy must be partly due to the selection of good-risk cases for operation, just as the high fatality with medically treated cases is often due to the limitation of the method of treatment to patients who are already moribund. We believe, however, that it may be wrong to consider the three possible methods of treatment as rivals; if the maximum immediate and late benefit to the patients is to be achieved, all three may well have a proper place in every series. In our opinion, tentative conclusions about the indications for each method of treatment are justifiable on the basis of the existing evidence. We assess them as follows.

Medical treatment has not been reported to provide a notably better immediate prognosis than the standard surgical treatment; it does not permit patients to be selected for immediate partial gastrectomy after inspection of the ulcer, and there is no reason to suppose that the late prognosis is any better than that achieved by simple surgical closure.

The method is contraindicated in the presence of bleeding or of pyloric stenosis, for a perforation after heavy eating or drinking, and in air-swallowers. Tanner (1951) sums up as follows: "The non-operative treatment demands frequently repeated expert clinical and radiological assessment, and any error in gastric aspiration, any momentary neglect, any lack of skilful observation, may be followed by disaster for the patient. . . . It is only safe in the hands of the enthusiast with ample medical and nursing assistance and is not suitable for routine usage." The method has been shown to be practicable, and is preferable when: (a) efficient surgery is not readily available; (b) other associated diseases—for example, recent coronary thrombosis—greatly increase the risk of surgery; and (c) perforation has occurred at gastroscopy, when the stomach is empty; for experience has shown that the perforation in this last group is often no longer detectable by the time laparotomy is performed.

Immediate partial gastrectomy has been shown to be a practicable method of treatment, compatible with an excellent immediate prognosis. As most ulcers which perforate acutely are on the anterior wall of the duodenum, the operation is technically easier to perform as an emergency for perforation than for bleeding, when the ulcers are often posterior and penetrating. It is the method of choice for a surgeon experienced in the technique when: (a) the perforation is gastric, and, although the ulcer may appear simple, there is in fact a considerable risk that it may hide an unrecognized carcinoma; (b) the patient gives a history of more than one year's dyspepsia and an ulcer has been diagnosed previously (because a high proportion of such patients will require a further operation if treatment is limited to simple closure); or (c) perforation and haemorrhage from an ulcer occur concomitantly.

We do not think it likely that immediate partial gastrectomy will be shown to be the method of choice for all perforations. It is possible that the immediate prognosis may be even better than that with simple closure of the perforations, by eliminating the deaths due to further complications arising from the persistence of the ulcer; but we have little firm knowledge of the ultimate results, and several reports have suggested that it may predispose to pulmonary tuberculosis (Pulvertaft, 1952). We do not, therefore, think that the operation can be justified as a routine procedure in duodenal ulcer patients in whom the ulcer has never previously been diagnosed and in whom the late prognosis with simple closure is reasonably satisfactory. Particularly is this so when the patients have no memory of prolonged discomfort from their ulcers to set against the symptoms of the dumping syndrome (should they arise).

Surgical closure of the perforation is now a highly satisfactory method of treatment, so far as the immediate prognosis is concerned. It is reasonable to continue to use it in the absence of positive indications for either of the other methods.

Summary

A series of 715 patients with perforated peptic ulcers, admitted during the period 1938-51, is reported.

Since 1947 there does not seem to have been any appreciable change in the fatality rate; in 340 cases, including those undiagnosed till after death, it has been 7.9%. Twenty patients were not operated on, mostly because the condition was not diagnosed or the patient was too ill; 17 died. In 301 patients simple surgical closure was carried out; 10 died, giving a fatality rate of 3.3%. Nineteen patients were treated by immediate partial gastrectomy without a death; in the first six months of 1952 the number so treated has been increased to 30. The concurrent association of haemorrhage and perforation was successfully treated by both simple closure and by immediate partial gastrectomy.

Seventy-four patients treated by simple closure for perforated gastric ulcers and an equal number of com-

parable patients with perforated duodenal ulcers were followed up after two to twelve years. Ten patients could not be traced. Eight (11%) of the "gastric" patients, but none of the "duodenal" patients, are known to have died of carcinoma of the stomach. Seven (5%) of all the patients died of peptic ulcer.

The late prognosis among the known survivors was unaffected by the sex or age of the patients or the site of the ulcer. It was affected by the length of history prior to the perforation and by whether or not the ulcer had been previously diagnosed; in the latter group 50% suffered a further gastric operation.

The advantages and disadvantages of the three current methods of treatment are discussed, and it is concluded that no one method should be the method of choice in all cases. In any one series all three methods have their proper place. Tentative conclusions about the indications for choice of method in individual cases are suggested.

We are most grateful to our colleagues at the Central Middlesex Hospital for permission to refer to cases treated under their care, and to Mr. J. D. Fergusson, Mr. F. A. Henley, and Mr. T. G. I. James for their advice in the preparation of this paper.

GRANULOMA OF THE NOSE AND PERIARTERITIS NODOSA

BY

H. J. M. STRATTON, F.R.C.S.Ed., D.L.O.
Senior Registrar, Woolwich Group of Hospitals

T. M. L. PRICE, M.D., M.R.C.P.
Physician, Lewisham and Woolwich Groups of Hospitals

M. O. SKELTON, M.B., Ch.B.
Pathologist, Group Laboratory, Lewisham Hospital

[WITH SPECIAL PLATE]

From case reports published during the past twenty-one years there gradually emerges the picture of a peculiar syndrome consisting of a chronic ulcerating granulomatous inflammation of the nose, nasal sinuses, and often pharynx, larynx, and trachea, which is followed after a time by generalized periarteritis nodosa, and which leads almost invariably to a fatal issue.

The dominant lesion at the outset of the disease causes a purulent discharge from the nose, which is usually also obstructed. The nasal mucosa presents a characteristic picture of ulcers with yellow crusts which bleed on removal, and necrosis of the bone may appear later. These symptoms are usually accompanied by low-grade fever, and within a few weeks the patient is obviously becoming seriously ill, with albuminuria, signs of renal and cardiac failure, and a rising blood

urea. The terminal illness is usually short, death occurring about six months after the onset of the nasal lesions. Necropsy shows characteristic lesions of periarteritis nodosa in many organs.

This syndrome was first described in 1931 by Klinger (1 case), and since then by Wegener (1939), 3 cases; Lindsay, Aggeler, and Lucia (1944), 1 case; Weinberg (1946), 1 case; and Howells and Friedmann (1950), 1 case. Four of these patients were males and three females; their ages ranged from 23 to 70, and the total duration of illness from six to thirteen months. In all of them the post-mortem findings confirmed the diagnosis.

We record here two cases of this syndrome seen recently. In both of these a diagnosis was made comparatively early in the course of the disease—in the first case on the microscopical appearance of the nasal granuloma, and in the second on account of the striking similarity of the nasal lesions to those seen in the first case.

Case 1

A bus inspector aged 49 was admitted to St. Nicholas Hospital, Plumstead, under the care of Mr. L. E. Gardiner, on June 18, 1951, for investigation of bilateral nasal obstruction, nasal discharge, and an aching pain over the nose of three weeks' duration. There was nothing relevant in his past history, and he had not been given sulphonamides.

Examination showed slight generalized swelling of the nose externally and a thick, blood-stained discharge; the nasal mucosa was widely ulcerated, and had a raw granular surface, covered in parts with a yellow crust. It bled easily when touched; there was no fetor. The patient's general condition was good apart from a slight pyrexia and some malaise. An x-ray film of his nasal sinuses was clear. A course of penicillin injections, 300,000 units daily for 12 days, cleared up the discharge, but did not heal the mucosal ulceration.

A biopsy of the nasal mucosa on June 25 showed appearances interpreted as possibly tuberculous, and an x-ray film of his chest on July 6 revealed tuberculous apical lesions of doubtful activity on the right side. He was given a course of streptomycin, 0.5 g. twice daily, for five weeks, with P.A.S.

Persistent failure to find the tubercle bacillus in the sputum led to revision of the diagnosis, and a further nasal biopsy (Special Plate, Fig. 1) on July 16 was sent to one of us (M.O.S.) and reported on as follows: "The material consists of fragments of granulation tissue containing a fair number of eosinophils, and a small number of multinucleated giant cells of foreign-body type and of Langhans's type. There are no areas of caseation, and no tubercle bacilli have been demonstrated; one cannot at this stage entirely exclude tuberculosis, but the condition this resembles most is not tubercle but the so-called 'giant-cell granuloma of nasal sinuses.' This condition has been reported as a presenting lesion in patients who have subsequently developed periarteritis nodosa."

At the beginning of August the patient developed slight left exophthalmos, and another x-ray film of his sinuses showed left antral infection. Mucopus containing *Staph. pyogenes* and pneumococci was washed out at puncture. Subsequently a muscle biopsy from the thigh showed a small acutely inflamed artery, confirming the diagnosis of periarteritis nodosa (Fig. 2). By the second half of August he had developed gross oedema of the limbs and a peripheral neuritis of the mononeuritis multiplex type. He became severely breathless with left ventricular failure, and a chest x-ray film showed "bat's wing" changes in the mid-zones. Throughout this illness the nasal picture was unchanged.

He was transferred to Lewisham Hospital on August 28 for A.C.T.H. treatment; three intravenous infusions, two of 30 mg. and one of 50 mg., were given without apparent benefit. He died on September 1.

Investigations.—July 19: E.S.R., 52 mm. in first hour (Wintrobe 100-mm. tube). August 5: haemoglobin, 8.89 g.%; red cells, 2,800,000 per c.mm.; white cells, 8,000 per c.mm. (polymorphs 72%, lymphocytes 26%); M.C.H., 31 $\gamma\gamma$; M.C.D., 7.2 μ ; E.S.R., 61 mm. in one hour. August 14: urine contained 40 mg. of protein per 100 ml. and a few red and white cells. August 27: haemoglobin, 7.96 g.%. August 29: blood urea, 84 mg. per 100 ml. Blood-pressure readings: July 18, 160/80; August 17, 180/120; August 28, 155/90.

Necropsy Findings.—Externally, oedema of legs. The heart showed hypertrophy of the left ventricle; all main arteries were healthy. Nasal, laryngeal, and tracheal mucosae were hyperaemic, and one minute granulomatous nodule was present in the tracheal wall. The lungs were airless, oedematous, and congested; there were a few thrombi in the terminal branches of the left pulmonary artery and a small caseous tuberculous focus at the left apex. Pus was present in the antra and ethmoid sinuses. The left kidney had a small infarct; many other organs showed effects of heart failure but were otherwise normal.

Histology.—Kidney: many glomerular tufts contained small fibrin thrombi and showed minute foci of fibrinoid necrosis of the capillary loops, with rupture and small haemorrhages into Bowman's capsule. In some places there were adhesions between the tufts and the capsule, and early crescent formation was present. A small recent infarct was present in the left kidney. No acute arteriolitis was seen, but an acute necrotizing arteritis was occasionally present. Other acute arteritic lesions, typical of periarteritis, were seen in the capsule of the adrenals, the lungs, a small branch of the left coronary artery, and one of the vasa nervorum of the left anterior tibial nerve. The mucosae of the maxillary antra showed inflammatory reaction, with only one giant cell.

Case 2

A maintenance worker aged 51 was first seen on August 13, 1951, with a three-months history of nasal catarrh and obstruction, mild earache and deafness, a husky voice, and some loss of weight. There was no record of his having had sulphonamides before coming to hospital. His general condition was good. The nasal mucosa was congested without ulceration or crusting, there was mucopus in his nasopharynx, and he had chronic laryngitis. An x-ray film showed infection of the left maxillary antrum, which was punctured on three occasions, some smelly pus being washed out each time.

Not much improvement resulted from these measures, and on September 21 a raw granular area, without crusting, was seen on the mucosa of the left side of the septum. A biopsy of this showed thickened transitional epithelium and underlying connective tissue with slight chronic inflammatory reaction. At about this time he began to feel ill, with night sweats, cough, and occasional rigors. Except that he looked ill and thin, a general examination on September 29 did not show any abnormal physical signs, apart from his E.N.T. condition.

He was admitted to St. Nicholas Hospital on October 4, as he had by then developed pains and weakness in his limbs. His septal mucosa was extensively ulcerated, and was covered with dirty yellow crusts which caused bleeding on removal. His tongue was red, smooth, and dry, and his pharynx injected and covered with sticky mucus. The appearance of the nose was so like that in Case 1 that a provisional diagnosis of periarteritis nodosa was made; in keeping with this, he was found to have a widespread mononeuritis multiplex involving all four limbs in a flaccid paralysis with equivalent sensory loss, and associated with considerable oedema. He also had a tachycardia; rales

could be heard throughout both lungs; and an x-ray film showed "bat's wing" shadows in both mid-zones. The diagnosis was confirmed by muscle biopsy.

Later, a second biopsy of his nasal mucosa showed scanty lymphocytic infiltration but no giant cells. As a further antrum puncture still produced a little pus, a polythene tube was inserted for penicillin irrigation. On October 23 cortisone therapy was begun at Lewisham Hospital, and he was given 100 mg. by injection twice a day until he died, uraemic and in heart failure, five days later.

Investigations.—October 23: haemoglobin, 56%; red cells, 3,120,000; white cells, 28,000 (lymphocytes 20%, polymorphs 78%, monocytes 2%); blood urea, 128 mg. per 100 ml. October 27: blood urea, 270 mg. per 100 ml. Blood-pressure readings: October 13, 190/110; October 24, 175/105.

Necropsy Findings.—Externally, some oedema of ankles. The pleural cavities had some free fluid and fibrinous adhesions. The heart showed slight right and left ventricular dilatation, but was otherwise healthy. All lobes of lungs

showed red areas of infarction. The pancreas had two small infarcts in its tail; and the spleen showed irregular pale-pink areas throughout the pulp due to necrosis in areas of infarction. The kidneys had no macroscopic vascular nodules; there was one infarct. Periarthritic nodules were seen along small branches of the superior mesenteric and left gastric arteries. There was flat ulceration in nasal cavities—none anywhere else in respiratory tract. Microscopically the kidneys were similar to those of Case 1. Periarthritic was seen in small arteries of the kidneys, liver, lungs, mesentery, ileum, sciatic nerve, soleus muscle, and in arterioles at centres of malpighian bodies of spleen. Right antral mucosa was normal; left antrum and nasal cavities showed chronic non-specific inflammatory changes. Other body organs were essentially normal.

Discussion

As Howells and Friedmann (1950) point out, there are in the literature several cases of periarthritic nodosa in which chronic sinus infection was noted in the previous clinical history without its significance being emphasized. Upper-respiratory-tract infection probably plays a more significant part in periarthritic nodosa than is generally

recognized, and the important feature of the particular syndrome here described is that it is sufficiently clear-cut to enable a diagnosis to be made early. In both our cases the subsequent development of periarthritic nodosa was predicted on the appearances of the nasal mucosa. The microscopical appearances of the fully developed granuloma with its large multinucleated giant cells (Special Plate, Fig. 1) are very striking. Giant cells, however, were not seen in the mucosa in Case 2, either in the biopsy specimen or in the fragments of nasal and sinus mucosa procured at necropsy.

The essence of this syndrome is that the upper-respiratory-tract lesions are the first, and at the outset the dominating, feature of the condition. The periarthritic nodosa picture develops subsequently. This course of events is shown in our two cases. Several cases have been quoted in the literature as examples of this syndrome which do not fulfil these criteria—for instance, the case described by Rössle (1936-7) in which the nasal lesions were incidental in the disease process and were not the initial changes; and the case of Banowitch, Polayes, and Charet (1942) in which a mediastinal mass of giant cell granuloma affected the lung and was associated with periarthritic nodosa. There were no nasal lesions in this case.

Limiting the discussion of the syndrome to those cases exhibiting upper-respiratory-tract ulceration with the subsequent development of periarthritic nodosa, one may speculate on the possible significance of this pattern of the disease process. It is a well-known theory that periarthritic nodosa results from a hyperergic antigen-antibody reaction in the tissues, particularly affecting the vessels but also leading to the development of the granulomatous lesions in the extravascular connective tissue, which sometimes show giant cells of foreign-body type. Such granulomatous lesions have been produced experimentally by Goddard (1947), in his researches on the Arthus phenomenon, by injecting egg albumen into the skin of guinea-pigs; and numerous others—for example, Klinge (1933), Bergstrand (1946), and Pagel (1951)—have described the occurrence of granulomata in the connective tissue in periarthritic nodosa and in acute rheumatism and many others of the so-called "collagen diseases"; thus the nasal lesions in this syndrome may be regarded as special types of paravascular granulomata in the sense of the term used by Pagel, and are in accord with the theory that the disease is a manifestation of hypersensitivity.

There seem to be two possible explanations of the pattern of development of this syndrome. It may be that the patients have already developed generalized periarthritic and that the nasal lesions are merely the first to become apparent. There is no evidence to show whether or not generalized periarthritic nodosa was present at the time these patients first complained of nasal symptoms, and the clinical history at least suggests that the generalized disease followed later; but the patients were not submitted to a general investigation on their first attendance at the E.N.T. department with nasal lesions, and there are no data on this point.

A second possibility is that the upper-respiratory-tract lesions represent the relatively localized site of an attack on the body defences by some injurious agent of bacterial or chemical origin, and that widespread arterial lesions develop subsequently in a body now sensitized. This view is favoured by Wegener (1939) in his survey of the condition.

Another problem concerns the possible relationship between this disease and the condition known variously as "malignant granuloma of the nose" (Woods, 1921) or "progressive lethal granulomatous ulceration of the nose" (Stewart, 1933). The majority of the cases of this disease, which is almost invariably fatal, have not been examined after death, and still fewer have been examined histologically. However, Case 1 of the six cases described by Woodburn and Harris (1951) as examples of this disease and the third of Williams's (1949) three cases showed periarthritic nodosa at necropsy. Woodburn and Harris's Case 1 had

FIG. 1.—Photomicrograph of section of spleen of intact male control guinea-pig which received one subcutaneous injection of trypan blue daily at 4 p.m. for six days and was killed the following day. Shows a moderate number of dye-bearing cells in the sinuses of the red pulp. The dye-bearing cells appear black in the photomicrograph. (Weak eosin. $\times 200$.)

FIG. 2.—Photomicrograph of section of spleen of intact male guinea-pig which received 0.5 mg. oestradiol benzoate intramuscularly daily at 10 a.m. for four weeks plus one subcutaneous injection of trypan blue daily at 4 p.m. during the last six days before being killed. Shows numerous dye-bearing cells in the reticulum and in the dilated sinuses of the red pulp. The dye-bearing cells appear black in the photomicrograph. (Weak eosin. $\times 200$.)

FIG. 3.—Photomicrograph of section of spleen of intact male guinea-pig which received 0.5 mg. oestradiol benzoate intramuscularly daily at 10 a.m. for three weeks plus one subcutaneous injection of trypan blue daily at 4 p.m. during the last six days before being killed. Shows a large number of dye-bearing cells in a dilated sinus of the red pulp. The dye granules, which appear black in the photomicrograph, sometimes mask the nucleus of the cell. (Weak eosin. $\times 650$.)

FIG. 4.—Photomicrograph of section of spleen of orchidectomized guinea-pig which received 0.5 mg. oestradiol benzoate intramuscularly daily at 10 a.m. for four weeks, plus one subcutaneous injection of trypan blue daily at 4 p.m. during the last six days before being killed. Shows sinuses of red pulp dilated and empty of cells. Only a few dye-bearing cells can be seen in the reticulum. The dye-bearing cells appear black in the photomicrograph. The splenic vein in this animal contained many dye-bearing cells. (Weak eosin. $\times 200$.)

FIG. 5.—Photomicrograph of section of prostate of intact male guinea-pig which received 0.5 mg. oestradiol benzoate intramuscularly daily at 10 a.m. for four weeks, plus one subcutaneous injection of trypan blue daily at 4 p.m. during the last six days before being killed. Shows dye-bearing cells in the acinar tissue between the acini. The acini are surrounded by a thickened layer of fibrous tissue. The dye-bearing cells appear black in the photomicrograph. (Carbol-fuchsin. $\times 200$.)

FIG. 6.—Photomicrograph of section of prostate of orchidectomized guinea-pig which received 0.5 mg. oestradiol benzoate intramuscularly at 10 a.m. for four weeks, plus one subcutaneous injection of trypan blue daily at 4 p.m. during the last six days before being killed. Shows a densely fibrous prostate. The acini are collapsed and the lining epithelium is thrown into folds. (Weak eosin. $\times 200$.)

two years' history of nasal obstruction, ultimately developing ulcerating lesions of the nose and trachea, and died after one year's illness; at necropsy an acute necrotizing arteritis was found in many organs. We feel that these two cases are perhaps examples of nasal granuloma with periarteritis, as described here.

We have been able to examine slides of nasal lesions and post-mortem specimens of four cases of classical malignant granuloma of the nose. No evidence of periarteritis nodosa was seen, and the local lesion was a chronic non-specific inflammation. Therefore we have no evidence to enable us to decide whether the classical destructive "malignant granuloma of the nose" is another manifestation of the condition previously discussed or something entirely different.

Summary

Two cases are described in which periarteritis nodosa was preceded by an ulcerating granuloma of the nasal mucosa. Seven similar cases, and possibly two others, have been collected from the literature.

The significance of the nasal lesions is discussed and the possible connexion pointed out between this condition and the so-called "malignant granuloma of the nose."

We wish to thank Mr. L. E. Gardiner for permission to publish Case 1; Dr. I. Friedmann, Dr. A. G. Stansfield, Mr. N. R. Jory, and Dr. R. H. D. Short for allowing us to see tissues from cases of "malignant granuloma" of the nose; Mr. S. E. Andrews for the photographs; and Mr. H. Eastwood and Miss K. M. Vale for technical assistance.

The Lebanon Hospital for Mental and Nervous Disorders at Asfuriyeh, near Beirut, was opened in 1900, and since then has passed through many excitements and upheavals, but the work has gone on unbroken. Apart from a financial crisis during 1946-7, the hospital has grown steadily, the peak number of in-patients being 501 during the summer of 1938. There are now some 23 buildings (contributed by four countries) on an estate of 38 acres beautifully situated on the foothills of Mt. Lebanon, about five miles from Beirut. The present number of beds is 450, but, with the opening this year of a large new building, there will again be room for 500 patients. The latter come from 14 or 15 countries and are of a dozen different religions. They are of all types and classes, from the rich to the destitute. The hospital also runs a neuropsychiatric clinic in Beirut, which is doing important work for early cases. Developments since 1948 include a training school for Lebanese and Near Eastern student nurses, with an Asfuriyeh certificate in psychiatric nursing. Psychiatric instruction to doctors is of longer standing, and the present medical director, Dr. W. M. Ford Robertson, is clinical professor of psychiatry at the American University of Beirut, and two senior psychiatrists also share in the work of teaching. There are also special courses at the hospital for graduate doctors and nurses of various nationalities. A copy of the annual report of the hospital can be obtained on application to the Lebanon Hospital office, Drayton House, Gordon Street, London, W.C.1.

SEGMENTAL ASPIRATION PNEUMONIA AND BRONCHIECTASIS*

BY

K. D. FORGAN MORLE, M.D., D.M.R.D.

Consultant Radiologist, Liverpool Regional Hospital Board;
 Clinical Assistant, Department of Radiology,
 University of Liverpool

AND

PHILIP W. ROBERTSON, M.D., M.R.C.P.

Squadron Leader, Medical Specialist, R.A.F.; Clinical
 Assistant, Royal Infirmary, Liverpool

[WITH SPECIAL PLATE]

In a previous publication we described the clinical features of a large series of cases of segmental aspiration pneumonia (Robertson and Morle, 1951) and suggested that the syndrome of primary atypical pneumonia could be largely explained on an aspiration basis. Reference was then made to bronchographic studies undertaken in these cases of segmental pneumonia. It was stated that a wide range of bronchial abnormality might occur within such lesions and that these changes might be serious and sometimes irreversible.

These changes are now described and their significance is discussed in relation to the natural history of bronchiectasis.

So far we have carried out bronchography about 600 times on over 300 cases of segmental pneumonia. From so large a series we feel that enough evidence is forthcoming to substantiate our view that many, if not most, of the cases of bronchiectasis originate from these segmental pneumonias occurring in association with upper respiratory infections.

Bronchograms

There are many degrees of deviation from the normal, and in a few borderline cases it has been found difficult to decide whether a bronchogram was abnormal or not. This difficulty, which appears to have worried other authors (Evans and Galinsky, 1944), is a matter of some importance, as changes of such minimal nature may represent the initial stages of disease, which may later become fully established.

We classified a bronchogram as abnormal if one or more of the following features were present. (a) Dilatation: this varied in degree from minimal changes in calibre to gross and obvious dilatation. (b) Crowding: approximation and crowding together of the bronchial shadows. (c) Failure to Fill: failure to obtain satisfactory filling of the peripheral bronchi of the region studied.

Further features noted in those bronchograms classified as abnormal on the basis of the above three criteria included distortion and angulation of the peripheral bronchi and apparent irregularity of the bronchial walls. Some elucidation of the three main abnormal features is perhaps necessary.

Calibre changes vary from loss of the normal degree of taper of the bronchus as the periphery is reached to severe and obvious dilatation. In an estimation of the significance of an apparently dilated bronchus there are several features to be taken into consideration. An illusion of dilatation may be caused by solid filling of a group of bronchi. Allowance must be made for the magnification of the

*The substance of this work formed a paper given at a meeting of the Thoracic Society in July, 1951.

image of the bronchus due to the distance of the latter from the film. In serial films care must be taken to allow for physiological change in calibre occurring at different phases of respiration.

Bronchial crowding is easily recognized, and is of course due to some degree of collapse. The coexistence of bronchial dilatation with bronchial crowding is well known and extremely common (Lander, 1946).

It is characteristic of bronchography that the appearances produced are transitory and that different stages of filling are recorded on serial films (Di Reinzo, 1949). For this reason it is unwise to be content with single films, and where necessary these should be followed by additional films after further posturing.

In general, a normal bronchial tree can be completely outlined without difficulty, and persistent failure to fill suggests bronchial abnormality. For this reason it is not possible to interpret bronchograms showing incomplete filling due to inadequate technique.

Bronchography performed in the presence of a resolving segmental aspiration pneumonia will usually show failure of filling of the peripheral bronchi within the affected segment. Further, there may be damming up of the lipiodol in the more proximal portion, indicating blockage of the peripheral bronchi by exudate. Persistent attempts to fill such a segment may lead to well-marked normal alveolar filling in surrounding normal regions—the affected region, in which neither the bronchioles nor the alveoli are filled, then being clearly demarcated. The inconstant changes referred to as rippling or beading of the outline of the bronchial wall could not be relied upon as an indication of abnormality.

The frequency with which the various bronchographic abnormalities are demonstrated in segmental aspiration pneumonia is closely related to the stage in the illness at which the bronchogram is done. Thus the incidence of abnormality is greater in the earlier stages of the illness; reversion of the bronchographic change tends to occur as resolution and re-expansion take place. The three main types of bronchographic abnormality mentioned above usually coexist, though any one may predominate over the others at different stages of the illness.

It is therefore of little value to express statistically the percentage of cases showing bronchographic abnormality. Any such figures would be wholly inaccurate and misleading. Even the incidence of persisting bronchial change is difficult to determine, for this depends upon the length of follow-up, the efficacy of treatment, and the possibility of some pre-existing disease in the affected segments. As a general impression from the investigation of over 300 cases it is felt justifiable to give a figure of about 60-70% as the incidence of bronchial abnormality in all cases of segmental aspiration pneumonia. Possibly about 5% of such pneumonic lesions have led to established bronchial abnormality despite adequate therapy and observation over a period of 18 months to two years. It is not known what the last figure would be if the cases were untreated, but it would probably be very much higher.

Natural History of Bronchiectasis

In this particular series, dealing as it does with chest infections and various stages of bronchiectasis, a history of previous significant chest illness would normally be regarded as of great importance, but in our experience it has proved unreliable. The difficulty centres on the word "significant." There can be few members of the general population who do not admit to winter coughs and colds, but these are not regarded as significant by either patient or general practitioner. Most of the present series gave a history of no more significant previous illness than such conditions, though 15% gave a history of "pneumonia." In some instances this previous history, together with a recent illness, led to the performance of bronchography on the supposedly affected side. It is interesting to note that the

percentage of abnormal bronchograms in such cases was little different from that of cases with no past history of chest disease.

One is continually faced with difficulty in interpreting the accuracy of the history: What does the patient mean by pneumonia? What does he mean by a chest cold? Doubtless in many cases either of these may have been an illness of the type described here. The patient will occasionally state that he has never had a chest illness but that he has had an illness similar to his present condition, in which there are chest pain and cough and radiological changes. There is therefore much unreliable material in the patient's history.

When one takes into account the more nebulous "chesty" colds and coughs a somewhat similar picture is evident. In approximately 13% of all cases such a history was given, and it was found that 79% of these had abnormal bronchograms. This latter group actually includes most of the more severe lesions. However, most of those with gross established and widespread bronchiectasis did not give a history which one might regard as typical of that condition and certainly no more suggestive than many who were shown to have normal bronchograms.

There are three principal points which it is wished to stress in connexion with the previous history of illness. (1) In most instances a history of a specific illness such as pneumonia is of no certain value other than indicating that there has been a chest illness. The diagnosis may well have been made on scanty evidence. The site and type of pneumonia are rarely known to the patient, and there is always the tendency for him to have received an exaggerated version of the childhood illness from his mother. (2) Although it was found that a high percentage of patients with a history of chest colds did show bronchographic evidence of disease, it must not be imagined for a moment that the history was definite enough to enable one to pick it out as "significant" as compared with the histories of a large group of general medical patients. (3) In any individual case only a survey of recent events was of help in deciding upon what investigations were necessary.

It is important to try to ascertain the age of any bronchial abnormality demonstrated in a pulmonary segment which has recently been the site of an inflammatory process. One must determine whether or not the inflammatory process was superimposed upon a pre-existing bronchial lesion. This point has been discussed from a slightly different angle by Grier (1944) and Scarlett (1946), who referred to the possibility of confusing primary atypical pneumonia with bronchiectasis which is the site of a pneumonic exacerbation; and from yet another angle by Blades and Duggan (1943), who stated that bronchograms obtained after atypical pneumonia may occasionally be misleading, and give the impression that the condition was true bronchiectasis. They showed that in several instances such bronchiectases reverted to normal, and they attempted to differentiate this from true bronchiectasis on clinical criteria. They do not seem to have appreciated, as did Ogilvie (1941), that this was an early stage in the natural history of bronchiectasis.

It is our view that in most instances the bronchial condition developed during the current illness. There are several points in support of this opinion: (1) so many of the patients could give no history of chest illnesses of any kind, however trivial; (2) all cases had been passed by mass miniature radiography examination within the previous few weeks; and (3) further evidence is provided by the demonstration of reversion to normal. Failure to conform to any one of these points must cast doubt on the age of the bronchial lesion.

This statement that the bronchial condition usually developed during the current illness is of fundamental significance. It indicates that illnesses such as the so-called "primary atypical pneumonia" syndrome can give rise to serious structural abnormalities within the affected segment. The fact that such structural abnormalities are

concealed calls for great care in the handling of these cases. It provides the reason for the persistence of symptoms or signs after an apparently straightforward "virus pneumonia"; it disposes of the fallacy that such illnesses are necessarily benign; and it offers a demonstration of the actual development of bronchiectasis.

The Forerunner of Bronchiectasis

What place in the natural history of bronchiectasis does this process occupy? It is our belief that this sequence of events is the forerunner of many cases of bronchiectasis. The importance of this statement lies in the appreciation of the commonness of segmental collapse and such illnesses. It has, of course, long been recognized that there is a close relationship between bronchiectasis and such collapse (Findlay, 1935; Andrus, 1937; Lander, 1946). It has not, however, been generally recognized that such atelectatic lesions are so frequent and that most of them may arise from an aspiration mechanism, as has been suggested by us. Such aspirated material is not necessarily derived from the upper respiratory tract, for local bronchial plugging may occur from failure to clear excessive bronchial secretion, as in generalized bronchitis or in asthma. Perhaps rather too much emphasis has been placed on glandular compression, foreign bodies, carcinoma, etc., which are well known to give rise to bronchiectasis but are infinitely less common. Furthermore, we believe that this type of illness forms most of the "bronchopneumonic" illnesses of childhood, the lesions being similar to those described by Lees (1950) in association with pertussis.

In some cases we have been able to observe that where there have been recurrent inflammatory episodes increasingly severe bronchial damage follows. This is suggestive of the possible course of the development of bronchiectasis.

Where obviously established and gross bronchiectasis is found, it is sometimes possible by careful history-taking or by inspection of Service medical documents to reveal an initial illness such as we have described. This may have been four to five years previously and at that time thought to be of little significance, but recurrent chest episodes of increasing severity and frequency followed. We believe that such a history is not that of infection superimposed on previously dilated and damaged bronchi but that of the gradual development of the condition. Finally, and, we feel, most significant of all, the site incidence of segmental pneumonia is identical with that of established bronchiectasis (Robertson, 1951).

Some Problems

Many problems are raised by the detection of segmental bronchial abnormality in a healthy relatively symptomless young man. Little guidance can be obtained from the literature for the long-term management of such cases, and, so far, our own experience has been limited to a three-years study.

In the management of such cases it is often most difficult to correlate the bronchographic changes with the patient's clinical state. How is one to foretell the local anatomical prognosis? Will it remain the same, or improve, or get worse? Having attempted to answer this, one then asks how the patient will be affected clinically. It is only the experience we have gained from serial bronchography on our earlier cases which has given us guidance on the likely course of the local lesion. For example, the segmental lesion may not clear radiologically and the patient may or may not have persistent symptoms; the segment may clear radiologically but troublesome symptoms remain; then, again, there may be apparent recovery radiologically and clinically, but the whole sequence may recur.

The object in all cases in which a segmental lesion has been recently demonstrated should be to arrange for a period of at least six months' observation and treatment. Bronchography should be employed as a guide to progress.

In our own work we have usually performed bronchography a second time at the end of about six to eight weeks, and, if still abnormal, again after four to six months. Most of our patients did in fact show reversion at the time of the first or second repeat bronchogram, and these have not appeared to be particularly prone to further trouble.

One of the most difficult types of case to handle is that in which bronchial damage can be persistently demonstrated but in which symptoms are so often minimal; such a condition might, under normal conditions, and remaining uninfected, be undetected for many years.

When the question of surgical treatment is raised there are again a number of points to consider. What is the risk of recurrent "pneumonia"? Is further damage likely to occur in the same or in adjacent segments? So far as the question of spread is concerned we have been able to show that further damage in the same or neighbouring segments can, and does, occur with the passage of time, although such spread may in turn be reversible if recognized.

Would it be justifiable to interfere surgically in the hope of avoiding more widespread disease with disabling symptoms in, say, 10 years, at which time conditions might be unfavourable for operation? The only patients of ours who were finally selected for local segmental resection with this in mind refused operation on the grounds of their present excellent health.

A slightly different problem is raised by the demonstration of a local segmental lesion in the presence of recurrent attacks of generalized bronchitis or asthma. It is important to recognize that such local lesions are merely incidents in the course of a generalized disturbance and naturally would not benefit to the same extent by resection. Once again the history of "recent bronchitis" may be grossly misleading, since it may indicate, as we have previously noted, repeated infection in a region with bronchial damage or an actual recurrent acute generalized bronchitis. It may be possible to differentiate between these two groups only by a period of observation, during which actual incidents may be studied.

Treatment

The purpose of this work is to indicate a major source of bronchiectasis and to suggest that the attack on this disease be shifted to a much earlier stage in its natural history.

There are two principal factors to be considered in dealing with the pulmonary lesion. These are the infection and the mechanical aspects. The lesion may be large and yet there may be little or no clinical upset. In such cases the mechanical obstructive elements predominate. On the other hand, even small radiological lesions may be responsible for a considerable degree of general illness. Treatment must be directed against either or both of these factors.

Many of the cases when first seen with their initial illness present features so strongly resembling "pneumonia" that there may be a temptation to administer the modern antibiotics at once. However, when the laboratory findings and x-ray appearances are seen it is very often evident that the condition is not consistent with this diagnosis in its more classical sense. This is even more true if the patient be first seen a day or two after the usually short acute stage. We have found that so many have recovered rapidly without specific therapy that the value of antibiotics is often subject to doubt. We do not believe that the use of aureomycin or chloramphenicol is justifiable on the grounds of a possible virus basis for the infection (Robertson and Morle, 1951). Detailed serological investigations, while possibly of academic interest, should not be allowed to cloud the appreciation of the fundamental nature of these segmental lesions. On the whole, it has seemed reasonable to restrict the use of antibiotics to those cases in which the infective element predominates.

The basis for therapy should rest upon an attempt to reverse the sequence of events which have led to the develop-

ment of the segmental pulmonary lesion. It is essential that material which has been aspirated should be removed, thereby establishing adequate aeration of the involved segment and removing the element of collapse. In addition to this process of re-aeration, drainage will prevent stagnation within the segmental bronchi and diminish the likelihood of damage to the bronchial walls.

Properly conducted postural drainage should be instituted, having first established the exact site of the lesion. Drainage may be assisted in some cases by the use of steam inhalations or by short-wave diathermy, especially when the sputum is particularly tenacious. The actual procedure of bronchography has often been observed to increase the production of sputum, with consequent local improvement.

On the other hand, bronchoscopy is not likely to prove helpful, since the bronchial obstruction is usually peripheral and multiple. The bronchial secretions have been found to be so thick and tenacious as to block the suction tube. This suggests the need for an efficient liquefying agent which could be used endobronchially, but so far none appears to be forthcoming.

Expectorant mixtures seem to have little or no effect on these lesions, while the use of opiates is "the most frequently prescribed frustrator of the vital defence of the lungs" (Jackson, 1950).

Summary

A study of the clinical and radiological features of segmental aspiration pneumonia is presented.

There is bronchographic evidence of varying degrees of bronchial abnormality within such segmental lesions. It is shown that in some instances quite well-marked bronchiectasis can be demonstrated, and though this is usually reversible it is not always so. The possible position of this sequence of events in the natural history of bronchiectasis, together with rational preventive treatment, is discussed. It is believed that most recognized established bronchiectases originate from such segmental lesions.

Without the co-operation of the medical authorities of the Royal Air Force, and in particular Air Commodore Rumball, the consultant in medicine, this work would not have been possible. Dr. P. H. Whitaker and Dr. Robert Coope, whose clinical assistants we are, have given us every encouragement and placed the full facilities of their departments at our disposal. Our thanks are due to the radiography staff of the Liverpool Royal Infirmary and to Miss Smith for the x-ray photographs. We are also grateful for much material assistance from the University of Liverpool.

It may surprise some that the rainfall last year over England and Wales exceeded by only 0.6 in. (1.5 cm.) the average value for the years 1881-1915. Yet such was the case, according to figures published in *The Times* this week by Dr. John Glasspoole. However, the year, in England and Wales, was drier than 1951 by 7.9 in. (20 cm.). Scotland and Northern Ireland experienced a rather drier year than average last year. The most remarkable meteorological event in 1952 was the 9 in. (22.9 cm.) of rain which fell at Longstone Barrow, four miles south of Lynmouth, during the 24 hours which began at 9 a.m. on August 15. This was the third largest daily measurement recorded in the British Isles.

INFLUENCE OF OESTRADIOL BENZOATE AND ORCHIDECTOMY ON THE RETICULO-ENDOTHELIAL SYSTEM

[WITH SPECIAL PLATE]

Oestrogens are used in the treatment of prostatic carcinoma and of cancer of the breast, urinary bladder, and other organs with good results, especially in the prostate. In the case of the prostate the beneficial action is accompanied by fibrosis (Fergusson and Pagel, 1945; Fergusson, 1948). Nicol and Helmy (1951) found that oestradiol benzoate, oestrone, stilboestrol, stilboestrol dipropionate, D.B.E. (α -di-(*p*-ethoxyphenyl)- β -phenyl-bromo-ethylene), and dienoestrol stimulated the reticulo-endothelial system in the ovariectomized guinea-pig and suggested that the beneficial effect of oestrogenic treatment in cases of cancer of the prostate may be due to stimulation of the reticulo-endothelial system and the transformation of macrophages in the prostate into fibroblasts and fibrous tissue (Jaffé, 1938; Maximow and Bloom, 1948).

The part played by the reticulo-endothelial system in the defence against cancer has been referred to by several writers. Stern (1941) showed that the function of the system as tested by the Congo-red method was impaired in 86% of patients with malignant disease. Kavetzki and Diadjuscha (1937) showed that stimulation of the reticulo-endothelial system lowered the incidence of development of cancer metastases in rabbits inoculated intravenously with Browne-Pearce carcinoma, whereas blockade of the system raised the incidence of tumour growth. Diadjuscha (1937) has also shown that implantation of Ehrlich carcinoma into mouse liver or spleen or of Flexner-Jobling carcinoma into rat testes was invariably successful when the reticulo-endothelial system was blocked, and rarely so when it was stimulated.

Present Investigations

Our investigations were designed to study the effects of oestradiol benzoate, orchidectomy, and their combination on the activity of the reticulo-endothelial cells in the spleen, liver, lymph nodes, and prostate, and on the amount of fibrous tissue in the prostate. For this purpose 28 intact male guinea-pigs and 24 double-orchidectomized guinea-pigs were used. One month was allowed to elapse after orchidectomy to ensure complete recovery from the operation and disappearance of testicular hormone from the blood. All the animals received one daily subcutaneous injection of trypan blue at 4 p.m. for six days and were killed by chloroform the next day. The dosage of the dye was calculated on the basis of 0.8 ml. of a 1% solution in distilled water per 100 g. of body weight. Six of the intact animals and ten of the orchidectomized animals were given the dye only, and served as controls. The remainder were divided into groups in which each animal received one daily intramuscular injection of 0.5 mg. of oestradiol benzoate at 10 a.m. for one, two, three, or four weeks; these animals received the injections of dye during the last six days of the hormone treatment.

and were killed the following day. Specimens of the prostate, spleen, liver, lymph nodes, bone marrow, skin and subcutaneous tissue, adrenal glands, and, when possible, the testes were fixed in Heidenhain's "susa" fluid. Sections were cut 10 microns thick and stained with dilute carbol-fuchsin or weak eosin. The activity of the reticulo-endothelial system was measured by the number of dye-bearing cells, and the intensity of the vital staining in the organs and tissues was examined.

Results

The results showed that in both the intact and the orchidectomized animals oestradiol benzoate produced hyperplasia and stimulation of the reticulo-endothelial macrophages, mainly in the spleen (Special Plate, Figs. 1, 2, and 3), liver, lymph nodes, and prostate, and that the degree of stimulation was roughly proportionate to the duration of the hormone treatment. In the orchidectomized animals the reticulo-endothelial system was more active, and oestradiol benzoate produced a greater response than in the intact animals.

In the spleen, prolonged oestrogenic stimulation appeared not only to produce a greater formation and activation of the reticulo-endothelial cells but also to assist their mobilization and liberation into the circulation. This was noted especially in the spleen of orchidectomized animals given the hormone for four weeks, in which the splenic sinuses were dilated and contained, in some animals, numerous dye-bearing cells, and in others a moderate number. In others the sinuses were practically empty (Fig. 4), although in the same animals the splenic vein and the intrahepatic branches of the portal vein contained a great number of dye-bearing cells. Furthermore, the peritoneal mesothelial cells covering the spleen became columnar and showed dye granules in the infranuclear zone as a result of the oestrogenic treatment, which confirms the findings recorded by Helmy and Nicol (1951) in female animals.

In the prostate, the dye-bearing cells appeared in the loose areolar tissue between the acini (Fig. 5). The vitally stained cells were very few in the intact animals not given hormone, but became numerous after oestrogenic treatment, and still more numerous when this was combined with orchidectomy. The thin layer of fibrous tissue which normally surrounds the prostatic acini became progressively thicker with hormone treatment, and the prostate showed the greatest degree of fibrosis in the orchidectomized animals which received oestradiol benzoate for four weeks (Fig. 6). Fibrosis was particularly marked in the region of the utriculus musculus. The arrangement of cells around the prostatic acini in the hormone-treated animals suggests that oestradiol benzoate leads to the appearance of macrophages around the acini and that if the treatment is maintained these macrophages change into fibroblasts and fibrous tissue. Orchidectomy also seems to influence both the deposition of the macrophages and their transformation into fibroblasts. The macrophages in the prostate probably come mainly via the blood stream from the spleen and other reticulo-endothelial organs, where their mobilization is stimulated by the oestrogens, and partly from proliferation of pre-existing local cells having mesenchymal potencies.

Conclusions

The stimulating effect of orchidectomy on the reticulo-endothelial system may be explained by: (1) The absence of the neutralizing effect of androgens on oestrogens which are normally found in the male animal and are probably produced by the suprarenal glands. This neutralizing effect was shown by Ihrke and D'Amour (1931), Browman (1937), and Robson (1938). (2) The stimulating effect of orchidectomy on the anterior lobe of the pituitary, leading to the output of more adrenotropic hormone, which in turn leads to the production of more oestrogens by the suprarenals.

The results of the present investigations, therefore, show that oestrogens and orchidectomy both stimulate the reticulo-endothelial system and in this manner probably increase the

general resistance against cancer; that in the prostate they induce the appearance of macrophages and later of fibrous tissue, which acts as a local defence against the spread of cancer; and that oestrogenic treatment combined with orchidectomy produces a more intense result than either alone.

RESPONSE IN DOGS TO RELAXANTS DERIVED FROM SUCCINIC ACID AND CHOLINE

BY

L. W. HALL, B.Sc., M.R.C.V.S.
Clinical Assistant, Royal Veterinary College

H. LEHMANN, M.D., Ph.D., F.R.I.C.
Senior Lecturer in Chemical Pathology, St. Bartholomew's Hospital

AND

E. SILK, B.Sc.
Research Assistant

It has recently been reported (Hall, 1952) that suxethonium is a useful relaxant in operations on dogs, and as such is a welcome addition to the surgical practice concerned with this species. There was, however, a difference between the effects of the drug in dogs and in man, dogs being more sensitive and responding with longer apnoea to smaller doses. In an investigation on succinylcholine sensitivity in man (Evans, Gray, Lehmann, and Silk, 1952) a correlation had been found between low pseudo-cholinesterase level in the plasma and prolonged response to succinylcholine. This observation, and experiments *in vitro*, suggested that in man the drugs produced depolarization, not only directly but also by inhibiting the true cholinesterase, thus raising the acetylcholine concentration in the neuromuscular end-plates, and that the short duration of this effect was due to the rapid hydrolysis of succinylcholine by the pseudo-cholinesterase of the plasma. We therefore decided to investigate the enhanced effect of suxethonium in dogs along these lines by finding out whether there were differences between the enzyme systems of man and dog.

Methods

All observations in dogs except one were made in the course of necessary treatment. "Brevidil E," which used to be suxethonium di-iodide and is now obtainable commercially as the dibromide, and "scoline" (suxamethonium chloride), which is succinylcholine dichloride, were both used *in vivo* and *in vitro*. There was no major difference in their behaviour. All doses used *in vivo* and *in vitro* are expressed in terms of the active cation. The *in vitro* techniques followed were the same as described previously (Evans *et al.*, 1952). They depend on the evolution of CO₂ from bicarbonate buffer by the products of ester hydrolysis; the activity

of the enzymes is expressed as μ l. of CO₂ formed per minute by 1 ml. of serum or packed red cells at 37° C. (see McArdle, 1940).

Results

In 25 operations on dogs suxethonium was given in dosages mostly from 0.08 to 0.15 mg. per lb. body weight; in some instances the amounts administered were even less. To man four to six times these dosages are administered, yet the apnoea produced in dogs was longer than that seen normally in man. It has to be conceded that in the chest conditions hyperventilation may have played a part in extending the duration of apnoea.

We then established that in dogs, as in man, succinylcholine and suxethonium inhibit the hydrolysis of acetylcholine both by the true cholinesterase prepared from red

True cholinesterase of red cells:					
Acetylcholine: 0.65 mg./ml.	18	—	—	1	—
Succinylcholine: 1.3 mg./ml.	16	—	—	2	—
Suxethonium: 1.4 mg./ml.	18	—	—	2	0

cells and by the pseudo-cholinesterase of the plasma, and furthermore, that succinylcholine and suxethonium themselves are hydrolysed by pseudo-cholinesterase and not by the red-cell enzyme (for details see Table I). The inhibition of acetylcholine breakdown by dog's serum in the presence of succinylcholine had already been shown by Bovet and his colleagues (1951).

In man the cause of prolonged apnoea after succinylcholine had been a low activity of the pseudo-cholinesterase of the plasma. We therefore thought at first that dogs might normally have a much lower pseudo-cholinesterase in their plasma than man. Table II shows that, although the values for pseudo-cholinesterase tend to be lower in dog than in man, in whom the normal range is 55 to 120 units, only one dog had an esterase value below 40, which might in man cause a significantly prolonged apnoeic

response to succinylcholine. However, there was a considerable difference between the level of true cholinesterase of the red cells in man and dog. The values for man are about 80 to 120 (although very occasionally they may be as low as 60 to 80); and it will be seen in Table II that we found them to be six to eight times lower in dogs.

As pointed out in the introduction to this paper, the action of succinylcholine in man can be visualized as a combination of it with the two cholinesterases. True cholinesterase + succinylcholine causes the pharmacological effect, and pseudo-cholinesterase + succinylcholine brings it to its rapid end. The duration of apnoea would then depend on the dosage of succinylcholine given and on the concentration of the two esterases combining with it—that is, equilibria will be established between the free succinylcholine and the succinylcholine adsorbed both on the true

cholinesterase on the one hand and on the pseudo-cholinesterase on the other. Of these the combination pseudo-cholinesterase + succinylcholine is unstable and results in hydrolysis of the adsorbed drug. This will free pseudo-cholinesterase, which will thus become available for the remaining free succinylcholine. As the free drug is also in equilibrium with that combined with the true cholinesterase a fall in its concentration will result in a release of succinylcholine from that combination and the pharmacological effect will progressively abate.

The difference between the action of succinylcholine or suxethonium in man and dog can be explained on the basis of these equilibria. With a low concentration of true cholinesterase less free succinylcholine or suxethonium is required for the inhibitory combination which produces subsequent depolarization, and, although the destruction by pseudo-cholinesterase is almost as efficient as in man, the drain on the remaining free choline derivative cannot have the same effect because in the dog lower concentrations would still suffice to occupy the smaller amount of true

cholinesterase available. However, it should be possible to increase the pseudo-cholinesterase of the plasma in the dog and thus to lower the concentration of free succinylcholine and suxethonium so rapidly that even the low concentration of the drug required for inhibition of the true cholinesterase that animal will be effectively attacked. We therefore injected a highly concentrated solution of pseudo-cholinesterase intravenously into four dogs in the course of operations for mastectomy or conditions requiring orthopaedic treatment, and compared the effect of equal amounts of suxethonium given before and after the pseudo-cholinesterase level of the plasma had been increased.

As will be seen in Table III, after the pseudo-cholinesterase had been effectively raised succinylcholine was as short-acting in dog as it is known to be in man. To exclude the effects of premedication and the possibility that apnoea was due to artificial hyperventilation, one experiment was performed in which only thiopentone was used for induction and no artificial respiration was given during apnoea beyond one inflation per minute. Table IV shows that the

raising of the pseudo-cholinesterase level was effective under these conditions. Blood-pressure readings were obtained throughout and allowed an exclusion of asphyxia. Both brevidil E and scoline were used and noted as such in terms of active cation.

Discussion

Our findings support the suggestion that the effect of succinylcholine and suxethonium is the outcome of an interplay between these compounds and the two cholinesterases. The fact that the dog is much more sensitive than man would then be explained by the finding of a six to eight times lower true cholinesterase concentration in the red cells. Similarly, the fact that the sensitivity of the dog can be lowered to levels seen in man by raising the pseudo-cholinesterase level of the plasma can be understood on the bases of these considerations. We have assumed that the two esterases in man and dog are the same enzymes, and that the differences in activity of blood and plasma are due to different enzyme concentrations. It is, of course, possible that there are species variations and that the affinities rather than the concentrations are different. However, the interplay between compounds and enzymes would have the same outcome whether the enzymes differ in concentration or in affinity. Apart from theories, our findings have two practical consequences: the absence of side-reactions in the dog when given human cholinesterase preparations justifies its trial in man in cases of succinylcholine sensitivity. The use of the enzyme will be of advantage in veterinary medicine, as it will convert succinylcholine and suxethonium from comparatively long-time relaxants into compounds acting for a few minutes only, thus bringing into the surgery of the dog the advantages found in the use of succinylcholine and suxethonium in man.

Summary

Dogs are more sensitive to suxethonium and succinylcholine than man. When injected with doses about one-fifth of those used in man they react with an apnoea of about five times longer duration.

The pseudo-cholinesterase concentration in dogs' serum is not much lower than that in man, but the true-cholinesterase concentration in the red cells is only about one-seventh. It is suggested that there is a correlation between higher sensitivity and lower true cholinesterase and that raising or lowering any of the two enzymes will raise or lower the time of apnoea after succinylcholine or suxethonium.

In five dogs raising of the pseudo-cholinesterase level in the circulating plasma shortened effectively the time of apnoea after suxethonium or succinylcholine. The theoretical and practical significance of these findings is discussed.

We should like to express our thanks to Dr. E. B. McLean, of the U.S.A., who provided us with a pseudo-cholinesterase preparation containing 21,000 units per ml. This solution will in due course become available commercially under the name of "cholase."

Research Assistant, St. Bartholomew's Hospital

Human blood contains two cholinesterases. One is found in the plasma, and is unspecific so far as acetylcholine is concerned; it is therefore called pseudo-cholinesterase (Ps.ChE.). The other is the true cholinesterase of the red cells (Tr.ChE.). When succinylcholine was rediscovered by Bovet, Bovet-Nitti, Guarino, Longo, and Marotta (1949) and recommended as a muscle relaxant, its short action was already ascribed to its enzymatic destruction by the blood (Bovet-Nitti, 1949); this work was done on rabbits. Evans, Gray, Lehmann, and Silk (1952a) showed that, in man, of the two enzymes the pseudo-cholinesterase was responsible for the hydrolysis of succinylcholine. Bourne, Collier, and Somers (1952) found a significant difference in the pseudo-cholinesterase level when they compared six patients who had recovered normally from the effect of succinylcholine with six others whose response lasted beyond eight minutes. Evans *et al.* (1952a) demonstrated an inverse relationship between the duration of apnoea and the pseudo-cholinesterase level in the serum. It was suggested that unduly prolonged response to the drug should be treated with

transfusion of whole blood, which even on storage contains some 30 units of pseudo-cholinesterase per ml. of plasma. We were then offered for therapeutic trial a concentrated solution of human pseudo-cholinesterase by Dr. McLean, of the U.S.A., and this preparation was first used in dogs, in whom it was found by Hall, Lehmann, and Silk (1953) to be highly efficacious in the reversal of apnoea following injection of succinylcholine. Encouraged by these results, we injected the enzyme preparation, which will become available commercially as "cholase," in one of us (P. W. S. G.) and, following this, into patients. Cholase is prepared by ethanol fractionation and is a subfraction of Cohn's globulin fraction IV-6 (Surgenor, 1949).

Material and Methods

The levels of pseudo-cholinesterase and true cholinesterase were measured in serum and in laked and washed red cells respectively by the manometric method as described by McArdle (1940). This technique measures the CO₂ liberated from a bicarbonate buffer by the products of ester hydrolysis, and the activity of the enzyme solutions as expressed as μ l. of CO₂ formed per minute by 1 ml. of serum or packed red cells at 37° C. The pseudo-cholinesterase was measured, using serum in a final dilution of 1 in 15 with 8 mg. of acetylcholine chloride per ml. as substrate; the true cholinesterase was determined with the final 1 in 75 dilution of packed, washed, and laked red cells with 0.8 mg. of acetylcholine chloride as substrate. Cholase activity was measured in final dilutions of 1 in 1,500.

Experimental Procedure.—Four patients were given thiopentone for induction of anaesthesia. A blood sample was taken for measurement of the cholinesterases. When breathing was regular and no effect on it by thiopentone was noticeable, succinylcholine was injected and the time of apnoea was measured with a stop-watch. When breathing was fully re-established renewed thiopentone had to be given in one case (No. 1), but in the others the induced sleep was still deep enough to make this unnecessary. Cholase was then injected intravenously, and after 90 seconds a second blood sample was taken for measurement of the enzyme levels. Succinylcholine was then again injected as before and the resulting apnoea was measured with a stop-watch. The whole experiment lasted less than 20 minutes in all four cases.

Results

Case 1.—Man aged 61, weight 11 st. 4 lb. (71.7 kg.). Induction, 0.5 g. thiopentone. Blood enzyme levels: Ps.ChE., 90 units; Tr.ChE., 138 units. 50 mg. succinylcholine chloride injected; apnoea of 130 seconds followed. On waking up, 0.5 g. thiopentone given. 12 ml. pseudo-cholinesterase (252,000 units) injected. Blood enzyme levels: Ps.ChE., 183 units; Tr.ChE., 149 units. 50 mg. succinylcholine chloride injected; apnoea of 66 seconds followed. Blood enzyme levels: 2 hours later: Ps.ChE., 185 units; Tr.ChE., 152 units. 18 hours later: Ps.ChE., 125 units; Tr.ChE., 149 units. 24 hours later: Ps.ChE., 129 units; Tr.ChE., 132 units.

Case 2.—Man aged 52, weight 14 st. (88.9 kg.). Induction, 0.5 g. thiopentone. Blood enzyme levels: Ps.ChE., 72 units; Tr.ChE., 124 units. 50 mg. succinylcholine chloride injected; apnoea of 210 seconds followed. When breathing was fully re-established 5 ml. pseudo-cholinesterase (105,000 units) was injected. Blood enzyme levels: Ps.ChE., 95 units; Tr.ChE., 129 units. 50 mg. succinylcholine chloride injected; apnoea of 110 seconds followed. Blood enzyme levels:—3 hours later: Ps.ChE., 86 units; Tr.ChE., 120 units. 24 hours later: Ps.ChE., 74 units; Tr.ChE., 131 units.

Case 3.—Woman aged 67, weight 8 st. 11 lb. (55.8 kg.). Induction, 0.5 g. thiopentone. Blood enzyme levels: Ps.ChE., 34 units; Tr.ChE., 99 units. 75 mg. succinylcholine chloride injected; apnoea of 375 seconds followed. When breathing was fully re-established 6 ml. pseudo-cholinesterase

(126,000 units) was injected. Blood enzyme levels: Ps.ChE., 73 units; Tr.ChE., 97 units. 75 mg. succinylcholine chloride injected; apnoea of 135 seconds followed.

Case 4.—Woman aged 63, weight 12 st. 4 lb. (78 kg.). Induction, 0.45 g. thiopentone. Blood enzyme levels: Ps.ChE., 23 units; Tr.ChE., —. 50 mg. succinylcholine chloride injected; apnoea of 555 seconds followed. When breathing was fully re-established 3 ml. pseudo-cholinesterase (63,000 units) was injected. Blood enzyme levels: Ps.ChE., 36 units; Tr.ChE., —. 50 mg. succinylcholine chloride injected; apnoea of 345 seconds followed.

Table I summarizes the pseudo-cholinesterase levels before and after pseudo-cholinesterase injection and the time of apnoea before and after the raising of the enzyme level.

TABLE I.—Pseudo-cholinesterase Level and Effect of Succinylcholine Before and After Injection of Cholase

Case No.	Pseudo-cholinesterase (Units)		Apnoea following Succinylcholine (Seconds)	
	Before Cholase	After Cholase	Before Cholase	After Cholase
1	90	183	130	66
2	72	95	210	110
3	34	73	375	135
4	23	36	555	345

It will be noted that the levels rise rather less than they would have done if all the pseudo-cholinesterase had remained in the blood stream. Table II shows the "leakage into the tissues." There was, as would be expected, more deficit in the person weighing 14 st. (88.9 kg.) (Case 2) than

TABLE II.—Injection of Pseudo-cholinesterase and Rise in Enzyme Level of Serum

Case No.	Total Units Enzyme Injected	Rise in Units per ml. Serum	Expected Rise (Plasma Volume taken to be 2,500 ml.)	Units not Recovered per ml. Serum
1	252,000	93	100	7
2	105,000	23	42	19
3	126,000	39	50	11
4	63,000	13	25	12

in the others, who weighed much less. This deposition of additional enzyme in the tissues must have led to destruction of succinylcholine in these tissues and lowered the factor of 200, which usually results when the units of pseudo-cholinesterase are multiplied by the minutes of apnoea following administration of 30–50 mg. of succinylcholine to an adult (Evans *et al.*, 1952a). Table III shows that this

TABLE III.—If Succinylcholine Chloride is Injected Into an Adult at a Dosage of 30–50 mg. the Resulting Apnoea Depends on the Pseudo-cholinesterase Level of the Serum: Pseudo-cholinesterase in Units $\times$ Apnoea in Minutes = 200

Case No.	Fall of (Enzyme Units $\times$ Minutes Apnoea) Factor on Injection of Cholase	
	Factor before Injection of Cholase	Factor after Injection of Cholase
1	213	208
2	213	165
3	252	166
4	198	143

relationship applied well in the cases to begin with, but that the factor was lowered after cholase injection, with the exception of Case 1, in which, in view of the large amount of enzyme injected, the leakage into the tissues was relatively insignificant when compared with the rise in the plasma level.

Cases 3 and 4 received blood transfusions during the operation, but Cases 1 and 2 could be followed up for one day, and it was notable that there was still a significantly increased pseudo-cholinesterase level after 24 hours, when

252,000 units had been injected, but not after 105,000 units. Thus it may be possible to protect a person by the prior injection of pseudo-cholinesterase, but to obtain a prolonged protection the dosages will have to be large. In none of the patients did we discover any excretion of pseudo-cholinesterase in the urine.

We have elsewhere dealt with the suggestion that thiopentone was the true causative agent in increased sensitivity to succinylcholine (Evans, Gray, Lehmann, and Silk, 1952b); it will be noted that, at least in Case 1, thiopentone was injected before the succinylcholine was given, with and without choline; the difference in the duration of apnoea can therefore not have been connected with thiopentone. Hall, Lehmann, and Silk (1953) also paid particular attention to this point in their work on dogs, and have excluded apnoea due to thiopentone or to artificial respiration in the animals. We performed a special test on one of us (P. W. S. G.), in whom we injected succinylcholine without prior thiopentone. We have referred to this briefly before (Evans *et al.*, 1952b); here are the details of this experiment:

Man aged 30, weight 15 st. (95.3 kg.). Blood enzyme levels: Ps.ChE., 82 units; Tr.ChE., 136 units. 10 mg. succinylcholine chloride injected; apnoea of 40 seconds followed. One week later: Blood enzyme levels: Ps.ChE., 95 units; Tr.ChE., 129 units. 3 ml. pseudo-cholinesterase (63,000 units) injected. Blood enzyme levels: Ps.ChE. 122 units; Tr.ChE., 123 units. 10 mg. succinylcholine chloride injected; this was followed by no apnoea.

Since our last publication dealing with two patients (Evans *et al.*, 1952a) we have seen more cases in which a prolonged effect of succinylcholine could be explained by the finding of a low pseudo-cholinesterase level in the serum. There were, however, two patients in whom the enzyme level was normal; both were suffering from cancer and inanition, and had altered electrolyte values in the serum—particularly a low serum potassium. It is conceivable that in such patients a paralysis of muscles will not be easily reversed, because of a loss of excitability. Recently nikethamide was recommended as an antidote against succinylcholine (Barron, 1952); it is possible that it was of use in this type of case. Nikethamide has not been seen by us to lower the response to succinylcholine in man *in vivo* or to have an effect on either true cholinesterase or pseudo-cholinesterase *in vitro*.

Summary

The injection of pseudo-cholinesterase shortens the apnoeic response to succinylcholine. Not all the pseudo-cholinesterase injected can be recovered in the plasma; 20,000–50,000 units are “leaking” into the tissues within a few minutes. In one patient who received 252,000 units (equivalent to about 2.5 litres of plasma) the serum enzyme level was still raised after 24 hours, but no enzyme was found in the urine.

The history of King Edward VII's Hospital for Officers is the subject of an interesting booklet recently published. The hospital was founded by Miss Agnes Keyser (“Sister Agnes”) during the Boer War. King Edward, a personal friend of Miss Keyser, fulfilled the last social engagement of his life at the hospital, of which he was patron. The booklet (price 2s. 6d.) is obtainable from the hospital, now at Beaumont Street, London, W.1, and proceeds from its sale will be devoted to the funds of the hospital.

BREAST-FEEDING IN THE OXFORD CHILD HEALTH SURVEY

PART I—A STUDY OF MATERNAL FACTORS

BY

CELIA WESTROPP, D.M., M.R.C.P., D.C.H.

(From the Institute of Social Medicine, Oxford)

The present investigation relates to 574 mothers* who regularly attended the Oxford Child Health Survey for at least a year. Its purpose is to compare the circumstances of mothers who failed to establish or maintain lactation with those who succeeded in feeding their babies for several months. It will shortly be followed by a descriptive account of the effect on the babies of breast- as opposed to bottle-feeding.

Prevalence of Breast-feeding

None of the mothers failed to put their babies to the breast at least once, but lactation had ceased in 88 within four weeks of delivery, and a further 82 had weaned their babies before the age of 4 months. At the opposite end of the scale there were 70 mothers who gave their babies nothing but breast milk for six months or longer, and 53 who were still giving their babies some breast milk after the age of 10 months. The mean duration of complete breast-feeding was 5.3 months (± 3.62) and of partial breast-feeding (weaning period) 3.7 months (± 1.90).

There was a general tendency for mothers who weaned their babies early to do so quickly, and for mothers who weaned them late to do so slowly. Thus half the babies breast-fed for more than six months had a weaning period which exceeded twelve weeks, whereas nearly two-thirds of the babies who were given bottle feeds within four weeks of birth were completely weaned in less than three weeks.

Compared with recent surveys in this country, the prevalence of breast-feeding is high (see Bibliography). In view of the method of recruiting into the Child Health Survey (Stewart and Russell, 1952) this is unlikely to be a characteristic of all Oxford mothers.

Factors Associated with Breast-feeding Habits

In the following account three groups of mothers will be distinguished: (1) those who did not begin weaning until their babies were over 4 months old (53.8%); (2) those who maintained complete breast-feeding for more than three weeks but less than four months (30%); and (3) those in whom lactation was never firmly established (16.2%).

Age and Parity

In the National Survey of all babies born in England and Wales during the week March 3–9, 1946 (Royal College of Obstetricians and Gynaecologists, 1948) it was found that, after standardizing for social class and parity, there was no consistent relationship between the age of the mother and the duration of breast-feeding, but first babies were breast-fed longer than other babies. Hughes (1942, 1948), and Dummer (1949) also found that the incidence of breast-feeding was higher among primiparae, but Norval (1947) and Dykes (1949, 1950) found no relationship between breast-feeding and parity, and Neale *et al.* (1943) thought that first-born babies had less breast milk than other babies.

In the present investigation there were 264 primiparae, of whom 111 were under 25 years and 20 over 34 years. In these two age groups 11% and 25% respectively failed to

*There are 580 babies in the Survey Group, but five were adopted and two were twins.

establish breast-feeding, and 42% and 35% maintained it for more than four months. The corresponding figures for primiparae of intermediate age were 9% and 65%.

For multiparae there was no distinction by age, but mothers with two or three children more often maintained lactation for over four months (59%) than either primiparae (53%) or mothers with four or more children (45%), though these differences only reach the 5% level of significance. When both parity and social class (Registrar General, 1938) were taken into consideration two distinctly different trends were revealed. For mothers in social classes I and II the incidence of prolonged breast-feeding increased steadily with increasing size of family; but in all other classes mothers with two or three children had a higher incidence than either mothers with first babies or mothers with four or more children. Despite previous observations to the contrary, there seemed to be no association between spacing of children and breast-feeding habits, but this may be due to the fact that only 30 mothers had produced two babies within a year.

To sum up, the observed relationships between breast-feeding habits, age, social class, and parity suggest that previous experience of maternity has a favourable effect on lactation, but that this is not enough to offset the adverse effects of heavy domestic commitments and a low wage packet.

Physique and Health

Breast-feeding habits were found to bear no relationship to the height or weight of the mothers, or to a combined assessment of physique, based on the height/weight ratio ($Ht/\sqrt{Wt}$). There was, however, a close association between health and lactation. Thus, 58% of mothers whose health was uniformly good after delivery breast-fed their babies for more than four months and only 14% failed to establish lactation. The corresponding figures for mothers whose post-natal health was poor are 38% and 24% respectively. These differences reach the 1% level of significance. No definite relationship between health and social class could be established, but there was a definite tendency for health to deteriorate with age and with succeeding pregnancies.

Social and Economic Circumstances

The relationship between social class and breast-feeding has been variously interpreted in different parts of the country. In the National Survey there appeared to be a distinct social gradient, mothers in the professional and administrative classes being more successful in establishing and maintaining breast-feeding than working-class mothers. Gordon (1942) at Ilford and Ross and Herdan (1951) at Bristol found the same tendency, but Robinson in Liverpool, Dummer in Hitchin, and Dykes in Luton found no consistent association between social class and lactation.

In the present survey 66% of the mothers in social classes I and II completely breast-fed their babies for more than four months, compared with 54% in social class III and 44% in social classes IV and V. The same trend was observed in respect of the period of partial breast-feeding, but in social classes IV and V a disproportionately large number of mothers continued to feed their babies for more than nine months. This tendency for a low general prevalence of breast-feeding to be associated with a high late prevalence is apt to cause confusion when comparing the breast-feeding habits of different groups of mothers.

As it was possible that an occupational classification no longer provided a reliable index of material prosperity, an alternative “amenities rating” was applied to the survey mothers (Stewart and Russell, 1952). The object of this was to distinguish mothers who enjoyed the best opportunities for child-bearing from those whose commitments or lack of facilities handicapped them in any way. The rating was based solely on objective criteria and took into consideration such things as the structural repair of the house, the water, sanitary and cooking arrangements, garden facilities, the number of persons per room, the presence of other young children, lodgers, “in-laws,” paid helpers, etc. According

to this index, 20% of the mothers were favourably situated, and 56% moderately and 24% severely handicapped. The corresponding proportions for prolonged breast-feeding were 64%, 54%, and 43%, differences which are significant at the 1% level.

The individual components of the amenities rating appear to have a cumulative effect. Thus, the relationships between household density—that is, persons per room—and lactation, and between outsiders in the home and lactation, were of the same order but of doubtful significance; but no direct association between the duration of breast-feeding and the presence or absence of a paid domestic helper could be demonstrated. There was little to distinguish mothers who shared the house with “in-laws,” mothers who took in lodgers to make ends meet, and mothers who were themselves lodgers in someone else's house; but compared with mothers who had a house to themselves the overall incidence of breast-feeding was low in all three groups.

Wages and housekeeping allowances were not incorporated in the amenities rating, since no figures were available for one-fifth of the mothers; but within the group which was assessed there seemed to be no consistent relationship between the amount of money spent on food and breast-feeding habits.

Only 38 mothers resumed gainful employment before the babies were 4 months old. In this small group the incidence of breast-feeding was exceptionally low, but how many of these mothers deliberately stopped feeding their babies and how many would not have continued in any case is not known. There were eleven unmarried mothers, five of whom continued to breast-feed their babies for over four months.

Maternal Efficiency

Marks were awarded for maternal efficiency on the basis of a number of subjective assessments concerning the appearance of the house and the child on three home visits made during the first year (Thwaites and Sutherland, 1952): 64% of the mothers scored 12 (full marks), 27.6% scored between 11 and 9, and 8.4% scored fewer than 9 marks. The corresponding proportions for prolonged breast-feeding were 61.1, 51.2, and 24.5%.

Since maternal efficiency is correlated not only with social class but also with health, parity, and the amenities rating, it is difficult to assess the significance of its association with breast-feeding. Taken at its face value, the relationship suggests that mothers who are good housekeepers have less difficulty in establishing and maintaining breast-feeding than mothers who are always at “sixes and sevens.” But whether this is a direct effect or merely due to the fact that “efficiency” is one of the ways in which health, education, income, and appropriate facilities manifest themselves it is impossible to say. Within the group with top marks for maternal efficiency were 47 mothers from social classes I and II who also attended a private mothercraft clinic. No fewer than 35 of these (approximately 75%) maintained full lactation for at least four months. In this clinic great stress is laid on the importance of breast-feeding; small complementary feeds are encouraged until lactation is established, and a long weaning period is advised.

Mode, Place, and Time of Delivery

Less than half the survey babies were born at home. The hospital and nursing-home deliveries included 34 forceps deliveries and 7 caesarean sections; but in spite of this the group as a whole had a relatively high incidence of prolonged breast-feeding (56%). Further analysis of the institutional deliveries showed that the mothers in social classes I and II represented a typical cross-section of the whole survey group in respect of “general health” and “obstetrical emergencies,” but the mothers in social classes IV and V included an exceptionally large number of abnormalities under both headings. Both subgroups were mainly composed of primiparae. When the corresponding rates for prolonged breast-feeding were inspected it was found that only 39% of the mothers in social classes IV and V breast-

fed their babies for four months, compared with 68% in social classes I and II. For mothers who were confined at home the overall incidence of prolonged breast-feeding was 50% with no variation in the different social classes.

The babies who were born in the winter and spring (December to May inclusive) were breast-fed longer than babies born in the summer or autumn, but the difference is of doubtful significance ($P < 0.20$). Neither sex nor birth weight appeared to influence breast-feeding habits.

Discussion

So interwoven are the factors which influence breast-feeding habits that it is not only impossible to assess their individual contribution but even difficult to distinguish favourable and unfavourable influences. It is, for instance, unlikely that previous experience of child-bearing has anything but a beneficial effect on lactation, but it is not until parity and economic status are separated from one another that the true physiological effect is seen.

The present investigation has shown that mothers with heavy domestic commitments and lack of suitable facilities tend to wean their babies early, but we are still no nearer knowing what in "the complex of adverse circumstances which accompany poverty" (Ryle, 1946) has the most harmful effect. Other observers have failed to establish a direct relationship between lactation and nutrition (Robinson, 1939). It is improbable, therefore, that the observed association is due to malnutrition. It could, however, be due merely to the fact that the commercial advertising of baby foods is more successful in working-class than in professional circles. Once established, breast-feeding is both simpler and cheaper than artificial feeding. It is therefore unlikely that a working-class mother with several children weans her baby merely to "save trouble." On the other hand, breast-feeding can be very tedious in the early days and, other things being equal, a mother with heavy commitments and inadequate assistance is less likely to be successful in establishing lactation than a mother who can devote more time and attention to the new baby.

The relatively high level of breast-feeding among mothers delivered in hospital could be due to a bias in favour of hospitals by mothers who are otherwise favourably situated to establish and maintain lactation, or to the setting itself, which is, domestically speaking, restful and one in which good habits could be encouraged not only by precept, but also by example. It has certainly been a feature of other investigations (Hughes, 1948; Dummer, 1949; Dykes, 1950; Royal College of Obstetricians and Gynaecologists, 1948), but the relative importance of temporary freedom from worry, "selective recruitment," and example has not yet been measured.

Enough has been said to show how difficult it is to disentangle even the few factors chosen for special study, and how impossible to arrive at firm conclusions. With the small numbers available, the survey data have done little more than confirm the observations of previous writers and provide a background for the survey children. It may, however, be possible for larger clinics to select one or two of the more promising lines of inquiry for closer study. Meanwhile, the relatively high incidence of prolonged breast-feeding in the group as a whole suggests that a target of "breast-feeding by 80% of mothers for six months [which] would materially reduce both morbidity and mortality rates in infancy . . . is perhaps more readily obtainable than is generally believed" (Cruckshank, 1945).

Summary

Among 574 mothers attending the Oxford Child Health Survey, 53.8% breast-fed their babies completely for over four months and 16.2% for less than three weeks.

Social and economic conditions have a pronounced effect on breast-feeding habits. If they are good the incidence of prolonged breast-feeding increases with the increasing size of the family; if not it will diminish.

The high prevalence of breast-feeding among mothers delivered in hospital emphasizes the importance of freedom from domestic commitments in the early days of lactation.

I am indebted to Sister Wood, of the Oxford Mothercraft Clinic; to my colleagues in the Child Health Survey, particularly to Miss Thwaites, until recently our social worker; and to Dr. Alice Stewart for her encouragement and help. The Medical Research Council contributed towards the expenses of this investigation.

Medical Memoranda

Cholangiography by Means of a Barium Enema

The inflamed gall-bladder containing stones not infrequently becomes attached to a neighbouring hollow viscus, and on occasion a stone or stones may ulcerate into the intestinal tract, either completing the passage safely or producing intestinal obstruction, the complication of obstruction being more likely when the fistula is between the gall-bladder and duodenum.

Examples of the spontaneous passage of gall-stones by the intestinal route were commonplace when biliary surgery was a rarity. The following case is worth recording because the safe passage of the stone or stones did not result in the fistula closing, owing to the normal channel being blocked by a stone in the ampulla of Vater. Moreover, the patient's symptoms were presumably due to the persistence of the fistula, and the presence of this fistula was demonstrated radiologically before operation.

CASE REPORT

The patient, a married woman aged 70, was referred to me by Dr. Russell Fraser. She had been a known diabetic since 1939. In 1947 she suffered from severe diarrhoea for about nine months, and this cleared up after a single injection of liver extract. Up to three months previously she remained well so far as her gastro-intestinal system was concerned, and then the diarrhoea recurred. The bowels were opened 10 to 12 times daily, and she was most affected at night and in the mornings, but the bowels were not opened in the afternoon. The stools were pale yellow and liquid, and there was no blood or mucus. Liver injections were tried again, but with no relief. There was no loss of weight. She also suffered from frequency of micturition, pruritus vulvae, and cataract, all these symptoms being attributed to the diabetes. It was thought that the diarrhoea was due either to the diabetes or to a neoplasm of the

Sigmoidoscopy did not show any abnormality. A barium enema (Dr. A. Jenkins) revealed a fistulous communication between the colon, in the region of the hepatic flexure, and the gall-bladder. The opaque material passed along what was thought to be the common duct, where there was a filling defect which was believed to be a stone at the ampulla of Vater (see illustration).

Operation was carried out November 16, 1951, and the findings were exactly as had been suggested radiologically.

Radiograph showing the filling defect.

The hepatic flexure of the colon was adherent to the liver, and when the two organs were separated the gall-bladder was brought into view and was seen to communicate with the colon by a fistula. The fistula was divided and the opening in the transverse colon closed in layers. The junction of the cystic duct and the common bile duct was identified, and these ducts and the common hepatic duct were seen to be dilated. The pancreas felt normal. The common bile duct was explored and a stone was removed from the lower end. Another stone was found in the right hepatic duct. The ducts were washed out with saline, and, after the patency of the ampulla of Vater had been confirmed by means of a sound, the gall-bladder was removed and a drain placed over the common duct.

The patient made an uninterrupted recovery. The diarrhoea stopped immediately and has not recurred since.

Serum Sickness

Antitetanus serum is given widely as a prophylactic measure in out-patient departments of general hospitals and by general practitioners throughout the country, and mild symptoms due to serum sickness are noted from time to time. The following case is interesting because of the splenic enlargement, a factor which may cause confusion in diagnosis from glandular fever and septicaemia. Splenomegaly has been reported in America, but apparently not in this country.

CASE REPORT

The patient, a girl aged 7 years, injured her left thumb so that the nail and pulp were hanging by a medial skin-flap. She was admitted to hospital on October 26, 1951, for suture under general anaesthesia, and was given a prophylactic dose of 1,500 international units of antitetanus serum subcutaneously into the right arm, and "distaquine" penicillin 250,000 international units six-hourly. The wound healed and she remained very well and was discharged on October 31. She returned to the out-patient department the next day, when the thumb was dressed, and appeared quite well. On November 2, when she reported for further dressings, it was noticed that her temperature was 99.6° F. (37.6° C.), was noticed that her temperature was 99.6° F. (37.6° C.), and on examination tender enlarged, firm glands were found in both groins and popliteal fossae. The spleen was palpable two fingerbreadths below the left costal margin, but was not tender. There was no rash.

The patient was admitted to a medical ward, and on further examination four hours later was found to have palpable glands in both anterior cervical triangles and in the left axilla. There was an area of skin in the left hypochondrium 4 in. (10 cm) in diameter, bright pink in hue, but not

irritating. She had no temperature at this time. Her throat was normal, and she had no clinical jaundice. There was no apparent infection, and glandular fever was suspected. Blood examination showed: red cells, 4,530,000; haemoglobin, 78%; leucocytes, 7,000; polymorphonuclears, 83%; eosinophils 1%; lymphocytes, 13.5%; monocytes, 2.5%. A Paul-Bunnell agglutination test was negative, as were the Widal and Brucella agglutination tests. The next day, November 3, the pink erythematous area on the trunk had disappeared, but the skin over the gland in the right groin was discoloured. No local infection was apparent. A vaginal swab was taken, which revealed no cause for the adenitis, and a course of penicillin was begun by injection into the right buttock.

On November 5 the glands were no longer tender, but the whole of the right buttock was red, though on palpation there was no tenderness. A few rubelliform spots were noticed on the abdomen. The penicillin was discontinued, the diagnosis of serum sickness having been made. On November 6 the buttock was normal in colour, but a rash was present on both legs. This consisted of circular lesions with pale centres encircled by red rings varying in size from 5 to 30 mm. in diameter. The rash spread down her legs and faded lastly from her feet on November 8.

The following tests were made on November 8 and 9: Antitetanus serum was diluted to 1/100 and 0.02 ml. was injected intradermally into the right forearm. Twenty minutes later a wheal measuring 12 mm. in diameter and a flare measuring 24 by 30 mm. were noted. Antitetanus serum was diluted 1/10 and one drop was inserted into the left conjunctival sac: there was no reaction or irritation. (Ciba in 1932 tested 465 patients with conjunctival and intradermal tests: 5.6% were positive to both tests; 21.3% were positive to the intradermal test only. All patients positive to the conjunctival tests were also positive to the intradermal test.) Crystalline penicillin was diluted 1/100 and 0.02 ml. was injected intradermally into the left arm. Twenty minutes later there was no reaction.

Strazza (1946) reported delayed sensitization to penicillin similar to serum sickness. On a scratch test the reaction to penicillin 15,000 units per ml. was negative. Gordon (1946) reported three cases and reviewed the literature on reactions to penicillin simulating serum sickness. There was no reference to enlargement of the spleen, but one case had glandular enlargement. Scratch tests were sometimes positive.

Diphenhydramine hydrochloride was begun on November 9, 20 mg. being given four-hourly. The glands in her neck, axilla, and popliteal fossae were no longer palpable on November 10. The glands in the groin had decreased in size and were not tender, and the spleen could just be felt on inspiration. On November 12 the spleen was no longer palpable.

Peterson and Bishop (1947) treated serum sickness with diphenhydramine hydrochloride, giving 50 mg. or more, up to 100 mg., six- to eight-hourly, depending on results. As relapse may follow withdrawal, they suggested carrying on for three days to a week, depending on the condition of the patient.

COMMENT

There was no history of asthma, urticaria, or hay-fever in the family, and this was apparently the first injection of horse serum the child had had. The first sign was a slight fever discovered seven days after the injection, though it is possible that the glands and spleen had enlarged before this time. The rash appeared on the tenth day, and varied in type over the next five days. The only complaint during these manifestations of serum sickness was tenderness in the groins.

I wish to thank Dr. H. R. E. Wallis for permission to publish this case and Dr. M. Marshall, house-surgeon, who transferred the child under my care.

Reviews

SURGERY OF THE OESOPHAGUS

Surgery of the Oesophagus. By R. H. Franklin, M.B., B.S., F.R.C.S. (Pp. 219; 90 illustrations. £2 2s.) London: Edward Arnold, 1952.

Mr. Franklin's pioneer work on the surgery of the oesophagus, doubtless inspired by his association with Grey Turner, is well known, and his book is bound to attract attention. His own most important contribution is in the account of the treatment of atresia of the oesophagus, in which he tells us that his were the first recorded successes outside the United States; at the time of writing he had eleven successes following primary anastomosis. This is a noteworthy achievement and emphasizes that, owing to carelessness or ignorance in diagnosis, many infants are still being deprived of the chance of survival by not being referred to a surgeon. It is interesting to note that he now recommends the transpleural approach; the original procedure of resecting several ribs and working extrapleurally recalls the early years of this century.

The book provides a concise and clear account of the problems of oesophageal surgery and can be read without effort. It is liberally illustrated, although two of the four coloured plates are useless and their omission might have lessened the cost of the book. An index of the illustrations should have been included.

A chapter is devoted to oesophagoscopy, and the author emphasizes the dangers of the examination. Although he mentions the importance of the correct position of the head for safe instrumentation, he gives no instructions, and indeed Fig. 46 shows both the head and the neck in full extension, a position in which introduction of the oesophagoscope is almost impossible and certainly dangerous. This figure should be replaced by a set of illustrations showing the varying position of the head and neck at the different stages of the examination.

The book is chiefly suitable for postgraduate students and general surgeons needing to acquaint themselves with the advances of oesophageal surgery. One remarkable omission is any reference to or analysis of the figures (either the author's or others') of operability, mortality, and prognosis after operation for carcinoma of the oesophagus.

R. C. BROCK.

E.N.T. INTRODUCTION

Diseases of the Ear, Nose, and Throat. By J. Douglas McLaggan, C.V.O., M.B., Ch.B. (Aberdeen), F.R.C.S., and Josephine Collier, B.M., Ch.B. (Oxon), F.R.C.S. Second edition. General Practice Series. (Pp. 438; 149 illustrations. £1 17s. 6d.) London: H. K. Lewis, 1952.

The authors are to be congratulated on this the second edition of this work. It is intended for students about to be introduced to the subject and for the recently qualified, and both classes will greatly benefit from reading it. The text is refreshingly clear, largely owing to the correct choice of words. In its 422 pages the authors cover the whole ground of diseases of the ear, nose, throat, oesophagus, and bronchi; nothing is omitted, but there must be no skipping by the reader else he will miss sentences which, though short, contain considered opinions based on wide experience. As teachers the authors know it is better to make dogmatic statements than to enter into verbose discussions which tend to confuse—for example, "The practice of enucleating tonsils to relieve quinsy is dangerous and unsurgical."

The anatomy throughout is brief but clearly emphasizes what is important to the parts under consideration. Indeed the whole book is full of common sense, as may be seen in the informative paragraphs where, writing of Ludwig's angina, the authors say, "the rarity of the disease contrasts forcibly with the prominence given to it in textbooks." They

stress the importance of bacteriology in the differential diagnosis of tonsil ulcerations; they might have added routine blood examinations. Writing of operations, they emphasize general principles, giving details of technique only for the simpler operations, and these are clearly illustrated.

The chapter on laryngeal paralysis reduces the whole complicated story to easily understood simplicity; these words also apply to the account of simple and malignant intrinsic growths. Lastly, the chapters on the bronchi and oesophagus maintain the high standard set by the rest of the work and are admirably illustrated by diagrams and radiographs. This is a most readable book and should be in the hands of those tackling the specialty and desirous of becoming experts.

W. M. MOLLISON.

HEART AND CIRCULATION

Disorders of the Heart and Circulation. Edited by Robert L. Levy, M.D. (Pp. 944; 368 figures. £4 11s. 6d.) London: Baillière, Tindall and Cox, 1952.

Although the publishers describe this work as a new book, many of the chapters are revised versions of those published previously in *Nelson's Loose-Leaf Medicine*; with several new ones they have been assembled in the form of a separate monograph for the convenience of those specially interested in cardiovascular disorders.

In arranging the sequence of the 34 contributions by 41 authors, the editor confesses that he found it impossible to adhere closely to an aetiological classification, but was influenced by anatomical, physiological, diagnostic, and therapeutic considerations as well. Despite this explanation, it is difficult to discern any significant design in the order of presentation, and the expressed hope that undue overlapping has been avoided is certainly not fulfilled. Thus more than half the introductory chapter on cardiocirculatory physiology is devoted to heart failure, and yet we have another whole chapter on the same subject by a different author. Then, in a 48-page chapter on diseases of the pericardium, Pick's disease is discussed fully (and very well); yet the next chapter is on "Chronic Constrictive Pericarditis." Continuing, we have Abbott's original article on congenital heart disease (116 pages) followed by a modern version in 60 pages by Bing. Rheumatic heart disease (Bland) is on both active rheumatic carditis and established valve lesions, and then the chronic valve lesions are given a chapter to themselves. Perhaps the best example of duplication occurs later in the book, when a chapter on cardiac neurosis is followed by one on neurocirculatory asthenia (subject matter the same).

Owing to the increasing complexity of medicine and the vast territory that has been opened up in recent years, it is often said that the day of the textbook by a single author is over. Before it is discarded for good, however, its advantages should be carefully noted, so that they may be retained in the polygenetic literature of the future. These advantages include uniformity of style and treatment, continuity, balance, and proper building up of the work, section by section, without gaps and without redundancies, into a recognizable, pleasing, and comprehensive whole—in short, graceful, economical, and sound architecture. In the polygenetic book the editor is alone responsible for this architecture; in this respect he assumes a highly important role and should be fully aware of it. When Robert Levy says—referring to the contributors—"obviously, it is their book," one must agree, and that is partly the trouble.

But that is not all there is at fault. A single author seems more alive to the fact that he will be judged by what he has written; a multitude of authors give the impression that they do not care quite so much. It is the old story of the fewer men the greater share of honour, and its corollary. And so, even if the book is accepted as an unrelated series of 34 essays on various cardiovascular subjects, it does not compare favourably, chapter by chapter, with several well-known treatises on heart disease written by single authors. Now this is serious, because the chief theoretical reason for encouraging multiple authorship

(apart from the time factor) is the belief that one individual cannot be expected to cover a variety of subjects as well as a group of experts, each allotted his own special field. This is where the contributors must recognize their own responsibilities and the editor exercise his right of frank criticism.

Finally, there is the index. This one occupies 2% of the 944 pages and must have been compiled by an able and industrious lay professional. But was it checked by a cardiovascular expert? Under angina pectoris, for instance, we have

in aortic insufficiency ..	383
in aortic stenosis ..	381
in coronary disease ..	450
in coronary heart disease ..	442

and no page reference to angina in anaemia, diabetes, hypertension, paroxysmal tachycardia, mitral stenosis, myxoedema, pulmonary hypertension, syphilitic aortitis, or thyrotoxicosis. Six surgical treatments for angina are given a page reference, but is there no medical treatment? QRS appears in three guises, as a complex, interval, and wave—and so on. I believe that a single author, responsible for everything in the book, would either compile the index personally or would check it carefully for gaps and redundancies as well as for accuracy: not that this index is bad, but neither is it good. Thomas Nelson and Sons have printed the book very nicely, and the figures are excellently reproduced.

PAUL WOOD.

THROMBOSIS

The Pathogenesis and Treatment of Thrombosis: With a Clinical and Laboratory Guide to Anticoagulant Therapy. By Irving S. Wright, M.D. Modern Medical Monographs (Pp. 78; 27 figures. \$3.) New York: Grune and Stratton, 1952.

This monograph is based on the George E. Brown Memorial lecture, presented before the American Heart Association in 1951. The demand for copies of the lecture far outran the number of reprints available, so that Dr. Irving Wright wisely decided to incorporate the material in a small book. He discusses clearly and concisely the modern views on blood coagulation, reducing into an easily comprehensible form the knowledge of the complex factors known to take part. He also briefly reviews the influence of physico-chemical phenomena and morphological changes in the blood and vessels which may play an important part in the initiation of thrombosis. The relationship of malignant disease, familial traits, cold haemagglutinins, and cryptoglobulinaemia to the onset of clotting are ably discussed.

About half the monograph is devoted to the methods now available to combat the onset and sequelae of thrombosis; all the main anticoagulants, as well as some which are little used over here, are mentioned and their characteristics compared. Finally, the most widely used laboratory methods for the study of blood clotting and the control of anticoagulant therapy are set out in the appendix.

This monograph should be of interest to all concerned with the care and treatment of patients with thrombosis. Though it does not present any new concepts, both its theoretical discussions and practical applications are of value to the clinician and laboratory doctor. Since it was originally designed to be presented as the spoken word, it is both clearly expressed and easy to read.

H. PAYLING WRIGHT.

INJURIES OF THE SPINAL CORD

Les Traumatismes de la Moelle Epinière. By Daniel Mahoudeau. (Pp. 196; 33 figures. 1,250 francs.) Paris: Masson et Cie., 1952.

This short monograph was written with the intention of summarizing the results of recent work on injuries to the spinal cord, chiefly by English-speaking workers, and largely determined by their experiences of spinal cord injuries in the second world war. It is built round a sound bibliography and forms an excellent introduction to the subject,

being a well-ordered and clearly set-out exposition of physiological principles. No statistics interrupt the even development of the subject.

From the practical point of view the volume fails on two accounts. First, the strict limitation of the subject to cord injuries and bare mention of cauda equina injuries robs it of much usefulness, as the two lesions are so commonly encountered together and the differential diagnosis, if not of immediate practical importance, is of great prognostic value. Secondly, there are no case histories. The apology tendered for this, that they would overburden the volume, is scarcely sufficient to justify such an important omission, for on them one is chiefly dependent for correlating and reinforcing the theoretical considerations as well as for practical guidance.

The author only outlines orthopaedic aspects of treatment. He does not mention stabilization of the spine after reduction of a dislocation. His account of nursing is rather general. Tidal drainage, though becoming less popular in Britain, receives pride of place in treatment of the paralysed bladder.

In short, this is an excellent study in applied physiology and an ideal book for a senior student particularly interested in neurology or a postgraduate beginning some special training in spinal injury. But it will only refresh the mind of the experienced neurologist.

J. G. BONNIN.

CHIROPODY

Chiro-podial Orthopaedics. By Franklin Charlesworth, F.Ch.S. Foreword by Sir Harry Platt, M.S., F.R.C.S., F.A.C.S. (Pp. 255; 131 figures. £1 5s.) Edinburgh: E. and S. Livingstone, 1951.

The author of this well-written book has qualifications which must be almost unique, for in addition to a practical knowledge of surgical boot-making and years of experience as the head of an active school of chiropody (one of a number which have failed to survive the advent of the Welfare State), he has handled many hospital patients with really troublesome feet. Mr. Charlesworth describes his techniques in the concise manner of a good teacher, and the text is freely illustrated. Most of the chapters are on matters of interest not only to chiropodists and orthopaedic surgeons but also to surgical technicians and boot-makers. But many of the problems and the methods of dealing with them are well outside the field of chiropody: lobster feet requiring special insoles and surgical shoes is a typical example.

Considering he is a qualified chiropodist, the author expresses a fine scorn for felt pads and strapping in prolonged contact with the foot. Some of the removable appliances he describes are similar to those obtainable under N.H.S. schedules, but others require so much personal skill and care that they are not likely ever to be freely obtainable. This applies particularly to Mr. Charlesworth's moccasin technique for the protection of tender areas and for filling up the space of missing toes; a soft leather moccasin is made to cover the foot and is then built up in certain places, often by applications of milk rubber latex, to a form which can be accommodated in a shoe of acceptable shape. Strangely enough, the author does not mention that useful addition to a sturdy walking shoe, a steel plate inserted lengthwise between the layers of the sole in order to prevent any buckling at the tread in cases of hallux rigidus, march fracture, osteochondritis of a metatarsal head, or amputation of the great toe.

As consultant chiropodist to the Hope Hospital, Salford, the author naturally favours a department of chiropody in every large general hospital, and in the final chapter he describes his own clinic, which appears to thrive in happy symbiosis with the orthopaedic department. But Mr. Charlesworth has come up the long and hard way, and the chances are slender that other men will follow his lead and acquire such a combination of special skills.

SILICA OR COAL?

All miners, no matter what mineral they are occupied in extracting, are exposed to some dust derived from rock, and almost all such dusts contain silica, partly free and partly combined in the form of silicates. Since free silica causes fibrosis in experimental animals, while other mineral dusts are either much less fibrogenic or entirely non-fibrogenic, it is natural that pulmonary fibrosis in miners should be attributed to the free silica in the dust. The classical type of silicosis with whorled collagenous nodules, giving rise to the characteristic nodular picture in radiographs of the chest, is found only in men exposed to dusts containing a high proportion of free silica, as in the gold mines on the Witwatersrand. It was chiefly the increasing use of radiography that led to the recognition that pulmonary fibrosis also occurred in workmen exposed to various dusts with a relatively low free silica content. But the appearance of these "mixed-dust pneumoconioses" both pathologically and radiologically was different from that of silicosis, and the question arose whether the fibrosis was due to silica modified in its effect by admixture with other components of the dust or whether these other components were themselves contributing to, or even responsible for, the fibrosis.

This question has been most keenly debated and thoroughly investigated in relation to the pulmonary fibrosis found in coal-workers. In this country the non-committal term "coal-workers' pneumoconiosis" has been applied to this disease in order to leave its pathogenesis open, but in America and on the continent of Europe the terms "anthraco-silicosis," "silico-anthraco-silicosis," or plain "silicosis" are used with the implication that the disease is fundamentally a form of silicosis. These opposing points of view were debated at a conference on silicosis held at the Silicosis Research Institute at Bochum,¹ and some of the evidence put forward by both sides is discussed below.

Pathological studies of the lungs of coal-workers²⁻⁴ have shown that there is a progressive series of histological lesions ranging from the typical whorled silicotic nodule of the rock-worker to deposits of coal dust in foci throughout the lung, and in the peri-

bronchial and subpleural lymphatics, with little or no collagenous fibrosis and only a slight reticulin reaction. While silica may be responsible for the collagenous fibrosis in the intermediate type of nodule, Heppleston⁵ has recently argued that the coal "macule," without collagenous fibrosis, develops in response not to the minute quartz content of the coal but to the coal substance itself, and that the later development of collagen in these deposits is simply due to the advancing age of the lesion. Supporters of the siliceous origin of mixed dust pneumoconioses⁶⁻⁷ maintain that free silica, even in very small amounts, is always responsible for any significant fibrosis and that these non-fibrous, impalpable deposits of coal dust should not be regarded as falling within the realm of pathology. It was Arnold⁸ who, in 1885, first distinguished "anthracosis simplex" from "anthracosis indurativa." Rüttner⁷ dismisses the soft nodules of anthracosis simplex as "a mere soiling (*blosse Verschmutzung*) of the lung" and, like Gardner,⁹ maintains that they have no effect upon the function of the lung. However, simple nodular silicosis has also been found to have no significant effect upon lung function,¹⁰⁻¹¹ yet no one would deny that it was a pathological condition. Gough³ and Heppleston¹² have emphasized that in the course of time focal emphysema may develop in and around the coal macules, and that this must result in some disturbance of function. Severe disability in coal pneumoconiosis is largely confined to men with massive fibrosis,¹⁰⁻¹³ which develops only in those who already have simple pneumoconiosis. A "mere soiling" of the lung which may have such serious aftermaths is surely a pathological condition.

The advocates of the siliceous origin of coal pneumoconiosis take their strongest stand on the fact that animal experiments—whether carried out by intratracheal, subcutaneous, or intraperitoneal injection or by inhalation—have with few exceptions¹⁴⁻¹⁵ shown that pure coal dust produces no fibrogenic reaction, but here the argument appears self-contradictory. Collis and Gilchrist¹⁶ and Gough¹⁷ first showed that coal-trimmers who are exposed to such pure coal dusts do in fact develop pulmonary fibrosis, and Wright¹⁸ has shown that after the inhalation of large quantities of coal dust, collected at a coal face where the prevalence of pneumoconiosis is high, rats do not develop even a reticulin reaction in the lung approaching that found in the coal focus in man.

Negative animal experiments cannot disprove the fibrogenic action of a dust in man. It is possible that the experiments have not extended over a long enough period or, more likely, that the reactions of

human and animal lungs differ. It may be argued that since silica does produce fibrosis in the lungs of animals it should do so even in the presence of coal if it is the silica that is responsible for the fibrosis in man. Alternatively, the human lung must be more susceptible to minute amounts of silica in association with coal than is the animal lung. If this were so the administration to animals of coal enriched in silica (by the admixture of a small amount of quartz) should produce lesions resembling the coal focus in man. Such experiments have recently been reported by King and his colleagues.¹⁹ Using intratracheal injection, they found that 2 mg. of quartz caused no fibrosis in the lungs of rats, since it was removed to the hilar lymph nodes, where some fibrotic nodules appeared. One hundred milligrams of pure anthracite or graphite dust remained in the lung, producing no significant fibrosis. But when 2 mg. of quartz was mixed with 98 mg. of coal nodular foci of reticulosis developed. The authors suggested that the large amount of coal upset the lymphatic drainage so that the silica was retained in the lung to produce its toxic effect. While this conclusion is justified their experiments throw no light on the relative roles of coal and silica in human pneumoconiosis. They only suggest, not unreasonably, that a man exposed to a negligible hazard from pure silica might be worse off if he also had to inhale much coal dust, or that a coal-miner who also does some rock work may get more pulmonary fibrosis than a worker on a pure coal face. Moreover, dusts administered by intratracheal injection may behave differently from inhaled dusts. Mavrogordato,²⁰ using the inhalation method, found that a mixture of coal dust and silica caused less fibrosis in the guinea-pig's lung than the same amount of silica alone.

What is needed now is information on the pathological changes occurring in men exposed to high concentrations of pure carbon dust. Such exposure occurs in the manufacture of carbon black and of carbon-arc electrodes. Fifteen years ago Löcktemper²¹ and Hollman²² showed that workers in the carbon-black industry develop radiological abnormalities similar to silicosis. Recently Brauss and Gärtner²³ have confirmed these observations, finding radiological changes in soot-workers identical with

those in coal-workers' pneumoconiosis, including both simple nodulation and massive shadows. Koelsch¹ reported similar findings in workers making carbon electrodes. Unfortunately, and mysteriously, none of these cases has yet been investigated pathologically. Until this has been done there is no certainty that pure carbon can produce pulmonary fibrosis in man. But the close association shown by Gough²⁴ between radiological and pathological findings in coal-miners suggests that when at last a pathological account of soot-workers' lung is published it will tell a story of changes closely resembling those found in coal-workers. The present assumption that carbon is a wholly innocuous dust on inhalation may then finally be shown to be wrong.

This debate is not only of theoretical interest, for it has important practical consequences. In this country, recognition that coal dust itself may cause disabling pneumoconiosis has led to a vigorous campaign of dust suppression at the coal faces of all mines where dust concentrations, regardless of their silica content, rise above an approved level of 650 particles per c.cm. in anthracite and 850 in other coal mines. In the U.S.A., too, measures are taken to suppress all dust in mines, but the suggested levels of safety are still related to the silica content. Rüttner⁷ advocates judging the hazard of any dust upon a mineralogical and chemical measurement of the silica content. This insistence on the orthodox silica theory was also shown by nearly all the German experts in the discussion¹ at Bochum to which we have referred, and it affects their mining practice. In German coal mines dust suppression is concentrated on rock dust, and coal dust is regarded as being harmless. This attitude is carried to remarkable lengths. Worth and Dickmans,²⁵ in a survey of 350 miners, found as much radiological abnormality in relation to years worked underground in men who had only worked on the coal face as in men who had also worked in rock. They conclude that rock dust must be carried on to the coal face from other parts of the mine to produce disease in the men working there. Koelsch alone among the German experts sounded a note of warning based on his experience among workers exposed to pure carbon dust, and agreed with the view that coal dust itself might be

fibrogenic. "We have not got so far in scientific investigation in Germany," he said, "that the problem can yet be considered to be finally settled." Until it is settled the British term "coal-workers' pneumoconiosis," which leaves the question of pathogenesis open and concentrates attention on the coal dust which has been shown to cause the disease, is greatly to be preferred to anthraco-silicosis or, worse still, plain silicosis.

SEROUS HEPATOSIS

Two varieties of hepatic cirrhosis have hitherto been recognized as associated with, or resulting from, malnutrition: the diffuse fibrosis that follows prolonged severe fatty infiltration, and the less regular form with nodular hyperplasia that follows non-fatal massive hepatic necrosis. Both are readily produced in experimental animals, the former by diets deficient in lipotropic factors, and the latter by diets deficient in the thio-amino acids and vitamin E. In our opening pages this week Professor K. R. Hill and his colleagues draw attention to a third variety, in which neither fatty infiltration nor liver-cell necrosis appears to play any significant part in pathogenesis. Their discussion springs from the study of 150 cases of liver disease in Jamaican children. The disease apparently passes through three phases, acute, subacute, and chronic, and about one-third of their cases fell in each category. The phase at which the children were first seen correlated roughly with the patient's age, the acute cases occurring in the youngest and the chronic cases in the oldest; most were aged between 1 and 3 years. In the acute stage the child is obviously ill, with a large tender liver and ascites as the outstanding features. In the subacute phase the children do not appear ill, but the liver is enlarged, although ascites is often absent. In the chronic stage the clinical picture is that of hepatic cirrhosis with the usual complications due to portal hypertension.

The anatomical evolution of the hepatic lesion has been followed in many cases by serial biopsies, and the sequence of events is clearly depicted. In the early stages there is a conspicuous distension of the perisinusoidal spaces of Disse, which appear histologically to be filled with a protein-rich fluid. At a later stage a strongly eosinophil coagulum occurs within Disse's space in many places, and in association with this coagulum reticulin fibres appear in excess of those normally present in this situation. An extension of this sequence of changes to the spaces of Mall in the portal tracts and around the inter- and intralobular vessels gradually results in an exten-

sive diffuse fibrosis. This is further enhanced by fibroblastic invasion of the coagula, the resultant fibrosis producing the distortion and destruction of the normal lobular architecture characteristic of cirrhosis. It is apparently only in these more advanced stages that the parenchymal cells show evidence of severe degeneration or necrosis. Fatty change, with few exceptions, is insignificant throughout the course of the disease.

This sequence of events is strongly reminiscent of the condition termed serous hepatitis by Roessle¹ and Eppinger,² in which the perisinusoidal spaces become conspicuous owing to their distension by a protein-rich fluid. Although these authors did not actually observe the evolution of this condition into cirrhosis, they both emphasized the impairment of nutrition of the liver cells that must result from interposition of a further barrier between the cells and their blood supply as well as the interference with the adequate removal of metabolites. Keschner and Klemperer,³ however, strongly criticized the concept that serous hepatitis is an important precursor of fibrosis, since they found a similar condition in 15% of a large series of necropsies. As they found, moreover, that 36% of their cases of heart failure showed the same picture, they were inclined to dismiss both the term serous hepatitis, with its implication of an underlying inflammatory aetiology, and the condition itself as an important precursor of fibrosis. The frequency with which a similar state seems to occur agonally, to which Popper⁴ has drawn attention, would seem to support this attitude. The development of hepatic cirrhosis in cases of long-standing congestive cardiac failure—so-called cardiac cirrhosis—in which the histological picture of serous hepatitis is so frequently seen, draws attention to the importance of the time factor in liver pathology. If a hepatic lesion is of short duration, recovery from it is often complete and without scarring. The same lesion, or even one of lesser extent, if present beyond a certain minimum length of time, leads to irreversible change accompanied by fibrosis. This is well seen in cases of carbon tetrachloride injury, fatty infiltration, and congestive heart failure, and undoubtedly is of great importance in the Jamaican children.

Two points of especial interest in this work from Jamaica—and there may be a connexion between them—are the remarkable rarity of fatty infiltration (only 5 of Hill's 150 cases) and the cause of the

accumulation of protein-rich fluid in the spaces of Disse. The diet of the affected children was both tragically monotonous and deficient in protein—animal and vegetable. In all other parts of the world where similar diets are taken, the outstanding hepatic lesion, at least in the early stages, is fatty infiltration. Despite many detailed studies, serous hepatitis has not been observed in these other areas. Yet in Jamaica an essentially similar diet produces not fatty infiltration but serous hepatitis. An important dietary difference may lie in the various vegetable infusions or "teas" which appear to be consumed in large quantity by these Jamaican children, and the toxicity of these infusions is now being investigated. The hepatic necrosis caused by ingestion of the alkaloids of *Senecio* (ragworts)⁵ points to the possible importance of such a line of inquiry. The enhanced susceptibility to many liver poisons that results from dietary protein deficiency may well be a factor in restricting the condition to people whose nutrition is inadequate. Even if this is the true explanation of the facts, the anatomical effect of the toxic agent is distinctly unusual. The great majority of hepatotoxic substances cause necrosis of liver cells as the most conspicuous lesion. In the "serous hepatitis" in Jamaica the absence of parenchymal necrosis is conspicuous, and the outstanding lesion appears to be an increase in permeability of the sinusoidal endothelium. But, since a similar histological appearance can be produced experimentally with allyl formate⁶ or histamine,⁷ the postulated properties of the hypothetical poison are by no means unique.

ASPIRATION PNEUMONIA AND BRONCHIECTASIS

The many current theories about the aetiology of bronchiectasis reflect the uncertainty about the exact mode of production of this disease. Bronchial dilatation can be caused, it has been postulated, by developmental abnormalities, by destruction and weakening of the bronchial walls by infection, by traction from peribronchial fibrosis, or by mechanical factors following pulmonary collapse. As we have previously commented, the view that bronchiectasis is commonly congenital in origin is now less widely held.¹ Although it cannot be denied that bronchiectasis sometimes arises from an abnormal development of the bronchial tree, such cases are exceptional, and even many of the cases of so-called "congenital cystic disease of the lung" are probably acquired after birth.² The relative importance of the other factors in causing bronchiectasis remains uncertain.

being approached in different ways. The clinician, with an eye to the progress of the patient and the radiographic changes in the bronchial tree, has focused his attention on the calibre of the bronchi and been drawn to the mechanical theory of bronchial dilatation, sometimes without due regard to the pathological changes in the lung. The pathologist, on the other hand, from histological studies, has emphasized the inflammatory and fibrotic appearance of the bronchial walls and surrounding lung, and has tended to regard such changes as being primarily responsible for initiating bronchial dilatation. Again, as Whitwell³ has recently suggested, the diversity of these views might indicate that bronchiectasis is not a single disease but only a common feature of a number of distinct pathological processes. From a study of 200 lung specimens removed at operation Whitwell found it possible to separate three pathological varieties of bronchiectasis, and correlation with the clinical findings in these patients suggested that the varieties were aetiologically distinct. He gave the name "follicular" to a type of bronchiectasis which, occurring in young patients, often followed measles or whooping-cough; in these cases subepithelial lymph-follicle formation and peribronchial interstitial pneumonia dominated the histological picture. It was thought that the disease began as a diffuse bronchiolitis following acute viral infections in childhood. In the second variety, bronchiectatic saccules were formed by the bulbous ends of the branches of the segmental bronchi, the intervening lung parenchyma remaining normal and fully aerated. This type of "saccular" bronchiectasis was found in older patients, and it was thought to start as a mural inflammation of the medium-sized bronchi, with consequent destruction of the bronchial walls. The initial infection was not severe enough to affect the alveoli, so collateral ventilation remained normal, and there was no alveolar collapse. The third variety, "atelectatic" bronchiectasis, included those cases where lobar or segmental bronchial dilatation was associated with pulmonary collapse. Stimulating as these findings are to the study of bronchiectasis, it must be noted that Whitwell was able to fit only about half of the specimens examined into one of these three categories, and it is not altogether surprising that some specimens showed features common to both follicular and atelectatic bronchiectasis.

Most clinicians agree that there is a close association between pulmonary collapse and bronchiectasis.

and there is ample evidence that the atelectasis occurring in such diseases as whooping-cough and primary tuberculosis often gives rise to bronchiectasis. Elsewhere in this issue of the *Journal* Drs. K. D. F. Morle and Squadron Leader P. W. Robertson describe investigations which show that bronchiectasis may also follow simple aspiration pneumonia. By doing serial bronchograms on 300 patients with this disorder they were able to demonstrate the development of bronchial abnormalities in over 60% of the patients. In most instances the bronchi returned to normal, but in 5% an established bronchial abnormality persisted for more than 18 months after the original pneumonia. It is fair to assume that most of these patients had developed permanent bronchiectasis as a result of their pneumonia, although it is possible that there had been a previous bronchial abnormality in some patients. This finding emphasizes once again the importance of understanding simple aspiration pneumonia.

Aspiration pneumonia may be defined as collapse and inflammation of a broncho-pulmonary segment following mechanical obstruction to a bronchus by the retention or aspiration of infected secretions.^{4,5} It is a common complication of catarrhal disorders of the respiratory tract; it is usually a benign illness which responds rapidly to postural drainage and chemotherapy. This type of pneumonia has been slow to achieve general recognition because it is often confused with virus pneumonia and because it can be diagnosed with certainty only by accurate radiographic location of the pulmonary lesion. Yet benign aspiration pneumonia is probably the commonest type of pneumonia encountered in present-day hospital practice.⁶ Last week Dr. John Fry reviewed in this *Journal*⁷ a series of patients with acute lung disease which he had seen in general practice. During a period of two years he found only seven cases of lobar pneumonia as compared with 70 who had a mild pneumonic illness. Of these, no fewer than 21 patients had an illness which conformed to the accepted pattern of aspiration pneumonia. It is evident that aspiration pneumonia is not only a common condition but also one which can give rise to bronchiectasis as a late complication.

SUCCINYLCHOLINE

The chemist and pharmacologist are continually presenting the anaesthetist with new tools to help him to solve the problem of how to obtain safe and selective muscular relaxation without the need to depress cerebral function by deep narcosis or endanger life by prolonged depression of the respiratory muscles. A compound recently used for these purposes is succinylcholine;

chemically it resembles two molecules of acetylcholine lying alongside one another. It is valuable because it produces a muscular relaxation that is profound but normally of a very short duration, and allows manoeuvres such as intubation to be safely carried out. Unfortunately in a few patients the action of succinylcholine is not so short-lived, and prolonged cessation of respiration (apnoea) may result. A possible explanation of this abnormal reaction is discussed in two papers in this issue by Dr. H. Lehmann and his colleagues. The findings confirm earlier observations^{1,2} that the prolonged action of succinylcholine is seen in patients who have an unusually low level of serum pseudo-cholinesterase. The evidence now presented suggests that injection of a preparation of concentrated human serum which is sufficient to increase significantly the pseudo-cholinesterase activity of the blood will at the same time reduce this period of apnoea in these sensitive patients. It is unfortunate that it was not demonstrated that successive injections of succinylcholine would produce similar periods of apnoea in the absence of injected enzyme, so that there would then remain no doubt that the shorter period of apnoea after the second dose and following the plasma infusion was directly related to the rise in pseudo-cholinesterase activity so produced. Similar attempts^{3,4} have been made in animals to raise the level of the true cholinesterase by adding concentrated enzyme preparations, but these have shown little or no effect on the rate of destruction of acetylcholine. It is therefore unlikely that such infusions would be of any value in the treatment of poisoning by anticholinesterase substances such as some of the modern insecticides or war gases. It seems probable that succinylcholine exerts its effects by occupying the sites on voluntary muscle normally occupied by the acetylcholine produced in response to a nerve impulse which contracts the muscle. But the mechanism for destroying succinylcholine is less efficient, so that a longer-lasting block occurs, and further impulses cannot affect the muscle until the succinylcholine has disappeared to leave room for acetylcholine. Acetylcholine is destroyed by both true cholinesterase and pseudo-cholinesterase, but succinylcholine only by the latter.

The means whereby the succinylcholine is removed from the muscle remain uncertain, except that there is diffusion back into the blood, because we do not know whether pseudo-cholinesterase exists in the muscle or at the myoneural junctions in man. In view of the interest in cholinesterase and substances that interfere with its action it is surprising how little information there is on the amounts of these enzymes present in the different tissues. Only Thompson and his colleagues^{5,6} seem to have attempted a survey, and this includes rat tissues and only the central nervous system of man. As true cholinesterase cannot reach the myoneural junction from outside it is unlikely that pseudo-cholinesterase

¹ Bourne, J. G., et al., *Lancet*, 1952, 1, 1225.

added to the blood will be any more successful. The effect of raising the amount of enzyme in the blood is probably to increase the speed at which the blood level of the drug falls so that no more can reach the muscles. It would therefore be interesting to know if human muscles do in fact contain pseudo-cholinesterase and, if so, whether the level here varies as it does in the serum. The attempt made to compare the action of succinylcholine in man and dogs on the basis of the cholinesterase activities of their bloods will not bear critical examination. Before jumping to any conclusions about these observed differences in man and dog in their response to succinylcholine it would be as well to bear in mind the comment recently made by Zaimis⁷: "Hitherto it has generally been assumed that results obtained from experiments on one mammal could safely be regarded as typical for mammals in general. It is now clear that results obtained from the muscles of any one mammalian species are valid only for this species and perhaps for the particular muscle upon which the experiments were made." Dr. Zaimis was discussing the results of her observations on the action of decamethonium and succinylcholine on muscles.

THE TREATMENT OF VENTRICULAR FIBRILLATION

Increasing interest has recently been shown in the treatment of cardiac arrest during operation, a subject always of importance to surgeons and anaesthetists since the dangers of chloroform were first recognized, and now of particular significance while operations are being performed on the heart itself. Such operations and those on the adjacent thoracic viscera have given opportunities for direct observation of the heart and have allowed the differentiation of two catastrophes—cardiac arrest and ventricular fibrillation. In cardiac arrest, or ventricular asystole, there is complete cessation of all heart action. In ventricular fibrillation the ventricular muscle contracts in an irregular and uncoordinated fashion, producing rippling movements which can be easily seen or felt but which are ineffective, causing no beat and no pulse. The two conditions thus cannot be distinguished except by direct observation of the heart or by electrocardiography, and so when the heart stops during an abdominal or limb operation it is impossible to tell in which fashion it has done so. The effect of ventricular fibrillation is as serious as that of asystole, since it is never spontaneously reversible.

The established treatment for cardiac arrest is cardiac massage. An essential adjuvant is the maintenance of adequate oxygenation by artificial respiration with pure oxygen. Cardiac massage has two possible effects: first, it stimulates the heart mechanically; secondly, it provides a limited circulation. The heart itself and the brain cannot survive undamaged if their blood supply is cut off for more than a very few minutes—probably four minutes is the maximum¹—whereas other organs are much more tolerant, the liver and kidney surviving up to about thirty minutes' ischaemia. Compression of

the aorta below the origin of the carotids concentrates the blood flow to the coronary vessels and the brain and so should be done if feasible. The heart cannot be massaged efficiently through the intact pericardium. If the chest is open, it is a simple matter to incise the pericardium; if not, the approach is through the upper abdomen, dividing the diaphragm and pericardium through the adherent area, or perhaps preferably by a left-sided intercostal incision through the fourth space, with division of costal cartilages. Massage should always be started as soon as possible after arrest has been diagnosed.² The injection of various drugs into the cavity of the heart is usually recommended, sometimes before massage is started, but the importance of maintaining a circulation is so great that massage must not be delayed. Pride of place is usually given to adrenaline. This is probably a mistake, for it has recently been shown^{3,4} that the action of adrenaline on the anoxic heart muscle is to cause ventricular fibrillation; it should therefore be avoided. Calcium chloride, 10%, increases the irritability of the heart, and is perhaps of value,⁵ but there is no known drug proved to remedy this condition. Once the heart's action is restored, it is important to maintain an adequate systemic blood pressure. For this purpose continuous administration of vasoconstrictor drugs such as methedrine or noradrenaline may be necessary for several hours.

The same measures have been recommended in the past for the treatment of ventricular fibrillation. It has long been known that ventricular fibrillation can be stopped in the experimental animal by an electric shock. A powerful electric current of short duration passed through the ventricles causes a complete tetanic contraction, which is usually followed by resumption of normal beat. There have been several reports from America of this procedure applied to human patients,⁶ and recently McMillan, Cockett, and Styles⁷ at St. Thomas's Hospital have published the first account from Britain. They describe a simple apparatus, working off the mains, capable of giving a series of interrupted shocks of various voltages, which was found to succeed in dogs without causing serious damage to the heart. Its use in three human patients is reported; in each case the fibrillation was abolished. In the first two after about half an hour asystole occurred and the patients died. In the third normal rhythm was restored and persisted, and this patient recovered; his recovery was not complete, for he showed evidence of cerebral damage, and an electrocardiogram suggested an anterior myocardial infarct. The electric apparatus is an ancillary method of treatment; cardiac massage should be used before it is tried and if necessary after, and full oxygenation maintained throughout. Beck, whose experience is very wide, has stated, "The beat can be restored in every normal heart."⁷ By speedy diagnosis and rapid action many of these surgical tragedies can be avoided.

meningitis. Local lesions of the mouth or throat, such as an impacted wisdom tooth or peritonsillar abscess, although they may cause difficulty in opening the mouth, are painful and can usually be distinguished from true trismus on careful examination. The abdominal rigidity of tetanus has simulated that due to acute abdominal conditions, but the absence of tenderness and presence of trismus should prevent this mistake. At a later stage reflex spasms, accompanied as they are by severe trismus and opisthotonos, are characteristic, but occasionally they have to be distinguished from other causes of fits such as meningitis, encephalitis, epilepsy, and hysteria, and the convulsions of strychnine poisoning are similar except that they do not cause trismus.

The diagnosis of tetanus is essentially clinical, and special investigations are of little value. Lumbar puncture should be avoided except in cases of real doubt. The isolation of the organism from the wound is difficult, often impossible, and too slow to be relied on.

Treatment

This is best considered under four headings: (1) antitoxin and wound toilet; (2) prevention of intercurrent infection; (3) sedation and control of reflex convulsions; and (4) nursing, feeding, and general management.

The aim of giving antitoxin in tetanus is to prevent further absorption of toxin from the wound and to neutralize any toxin in the tissues or circulation before it can reach the nerve cells. If this can be given before a lethal dose has reached the nervous system the patient's life may be saved. To this end a large dose of 200,000 I.U. should be given, preferably intravenously, at the earliest possible moment. If the whole of this dose is not available when the patient is first seen a smaller dose should be given and the rest as soon as possible. A smaller dose given early is probably more effective than a larger dose some hours later. In patients with slight wounds it is unnecessary to give further antitoxin after the single large initial dose, but with severe infected wounds 50,000 units should be given intramuscularly once a week until healing has occurred. This is hardly ever necessary after civilian wounds. Nothing is gained by giving intrathecal antitoxin, and lumbar puncture is liable to excite spasms.

When antitoxin has been given the wound should receive appropriate treatment. Broadly the aim should be to convert an anaerobic into an aerobic infection, with the minimum disturbance of tissues, by thorough drainage and removal of necrotic tissue and foreign bodies.

One of the great risks of tetanus is secondary lung infection. As a prophylactic measure against this 500,000 units of penicillin should be given daily from the outset, and if infection develops in spite of this other appropriate antibiotics may be necessary.

It cannot be too strongly emphasized that the control of reflex convulsions by sedatives and relaxants is only symptomatic treatment. Complete control has little effect in prolonging life in a patient who has already absorbed a lethal dose of toxin. The aim should be to control the severe spasms which exhaust and are dangerous, without depressing respiration so much that the risk of chest complications is increased. Tonic rigidity alone is relatively harmless and can be left alone. In the early stages or in mild cases slight reflex excitability is best treated by large doses of ordinary sedatives such as potassium bromide, chloral, or phenobarbitone. For reflex convulsions bromethol is the drug of choice, but at present is difficult to obtain. This is given rectally as for basal anaesthesia in doses of from 0.07 to 0.1 ml. per kg. of body weight (estimated) twice or even three times daily in severe cases. As an alternative paraldehyde may be given rectally in normal saline in doses of 30 minims per stone of body weight (0.25 ml. per kilo.) two or three times daily or in one-quarter of this dose intramuscularly. Mephenesin antagonizes the convulsions produced by strychnine, probably by depressing reflex activity in the spinal cord, and has been favourably reported on in tetanus. It may be given either intra-

muscularly or orally in doses of 0.5 to 1 g. for an adult, repeated every few hours according to the effect produced. Opinions vary as to which route is better, but it seems to be relatively more effective in mild than in severe cases. Tubocurarine appears to be liable to excite respiratory spasm and is dangerous. In using sedatives and relaxants in tetanus the first dose should be on the small side and the increment judged by the response.

Because reflex convulsions are excited by stimuli of all kinds tetanus patients should be nursed as quietly as possible in a darkened room. All manipulation such as feeding and giving injections should be done while the patient is most deeply under the influence of sedatives. Nourishing fluid feeds should be given as regularly as possible, and a special nurse is essential in severe cases. When trismus is severe nasal feeding is necessary and intravenous fluids may be required. The mouth should be kept as clean as possible to lessen the risk of aspiration pneumonia, and cyanosis controlled by warmed nasal oxygen. Good nursing may have great influence in turning the scales in borderline cases.

Prognosis

In assessing prognosis the factors which have to be considered are whether passive immunization has been given, the length of the "incubation period," the length of the "period of onset," the severity and site of the wound, the violence of the spasms, the age and physique of the patient, and the presence of intercurrent disease. The "incubation period" is the length of time between the receipt of the wound and the first symptom, which is usually trismus. If infection with *Cl. tetani* has occurred some time after the wound was received this may be shorter than it appears, and therefore misleading. An incubation period of less than seven days means a bad prognosis, but when more than 10 days it is relatively good. When the "period of onset" is less than 48 hours the chances of recovery are slight, but when more than three days relatively good, and they improve with every day convulsions are delayed. If prophylactic antitoxin has been given the attack is usually mild. A severe or heavily infected wound makes the prognosis worse, and it is bad in infants or the aged or those enfeebled by intercurrent disease. The best prognostic yardstick is the period of onset, and this should always be used in assessing the result of any new form of treatment.

It will be seen that tetanus still presents many practical problems in prevention, diagnosis, and treatment. The ideal relaxant has yet to be found, and there is no specific remedy against toxin in the nervous system. The paradox remains that, although preventable, tetanus still occurs in civilian practice. Notification with details of age, sex, occupation, type of wound, and whether active immunization had been given might yield useful data which would make it easier to apply active immunization to certain limited sections of the population.

Next Refresher Course Article.—"Antenatal Care," by Professor W. C. W. Nixon.

A special programme of health education by World Health Organization teams was recently carried out under the auspices of the Egyptian Government in an isolated village in Upper Egypt (*Chron. Wld Hlth Org.*, 1952, 6, 355). Here a venereal disease control campaign included a complete serological survey of the population of about 9,000 persons and treatment with penicillin of all infected persons and their contacts. Social workers had the task of visiting homes and obtaining the co-operation of village people. Though there had never before been a public meeting for women in the village the team was successful in arranging shows of films and other meetings for them. While blood samples were being taken a rumour went round the village that the blood was being used in the manufacture of certain beverages, but it was successfully dispelled. In the end about 85% of the population submitted to blood tests.

THE ELDERLY AMPUTEE

BY

D. S. MCKENZIE, M.B., Ch.B.

(From the Ministry of Pensions Limb Fitting Centre, Roehampton)

Since the advent of the National Health Service the Ministry of Pensions Limb Service has been called upon to treat large numbers of elderly patients, and it was therefore felt that a more detailed study of the results obtained by current methods would be of value and perhaps form a guide to the minutiae of technique and selection in future.

At the inception of the N.H.S. the experience of the Limb Service in the rehabilitation of elderly patients was not extensive, the technique of rehabilitation having been evolved primarily in relation to active ex-Service men. This technique had, however, met with success, and we were encouraged to adopt the same methods, modified only in so far as the programme was adapted to the physical capacity of the higher age groups and the more enfeebled.

Enough time has now elapsed to assess results in respect of the first 6,000 N.H.S. patients accepted for prosthetic treatment at Roehampton. Of these, 344 were "primary" cases—that is, patients who had not yet worn a prosthesis—aged 65 or more, representing some 30% of all the primary lower-limb cases received during the same period. It has been estimated that 4,000 to 5,000 major amputations are performed each year in the British Isles in times of peace, so that the Limb Service can expect some 1,350 new elderly patients annually. The wastage from death and intercurrent disease is, of course, considerable, and only a proportion are successfully equipped with prostheses; but elderly patients requiring continued supervision by the Limb Service throughout the years cannot be expected to be less than 5,000 to 6,000 at any given time.

Technique

The technique adopted in the treatment of this age group has followed the same general plan as that used in the past. Patients are seen as out-patients in the limb centre as soon as possible after reference from hospital. There seems to be no general decision concerning the stage at which cases to be seen by the limb surgeon at an early stage, while others wait until the patient has been discharged to his home.

At first the limb surgeon makes a local and general examination and assesses the capabilities. If further stump or general treatment is indicated he will normally refer the patient back to his hospital with suitable recommendations, unless he feels that the special experience of the Roehampton staff is required. At the earliest possible stage a pylon is ordered for thigh cases, while below-knee cases normally are fitted direct with the permanent prosthesis. The pylons are fitted direct with the "durestos" sockets (Scales, now used are provided with "durestos" sockets (Scales, 1950), and are very light. They can be made in a very short time, and rehabilitation can begin at an early date and so promote morale. It is found that many patients and so promote morale. It is found that many patients referred to this centre have not persisted with stump exercises and bandaging, the details of which technique have been published by the Ministry of Pensions (1951). Omission of this treatment, or failure to persist in it, results in a flabby stump with terminal oedema and general debility with lack of muscular tone, and in delays and difficulties in limb-training which are in some cases insuperable.

Training in walking is started as soon as possible after delivery of the pylon. We find it better for morale if this is carried out by daily attendances on an out-patient basis, and only those who have too far to travel or have complicating factors are admitted to the hospital. The training consists of individual balancing and walking exercises between handrails, progressing to walking with sticks, stair-climbing, walking on slopes and cambers, etc., and instruction in meeting all the ordinary needs of existence. In conjunction with this, group therapy is employed in the form of suitably modified remedial exercises designed to promote general improvement in muscle tone, to improve reactions, and to stimulate morale. The training is continued until the patient is fully independent or until no further progress can be made. Thus the single below-knee amputee may have two weeks' and the double-thigh subject four or more weeks' training.

After training, the patient is kept under observation by a follow-up, and the permanent prosthesis is prescribed when function merits it. Further training is given after delivery of the permanent prosthesis.

Results

An attempt has been made to assess results obtained in the 344 cases under review in relation to the age and sex of the patient, the site of amputation, the cause of amputation, and the presence or absence of complications. Rehabilitation was regarded as successful in 171 (49.7%). No very exacting criteria have been taken, but cases were considered to be successful if appreciable and regular daily use has been made of the prosthesis for a period of not less than six months from completion of fitting and instruction. Failure occurred in 101 cases (29.4%). Death supervened during rehabilitation procedures or within six months of completion in 31 cases (9%). Fitting was not attempted in 16 cases (4.6%), the result remains uncertain in 5 cases (1.5%), and follow-up has failed to trace 20 patients (5.8%).

TABLE I.—Results in Relation to Age

Age:	85+	80-4	75-9	70-4	65-9	Total
S ..	3 (50%)	7 (29.3%)	31 (41.3%)	54 (52.4%)	76 (55.9%)	171 (49.7%)
F ..	2 (33.3%)	9 (37.5%)	26 (34.7%)	28 (27.2%)	36 (26.5%)	101 (29.4%)
D ..	0	2 (8.3%)	9 (12%)	9 (8.7%)	11 (8.1%)	31 (9.0%)
NT ..	0	2 (8.3%)	5 (6.7%)	7 (6.8%)	6 (4.4%)	20 (5.8%)
NA ..	1 (16.7%)	2 (8.3%)	4 (5.3%)	3 (2.9%)	6 (4.4%)	16 (4.6%)
U ..	0	2 (8.3%)	0	2 (2.0%)	1 (0.7%)	5 (1.5%)
Total	6 (1.7%)	24 (7.0%)	75 (21.8%)	103 (29.9%)	136 (39.6%)	344

S=Satisfactory. F=Failure. D=Death. NT=Not traced. NA=Not attempted. U=Uncertain.

Table I shows, as would be expected, an increasing failure rate with age. The high proportion of successes in the oldest group is probably not significant, owing to the small numbers involved, except to show that age itself is no bar to successful rehabilitation. The oldest patient to be treated was a woman born in 1860 who had had the right leg amputated above the knee when she was 5 years old but had never worn a prosthesis. To this extent she was perhaps not strictly a primary case, as she had not recently had a debilitating illness or undergone major surgery. She has been included, however, on the ground that it was her first attempt with a prosthesis. She was fitted with a pylon in November, 1948, and with an articulated prosthesis seven months later. She made uninterrupted progress despite domestic difficulties, and when last seen in September, 1951, she was "making better use of her leg than many half her age." At the other end of the scale six of the youngest patients were so debilitated that limb-fitting was not attempted, and over 25% have failed to learn to manage a prosthesis. The oldest double-thigh amputee to make successful use of prostheses was 81.

The incidence of failure has been higher in females. Table II shows the relative figures. There were approximately twice as many males as females in the series.

TABLE II.—Results in Relation to Sex Distribution

	S	F	D	NT	NA	U	Total
Male ..	119 (52.1%)	55 (24.2%)	24 (10.5%)	13 (5.7%)	12 (5.3%)	5 (2.2%)	228
Female	52 (44.8%)	46 (39.7%)	7 (6.0%)	7 (6.0%)	4 (3.5%)	0	116

The death rate was appreciably higher amongst the males. It may be that they approached their rehabilitation with greater determination to overcome their disablement, in many cases possibly through a feeling of economic compulsion, which could explain the higher success rate at the cost of shortening life in some of them. The numbers are not large enough for us to draw more than tentative deductions on this score, particularly as the death rate in general in this age group is higher in males.

TABLE III.—Site of Amputation

	Single A.K.	Single Thro. K.	Single B.K.	Double A.K.	One A.K. One B.K.	Double B.K.	Upper Limb	Total
S ..	118 (49.4%)	5 (2.1%)	26 (10.8%)	14 (5.8%)	3 (1.2%)	3 (1.2%)	2 (0.8%)	17
F ..	73 (30.5%)	2 (0.8%)	9 (3.8%)	16 (6.8%)	1 (0.4%)	0	0	101
D ..	21 (8.8%)	0	5 (2.1%)	3 (1.2%)	0	0	0	31
NT..	11 (4.6%)	0	5 (2.1%)	3 (1.2%)	0	0	0	20
NA	12 (5.0%)	0	0	2 (0.8%)	0	0	0	16
U ..	4 (1.7%)	1 (0.4%)	0	0	0	0	0	5
Total	239	8	45	38	9	3	2	

The preservation of the knee-joint is, of course, normally an advantage. However, the low success rate among those who have suffered double amputation—one above and one below the knee—the high death rate, and the high proportion for whom limb-fitting could be attempted (Table III), support the apparently paradoxical view held by me that in patients of this age rehabilitation, at least to a measure of independence, has been more readily effected among those who have had a double amputation at or above the knee. This is in direct relationship with the technique employed in the latter case, because initial rehabilitation is undertaken on short pylons, on which the patient is kept as near the ground as is permitted by the longer of the two stumps, and effort is minimized. A recent development of this technique, not included in this series, is the addition of rocker bases to the short pylon, which further reduce the expenditure of effort. The results of this method are most promising but it would be premature to give figures at this stage. (Note: The supply and use of short pylons has been regarded as a successful outcome in the double above-knee cases, although only five of them progressed to full-length articulated limbs within the period of review.)

Disarticulation at the Knee

Although the numbers are small, it is interesting to note the high success rate of disarticulation at the knee. (This includes two Stokes-Gritti amputations, of which one failed.) The success of these cases tends to confirm the impression gained that such patients learn to walk more readily and gain balance and confidence more quickly than those with the conventional above-knee amputation. This is probably because, with a disarticulation at the knee, end-bearing can often be tolerated, thus permitting the axis of the body weight to be borne through the femur instead of through the ischium, and requiring less readjustment. It is necessary to provide a somewhat more cumbersome prosthesis for the disarticulation case owing to the bulbous extremity

of the stump, and it is probable that the gait can never be so good as that obtained with the prosthesis designed for the ideal stump, but it is felt that for the elderly these disadvantages are outweighed by the relative ease of the early rehabilitation and, above all, by the fact that such an operation is the simplest one and is attended by the minimum of shock.

In only one of the cases (the one classified as uncertain) was there any breakdown of the stump, and it would seem that disarticulation could be adopted with advantage for many more patients in the age group under consideration. The Stokes-Gritti stump has never proved very satisfactory among ex-Service men from the limb-fitting point of view; end-bearing is seldom tolerated, and the terminal soft tissues are prone to circulatory deficiency, possibly owing to the fact that the flaps may have been taken too high to obtain advantage of the anastomosis round the knee. There seems no reason to expect better results in the higher age group than in the younger patients we have seen in the past, and the bone section involved would cause the very surgical shock which one wishes to avoid. We therefore do not see any place for the Stokes-Gritti amputation or any other modification of the classical disarticulation at the knee for the elderly patient.

Cause of Amputation

The most significant fact, as shown in Table IV, is that diabetics have relatively poor prognosis with regard to both rehabilitation and survival. As might be expected, in the

TABLE IV.—Cause of Amputation

	S	F	D	NT	NA	U	Total
Diabetes ..	20 (34.5%)	22 (38.0%)	9 (15.5%)	4 (6.9%)	3 (5.1%)	0	58
Embolism ..	0	1 (50%)	1 (50%)	0	0	0	2
Thrombosis ..	4 (33.3%)	3 (33.3%)	1 (8.3%)	1 (8.3%)	1 (8.3%)	1 (8.3%)	12
Raynaud's disease	2 (100%)	0	0	0	0	0	2
Other forms of gangrene	90 (50.6%)	55 (30.9%)	12 (6.7%)	11 (6.2%)	8 (4.5%)	2 (1.1%)	178
Ulceration ..	24 (61.6%)	8 (20.5%)	2 (5.1%)	2 (5.1%)	1 (2.5%)	1 (2.5%)	39
Neoplasm ..	10 (55.6%)	4 (22.2%)	2 (22.2%)	0	0	0	18
Trauma ..	11 (61.1%)	3 (16.7%)	1 (5.6%)	1 (11.1%)	1 (5.6%)	0	18
Pyogenic infection	6 (75%)	1 (12.5%)	0	0	0	0	8
Tuberculosis ..	1 (33.3%)	2 (66.7%)	0	0	0	0	3
Aneurysm ..	2 (50%)	0	1 (25%)	0	1 (25%)	0	4
Elephantiasis ..	1 (50%)	1 (50%)	0	0	0	0	2
Total ..	171	101	31	20	16	5	344

acute pyogenic and traumatic groups the success rate is high. This is probably because they have not suffered from prolonged debilitating illness. The presence or absence of concomitant disease or disablement is of more direct prognostic significance.

Complications

The complications (Table V) were in the main cardiovascular and respiratory, and disorders of locomotion. The latter include disabilities of the upper limbs, owing to the fact that these patients have at least to learn to walk as quadrupeds. Specific complications, together with numbers of cases exhibiting each complication, are shown in

TABLE V.—Complications

	S	F	D	NT	NA	U	Total
Complications present	81 (40.1%)	66 (32.7%)	20 (9.9%)	14 (6.9%)	16 (7.9%)	5 (2.5%)	202
Complications absent	90 (63.4%)	35 (24.7%)	11 (7.7%)	6	0	0	142

Table VI. It will be appreciated that two or more complications may have been coexistent in individual cases. The figures emphasize the importance of defects of the contralateral leg, the arms, vision, heart disease, and deafness.

TABLE VI.—Specific Complications

	Total	Successful	
		No.	%
Defects of contralateral leg ..	72	26	36
Defects of stump ..	56	26	46
Gross obesity ..	31	16	52
Hernia and hydrocele ..	18	9	50
Myocardial disease ..	17	5	29
Defects of upper limbs ..	15	4	27
Chronic bronchitis, with dyspnoea on exertion ..	13	6	46
Defective vision ..	11	2	18
Intercurrent hemiplegia ..	9	3	33
Deafness ..	8	2	25
Cerebral arteriosclerosis ..	7	3	43
Psychological overlay ..	4	1	25
Dermatitis (general) ..	4	1	25
Previously treated neoplasm in breast ..	2	2	100
Tabs dorsalis ..	2	1	50
Intercurrent prostatectomy ..	2	1	50
Bedsore ..	2	—	—
Scoliosis, peripheral neuritis ..	1	—	—
Prolapsus uteri ..	1	—	—

The last of these is interesting, and its inclusion among the complications is probably explained by the fact that the deaf person retires into himself and is difficult to bring into group therapy and into the atmosphere of optimism one can cultivate in his more fortunate fellows. Obesity has been less of a handicap than might have been expected.

Discussion

The results in these cases show that no single complication encountered can be regarded as an absolute contraindication to limb-fitting. On the other hand, one cannot simply regard the elderly amputee as having a stump for which all that is required is to fit a prosthesis to enable him to walk. On the contrary, the stump is by no means the most important part of the problem. A comprehensive examination must be made of the patient's entire physical and mental make-up, and suitable treatment of any concomitant disability instituted in conjunction with prosthetic rehabilitation.

The complicating factors are, in fact, wider even than this. The environment to which the patient returns on discharge is of vital importance. We not infrequently see patients who have made good progress and who are discharged from the walking school able to control their prosthesis and to look after themselves fairly well. Yet when we see them on follow-up we find they have hardly worn the prosthesis, and the musculature has lost tone to the extent that they can no longer control it. Inquiry reveals that they live alone, perhaps in an upstairs flat, or it may be that they have simply lacked the incentive to make the effort to persevere. It would seem that here is a problem of welfare which is outside the scope of the Limb Service, and falls more within the province of the social medicine specialist.

Again, we have had to contend with patients who have acquired an unwarranted optimism concerning what can be done for them. They expect to be provided with a prosthesis with which they can walk immediately and without effort. They may be in poor physical condition, and often their stumps may be flabby, neglected, and quite unprepared for wearing a prosthesis. It is impossible to convince some of them that they will not be able to manage a prosthesis other than by letting them try for themselves on a pylon. The effect on morale of the inevitable failure can be imagined. We have known of patients admitting that they had been prevailed upon to accept amputation by the promise of easy function with a prosthesis. The psychological approach from the limb surgeon's point of view is much simplified if a more conservative briefing has been given in the general hospital and the patient has been

warned beforehand that he will have a prolonged and strenuous programme before him, but that if he will make the effort he should be able to walk. This programme should be initiated from an early date and maintained throughout by a regime of active physiotherapy, directed not only to the stump but to the whole bodily musculature, together with occupational and diversional therapy suited to the intellectual standard of the individual. The programme can with advantage be phased, each phase having a target which must be attained before the next phase is started (Marjory Warren, 1950, personal communication). This may seem a counsel of perfection unrelated to the pressure on hospital beds in these days, but it is my belief that there would actually be a saving of time, and therefore of beds, if such a programme were in uniform use.

The following brief case histories illustrate some of the points raised.

Case 66.—A married woman aged 68. Double above-knee amputation, the later amputation being performed on December 22, 1948, for gangrene of unspecified nature. She was grossly overweight. W.R. positive; prior to the amputation she had been diagnosed as tabetic. She made uninterrupted progress on short pylons, and, although she did not progress to full-length articulated limbs, she obtained enough function from the short pylons for the result to be regarded as an unqualified success.

Case 69.—A man aged 81. Amputation of right thigh through lesser trochanter following road accident. There was an unreduced congenital dislocation of the left hip. He lives by himself. He learned to manage a "through hip" (tilting table) prosthesis without difficulty, and in spite of his unfavourable home circumstances continued to make good use of it.

Case 223.—A married woman aged 66. Left above-knee amputation as a result of old-standing osteomyelitis. She had generalized seborrhoeic dermatitis, was deaf, and had defective vision (6/60 R. and L.). Despite this, she did well on a pylon prosthesis, and also learned to manage an articulated prosthesis competently. Four months later she was found to have given up the effort and had reverted to a wheelchair existence.

Case 257.—A man aged 69. Right above-knee and left below-knee amputation. Despite his excessive weight he made an uninterrupted and rapid rehabilitation, which was maintained.

The cause of death in the 31 patients who died during or immediately following limb-fitting procedures was as follows: coronary occlusion, six; hypertensive myocardial failure, four; diabetic coma, three; pneumonia, hemiplegia, and secondary carcinomatosis, two each; renal failure in association with diabetes, diabetic gangrene of contralateral leg, senile gangrene of contralateral leg, dissecting aneurysm with renal suppression, and perforated gastric ulcer, one each. In seven cases the cause of death could not be ascertained. Only one death occurred while the patient was actually undergoing fitting of the prosthesis or training in walking; this patient collapsed and died of acute cardiac dilatation in the walking school. He was a hypertensive subject.

In consideration of the fact that all cases in the series were under observation for upwards of a year, the death rate gives no cause for alarm or for modification of policy. It is very doubtful if the effort of limb-fitting had any material effect in shortening life, and, even if it did, the majority of patients would prefer to make the attempt rather than pass the rest of their life in a chair. The manifestly bad risks were not attempted.

Summary

A series of 341 consecutive primary amputees of 65 years or more who have been referred to Roehampton Limb Fitting Centre for a prosthesis has been reviewed.

The results suggest that no single factor will determine the selection of patients suitable for limb fitting, and that an assessment must be made of the entire physical and mental make-up. Age itself is not an adverse factor, and there is no evidence that wearing a prosthetic limb has shortened life significantly.

Self-demand Feeding

SIR,—I should like to make a few remarks on Professor R. S. Illingworth's interesting letter (December 20, 1952, p. 1355). Self-demand feeding will not fulfil its purpose if it is to become a rigidly imposed doctrine as has been scheduled feeding in the past. Of the many maladjusted children to-day who have failed to fit into their environment a high proportion have broken down under the strain of too great pressure to conform at an age when their capacities for such adjustment were inadequate; but it should not be overlooked that many children have grown up and adjusted themselves in such a regime. I have met mothers who felt so insecure without this kind of order in their lives that the anxiety and tensions which were aroused adversely affected their relation to the baby, and feeding suffered accordingly.

When deciding which method is best the question to be asked is which will suit this particular mother and baby. This can only be decided by the couple themselves. If a free hand is given at the start they will establish a regime that suits them. Feeding is the first social activity the child experiences, and the first social relationship begins then; this lays the foundation for future relationships in the wider social sphere.

An important aspect of wise mothering is the use of a kindly discipline that protects the infant while he is too young to know what is necessary for his survival; but because his needs often cut across his wishes such "discipline" is only possible with a minimum degree of disturbance from someone who has made it her business to understand him and can use it with insight. It would be disastrous, in my opinion, if self-demand feeding should be thought to imply that the mother is to be completely at the mercy of her baby's omnipotent demands, just as it has been disastrous in the past when the baby has been completely at the mercy of such demands from the mother. For this reason I share Professor Illingworth's misgivings about the term "self-demand schedule." It would seem to me only common sense to allow two people who are so important to each other to determine for themselves how best they can establish a good feeding relation.—I am, etc.,

MARION MACKENZIE.

Overfeeding in Early Infancy

SIR,—I was most interested to read "Overfeeding in Early Infancy," by Dr. Ian G. Wickes (November 29, 1952, p. 1178). I found this article very instructive, and there is so much in it with which I agree. I have had over 20 years' concentrated experience in the feeding of infants, and have a vast correspondence with mothers and nurses on this subject.

It is true in most breast-feeding cases that if the infant is allowed to determine his own requirements overfeeding takes care of itself. I have, however, met many cases of definite overfeeding with the symptoms of this disorder as described by Dr. Wickes. Often opportunity for diagnosis is not possible until symptoms and conditions have generally altered and the breast milk is likely to have lessened considerably. Underfeeding may very easily follow overfeeding, and, for this reason, underfeeding is sometimes mistakenly pronounced to be the cause of the original trouble. Diagnosis of overfeeding by reason of a large weight gain alone is not justifiable; other points should also be noted before such a diagnosis can be considered. Babies are individuals, no hard and fast rule can be made, and each infant's particular needs should be respected.

Surely it is misleading to group the breast- and bottle-fed babies together in this discussion? The breast-fed infant can be over- or underfed, but normally the balance of his food remains stable and perfect. In contrast, the artificial mixtures can be variable and the balance should be considered even before quantity per feed. It is pointless to pronounce that the artificially fed infant is either over- or underfed without first knowing the content of his feeds and the proportion of one ingredient to another, as well,

of course, as his symptoms. It is, in fact, difficult to overfeed a bottle baby but easy to underfeed him. Refusal to finish feeds often means that his mixture is too concentrated, and I find that appetite sharpens when the balance of the mixture is corrected.—I am, etc.,

E. MORRISON.

Parenteral B₁₂ in Acute Leukaemia

SIR,—Dr. Ian Welsh (November 22, p. 1133) details his experience with larger-than-ordinary parenteral doses of B₁₂ ("ordinary" in this case referring to the dose employed in Addisonian megaloblastic arrest anaemia, to date the only unequivocal indication for B₁₂ administration) in acute leukaemia. Results relating to duration of life are tabulated along with a qualitative designation (plus or minus) whether some degree of remission may have been induced. Dr. Welsh seems inclined to the opinion that his results were essentially negative, a conclusion that may also have been implemented by the fact that transfusion and antibiotic administrations were interspersed at the direction of attending physicians, and by Dr. Welsh's apparent cognizance of the additional fact that either of these modalities can be responsible for remission of acute leukaemia.

Whether the B₁₂ administered took the form of liver- or streptomycin-derived material and, if the latter, whether it was of "crystalline" or "crude parenteral" grade might be germane to a negative report were it not for the fact that my own experience with any of these sources of B₁₂ affirms the modest conclusion reached by Dr. Welsh. My reason for the present affirmation is twofold. First, in 1950, along with Dr. Harry L. Fox, I published a paper entitled "Innocuity of Protracted Administration of Special Fermentation Concentrates of B₁₂ as Demonstrated in a Patient with Acute Leukaemia" (*Ohio St. med. J.*, 1950, 46, 784). The patient remained in prolonged remission, and, though the body of the mistitled paper contains the belated explanation that it was the mycin antibiotic content of the streptomycin-derived fermentation material—not its B₁₂—that induced and maintained remission, we have been erroneously confronted with the advocacy of B₁₂ administration for this condition.

That onus might stoically be borne were it not for the second point, that I believe parenteral B₁₂ to be not only ineffective but to have been materially harmful to patients whose anaemia is of the erythroblastic arrest (rather than megaloblastic arrest) type, a situation not infrequently extant in the so-called "haemolytic" anaemias as well as the usually refractive anaemia of acute leukaemic subjects. Like Dr. Welsh's conclusion about ineffectiveness, my own on its invidiousness must necessarily rest on impression, but my conclusion in this regard is so strong that I will risk neither its dispelling nor its fortification at the cost of direct human experimentation. The risk would involve the latter, for, on my own acute leukaemic service, needling, whether for supernumerary haematological "follow-up" or for other than urgent medications (and this includes transfusion), is kept at a bare minimum. Opportunity for direct observation has, however, not been altogether lacking, because on other haematological services strong appeal has resided in giving what general physicians have been told is the most active "haematinic" yet uncovered—one that is effective in far smaller amounts than any other common pharmaceutical and, without too much specification around the last point, is completely devoid of toxicity. I have thus seen doses of from 0.1 to 1.0 mg. given to acute leukaemic patients as well as those with aplastic anaemia, not always as a desperation measure, and, though I cannot at present prove my point, I believe the majority of these patients have reacted poorly and have even initiated haemorrhagic phases more than coincidentally to the B₁₂ injection. Being without ability to firmly document this belief, refuge must be taken in the rationalization that most acute leukaemic patients are hypersensitive individuals; they react poorly to a host of agents which those who do not have a disease of adaptation will readily tolerate.

The overall life duration in the series presented by Dr. Welsh does not compare unfavourably with numerically equal series in which B₁₂ was not given, and this may serve to mitigate a possible contention that such administration is noxious. In fact, these durations are easily as good as, if not better than, in some contemporary series accrued while the aminopterin fiasco was emerging. The justifiability of utilizing life duration figures in comparison has been questioned; their only possible merit lies in overtreatment, whereas "remission rate" as a therapeutic criterion is open to the more dubious question of definition. Be that as it may, my own life durations of acute leukaemias in a series incorporating all ages

statistically significantly so, time alone will tell. In the latter series the mainstay of treatment has been the relentless, continuous daily administration of just enough oral terramycin with milk to maintain a Gram-positive, odourless stool. The severe potassium loss and sodium retention exhibited by many leukaemics on this antibiotic ingestion regime is anticipated and met with a high potassium intake and sodium restriction. Where preponderant mineralocorticoid effects (joint or bone pains, rapidly enlarging glands and intractable oedema) persist, the antibiotic dose is supplemented by a small one of the glucocorticoid, oral cortisone.

The patient's haematomorphology is studiously ignored, because the clinical condition seems a much better index of progress. The numbers of circulating formed elements are permitted to find their own equilibrium level compatible with life, which they frequently do. As a corollary of this go fact, transfusions are seldom resorted to; in cases which go to erythroplasia there is no other alternative than transfusion, but these always take the form of packed, unwashed cells. By studious deletion of those agents which contribute to overtreatment, including B₁₂ injections, average life duration in the present series is now about four times that calculated from Dr. Welsh's table. I am hopeful of doing even better in the future.—I am, etc.,

ROBERT D. BARNARD.

Measurement of Tissue Components Radiologically

SIR,—Dr. Frank Falkner and Miss Sylvia Wisdom in their article "Measurement of Tissue Components Radiologically" (December 6, 1952, p. 1240) appear to have exaggerated the simplicity and accuracy of their "new" technique and also exaggerated the difficulty of the tele-radiographic method. With teleradiography the object is not to reduce the overall magnification (which in any case is easily corrected mathematically) but to produce a nearly parallel beam which prevents differential magnification of the tissues being measured due to these lying in more than one plane.

Their technique seems to be based on the false assumption that the outlines of skin, muscle, and bone in a cross-section of a limb may be represented by three concentric circles and that of a maximum diameter of all three structures will fall in one plane which will be parallel to the film. In fact, the outlines are neither circular nor concentric, nor are they symmetrical; thus the two points on an outline where the rays of the anode are tangential will often be different distances from the film, thus to measure the diameter of these outlines in one limb by the "new" method six object/film distances have to be measured. Even assuming this can be done, what distances is it proposed to measure—the actual distance between the two points where the rays are tangential or the distance apart in the plane parallel to the film? In either case three exercises in trigonometry will be necessary for each limb.

But can the object/film distances be measured? The shift of technique is a well-known method of estimating the depth of opaque foreign bodies. But foreign bodies have fixed identifiable points the shift of which can be measured. With solid objects without recognizable points any tube shift which will produce a measurable shift of the shadow will produce a different profile of the outline so that the tangential rays will cut the outline at different points on this circumference, and it is not difficult to conceive possible limb shapes where these points would be widely separated. The excessively short anode film distance used in the "new" technique will mean that the points on the outline (even a circular outline) where the rays are tangential will not be on the maximum diameter. The error will be greater the larger the diameter and, therefore, disproportionate between the diameter and, therefore, disproportionate evidence of the same structures as the limb grows. The experiment with a rigid metal object (we are not told its shape but it, presumably, had fixed points) seems merely a repetition of foreign body localization. The second experiment used only one cross-section of a cadaver. What we need to know is the error involved over the whole range of size and shape of limb cross-sections from infants to adults.

The disadvantages of teleradiography are not as great as Dr. Falkner and Miss Wisdom suggest. The output of the apparatus they employ at 60 cm. is 15 mA for $\frac{1}{4}$ second. Using a distance of 180 cm. (6 ft.) only nine times this exposure is required—namely,

15 mA for one second, or 135 mA for $\frac{1}{4}$ second are appropriate. This compares with their statement that 200 to 400 mA for $\frac{1}{4}$ second is required. Their third criticism of teleradiography is that the centre of the limb can only be guessed and cannot be accurately positioned relative to the film. Substituting a doubtful radiographic technique introduces much more error—for example the image shift measurement, a few millimetres at the most, cannot be judged with any great accuracy bearing in mind that ± 1 cm. may represent a 10–20% error. Contrary to the statement of Dr. Falkner and Miss Wisdom, scatter is not influenced by the choice of methods. In the teleradiographic method the beam is limited to the part being examined by devices known as cones. Further, if the examinations are to be repeated often enough for irradiation dangers to be considered then the very short anode film distance of the "new" method will materially increase the dose to the skin nearest to the tube.

Dr. Falkner and Miss Wisdom complain of the expense of apparatus for teleradiography. We doubt if the price of two 15 mA units will be much less than one 100 mA unit, since 15 mA units are in demand for portable work, whereas 100 mA units are obsolete and large numbers have been scrapped recently and are, presumably, available second-hand. The only advantage of the new method over teleradiography, using a 60–100 mA unit, is an insignificant reduction in exposure time which cannot justify the introduction of a "new" technique which appears to have so many sources of error.—We are, etc.,

External Popliteal Palsy

SIR,—External popliteal palsy is not quite so simple as Drs. Hugh Garland and Doreen Moorhouse (December 27, 1952, p. 1373) would make it appear. To mention only one difficulty, the bifurcation of the sciatic nerve often occurs inside the pelvis, and then an "uncomplicated" palsy may result from a lesion well above the level of the head of the fibula—for example, in the piriformis muscle, which is frequently pierced by the external popliteal division.

In an article on electromyography (*Lancet*, 1950, 1, 937), I described a case which resembled several of theirs in that the palsy came on after squatting in an awkward position. But in my case the electromyograph revealed signs of denervation in the short head of the biceps femoris, proving that the lesion was situated at least above mid-thigh level. Weakness of the short head is not easy to demonstrate clinically, because the long head (innervated by the medial popliteal nerve) remains intact; but either head alone can readily be explored with a needle electrode. It is possible that, if the patients of Drs. Garland and Moorhouse had been tested in this way, evidence of lesions above knee level might have been found in some of them.—I am, etc.,

London, W.1.

FRANK SARGENT.

Smoking and Cancer of the Lung

SIR,—The conclusions of Dr. R. Doll and Professor A. Bradford Hill (December 13, p. 1271) leave no doubt that cigarettes are the main carcinogenic factor in this disease. This is of vital importance to the whole nation. 13,233 people died of this cancer in 1951. A correlation between the rising curve of tobacco consumption with that of deaths from lung cancer, over the last 25 years, suggests that the annual increase of approximately 1,000 deaths will continue until 1965 unless action is taken quickly. It is probable that nearly 25,000 people will die each year by that time. This is a most serious challenge in the social history of our generation. The facts must be made known to the whole community, and the Government, the manufacturers, the medical profession, and the consuming public must face their responsibilities.

The Government problem is primarily one of public health, for many men are dying an avoidable death before the age of 65. Publicity and consequent prevention can only come from central action, and all the power of the Press must be harnessed in this great campaign. A drop in revenue from the tobacco tax is inevitable, but £610m.

annual tax cannot justify silence on the cause of the mounting death rate. The legal responsibility of cigarette manufacturers should be clarified, for it can be an offence to produce goods which are harmful to the health of the consumers. The profession itself must now meet a very personal responsibility in preventive medicine. For years clinicians have tended to pay lip service to the wider aspects of prevention of disease. If we continue to smoke, our patients will follow our example. Are we justified in encouraging them to take this risk? Whatever decision we make about our own health we must tell them of their risk. Doctors who see men slowly dying of this unpleasant and painful death must feel impelled to prevent such deaths in the future. The general public will respond if they are given a sufficiently bold lead. The nation cannot afford to lose many of its most able and industrious men at the peak of their careers.

The following facts should make us press for a saner import policy. Expenditure on the import of cortisone and A.C.T.H. was officially limited to £216,428 in the 12 months ending October 31, 1952. In the 12 months ending March 31, 1951, 221,200,000 lb. of imported tobacco were smoked. Thus beds are filled with dying patients while beneficial and life-saving treatment is denied to sufferers from other diseases.—I am, etc.,

London, N.W.10.

HORACE JOULES.

Treatment of a Case of Shock

SIR,—We feel that it may be of value to record the following case of volvulus of the small bowel with vascular collapse treated by intravenous infusion of "levophed" (noradrenaline). We are informed by Messrs. Bayer Products Ltd. that the use of intramuscular ephedrine to facilitate withdrawal of noradrenaline has not previously been described.

The patient, a woman aged 65 years, was admitted on May 10, 1952, with a history of acute abdominal pain which had commenced eight hours previously. Her blood pressure on admission was 135/70 mm. A diagnosis of small-bowel obstruction was made, and gastric aspiration and intravenous saline were commenced in preparation for operation. In spite of this her condition deteriorated rapidly and her blood pressure began to fall. A transfusion of whole blood gave no improvement, and intramuscular and intravenous methedrine was also tried without effect. The blood pressure continued to fall until, five hours after admission, she was in severe shock and the pressure was unrecordable. An infusion of normal saline was set up containing 8 mg. of noradrenaline to the 35-oz. (994-ml.) bottle and the drip commenced fairly rapidly. Within 30 seconds the patient sat up in bed and vomited, and her blood pressure was found to be 160/100 mm. The drip was slowed to approximately 30 drops/min. and the pressure stabilized at 120/80 mm. During transport to the operating theatre the drip was inadvertently speeded up and her pressure rose to 260 mm. systolic. During the operation the systolic pressure was maintained without difficulty at 120 mm. At operation the peritoneal cavity was full of blood and a volvulus of the small bowel was found. The involved bowel was gangrenous and more than 7 ft. (2.13 m.) of small intestine was resected.

Post-operatively it was found to be impossible to discontinue or even slow the noradrenaline drip. Every attempt to do so resulted in an immediate fall in the blood pressure. In addition, it was found that increasing amounts of noradrenaline were required to maintain a steady pressure. It was decided to try the effects of intramuscular ephedrine, and gr. $\frac{1}{4}$ (32 mg.) at three-hour intervals was given. As a result it became possible gradually to slow the noradrenaline drip, and after a further 12 hours it was discontinued completely, with the patient's blood pressure remaining steady at 140/85 mm.

In this case we have no doubt that the intramuscular ephedrine was the operative factor in the stabilization of the blood pressure, and without this the patient would not have survived, as the noradrenaline appeared to have been gradually losing its efficacy over the preceding 24 hours. The patient's subsequent recovery was uneventful, and when last seen she was well and without symptoms.—We are, etc.,

J. WILSON MUGGOCH.

J. R. DYER.

London, E.3.

Operative Treatment of Hallux Valgus and Rigidus

SIR,—Mr. N. Ross Smith in his article "Hallux Valgus and Rigidus Treated by Arthrodesis of the Metatarso-phalangeal Joint," published in your issue of December 27, 1952, p. 1385, claims that the operation he describes will preserve the function of the great toe. He pours scorn on the operations designed to produce a pseudarthrosis of the first metatarso-phalangeal joint because they all fail to preserve this function. The new arthrodesis requires a relatively extensive operation, including fixation of the cartilage-denuded metatarso-phalangeal joint with a screw, stainless steel wire, or staples (either of the two latter admittedly to cause trouble in removal later). After two weeks the foot has to be immobilized in plaster-of-Paris, which has to be retained for six weeks. The metal internal sutures will then need to be removed, and finally adjusted footwear will be required. The advantages claimed over the other operations are that walking in the plaster cast can be started after two weeks and physiotherapy is hardly needed. As a result of all these complicated manoeuvres it is stated that there is freedom from pain and disablement in 58% of patients and a further 31% are to be thought satisfactory if sufficient account is taken of the other causes of disablement in the foot.

In the conventional pseudarthrosis operations it is to be expected that, after a fortnight's freedom from weight-bearing and with due attention to the rehabilitation of the intrinsic muscles of the feet, a fully mobile foot will result and that the patient will be capable of walking in normal footwear. Cleveland and Winant¹ published a series of results of 193 Keller's operations for hallux valgus and rigidus, and 93% of excellent results are claimed. Bonney and Macnab² published a similar series of 188 arthroplasties and modestly claim reasonably good results, but admit the need for further research.

It is difficult to see why fusion of the first metatarso-phalangeal joint of the foot should be more rational than arthroplasty, or that it can preserve the function of the hallux any better. The author suggests that the failures in his series are caused by fixation of the fused joint at less than 30 degrees of dorsiflexion, but a big toe at such an angle must prove in itself something of a disability when putting on a shoe. Whatever may be gained cosmetically by the new operation is probably lost in the inevitable rigidity of the foot which will result partly from the fused joint and partly from prolonged immobilization of the foot.

Statistically the new operation has no advantages to claim over the conventional arthroplasties, while they have the distinct recommendation that there is a fair chance of restoring the proper muscular control of the foot. The Mayo, Keller, and Girdlestone operations may very well be far from ideal, but at least no farther than the new procedure advocated. If it be conceded that the arthrodesis may finally produce a relatively painless semi-rigid foot which is cosmetically satisfactory, then it might be fairly suggested that a rigid foot equally immaculate cosmetically and quite painless could be more expeditiously produced by amputation below the knee.—I am, etc.,

Leeds.

Routine Dental Treatment

SIR,—The letter on the above subject from Brigadier R. A. Broderick (January 3, p. 43) is so one-sided as to be misleading. The dental hygienists whom he praises could in their second year be trained to do other operations equally efficiently, and as there are long waiting-lists in every large hospital for children requiring the operation of "Ts. and As." is this his answer?

What of the profession of dental surgery? It became a "closed" profession after much effort in 1921 (long after the medical profession). Are we now to admit "half-

qualified" dentists, and, if so, how is the general public to differentiate? Brigadier Broderick owes it to his juniors that they enjoy the same professional standing as he has done during his professional life. It should be known that it is necessary to acquire the same technical skill to fill both temporary and permanent teeth, and the extraction of temporary teeth is by no means always easy.

The dental schools are full of students training (four years or more) to be fully qualified dental surgeons: are they to be displaced to make room for these "dental nurses"? The idea of utilizing dental nurses emanated from New Zealand, where the conditions for their employment are peculiarly suitable, but these conditions do not exist in this country.—I am, etc.,

Newtown, N. Wales

E. DAVIES-THOMAS.

SIR,—Brigadier R. A. Broderick (January 3, p. 43) has mentioned that the British Dental Association is strongly opposed to ancillary dental workers, but has failed to refute its case in any way. He has assumed, perhaps quite unwarrantably, that the large numbers of children with badly decayed teeth are owing to lack of skilled attention being available. He seems to envisage the use of ancillaries in general hospitals to provide "simple fillings" for those who attend, probably both out-patients and in-patients being in-attendant. Brigadier Broderick knows as well as any other dental surgeon that spasmodic provision of fillings is worse than useless, and that follow-up inspections and further fillings are essential if further caries is not to destroy teeth already filled. Without adequate follow-up patients lose faith in fillings, and when a dental surgeon tries to persuade them to save teeth at a later stage they refuse point-blank because they know fillings are "no good."

Brigadier Broderick has not said how he could define a "simple filling," nor has he stated what distinguishes a difficult extraction. Surely he is not suggesting that all deciduous teeth are easy to extract. Does he think dental surgeons could use hypodermic syringes in the mouth, and ancillaries could use hypodermic syringes from being inhaled under avoid fragments of carious teeth from being inhaled under general anaesthesia? It would be interesting to know how Brigadier Broderick would answer the British Dental Association's point that to train ancillaries would not increase total dental man-power because the supply of dental teachers is limited and the effective life of women trained in this kind of post is only 10 years; also what objections he has to the British Dental Association's belief that the most effective way to deal with the problem is to enlarge existing dental schools and to turn out more fully qualified dental surgeons.—I am, etc.,

Birmingham.

C. N. JEFFRIES.

POINTS FROM LETTERS

Puerperal Psychiatric Illness

Dr. ELLIS STUNGO (London, W.1) writes: I cannot agree with Dr. R. E. Hemphill's emphatic assertion (December 6, 1952, p. 1232) that pregnancy seems to insulate and protect women from psychological and social stresses and strains of the greatest severity. His comprehensive survey of puerperal psychiatric illness was carried out on women delivered at maternity hospitals the majority of whom were, no doubt, either enthusiastic potential mothers, or, alternatively, multiparae who had accepted their pregnancies as a matter of course. My experience of pregnant women has included many who for some reason were unwilling to have the child, and the psychiatric conditions they exhibited have varied from mild reactive depressions to severe schizoid states. I have seen so many cases of attempted suicide in this category of case women that I am convinced of their special vulnerability, and I believe that the incidence of suicide in this category of case is high. I certainly agree that women who are desirous of physical and psychological health, and I would suggest that the degree of "insulation" varies directly with enthusiasm for their pregnancies. An additional survey to that of Dr. Hemphill's valuable investigation which I am sure would prove most rewarding, might be conducted into the incidence of psychiatric illness in unwillingly pregnant women before, during, and subsequent to the puer-

perium. It would be interesting to ascertain the psychiatric history and destiny of women denied a therapeutic abortion. My experience is that a proportion of them either kill themselves, become chronically ill, enter into unsatisfactory marriages with detrimental repercussions on their mental health, or become prostitutes, alcoholics, or delinquents. While the risk of psychiatric illness must not be too readily invoked or exaggerated by doctors sympathetic to the termination of a pregnancy in a particular case, it must not be too lightly disregarded by those antagonistic to interference with an otherwise normal pregnancy. The welfare of the nation is involved either way, and research is urgently indicated into the incidence of psychiatric illness in (a) those women whose pregnancies are interrupted on psychiatric grounds and (b) those compelled to carry on.

Second Attack of Chicken-pox

Dr. N. H. H. GOLLEDGE (Horn, Sussex) writes: I have had the impression that genuine second cases of chicken-pox were comparatively rare. I have just encountered an example in which the interval between the two attacks was only six months. Both attacks occurred in time of minor epidemic. On the first occasion there was a moderate typical rash, but in the second attack there was a severe eruption preceded by general constitutional upset and headache for three days. The rash was again absolutely typical in appearance and distribution. I should be interested to know whether any of your correspondents have had a similar experience.

"Et al., etc."

Dr. R. E. M. COKE-HARVEY (Berkhamsted) writes: Dr. A. J. Jex-Blake (December 6, p. 1259) is baying down the scent of an illusory "space-saving abbreviation for the printer." Whereas "et al." for the singular "and another" is a real abbreviation confirmed by time and use, the plural "and others" ("et alii") is more elegant and correct, and takes up no more space than "et al." Moreover, if Dr. Jex-Blake wishes to write the neuter form "and other things" ("et alia") does he flee the Scylla of the full form for the same old Charybdis of "et al.," thereby causing a possible confusion?

Remedy for Drunkenness

Dr. A. H. BARTLEY (Tumatumari, British Guiana) writes: I wonder if any of your readers have ever used any of the intravenous barbiturates when confronted with a wildly excited, abusive, and sometimes dangerous drunkard. As an orderly medical officer in a British colonial hospital in 1948, I was frequently called to deal with such types. They were somehow more quarrelsome, noisy, and dangerous than those met with in the United Kingdom. This of course may be due to the cheap and poor quality liquor consumed. Since all forms of remonstrance and sedation failed to quieten these cases, it occurred to me that an intravenous barbiturate would be effective. I used pentothal sodium 1 g. in 10 ml. distilled water given slowly, as apnoea may occur if given quickly. Immobilization was easily obtained with the assistance of the usually numerous onlookers. The sudden change from bedlam to peace and quietness is so marked that it makes one feel one has really done mankind a service. . . . No dangers or side-effects have been met with in the dozen or so cases I have dealt with.

Any Answers?

Dr. JOHN C. GILLIES (Selby, Yorks) writes: Whoever has had the good fortune to peruse the leading article entitled "The Patient Tells His Story" (December 6, p. 1246) must have observed with regard to the C.M.I. that it trespasses a trifle on the orthodox magnitude of such systems of interrogation. Scorning what we may designate as the customary O.P. investigation, it positively swells into somal and psychical territories far and away beyond the accepted frontiers. Picture to yourself the harassed G.P., ill-tempered, short of time, his attention perforce attracted by the dazzling phantoms of universal benevolence. All other considerations drop from his mind what time he struggles to grasp the collective interests of the species. No 195 questions, for such wretches as he who toil behind the testimonial curtain. Only one question, essential, overriding, and universal, waits for an answer, "Do you want a certificate?"

Correction

It is regretted that the word "Foley" was wrongly inserted in the last sentence of a letter from Mr. B. H. Page on "The Catheter and the Prostate" (see *Journal*, December 27, 1952, p. 1415), and this resulted in restricting the meaning of the sentence. Mr. Page wished to draw attention to a complication caused by various types of rubber catheter and probably least of all by the Foley type.

Obituary

CHARLES H. MELLAND, M.D., F.R.C.P.

Dr. Charles Melland died in Manchester on January 8 at the age of 80. With his passing Manchester has lost not only a distinguished physician but the last member of a family which has given its service in the best medical tradition for well over a century.

Charles Herbert Melland, whose father, Frederick Melland, was a Manchester surgeon, was born on October 20, 1872. From Manchester Grammar School he went on to Owens College. After a distinguished career as a student—he won the Platt Physiology Exhibition—he qualified in 1894, graduated M.B. (London) with first-class honours in 1897, and proceeded M.D. in 1900.

He held a number of senior house appointments, serving as resident medical officer at the Manchester Royal Infirmary and at the City of London Hospital for Diseases of the Chest, Victoria Park. In 1902 he became a Member of the Royal College of Physicians, and two years later he took the B.Sc. of Victoria University. From 1901–5 he was director of the clinical laboratory at the Royal Infirmary. During his years of study he widened his knowledge by Continental travel and increased his medical experience in the clinics of Vienna and Graz. On his return to Manchester he started consulting practice, and became a physician to Ancoats Hospital, to which he gave devoted service until his resignation from it in 1914 on his election to the staff of the Royal Infirmary. From then on until his retirement from the active staff in 1932 he was a teacher and was able to be in contact with a rising generation: the association was a happy one for both teacher and students.

In 1906, when the Royal Commission on the Care and Control of the Feeble-minded was collecting evidence, Melland was appointed medical investigator, and his report on the incidence of feeble-mindedness and epilepsy in Manchester was embodied in the commission's blue book. As a result of this work he was appointed honorary physician to the National Association for the Care of the Feeble-minded. In the 1914–18 war he served in the R.A.M.C., being attached to the Second Western General Hospital. Dr. Melland was elected F.R.C.P. in 1921.

T. H. O. writes: As a physician, trained in the old order before the advent of x rays and the clinical laboratory, Charles Melland proved himself a man of vision who kept abreast with the times, and though his particular interests were diseases of the blood his knowledge was wide and his clinical acumen was always regarded with respect. He himself, even in his later years, remained a man of broad outlook, interested in many branches of knowledge. Despite an increasing lameness he was often to be found at medical gatherings, delighting on more convivial occasions to meet his colleagues at some reunion or dinner, and it was obvious how much he enjoyed the gathering of his friends to celebrate his eightieth birthday. Apart from medicine, two things interested him to the very end—mountains and lacrosse. As a young man he had been a noted lacrosse player, and even in old age he would travel long distances in order to watch the fortunes of the university team. Although not a mountaineer in the strict sense of the word, he had an abiding passion for mountains, and whether fell-walking in the Lake District or in Wales, or on holiday in the

Dolomites or Alps, he found in them something which stirred his imagination and brought content. His memory was stored with them and he would delight to talk of them, even about those which he had never seen.

Kindly and considerate, Charles Melland upheld a great tradition and we feel the poorer for his loss, and if in later years an increasing infirmity and the loss of a loved wife marred his old age it was borne cheerfully and with courage, and death came mercifully and without pain. He leaves a son and daughter, to whom we offer our sincerest sympathy.

HAROLD ORR, O.B.E., M.D., F.R.C.P.(C.), F.A.C.P.

For the first time in its history the Canadian Medical Association lost its serving President by death when Dr. Harold Orr, of Edmonton, Alberta, died in Toronto on December 26, 1952. Dr. Orr assumed the presidency of the association at its annual meeting in Banff in June last year. During the three succeeding months he and Mrs. Orr travelled more than 8,000 miles in Canada attending the annual meetings of the provincial divisions of the association. Early in October he departed for Athens to represent Canada at the Sixth General Assembly of the World Medical Association. Shortly after his arrival in Greece the first signs of coronary insufficiency presented themselves, but Dr. Orr managed to carry on until his return to London, England, where he was in hospital for three weeks. He then departed for home by boat, but on arrival in New York was again obliged to enter hospital, where he remained for four weeks. Once again he resumed his homeward journey, getting as far as Toronto, where he suffered a very severe coronary occlusion from which he failed to recover.

Born in Toronto in 1889, Harold Orr graduated in 1911 at the University of Toronto. He engaged in general practice in Medicine Hat, Alberta, until the outbreak of the first world war, when he joined the Canadian Army Medical Corps and served as a medical officer for five years, being twice mentioned in dispatches. He returned home with the rank of lieutenant-colonel, and was awarded the O.B.E. After training in dermatology and syphilology in London, Dr. Orr established himself in specialist practice in Edmonton, and was appointed clinical professor of dermatology and syphilology in the faculty of medicine, University of Alberta. For more than 20 years he most efficiently supervised the division of venereal disease control in the department of public health of the Province of Alberta.

While a comparatively young man, Harold Orr had crowded into his life a full measure of accomplishments of which any member of the medical profession could be justly proud. Always interested in the welfare of his chosen profession and the community in which he served, he could be counted upon to assume with cheerfulness whatever responsibilities were laid upon him and to carry them out with efficiency. He had served as president of the Alberta Division prior to his election to the office of President-Elect of the Canadian Medical Association. In debate he was clear, incisive, and always fair. He possessed those rare qualities of head which permitted him to get to the heart and core of a question quickly and intelligently.

Canadian medicine mourns the passing of a great leader, a warm-hearted companion, and a brilliant mind. He made his contribution to humanity in full measure. He leaves to mourn him his wife and one daughter.—T. C. R.

ROYDEN S. WALE, M.D., F.L.S.

Dr. R. S. Wale, who was pathologist to the Leicester General Hospital, died in London on November 21, 1952, at the early age of 45.

Royden Samuel Wale was born on December 22, 1906, and was educated at King's College School, Wimbledon, and at King's College Hospital, where he graduated M.B., B.S. in 1931, and he was a keen and competent athlete, playing rugby football, squash, rackets, and tennis for his hospital. His love for pathological work was kindled while he was a dresser to the late Sir G. Lenthal Cheatle, and in 1930 they

published jointly a short paper on "A Lesion Common to Breast and Prostate Glands" in the *British Journal of Surgery*. After graduating in 1931, Wale worked under Dr. R. D. Lawrence in the diabetic department and under the late Dr. E. ff. Creed in the pathological department at King's College Hospital, which he left after holding a series of appointments to become assistant pathologist at the Royal Cancer Hospital. He

proceeded M.D. in pathology in 1935. At the outbreak of war in 1939 his services were retained in the Emergency Medical Service, and in 1942 he was placed in charge of the pathological department of the Leicester General Hospital, where he quickly endeared himself to his colleagues and associates. His main medical interests were morbid anatomy and histology, but his library of books on physics, astrophysics, mathematics, botany, entomology, music, and the theatre was a hall of mirrors reflecting many facets of his versatile mind. Like so many medical men, he developed an interest in alpine flora. As a result of his own excursions to the Balkans and with the help of friends who travelled abroad he amassed a unique collection of *semperviva*, which he cultivated and studied, ultimately attempting to clarify and reclassify the genus in articles published in the *Bulletin* of the Alpine Garden Society. His work brought him national and international recognition, and his election as a Fellow of the Linnean Society in 1936 attested to the value of his investigations.

Wale also willingly undertook administrative responsibility and became secretary, and later chairman, of the Leicester General Hospital medical consultants committee. He sought tirelessly to encourage hospital improvements and to wed the best of the old medical service to the good of the new National Health Service.

It was some eight years ago that he first diagnosed his own lymphatic leukaemia. It remained an everlasting source of wonder, admiration, and inspiration to many of us who worked with him to see how calmly and unflinchingly he bore his cross. His kindness, forbearance, and consideration for both the medical and domestic staffs will long be remembered. When life became a frightful burden his courage and sweet stoicism glowed ever brighter.—J. O.

M. H. WOSTENHOLM, F.R.C.S.

We record with regret the death on December 12, 1952, as the result of a motor accident, of Mr. M. H. Wostenholm, who was an ear, nose, and throat surgeon at the Bedford General Hospital. His wife was killed at the same time.

Born on May 31, 1915, in South Africa, Maurice Humphrey Wostenholm came to England in 1935 to study medicine at Cambridge and at the London Hospital, where he qualified M.R.C.S., L.R.C.P. in 1941. After holding resident appointments at the London he joined the R.A.M.C. in 1942, and served until 1946 as a graded surgeon with the rank of captain. On his return to civil life he was appointed first assistant in the aural department at the London Hospital, and in 1947 he became F.R.C.S. He was appointed a consultant ear, nose, and throat surgeon on the staff of the Bedford General Hospital about 18 months ago, and he also held an appointment at St. Albans City Hospital. Mr. and Mrs. Wostenholm leave three young sons.

Dr. DAVID LEWES writes: The tragic news of the sudden death of Maurice Wostenholm and his wife will fill with sorrow all who were privileged to know that able young surgeon. Those whose good fortune it was to come into contact with him will bear testimony to his spontaneous kindness, and his patients will always remember him with gratitude both for his skill as a surgeon and for his whole-hearted sharing of their personal problems. From his earliest days at the London he was fired with enthusiasm in all he did, and his gay spirit, which was infectious, livened and cheered his many friends. He worked hard and played hard. In his daily life he gave vital meaning to the motto above the entrance to the medical college where he worked: *Amara lento tempera risu*—temper the difficult things in life with a smile. He faced difficulties with a slow smile and he possessed in rich measure those rare qualities—equanimity and imperturbability. Our hearts go out in sorrow to his parents and to other relations and to his three little boys.

Mr. KENNETH B. BELLWOOD writes: In the tragic death of Mr. Maurice Wostenholm, Bedford General Hospital has lost a most vital and capable member of the staff; indeed, in the 18 months, or even less, since he joined us he had already become much liked and respected. In the ear, nose, and throat department, in which we were jointly responsible, I soon became aware of his amiable and helpful character. Both as a clinician and as a surgeon he had good experience and judgment. It was always pleasant to meet and to discuss matters with him, and I regret that our friendship was so soon cut short, when it seemed that he was keen to develop the department both now and in the future. We have lost a young and a most promising friend and colleague.

Dr. M. D. C. HOSFORD writes: Mr. Wostenholm's work as a surgeon was brilliant, and his enthusiasm, energy, and tireless attention to all the details of his work will make his tragic death at the outset of a brilliant career a serious misfortune to his patients and all with whom he worked. He and his wife were delightful companions and missed by a wide circle of friends.

Dr. LESLIE EDWARD HUGHES, who died at the age of 75 after a short illness, was the youngest son of the late Dr. D. S.

ham, Norfolk. He was a medical student at St. Bartholomew's Hospital, and after qualifying in 1902 he put in the long period of six years in various house appointments at the Norfolk and Norwich Hospital, finally becoming senior resident surgical officer there. Throughout his life he was very keen on surgery and midwifery, and when he joined the late Dr. C. P. Hooker in partnership at Cirencester in 1907 he quickly made a name for himself as a sound surgeon and an exceptionally good accoucheur. Indeed, his figure of 3,000 confinements with only two maternal deaths—confinements often carried out in home conditions leaving much to be desired and without all the modern advantages and with no institution for difficult cases—is one which cannot often have been surpassed. As a surgeon to Cirencester Memorial Hospital he proved his skill and judgment over many years. At the outbreak of war in 1914 Dr. Hughes offered his services to the R.A.M.C., but his offer was refused, as he was just over the age limit prevailing then. Not to be deterred from serving his country, Dr. Hughes enlisted in the Grenadier Guards and went through the recruits' training for three months. Representations from influential quarters secured a relaxation of the age limit in his case, and he was posted as medical officer to the Gloucester Regiment. He went on active service in 1915 as regimental medical officer to the Oxford and Bucks Light Infantry, and remained with the unit until the autumn of 1918, when he was promoted temporary major and posted as surgical specialist to a casualty clearing station on the Murmansk front. He was mentioned in dispatches four times, was awarded the Military Cross, and was recommended for the D.S.O. Returning to Cirencester in 1919, he resumed his partnership until Dr. Hooker's retirement, and he then continued in single-handed practice until his own retirement in July, 1948. He had great misgivings about the new National Health Service Act. Dr. Hughes was a keen shot and took a great interest in the work of the British Legion, having been chairman of the benevolent committee of the Cirencester branch for many years. He was unmarried.—J. H. G.-W.

Medico-Legal

DAMAGES AGAINST CASUALTY OFFICER

In the recent case of *Payne v. St. Helier Group Hospital Management Committee and Another*, the court held that a casualty officer at the hospital had been negligent. Since the casualty officer was employed by the management committee of the hospital, the hospital also became liable, but, in awarding damages to the plaintiff, the judge made an order indemnifying the committee against the doctor in respect of the whole sum awarded as damages, and in respect of two-thirds of the committee's costs. Because of some notable features the case is reported at length below.

The plaintiff, Mrs. Payne, was the widow of a horse-keeper employed by United Dairies. At about 5 o'clock in the morning of July 10, 1950, Mr. Payne was kicked in the abdomen by a horse that slipped when he roused it. He consulted his doctor, who referred him to the hospital. A casualty officer examined him at 2.30 p.m., some 9½ hours after the injury had been sustained. This practitioner had been professionally qualified for two years. He observed and recorded in the notes a bruise as large as the palm of a hand in the right iliac fossa. He recorded also that there was no sign of bony or visceral injury. He sent the patient home to go to bed and to call in his own doctor.

On July 28, eighteen days later, the patient had become lacerated, and was readmitted to hospital. The diagnosis was peritonitis. An operation was performed on August 2. Although a peritoneal haematoma was found, but the peritonitis was not attributed with the finger of the operator and gas walking in the lake. The wound was drained. A further operation was performed on August 21 for general perito-

nititis and faecal fistula. The patient's condition was by this time very poor, and an anastomosis was made of small bowel to transverse colon. Death followed on August 30, 51 days after the original accident.

Mrs. Payne, the widow of the deceased, said in evidence that her husband had vomited after his arrival home from work on the morning of the injury. He had also vomited repeatedly while at home after return from hospital. He was able to keep nothing down, not even a switched egg. During the period when he was at home he got up for necessary purposes, came down for short periods to sit by the fire, and went out a little. On one occasion he had attended for a short time a cricket match in a neighbouring sports field.

Casualty Officer's Evidence

The casualty officer in evidence stated that, when he first examined the deceased on his arrival at hospital on the day of the injury, he had found slight surface bruising of the right iliac fossa. He had palpated the abdomen, and the bone, but had been unable to find any sign of bony or visceral injury. The abdomen was soft and moved with respiration, it was not tender, there was no muscle guarding, and sounds of bowel movement could be heard. There was nothing abnormal in the man's pulse rate and he was not in any way collapsed. He had told the patient to go home and go to bed and to call in his own doctor.

General Practitioners' Evidence

The patient's general practitioner said in evidence that when he had sent the patient to hospital he had had in his mind that the surgical consultant would be in attendance at the hospital on that afternoon and would have an opportunity of seeing him. He wished in the case of such an injury to have a second opinion. He did not specifically ask in his letter of recommendation for a consultant's opinion. On the following morning Mrs. Payne had called at his surgery and told him that there was no internal injury, and that the injury was not considered to be serious, but that she had been asked to call her own doctor in again. He saw the patient next morning and examined him. There was still some tenderness but rather less than on the previous day. Shock was less marked and he seemed to be a little better. There was definitely no deterioration in his condition on this occasion. He told him to rest and to let him know if anything went amiss. He got no further call to see Mr. Payne, but visited him on July 17, when he was still in bed. He was getting up to go to the toilet and had had some diarrhoea. There was no other abdominal symptom and the bruising was less. He did not remember Mrs. Payne or her husband mentioning vomiting to him; had either done so he would certainly have referred the patient to hospital again. He told Mr. Payne that he was going on holiday on July 18, but that he should see on July 24 the colleague who was doing his holiday work, and who would come and visit him before if he felt worried in any way.

Mr. Payne did in fact visit this colleague on that date and informed the colleague, it was said in evidence, that he was feeling much better and anxious to return to work, but was still troubled by a fair amount of wind. This doctor said in evidence also that the patient appeared strained, but that his abdomen presented no tenderness whatever and no muscle guarding. There was a suggestion, however, of some abdominal distension. He did not remember Mrs. Payne or her husband mentioning vomiting to him; had either done so he would certainly have referred the patient to hospital.

On July 28 this doctor had a call from Mrs. Payne and visited the patient again in his home. He was in bed in a cold sweat, his breathing was somewhat laboured, he looked drawn, and was a very sick man. His abdomen was grossly distended. With a diagnosis of early paralytic ileus he referred the patient to hospital for admission. He did not at that time present the signs of peritonitis.

On admission to hospital, as recorded above, the two successive operations were performed and the patient died on August 30.

Evidence of the post-mortem findings was given by Dr. David Haler, the coroner's pathologist. He had found at necropsy a state of general peritonitis, a subphrenic abscess, a bruise of the abdominal wall and necrosis of the muscles in the hollow of the ilium, necrosis and perforation of the caecum, an external fistula from the caecum through the wound of the first operation, and the anastomosis which had been performed at the final operation. He gave it as his opinion that the caecum had been bruised at the time of the original injury and that, if operation had been performed then, the subsequent course of the patient's illness and his death would in all probability have been averted.

Expert Witnesses

Sir Hugh Griffiths, surgeon to the Albert Dock and other hospitals, gave it as his opinion that the caecum had been bruised by the original injury, and that an abscess had formed in relation to the bruised caecum, bursting later to give a general peritonitis and to occasion death. He was of opinion that if the patient had been submitted to operation at the time when he was first sent to hospital the later effects of the injury would have been avoided by prompt attention to the bruised caecum. Bruising could not occur from the impact of force unless tissue was bruised between that force and a hard structure such as bone. The bruising of the right iliac fossa indicated that the tissues of the right iliac fossa had been pressed between the horse's hoof and the hollow of the ilium. The caecum would anatomically lie between the force of the hoof and that bone. He took a serious view of all abdominal injuries and had made it a rule in his hospital that all abdominal injuries, like all head injuries, were admitted for 24 hours for observation at least. He did not regard one act of vomiting after such an injury as necessarily serious; but, with that amount of bruising, if a patient had vomited on more than one occasion he would operate, even in the absence of signs of perforation. By so operating, bruised bowel could be removed before actual perforation occurred. He did not blame the casualty officer—it was inexperience.

Professor Ian Aird said in evidence that he was puzzled by the whole circumstances of the case and could not explain why peritonitis had occurred so late. Perforation of the caecum and necrosis of the caecum which was productive of peritonitis could not be present for more than a few days. He suspected that the subphrenic abscess, a condition notoriously difficult to detect, and which was certainly present at death, had played a more important part than had been suggested by other evidence. He would not have operated on the day of the injury in the presence of the symptoms and signs which had been described. He would not operate even in a case of suspected bowel rupture unless there were actual signs of perforation, tenderness, and rigidity of the abdominal muscles at least. He did not regard bruising of the character described, even if associated with vomiting on two occasions, as an indication for abdominal exploration. He did not think necessarily that the patient should have been admitted when he presented at hospital. It was desirable to admit for observation patients after abdominal injury of this kind who were seen within a short time of the injury, but, if there were no signs of perforation present after nine and a half hours, it was safe to conclude that no urgent emergency would be likely to arise and to permit the patient to return home to the care of his own doctor. He did not believe that the severity of an injury could be deduced from the presence or extent of bruising, and he could not agree that for bruising to occur it was necessary for tissues to be compressed between an external force and bone. An external force alone could cause bruising to soft tissues, as it did for instance in the loin quite commonly, where there could be no question of crushing of tissues against the distant spine; such organs as the brain and the lung too could be bruised within the intact walls of the cavities which enclosed them. He thought it wrong to conclude that an earlier operation, even if it had been performed in this case, would have averted the later consequences. He found

it impossible to say at what time he would have advised that operation be done in this particular case. The patient was not thought to be in urgent need of operation even when finally admitted to hospital 18 days after the original injury.

Judge's Comments

Mr. Justice Donovan awarded the widow £2,640 in damages, holding that the casualty officer was wholly liable and indemnifying the hospital in respect of its responsibility for him. He admitted that the clinical tests made by the casualty officer were correct, but he was of opinion that the casualty officer had failed to observe a rigidity of the abdomen which must have been there, and to notice that the patient was suffering from pain and shock. If these conditions were present in addition to the bruising, then the diagnosis and treatment represented less than the exercise of reasonable care. It was wholly unjustifiable to send the man home and not to detain him for examination by a consultant. It was reasonable to conclude that, if the man had been seen by a consultant, timely operation would have been performed, and the deceased in all probability would have survived.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1943-51 are shown thus -----, the figures for 1952 thus ————. Except for the curves showing notifications in 1952, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

A large fall occurred in the number of notifications of infectious diseases in England and Wales during the week ending December 27, 1952. The largest decreases in the number of notifications were 5,262 for measles, from 19,551 to 14,189, 631 for whooping-cough, from 1,748 to 1,117, 523 for scarlet fever, from 1,881 to 1,358, and 143 for dysentery, from 327 to 184.

The largest declines in the incidence of measles were 912 in Essex, from 2,327 to 1,415, 801 in London, from 1,797 to 996, 545 in Middlesex, from 1,329 to 784, 410 in Kent, from 1,181 to 771, and 301 in Yorkshire West Riding, from 1,297 to 996. The largest falls in the number of notifications of whooping-cough were Lancashire 69, from 290 to 221, and Cheshire 63, from 134 to 71. The largest decreases in the incidence of scarlet fever were Essex 77, from 162 to 85, and Lancashire 59, from 229 to 170. During the week 26 cases of diphtheria were notified, 3 more than in the preceding week. No case of diphtheria was notified in the southern section of the country comprising London, the south-east, the south-west, and the south midland counties.

33 cases of acute poliomyelitis were notified; these were 5 fewer for paralytic and 9 fewer for non-paralytic cases than in the preceding week. The largest returns were Middlesex 4, Sussex 3, and Berkshire 3 (Maidenhead M.B. 3).

The largest centres of dysentery were Lancashire 44 (Liverpool C.B. 21), Lincolnshire 38 (Grimsby C.B. 37), London 23, Kent 23 (Penge U.D. 19), and Westmorland 13 (Kendal M.B. 13).

Week Ending January 3

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,716, whooping-cough 2,165, diphtheria 25, measles 30,497, acute poliomyelitis 37, dysentery 262, paratyphoid fever 0, and typhoid fever 1. The number of measles notifications is about double that of the previous week.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **December 27**
(No. 52) and corresponding week 1951.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

§ Includes puerperal pyrexia.

Medical News

Careers in Medical Research.—The Medical Research Council has issued a useful pamphlet entitled "Opportunities for Appointment to the Scientific Staff" for those considering a career in medical research. The pamphlet deals briefly with the Council's constitutional position and states the conditions of work and terms of service for its staff. Then follow a classified survey of the current research programme and a list of the Council's establishments. The Council's method of recruitment is by recommendation from the director of the unit at which an applicant wishes to work. Copies of the pamphlet may be obtained, free on request, from the secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1.

Travelling Medical Fellowships.—The Medical Research Council invites applications for the following Travelling Fellowships for the academic year 1953-4:

Rockefeller Fellowships.—These Fellowships are intended for graduates who have had some training in research work in clinical medicine or surgery, or in some other branch of medical science, and who are likely to profit by a period of work at a centre in the United States or elsewhere abroad, before taking up positions for higher teaching or research in the United Kingdom. Fellowships tenable in the United States will normally carry a maintenance allowance at the rate of \$2,600 per annum for a single Fellow and \$3,600 per annum for a married Fellow. Provision will also be made for travelling and other approved expenses. The last date for application is March 15.

Eli Lilly Fellowships.—Four Fellowships, tenable in the United States, will be available for the academic year 1953-4, and the awards will in general be made on terms and conditions similar to those attaching to the Rockefeller Travelling Fellowships in Medicine. The last date for application is March 15.

Dorothy Temple Cross Research Fellowships.—The object of these Fellowships is to give special opportunities for study or research to suitably qualified British subjects "intending to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis in all or any of its forms." The Fellowships will, as a rule, be awarded to candidates who wish to make their studies or inquiries elsewhere than in the United Kingdom. The Fellowships provide for the payment of a maintenance allowance at the rate of £650 per annum for a single Fellow and £900 per annum for a married Fellow, subject to appropriate adjustment in the case of Fellowships tenable at centres outside the sterling area; in addition, an allowance will be made for travelling and other approved expenses. The last date for application is March 15.

Alexander Pigott Wernher Memorial Fellowships.—These Fellowships are intended for suitably qualified medical graduates who are likely to profit by a period of work in ophthalmology or otology at a centre abroad before taking up positions for higher teaching and research. The awards, which will normally be tenable for one year, are at the rate of £650 per annum for a single Fellow or £900 per annum for a married Fellow, subject to appropriate adjustment in the case of Fellowships tenable at centres outside the sterling area. In addition, an allowance is made for travelling and other approved expenses. The last date for application is March 31.

French Government Exchange Scholarships.—Under the terms of a reciprocal arrangement with the Centre National de la Recherche Scientifique two scholarships, tenable at research institutions in France during the academic year 1953-4, are open to British workers in medical science (excluding clinical medicine). The scheme is intended for young graduates in medicine or science who have already had some experience in a branch of medical science. Candidates must be of British nationality and have at least a working knowledge of French. The scholarships will normally carry a maintenance allowance within the range of 45,000-90,000 francs a month, according to qualifications and experience, and married men will receive a supplementary allowance (payable in sterling by the Council). Provision will also be made for travelling expenses to and from the place of work. The last date for application is March 31.

Further details of these Fellowships and forms of application may be obtained from the Secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1.

Anglo-French Exchange Bursaries.—Applications are now invited for bursaries which will be awarded this year to young British doctors under an exchange scheme arranged by the French Embassy in London between the Institut National d'Hygiène, in Paris, and the Ciba Foundation, in London. The value of the French grants is 60,000 francs a month, tax free. Grants will be awarded for periods of two to four months to doctors who wish to obtain clinical experience or carry out medical research in France. Applications for the bursaries should be sent before March 31 to Dr. Wolstenholme, Director; Ciba Foundation, 41, Portland Place, London, W.1.

Scholarship for Medical Women.—The Royal Society of Medicine announces that a William Gibson research scholarship will be awarded in July to date from October, 1953. The scholarship, which is tenable for two years and is at the rate of about £200 a year, is open to "qualified medical women who are subjects of the British Empire." Further details may be obtained from the secretary, Royal Society of Medicine, 1, Wimpole Street, London, W.1. The last date for applications is June 1.

Laboratory for Dr. Funk.—On January 13 Dr. Louis H. Bauer, president of the American Medical Association, presented a new research laboratory to Dr. Casimir Funk, the noted biochemist who coined the word "vitamin" (originally "vitamine"). The laboratory, which is in Manhattan, New York, was paid for by the Funk Foundation for Medical Research, a fairly recently founded non-profit organization interested especially in cancer research. Here Dr. Funk is proposing to carry out a much-expanded research programme. Dr. Funk was born in Warsaw 69 years ago, and it was while he was at the Lister Institute, London, that he did much of his well-known work on the metabolism of the B vitamins.

*** Care of the Premature Baby.**—The Southmead General Hospital Group Management Committee has published a booklet called "The Care of the Premature Baby in the Bristol Area." Prepared jointly by the departments of child health and public health, the booklet describes the services which have been developed at Bristol to deal with premature infants. It was originally intended for private circulation among paediatricians and laymen faced with establishing similar services, but in view of the large demand it is now made more widely available. Copies may be obtained from the Management Committee, Southmead Hospital, Bristol.

Sir Heneage Ogilvie, consulting surgeon, Guy's Hospital, has been appointed praelector in the faculty of medicine at St. Andrews University for the session 1952-3. During his tenure of office he will take part in the teaching and clinical work of the department of surgery and deliver a series of open lectures.

Professor F. H. Bentley has resigned the Chair of Surgery in the University of Durham to take up a research and teaching appointment under the Sommer Memorial Trust, combined with the practice of surgery, in Portland, Oregon.

Star and Garter Home Commandant.—Colonel Geoffrey Anderton has been appointed Commandant of the Star and Garter Home for Disabled Sailors, Soldiers, and Airmen at Richmond in Surrey in succession to Major Cecil Burnham. Colonel Anderton entered the R.A.M.C. in 1928, and in the last war he was mentioned in despatches in 1943 and in the following year was appointed O.B.E.

Emergency Bed Service: Applications and Admissions.—During the seven days ending January 12 the number of applications made by doctors to the London Emergency Bed Service for admission of patients was 1,758, of whom 80.78% were admitted. A white warning indicating that the percentage of admissions fell to 82½, was issued on January 6.

COMING EVENTS

Health in Industry.—The Industrial Welfare Society has arranged a course of lectures on "Positive Health Measures in Industry." The lectures, all of which begin at 6 p.m., are to be held at the offices of the Society, 48, Bryanston Square, London, W.1. The titles and speakers are as follows: January 22—Organization of First Aid in Work Places, by Dr. Neil G. Marr; January 29—Sickness Absenteeism, by Dr. P. Fitzsimons; February 5—Posture and Movement in Relation to Industrial Health, by Dr. W. F. Floyd; February 12—Health Education in Industry, by Dr. F. M. Oldershaw. The fee for the course is £1 10s. for members and £2 for non-members. Further information may be obtained from Mrs. O. K. Skelley, Industrial Welfare Society (Inc.), 48, Bryanston Square, London, W.1.

Postgraduate Course for General Practitioners.—Cambridge University Medical School has arranged a further postgraduate course at Addenbrooke's Hospital, Cambridge, on January 24 at 10.30 a.m. It will take the form of a symposium on radiotherapy, and will include lecture-discussions and demonstrations. The course is open, free of charge, to general medical practitioners whose names are on the National Health Service list. Those wishing to attend are asked to notify the secretary, Cambridge University Medical School, The Naval Hut, Downing College, Cambridge, immediately.

British Association of Allergists.—The annual general meeting of the British Association of Allergists will be held at the Royal Society of Medicine, 1, Wimpole Street, London, W.1, at 11 a.m. on January 24. Speakers will include Dr. N. C. Oswald, Professor J. Gough, Dr. H. O. Schild, Dr. MacKenna, and Dr. I. B. Sneddon.

Congress of Universities.—The Seventh Quinquennial Congress of Universities of the British Commonwealth will be held at Cambridge in July.

NEW ISSUES

British Journal of Venereal Diseases.—The next issue (Vol. 28, No. 4) will be available in a week's time. The contents include: CHANGING CONCEPTS IN THE SERO-DIAGNOSIS OF SYPHILIS: SPECIFIC TREPONEMAL ANTIBODY VERSUS WASSERMANN REAGIN. R. A. Nelson, Jr. CARDIOLIPIN-ANTIGEN. II: A QUANTITATIVE EXAMINATION OF SENSITIVITY. Henning Schmidt. STATISTICAL APPENDIX by Michael Weiss Bentzon. PLURALITY OF ANTIBODIES IN SYPHILITIC SERUM AND CLINICAL PRACTICE. Vittorio Puccinelli. RESULTS OF TREATMENT OF GONORRHOEA WITH PENICILLIN ALONE AND WITH PENICILLIN AND SULPHONAMIDE. G. O. Horne, J. B. Blittner, and J. R. G. Buchanan. THE INCIDENCE AND DEMONSTRATION OF BIOLOGIC REACTIONS IN ROUTINE WASSERMANN TESTS. H. M. Rice. MANAGEMENT OF VESICAL DYSFUNCTION OF NEUROSYPHILIS BY TRANS-URETHRAL RESECTION OF THE VESICAL NECK. W. Fowler. HERPETIC URETHRITIS. Juvenal Esteves and Manuel R. Pinto. ACUTE GONORRHOEA DUE TO A STREPTOMYCIN-RESISTANT GONOCOCCUS. W. J. Ryan. ACETARSOL PESSARY DERMATITIS. J. O. Doyle.

British Journal of Industrial Medicine.—The next issue (Vol. 10, No. 1) will be available in a week's time. The contents include:

THE INFLUENCE OF HORMONES ON THE DEVELOPMENT OF SILICOTIC NODULES PRODUCED BY INTRAPERITONEAL INJECTION OF QUARTZ. Erich Schiller. THE ACTION OF DIFFERENT FORMS OF PURE SILICA ON THE LUNGS OF RATS. E. J. King, G. P. Mohanty, C. V. Harrison, and G. Nagelschmidt. SOME PSYCHOLOGICAL CONFLICTS CAUSED BY GROUP BONUS METHODS OF PAYMENT. Norah M. Davis. EMOTIONAL STABILITY IN COLLIERY WORKERS. Alastair Heron and Dorothy Braithwaite. AN INVESTIGATION INTO THE REMOVAL OF RADIOACTIVE CONTAMINATION FROM THE HANDS. James Gregory. A FIELD STUDY OF OCCUPATIONAL DEAFNESS. Colin M. Johnston. AGE AND INDUSTRIAL ACCIDENT RATES. H. F. King and D. Speakman.

Issued quarterly; annual subscription £2 2s., single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

Details in this column are necessarily brief. Further information and tickets where required (marked ●) should be obtained from the institution concerned.

Monday, January 19

HUNTERIAN SOCIETY.—At Mansion House, 8.30 p.m., Hunterian Society Lecture by Dr. J. Van Laer (Holland): Auto Mutilation of Prisoners. ROYAL EYE HOSPITAL.—5 p.m., Dr. T. H. Whittington: Refraction Work in the Young and the Old. Aphakia.

Tuesday, January 20

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. A. S. Parkes, F.R.S.: Preservation of Living Cells at Low Temperatures. CAERNARVONSHIRE AND ANGLESEY PAEDIATRIC CLUB.—At Clinic, Sackville Road, Bangor, 4.30 p.m., Dr. E. G. G. Roberts: Paediatric Radiology. ●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Professor P. B. Medawar: Pigmentation. LONDON UNIVERSITY.—6 p.m., Sir Godfrey Thomson, D.Sc., Ph.D.: Geometry of Mental Measurement. SOCIETY FOR THE STUDY OF ADDICTION.—At 11, Chandos Street, W., 8 p.m., Detective-Sergeant G. Lyle: Dangerous-Drugs Traffic in London. Discussion will follow. SOUTH WEST LONDON MEDICAL SOCIETY.—8.30 p.m., Dr. Kenneth Cameron: Common Psychiatric Problems in Childhood. WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Mr. J. Minton: Ocular Manifestations in Nervous Disease: Part I.

Wednesday, January 21

EUGENICS SOCIETY.—At Burlington House, W., 5.30 p.m., Dr. J. D. Nisbet, Ph.D.: Family Environment and Intelligence. ●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Inflammation. INSTITUTE OF UROLOGY.—At St. Paul's Hospital, 4.30 p.m., Mr. J. E. Semple: Differential Diagnosis of Renal Pain. LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., Sir William MacArthur: History of Smallpox in the British Isles. LONDON UNIVERSITY.—6 p.m., Sir Godfrey Thomson, D.Sc., Ph.D.: Geometry of Mental Measurement. MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Dr. A. L. P. Peeney, Dr. A. M. Nussey, Dr. W. C. Smallwood, and Mr. C. Rudd: A Symposium on Cortisone and A.C.T.H.

Thursday, January 22

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Mr. H. J. Seddon: Certain Aspects of Nerve Repair. ●INSTITUTE OF CHILD HEALTH.—5 p.m., Dr. J. G. Scadding: The Chronic Cough. ●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Mycology.—Pathogenesis of Tinea Capitis. LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Dr. M. K. Alexander: Case of the Stevens-Johnson Syndrome; Dr. A. H. Cruickshank: Case of Chiari's Disease; Dr. K. McCarthy: Generalized Vaccinia. LONDON UNIVERSITY.—6 p.m., Sir Godfrey Thomson, D.Sc., Ph.D.: Geometry of Mental Measurement. OXFORD UNIVERSITY.—5 p.m., Dr. G. W. Corner (Washington): Medicine in the Poems of Chaucer. ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor C. G. Rob: Intermittent Claudication and Gangrene of Toes by Arterial Grafting. UNIVERSITY COLLEGE.—At Physiology Theatre, 5.30 p.m., Professor F. Bergel: Some Chemical Aspects of Normal Growth.

Friday, January 23

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. I. Muende: Anomalies of Pigmentation. ROYAL EYE HOSPITAL.—5.30 p.m., Mr. Howard Reed: Visual Fields. ROYAL INSTITUTE OF PHILOSOPHY.—At University Hall, 14, Gordon Square, W.C., 5.15 p.m., Mr. A. H. Smith, M.A.: Moral Philosophy in Ancient Greece. ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Symposium: Diabetes Mellitus. ROYAL SANITARY INSTITUTE.—At Town Hall, Bournemouth, 10 a.m., Lord Douglas of Barloch: Soil, Food, and Health; Dr. K. O. A. Vickery: Keystones of Positive Health.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Barwise.—On December 29, 1952, at Frome St. Quinton, Dorchester, to Dr. Maureen (formerly Bassett), wife of Dr. David Barwise, a son—Michael David. Fairley.—On December 20, 1952, at the R.A.F. Hospital, Rinteln, Germany, to Dorothy Jean (formerly Orr), wife of Dr. J. H. Barrie Fairley, M.B., B.S., D.A., a daughter. Gray.—On January 1, 1953, at St. David's Hospital, Cardiff, to Marion (formerly Muir) and Dr. Peter Gray, a daughter.

DEATHS

Abbott.—On January 3, 1953, at 21, Vallance Gardens, Hove, Sussex, Horatio White Abbott, M.D., late of Holloway, London, N. Carr.—On January 2, 1953, Jack Carr, M.R.C.S., L.R.C.P., of Manchester, Lancs. Hughes.—On January 2, 1953, at 1, Seaford Lodge, Barnes, London, S.W., John Hughes, M.B., B.Ch., D.P.H., aged 67. Richards.—On January 1, 1953, at Brynhyfryd, Aberavon, Port Talbot, Glam., William Jones Richards, F.R.C.S., aged 79. Ware.—On January 5, 1953, Arthur Maitland Ware, M.D., of Tying Down, Guildford, Surrey, aged 78.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Regular Douching

Q.—What are your views on the desirability of routine vaginal douching for reasons of personal cleanliness?

A.—There is no need for the normal woman ever to use a douche for the purpose of keeping the vagina "clean." The vagina can very well look after itself in this respect, even to the extent of clearing itself of degenerating blood and endometrial debris within 24 hours of the end of menstruation.

Douching without a clear indication is not only unnatural and unnecessary but may well be harmful. The vagina and cervix depend for health on the particular environment provided by their secretions and by their bacterial inhabitants. Douching tends to wash these away and may modify the pH of the vagina, thereby encouraging vaginal infections and possibly erosion of the cervix.

Disinfection of Telephones

Q.—In many industrial concerns it is the practice to "disinfect" the telephones once a week by wiping the mouthpiece of the instrument with a piece of paper impregnated with a disinfectant. It has been stated that the disinfectant action is retained over the week elapsing between treatments and that the procedure is of benefit in minimizing the spread of possible infection (e.g., influenza, etc.). Is there any reliable evidence for this?

A.—So far as is known no convincing evidence has ever been produced that respiratory tract infections are spread by way of telephones, and a consideration of the mechanics of possible transmission does not suggest that such spread is very likely. One does not ordinarily touch the mouthpiece of the telephone when talking, so that transference by physical contact is improbable, and, since any microbes that are coughed into the mouthpiece are coated with saliva or sputum, they may be expected to adhere to the instrument or to the mouth. It seems very unlikely that any of air from the mouth. It seems very unlikely that any tolerable antiseptic would long remain sufficiently active on the surface of the instrument to kill bacteria embedded in a protective coating. However, pathogenic bacteria can only very rarely be recovered from the mouthpieces of telephones even when they are not disinfected. At the same time the cleansing associated with "disinfection" may be useful from an aesthetic point of view.

Heat Spots

Q.—What are "heat spots"? How are they best treated?

A.—"Heat spots," or papular urticaria, is the usual pattern of urticaria seen in children between the ages of about 1 to 5 years. It differs from the adult pattern in that the lesion is not well demarcated and resembles a flea-bite. When the wheal and flare have subsided there remains a central papule, due to lymphocytic infiltration, which persists for seven to ten days. This papule is readily excoriated in an attempt to relieve itching. The condition is more frequently seen in the summer.

The causes of urticaria in childhood are similar to those of adult urticaria. Most cases relate to gastro-intestinal disturbance and are relieved by attention to diet, care of

bowels, and the administration of alkalis. A proportion of the more persistent and intractable cases have an emotional basis and require treatment from this aspect. Specific food allergy, parasitic infestation, focal infection, constipation, carbohydrate excess, nervous instability, and emotional upsets are important causes.

It may be difficult to differentiate insect bites from papular urticaria, and the former may provoke the latter. The season and circumstances may help; an irregular rather than a symmetrical distribution and the presence of a puncture would suggest bites. Bites more readily become infected. In both affections lesions may be vesicular or bullous, especially on hands, feet, or lower legs, and more commonly in the very young and in hot weather. Infection may also be associated with blister formation.

Calciferol in Bazin's Disease

Q.—Have large doses of calciferol been found to be of any use in Bazin's disease? The case I have in mind is that of a woman aged 40 who has had chronic ulceration of her lower leg for about six years. The ulcer, having formed, will not heal unless skin-grafted. The case has been classified as Bazin's disease at hospital, but tuberculosis has not been found on biopsy. The ulcers have failed to respond to any antibiotic given systemically.

A.—Reports of the treatment of Bazin's disease with calciferol have not been very encouraging. The condition is, of course, rare in this country, particularly in a woman of this age. As tuberculosis was not found on biopsy the diagnosis should be called seriously into question, and if doubt still remains guinea-pig inoculation should be carried out. If the diagnosis of tuberculosis can be substantiated isoniazid is suggested as a treatment more likely to succeed.

Salty Taste in Mouth

Q.—My patient complained first of a bad taste in the mouth; this was traced to tonsils, which have been removed. Ever since then she complains bitterly of a permanent salt taste, and I write to ask the cause of this. Her gums and teeth are beyond reproach.

A.—A patient commonly complains of a salty taste in the mouth when there is bleeding from the gum margin or discharge into the mouth from parodontal disease or a chronic abscess or cyst. The first two of these causes are excluded if the statement that the teeth and gums are beyond reproach means that there has been a thorough clinical examination, including vitality tests of the teeth, and full mouth radiographs. A chronic abscess or cyst may discharge its contents into the mouth through a small sinus which is sometimes very difficult to find; but the lesion would show in a radiograph as a radiolucent area. In the case of a cyst the area would be limited by a white line.

In the absence of these causes, any interference with the mechanism of taste must be investigated, special attention being given to the lingual and glosso-pharyngeal nerves.

Bitter Taste in Mouth

Q.—A woman of 47 has complained of a bitter acid taste in the mouth for 18 months. The condition is worse when dentures are worn. Dental examination reveals no abnormality, and acrylic dentures have been changed to vulcanite. The patient has not yet reached the menopause. Can you advise on the cause and treatment?

A.—So little is known about this troublesome complaint that the implications in the question very nearly supply such answers as can be given.

A bitter, acid taste occurs most usually in women of middle life, and it seems that it is nearly always associated with the wearing of dentures. Dental experts suggest that the complaint is less common now that plastic dentures are

used more frequently than vulcanite ones. Biopsies have been taken of the gums without providing any solution to the problem, and extensive gingivectomies undertaken in the hope of eradicating hypothetical sepsis have proved unsuccessful. The age of the patients naturally suggests that the endocrine changes of the menopause may be causative, and oestrogens are invariably given a trial, but usually are without benefit. In the belief that the condition may be due to a vitamin deficiency, nicotinic acid and vitamin-B complex have been tried in almost every case, and allergy has been invoked as an explanation, but antihistamine drugs are without effect. The possibility that some heavy metal such as mercury is being excreted by the salivary glands should not be overlooked. Diabetics and those suffering from pernicious anaemia occasionally complain of this symptom, and when this is so specific treatment usually leads to their complete relief. Naturally a psycho-neurosis has been invoked to explain most of the cases, and this may be so in some of them, but the truth is we know little about the condition and the treatment is empirical.

Post-mortem Removal of Eyes

Q.—*I should welcome advice on the post-mortem removal of eyes for later corneal grafting. (a) Am I right in believing that the consent of the executors is necessary, apart from the expressed wish of the deceased? (b) Is any eye with a healthy cornea suitable? (c) Must the eyes be removed within two hours of death to be of any use? (d) Into what solution should they be put? (e) To whom and where are the eyes to be sent? (f) Are there any special details of technique for this operation?*

A.—The answers to these questions are as follows:

(a) The consent of the executors is not necessary, but the eyes may not be removed if the surviving spouse or any surviving relative objects.

(b) The answer to this is yes, except where there is melanoma of the iris, glioma of the retina, or syphilis.

(c) Successful grafts have been obtained from eyes removed within 10 hours of death, but the sooner the eyes are removed the better the grafts are for optical purposes.

(d) The eyes should be placed in liquid paraffin in a sterile wide-mouthed stoppered jar, and kept in a refrigerator at 4° C.

(e) Eyes should be sent to the ophthalmic surgeon of the nearest centre at which corneal graft surgery is practised.

(f) There are no special details of technique in this operation except that the eyeball must not be opened. The standard technique of enucleation is used.

Treatment of Bed-wetting

Q.—*Is hypnosis useful in the treatment of bed-wetting?*

A.—Hypnosis, according to those who have practised it, is often useful in the treatment of bed-wetting. It is, of course, a symptomatic treatment, and should be applied only when the case has been investigated, an opinion reached about the causes of the bed-wetting, and a decision made that hypnosis is suitable.

Dyspeptic Constables and Others

Q.—*Can you give me any information on the incidence of peptic ulcers in policemen? A constable has advanced a claim that his ordinary duties have been a major factor in the development of a gastric ulcer, and I shall be glad of advice.*

A.—According to Ihre and Müller (*Acta med. scand.*, 1943, 116, 33) the proportion of policemen among male ulcer patients in Stockholm is the same as the proportion among all other male patients with medical illnesses—in each case 1%. No special study of policemen was made in the recent investigation into occupational factors in the aetiology of gastric and duodenal ulcers undertaken in this country (*Spec. Rep. Ser. med. Res. Coun. (Lond.)*, No. 276, 1951). The conclusion that "less variation of incidence

has been found than might have been expected, if conditions of work played an important role in the genesis of the disease" may, however, be relevant. This is perhaps particularly so since the ulcer in the case referred to in the question is a gastric ulcer. Anxiety about work appeared to be unduly common in subjects with duodenal ulcer, but not in subjects with gastric ulcer. No evidence could be obtained that shift work or irregular meals played an important part in the causation of either type of ulcer. The most striking finding with regard to gastric ulcer was its greater prevalence among the poorer social classes and decreasing incidence as economic status improved. This would not, presumably, be considered evidence that the conditions of a policeman's life conduced to the development of gastric ulcers. A review of the literature on occupational factors in peptic ulcers is included in the M.R.C. publication.

NOTES AND COMMENTS

Corneal Herpes.—Dr. C. HEATH and Dr. F. A. WHITLOCK (Truro) write: Your expert states that none of the new antibiotics has proved effective against the herpes group of infections ("Any Questions?" December 6, 1952, p. 1270). Surely it is recognized that the virus of herpes simplex is sensitive to aureomycin?^{1,2,3} It is true that, once established beneath the corneal epithelium, the infection may prove inaccessible to surface applications, but in suitable cases it may be controlled. Recently a child of eight months gravely ill with Kaposi's varicelliform eruption—a condition usually regarded as the result of herpes simplex infection superimposed on an infantile eczema⁴—was found to have widespread dendritic ulceration of both corneas. After treatment with aureomycin by mouth and ocular, aureomycin and atropin, to the eyes, the child made a complete recovery, the corneas healing without developing other forms of herpetic keratitis and without scarring. It seems most unlikely that this would have occurred without benefit of aureomycin.

4. Ruchman, I., Dodd, K., and Welsh, A. L. (1947). *Arch. Derm. Syph.*, 56, 846.

OUR EXPERT writes: There is no critical evidence that aureomycin has any effect on the herpes virus. This is borne out by an immense literature, and is generally accepted by virus experts, though it is true that there are a number of clinical reports to the contrary. Experimentally all that has been claimed for the newer antibiotics has been that they may have some prophylactic or inhibiting action on the virus. Experimental studies on the eye have led to essentially the same negative conclusion (Geller and Thygeson, *Amer. J. Ophthalm.*, 1951, 34, 165; Hallett *et al.*, *Arch. Ophthalm.* (Chicago), 1951, 46, 33). The case reported by your correspondents is interesting, but, like all isolated case reports, is open to more than one interpretation. My own clinical experience with herpes infections of the eye treated with the newer antibiotics has been distinctly disappointing.

Correction.—In a paragraph headed "Methorphan Scheduled" (January 3, p. 52) attention was drawn to an Order in Council relating to 3-methoxy-N-methylmorphinan. It was wrongly implied, however, that this substance was the same as methorphan. Methorphan is 3-hydroxy-N-methylmorphinan and it has been scheduled since July, 1951.

LONDON SATURDAY JANUARY 24 1953

THE PHENOMENA OF EPILEPSY*

BY

DENIS WILLIAMS, M.D., D.Sc., F.R.C.P.

Physician in charge of Neurology, St. George's Hospital, Physician to Out-Patients, the National Hospital, Queen Square

The question, "Is this epilepsy?" seems to be asked more often and in more various circumstances than it used to be. It may simply relate to attacks of unconsciousness, or to focal disturbance of movement or sensation, but, even so, the answer is unusually important because of its social and economic implications to the patient and his family, quite apart from the problem of treatment and management. Other groups of people are interested too. Employers want to know, sometimes more to safeguard themselves than to protect the patient; public servants have to administer insurance and superannuation regulations; armed Forces have to protect their efficiency from the sudden disruption of a fit or the administrative consequence of its recognition. Teachers want to prevent their pupils from seeing an epileptic attack in another to the ruin of his own schooling; or lovers about to mate calculate the risks of procreation in this respect.

With the assumption of social responsibility by others, and with a more enlightened approach to the study of and with a more enlightened behaviour, many more people antisocial and aggressive behaviour, many more people became interested in the answer. Those philanthropists who were concerned about crime and the criminal recognized that some aberrant behaviour or abnormalized that some thoughts might be epileptic, that a cause might be found, and chemical treatment prove successful where psychiatric and social had failed. The child psychologist studying a child with temper tantrums asked whether this might be epileptic. The prison medical officer faced with an intractable Borstal problem, or the inter-psychiatric physician dealing with a long story of intermittent unusual behaviour, has been faced with the same problem. Then lawyers, encouraged by the physicians for the defence in cases of comparatively gainless crime, advance the argument, "This may be epilepsy," so that finally the judge or his jury have to answer the question.

The Diagnosis of Epilepsy

With all this, the ordinary doctor had been seeing many ordinary patients with attacks of loss of memory or consciousness, of muscle-twitching, of feelings of faintness or of unreality, or of transient disturbances of vision, for every unusual one who presented a social problem. Usually there are no physical signs to help him in this diagnosis, for the patient is well when he tells his story, so that he must base his opinion on

minute retrospective facts found by careful questioning of subject and observers. The true interpretation lies in deduction, with the same scrupulous regard for facts as is found in police detection. It is rarely that this method fails, and, allowing the place of experience of the usual and unusual in arriving at a correct diagnosis, the neurologist may succeed simply by taking a more careful history and by sticking to the evidence he has found. In the unusual case, diagnosis may at the time be impossible for want of evidence, or in doubt because of its nature. When this is so, opinions may be given too freely, the term "epilepsy" applied too carelessly; and, when such assumed accuracy seems dishonest, diagnostic uncertainty is expressed as "epileptoid states" or "epileptic equivalents"—phrases which reflect as great confusion of thought in the physician as there is confusion of feeling and behaviour in the patient.

How, then, is the diagnosis of epilepsy to be made? When the distinction is between a faint and a fit there may be no great difficulty, but when the diagnosis rests upon a story of complex disturbances of behaviour, or prolonged disorder of thought or feeling, it may be most bewildering. Clinical observation, aided by electrophysiology and experimental neurosurgery, has very widely expanded the recognized field of disorders caused by epileptic disturbances and has made many definitions worthless. We know that epilepsy can occur without loss of consciousness, without amnesia, without involuntary movement, and without any of the simple features which would enable us to make a certain diagnosis of epilepsy. None of the definitions will do, for they are all too narrow.

The Nature of Epilepsy

Whenever an epileptic disturbance is recognized by the patient or by others there is an abnormal discharge of electrical energy in the brain. It is more accurate to consider the disturbances which are seen in the electroencephalogram as the accompaniment of the disturbance experienced by or seen in the patient rather than as its cause. They are both related to the same cause. Lennox found so much difficulty in defining epilepsy that he called it a cerebral dysrhythmia, having in mind the disordered electrical rhythms invariably present in the attack. In fact, epileptic states are accompanied by a cerebral electrical dysrhythmia, and the electrical disturbances may be closely related to the nature of the clinical attack, but they are not the cause of the attack.

4803

*Address to the Guildford Division of the British Medical Association given on December 11, 1952.

single, in transient bursts, or more prolonged as in a major convulsion. The major convulsion is in fact the ultimate intensity of this form of epileptic discharge. Focal clonus probably indicates a local organic lesion, and when it begins in adult life the possibility should be considered of the lesion being recently acquired. If the attacks change their character progressively the lesion is probably an advancing one. But the pathological nature of the lesion does not alter the fundamental character of the clonic attack. After the causal lesion has been investigated, and if possible recognized, chemical treatment of all attacks with clonus follows the same plan—usually the use of barbiturates and hydantoins.

Attacks with Co-ordinated Movements

There are many attacks in which the movements are smooth and natural, not clonic. Here the epileptic disturbance has arisen in a part of the cortex responsible for co-ordinating and integrating movements. Because of this the cortical discharge causes response in the body which is physiologically integrated, so that, for instance, when muscles contract there is inhibition of antagonists. This is in contrast to the unphysiological simultaneous contraction of agonists and antagonists in the tonic-clonic fit. Because the movement of limbs in these attacks is necessarily co-ordinated, it appears to the observer to be reasonable and to have purpose, although as it is invoked by a primitive epileptic disturbance it is devoid of purpose. Attacks of this sort have been called "psychomotor" or "epileptic equivalents." They are in fact focal epileptic attacks involving cortical association areas, which used to be called silent areas, but which are responsible for the integration of feeling and movement. The movements or feelings which are invoked are consequently more elaborate than in other sorts of attacks. They are commonly seen when a focal fit begins in a temporal or a frontal lobe.

The movements which are seen in these attacks may range from a single act, such as deviation of the eyes, licking, swallowing, or movement of a hand, but they include complicated rituals, salaams, and simple aggressive acts. Most of the prolonged purposive movements seen in association with epilepsy occur in the post-epileptic confusional state, are post-ictal, and are not strictly epileptic.

Post-ictal Activity

It may be difficult to tell when the abnormal behaviour is occurring during the actual epileptic fit (ictal) or after it (post-ictal), particularly when an insignificant and brief fit is followed by a long post-ictal confusional state causing the restless behaviour of a fugue. As a rule the behaviour seen in the fit is apparently spontaneous, and, being the result of the epileptic disturbance of the brain, is stereotyped, short-lived, and without relation to circumstance. The post-ictal activity, whether it is restlessness, aggression, or a fugue, is due to the state of confusion, and so it is simple in its form, evoked by stimulation; when purposeful, primitive, or stupid in its purpose its form is often determined by past experience. It seems automatic. The confused person just walks, or fumbles with clothes, undresses routinely or blindly, resists help or interference. While there can be no real purpose in the ictal activity, any purpose in the post-ictal is immediate and very crude. No prolonged, elaborate, and intelligently purposeful fugue state is epileptic. Very rarely the actual epileptic attack may consist of a lowering of consciousness (confusion) and so simulate the post-epileptic state described in this paragraph.

Sensory Attacks

As sensation must be experienced by the patient there cannot be a sensory equivalent of the major tonic-clonic fit, since consciousness cannot be retained when the epileptic discharge has spread over both hemispheres. The form of sensory disturbance in epilepsy may be negative (loss of sensation) or positive (a hallucination). These may affect common sensation, special senses, or emotions, and mixed forms are common.

The commonest kind of sensory disturbance encountered in epilepsy is very crude—simply tingling at an extremity: but disturbance of proprioception with changes in the shape or position of a limb are met. Epileptic pain is uncommon, but is experienced as a mixture of intense pains, often with a sensation that the limb is in an unnatural position. While tingling is the sensory counterpart of a focal clonic fit, the more complex disorders of feeling, relating to the shape of a limb and causing sensations of bodily or spatial distortion, are the counterpart of the attacks in which co-ordinated movements occur.

Similarly, although when special senses are involved in the epileptic experience they are felt in a most primitive manner—as an unrecognized smell or taste, or flashes of white light—they may be co-ordinated with elaborate formed hallucinations when the epileptic discharge happens to involve one of the special sensory association areas. The most common examples of these are the elaborate, animated, and coloured scenes witnessed by the subjects of lesions in the parieto-occipital area. When even more highly organized areas of cortical integration in the temporal lobes are affected, hallucinations made up of the blending of several sensations may be indivisibly experienced. These may be accompanied by spontaneous and transient emotional disturbances.

The episodic disorders of emotion experienced during temporal lobe attacks have not yet been studied in sufficient detail, perhaps because they are easily overlooked by the questioner, but also because they may suggest to him a psychological disorder rather than a physical disturbance. They may contain any possible emotional experience, any combination of emotions, or any linking of emotion with simpler sensations, and they may evoke appropriate visceral or somatic behaviour. They must be recognized as being epileptic if the patient's problem is to be fully understood.

Prolonged Disorders of Behaviour or Feeling

In status epilepticus, focal or general, abnormal states of movement, sensation, or consciousness may last for many hours. It is usually possible to recognize the individual attacks of the status and so to establish the responsibility of epilepsy for such a prolonged disorder. Otherwise some other cause for the disorder should be sought, since a single epileptic attack is so short-lived. Prolonged amnesic states, fugues, stupor, coma, or aggressive or unsocial behaviour are unlikely to be epileptic in the absence of status, for even post-ictal confusion lasts for minutes rather than hours. In particular, as I have said, activity which is motivated, or which uses past learning, cannot be epileptic. The soldier, absent without leave, who finds his way home by road and rail with no memory of the process, could not have done so in an epileptic attack; neither can the criminal who has amnesia for an act of violence directed against a selected subject with an appropriate weapon, however obscure the motive or violent the act. In cases of this sort organic causes having been studied, natural or neurotic motives must be sought, and any evidences of a psychopathic or psychotic personality should be assessed.

It might be said in criticism of this didactic and rigid distinction between epilepsy and other states that the borderland between epilepsy and psychopathy is a narrow one, hardly explored, and that the basis of neither state is understood. That is no justification for a mongrel diagnosis such as that of "epileptoid state" or for the subterfuge of calling inexplicable behaviour epileptic upon tenuous or inappropriate evidence.

A sixth revision of the *Index of Modern Remedies* has been published by the *Scottish Chemist*, 240, Albert Drive, Glasgow, S.1. It includes much information on proprietary preparations and takes note of the 1951 addendum to the *B.P.*, the *National Formulary*, 1952, and the *Pharmacopoeia Internationalis*. It is a most useful handbook for all who need an up-to-date guide to modern drugs. The price is 5s., and in London it may be obtained from H. K. Lewis, 136, Gower Street, W.C.1.

ACUTE DISSEMINATED ENCEPHALOMYELITIS TREATED WITH A.C.T.H.

BY

HENRY G. MILLER, M.D., M.R.C.P.

Assistant Physician, Royal Victoria Infirmary, and Lecturer
in Neurology in the Medical School, King's College,
Newcastle-upon-Tyne

In 1951 I drew some analogies between the neurological syndromes of serum sickness, polyarteritis nodosa, and acute disseminated and post-exanthematous encephalomyelitis (Miller, 1951). All these conditions show a tendency to gross and often evanescent focal symptoms arising at every level of the nervous system, occasional apoplectic syndromes suggestive of lesions involving major cerebral blood vessels, and pathological changes concentrated in close relation to the cerebral vasculature. It was suggested that some such cases of acute disseminated encephalomyelitis may have their foundation in an allergic vasculitis—an "urticaria of the nervous system"—and trial of cortisone or A.C.T.H. in the treatment of these conditions was suggested.

Although these drugs are known to be without beneficial effect in experimental acute infections of the nervous system of virus origin, such as equine encephalomyelitis and Lansing poliomyelitis (Milzer, 1951), Moyer and his co-workers showed in 1950 that adequate dosage with A.C.T.H. protects effectively against the clinical manifestations of experimental "allergic" encephalomyelitis produced in guinea-pigs by repeated injection of heterologous (rabbit) brain emulsion. Pathological changes in the brains of the protected animals were minimal. Whether such protection is due to inhibition of antibody formation or to a more purely vascular reaction at the site of the lesion (as in inhibition of the Shwartzman phenomenon) is undecided.

Kabat *et al.* (1952) have produced pathological evidence suggesting that the inhibitory effect of cortisone (Kabat *et al.*, 1951) on the development of the similar experimental encephalomyelitis produced in the rhesus monkey by injections of heterologous and homologous brain tissue emulsified with Freund adjuvants (Kabat *et al.*, 1947; Morgan, 1947) is due to suppression of the granulomatous response to the antigenic brain emulsion at the site of injection. It is possible that this local granulomatous reaction is responsible for antibody production; at any rate it appears to be an invariable accompaniment of the development of encephalomyelitis under these experimental conditions (Kabat *et al.*, 1948). Kabat's assumption that the local response plays a causal part in the pathogenesis of the encephalomyelitis is, however, not beyond question: suppression of the neurological illness could be interpreted as a parallel effect of cortisone on hypersensitivity reactions rather than as a secondary result of suppression of the granuloma.

Evidence of the mode of action of cortisone and A.C.T.H. in anaphylactic hypersensitivity in general is somewhat conflicting, and Kabat *et al.* (1952) believe that the balance of such evidence is in favour of inhibition of antibody production as the effective mechanism. In support of this is the observation that whereas these drugs completely or almost completely inhibit the active Shwartzman phenomenon, which depends on the active production of antibody, they are much less effective

(if indeed they have any action at all) in inhibiting the passive Shwartzman phenomenon caused by reaction of antigen with antibody already present. In their view the undoubted inhibition of experimental acute disseminated encephalomyelitis by cortisone and A.C.T.H. is probably due "to an alteration in the experimental conditions shown to be necessary for the production of the disease, rather than to any fundamental effect on the disease itself." The pathogenesis of human acute disseminated encephalomyelitis is unknown, and Kabat's view, if correct, provides a further reason for hesitancy in anticipating an effect of cortisone on the human disease analogous to that seen under experimental conditions. Furthermore, should the action of the drug be in fact due to inhibition of antibody production, it is understandable that, even granting the existence of some pathogenetic relationship between experimental allergic and human—for example, post-infective—encephalomyelitis, prophylaxis of the disease in man might be possible but therapy ineffective if the established condition represents a response to antibody already formed at the onset of the illness.

It had previously been shown that some protection against the development of experimental allergic encephalomyelitis was offered by the administration of nitrogen mustard (Koprowski *et al.*, quoted by Moyer *et al.*, 1950) or of salicylates (Good *et al.*, 1949), both of which block antigen-antibody reactions. Antihistamine drugs (Lumsden, 1949) have also been shown to offer some protection against allergic encephalomyelitis in the guinea-pig, though they were without therapeutic effect in the established condition. In this last instance, however, pharmacological evidence would suggest a suppressive action on the "peripheral" pathological expression of an antigen-antibody reaction rather than an inhibition of the reaction itself.

In 1949 Pickar and Kramer reported prompt improvement of a single case of encephalomyelitis following antirabic vaccination (showing a strongly positive skin reaction to the vaccine) after the administration of diphenhydramine hydrochloride.

Glaser and Smith (1951), in reviewing encephalomyelitic syndromes following antirabic therapy, described a fatal case in which 100 mg. of cortisone was given to the patient before he expired. Garrison (1952) reported "dramatic improvement" in a single case of encephalomyelitis complicating antirabies vaccine (phenolized rabbit-brain virus) treated with large doses of cortisone (375 mg. daily for two days, and 100 mg. daily during the subsequent four days). This patient showed great improvement within 24 hours, by which time his high fever subsided. He remained drowsy, however, for four days and retention of urine persisted for six days: five weeks later a single extensor plantar response was the only residual evidence of his illness.

The present paper reports results obtained in a preliminary series of seven cases of acute disseminated encephalomyelitis treated with A.C.T.H. The difficulty of assessing the value of therapy in this disease is evident, as the condition often recovers spontaneously with dramatic suddenness. The results obtained cannot be claimed to be conclusive, but they suggest that the drug may have some value in the therapy of human encephalomyelitis in keeping with its known effectiveness in protecting animals against experimental "allergic" encephalomyelitis.

Two years previously this boy had sustained a fractured skull, with transient loss of consciousness, but he made an excellent recovery and had no subsequent symptoms except for occasional headaches and rather unruly difficult behaviour of doubtful significance.

On the morning of May 19, at which time he was recovering from a severe head cold contracted one week previously, he awoke complaining of dizziness, headache, and double vision on looking to either side. He fainted on endeavouring to leave his bed, and within six hours of the onset became drowsy, though he could be roused.

On examination 15 hours after the onset he was stuporous but talked sensibly on being wakened. He complained of occipital headache, double vision, and giddiness on raising his head from the pillow. The positive signs on examination were meningism, gross nystagmus which was present in all positions of the eyes and maximal on lateral deviation, gross generalized hypotonia, sluggish deep reflexes in the arms, and almost extinct knee- and ankle-jerks. The plantar responses were flexor and the abdominal reflexes tired easily. The spinal fluid was entirely normal and the electroencephalogram showed diffuse theta activity with paroxysmal bursts of higher amplitude but no evidence of a focal lesion.

The boy was given 50 mg. of A.C.T.H. intramuscularly on admission and 25 mg. six-hourly during the subsequent 72 hours. Twelve hours after treatment started he was more alert, nystagmus was less sustained, and the right ankle-jerk was easily obtained. Re-examination 36 hours after the onset of treatment showed complete disappearance of meningism and nystagmus. Diplopia had disappeared, headache was the sole subjective complaint, and reflex changes were as before.

On completion of treatment there were no symptoms, and the only abnormal signs were sluggish knee- and ankle-jerks. Hypotonia had completely disappeared. Ancillary investigations were entirely negative.

Discussion

The hypothesis on which this therapeutic experiment is based is that the clinical syndrome of acute disseminated encephalomyelitis in man may arise on the basis of vascular and perivascular changes in the nervous system which are interpreted as pathological expressions of a non-specific hypersensitivity reaction of anaphylactic type, probably primarily vascular but involving, either simultaneously or secondarily, the extravascular mesenchymal tissues of the neuraxis. Some hope that the disease in man might be influenced by cortisone or A.C.T.H. is offered by the observations that these drugs exercise a powerful prophylactic effect on experimental "allergic" encephalomyelitis, which is in some ways strikingly similar to the human disease; and that they suppress the established general manifestations of serum sickness—a frank expression of hypersensitivity which may rarely be complicated by an encephalomyelitic syndrome.

Even if theoretical and practical objections to this hypothesis prove invalid, and it is ultimately shown to be an approximation to the truth, the limitations of its therapeutic application are at once apparent. The most that could be hoped for on theoretical grounds is that physiologically effective dosage of cortisone or A.C.T.H. might diminish the inflammatory response by decreasing or abolishing exudation from damaged blood vessels, and might possibly accelerate the absorption of exudate and the resolution of inflammatory change which presumably occur during spontaneous recovery. This implies two practical limitations: first, that the drug would be likely to influence the condition only during the phase of exudation and acute inflammation; and, secondly, according to this hypothesis the focal and general neurological symptoms of encephalomyelitis arise from damage to neurones and their processes by oedema, haemorrhage, or toxic substances essentially secondary to vascular-mesenchymal inflammation: any detectable clinical response to therapy could at best be anti-

cipated only in relation to symptoms arising from neural lesions not already irreversible by reason of their duration or their initial severity. Even on theoretical grounds no response would be expected, for example, in the rapidly fatal encephalomyelitic illness of which the pathological basis is a diffuse cerebral purpura, or in those cases of severe myelitis which are characterized by actual necrosis of the spinal cord.

Critical consideration of the present small series of cases does nothing to invalidate these theoretical views, and offers a small amount of admittedly fragmentary clinical evidence in their support.

The mortality of encephalomyelitic cases admitted to the Royal Victoria Infirmary is in the region of 27% (8 of 30 cases occurring between 1930 and 1940), and somewhat similar figures are reported by most other observers. Certainly in "spontaneous" cases and in those following Jennerian vaccination, and probably in post-exanthematous instances, fatalities occur almost entirely among patients in whom coma is a clinical feature. Only one of the present patients, however (Case 4, following chicken-pox), was ever more than stuporous, and although this was an unusually severe illness, encephalomyelitis following varicella is widely regarded as having a rather better prognosis than similar illnesses following some other exanthemata such as measles. The absence of fatalities in the present series is therefore valueless in the assessment of treatment.

In one case (Case 6, subacute ascending and probably necrotic myelitis) treatment with A.C.T.H. clearly exerted no beneficial effect: unequivocal clinical deterioration occurred during both an initial uncontrolled and later a controlled course of treatment.

In neither of the instances of encephalomyelitis following chicken-pox (Cases 2 and 4) was the course or duration of the illness materially different from that which is often seen in untreated cases, though the improvement which coincided with increased dosage in Case 2, and that which followed an initial phase of deterioration in the much more severe Case 4, are compatible with the view that the drug exercised a favourable effect on the condition.

In Cases 5 and 7, clinical improvement was evident within six and twelve hours of the initial injection of A.C.T.H. respectively, and a similar response has since been observed in a sixth encephalitic episode in the former case that is not detailed here. Unfortunately the previous history of cerebral trauma in both these cases, as well as the remarkable familial incidence, renders diagnosis ultimately problematical. Cases of relapse and recurrence of encephalomyelitis are not rare, and several have been personally observed, though never with so many attacks as have been seen in Case 5. However, the encephalitic nature of the syndrome with a maximal though not exclusive incidence on the cerebellum or its connexions, its relation to preceding banal infection, its rapid and complete resolution clinically and electroencephalographically, and the absence of spinal-fluid changes, would appear to render any diagnosis other than acute disseminated encephalomyelitis difficult to sustain.

In Case 3 the improvement in mental acuity and in the clinical manifestations of the transverse cord lesion which was observed within 12 hours of the first injection is surprising, even on theoretical grounds, in view of the 12-day history of the condition. It should be noted, however, that this patient was still deteriorating clinically when treatment began, which presumably argues a continuing inflammatory reaction in the nervous system, and that he was left with appreciable disability, in keeping with the duration of his cord lesion. The slight relapse which occurred four days after completion of treatment is perhaps also a point in favour of the view that A.C.T.H. may have exercised a suppressive effect on the symptoms in this case.

These cases are numbered in the order in which they were treated, and it is ironical that the evidence in favour of a therapeutic response is more suggestive in Case 1 than in any subsequent patient. In this instance a combination of

circumstances—in particular an intelligent patient and a very alert practitioner—led to reference of the case at a much earlier stage in the development of the disease than is usual. Although clinical deterioration until treatment was instituted was rapidly progressive, it is clearly impossible to claim with any certainty that the apparent response was more than coincidental. Nevertheless the relapse associated with objective evidence of physiologically inadequate dosage, and the resumption of improvement when dosage was increased, as well as the remarkably complete recovery which was evident within a matter of days, render coincidence a not entirely satisfying explanation: that resolution of the condition was related to the administration of A.C.T.H. would appear to be a distinct possibility.

Acute disseminated encephalomyelitis is a rare disease, and, although it is fully appreciated that no firm conclusions can be drawn from the present small series of treated cases, they are reported in the belief that the results are suggestive enough to merit similar trial on a larger scale. In the absence of any other effective or rational therapy such a trial would appear justifiable, though a word of caution is advisable. Diagnosis of acute encephalomyelitis following exanthemata is usually simple, but the "spontaneous" examples, and those following non-specific infections, may present difficult diagnostic problems. Administration of A.C.T.H. to cases of virus disease such as poliomyelitis is at best useless, and recent evidence suggests that it may be actively harmful. In bacterial infections such as cerebral abscess or tuberculous meningitis its use might well be disastrous. For these reasons, and also in order not to confuse assessment of the value of the drug in the disease under consideration, the employment of this experimental therapy should be limited to cases of acute neurological illness in which an unequivocal diagnosis of encephalomyelitis can be competently sustained. The present paper shows that in such cases the drug is harmless if nothing more.

Summary

Seven cases clinically diagnosed as acute disseminated encephalomyelitis have been treated with A.C.T.H. They comprise two cases of encephalomyelitis following varicella, two cases of transverse and one case of subacute ascending myelitis, and two (familial) cases of encephalitic illness following non-specific infection, in one of which there have been recurrent encephalitic illnesses. Acute disseminated encephalomyelitis has a pronounced tendency to rapid, spontaneous, and often complete recovery, and no final conclusions regarding the efficacy or otherwise of A.C.T.H. can be reached without extended observations on a scale which would permit of statistical evaluation. It is believed that the results reported here are suggestive enough to justify further trial.

I wish to thank practitioners and consultants in Region No. 1 who have been kind enough to refer cases for treatment, Dr. G. A. Smart for help and advice on technical aspects of the use of A.C.T.H., and Dr. M. J. Evans for his clinical assistance.

ANURIA TREATED BY CORTISONE*

BY

HENRY MOORE, M.D., D.Sc., F.R.C.P., F.R.C.P.I.

Professor of Medicine, University College, Dublin; Senior Physician, Mater Misericordiae Hospital, Dublin; Consulting Physician, National Maternity Hospital, Dublin; Chairman and Clinical Director of the Cortisone Committee of the Medical Research Council of Ireland; Member of the Medical Research Council of Ireland

AND

D. K. O'DONOVAN, M.D., Ph.D.

Associate Professor of Medicine, University College, Dublin; Visiting Physician, St. Vincent's Hospital, Dublin; Member of the Cortisone Committee of the Medical Research Council of Ireland

The present trend in the treatment of anuria is in favour of a conservative policy using a balanced fluid and electrolyte intake with a low-protein diet in the hope of a spontaneous remission (Bull *et al.*, 1949). In cases in which gross oedema or some electrolyte imbalance has already occurred active measures to substitute for the kidney must be used.

Methods of treatment based on the primary aetiology, such as decortication, nerve block (surgical or pharmacological), alkalization of the urine, etc., are not often successful. This relative failure may be due to the presence of other unsuspected aetiological mechanisms. The possibility that an acute allergic reaction in the kidneys is a causal factor in some cases is considered in this communication. To test this hypothesis we have tried the effect of cortisone in a miscellaneous group of four cases of anuria. The cortisone used was cortisone acetate ("cortone"), and was given by intramuscular injection, except where oral administration was specified.

Case 1

A man aged 33 was admitted to the Mater Misericordiae Hospital on October 27, 1950, suffering from rheumatoid arthritis, grade II, of ten years' standing. The previous history was irrelevant. There were four areas of alopecia areata on the scalp. His general physical examination was otherwise normal, but the urine contained a very faint trace of albumin, a few squamous cells, and a very rare leucocyte. The electrocardiogram was normal; the blood pressure was 140/80; and the E.S.R. 45 mm. (1 hour). Seven days after admission he was started on cortisone treatment. By November 30 the arthritis had improved by 80%, and cortisone was discontinued on November 26.

By December 1 a relapse of the arthritis was evident and cortisone treatment was resumed: 100 mg. a day orally, in three doses, was given, and because of a favourable response it was reduced to 50 mg. on December 5. As, however, a considerable amount of fluid had developed in the left knee, the dose was increased to 100 mg. a day by mouth on December 13. On December 15 the patient returned home on this dosage, and on the 24th he developed acute pharyngitis with pyrexia of 101° F. (38.3° C.), and was treated with penicillin. Some hours later there was a transient erythematous rash on the trunk. On December 25, contrary to instructions, he ceased taking cortisone; next

*Fourth report of the Cortisone Clinical Subcommittee (Professor Henry Moore, Professor W. J. E. Jessop, and Professor D. K. O'Donovan) to the Medical Research Council of Ireland. The material embodied in this report was part of a series of lectures delivered by one of us (H.M.) at the Mayo Clinic, the University of Minnesota, and the University of Chicago (June, 1952).

On November 29, 1951, he complained of symptoms of pyrexia. Next day his temperature was 99.5° F. (37.5° C.), his pulse rate regular 80, and there were a few scattered rhonchi at the base of the left lung. At that time there were no urinary symptoms. A dessertspoon of "cremomerazine" was prescribed every four hours with rest in bed and abundant fluids. On December 3 his temperature was normal, but it was discovered that he had taken 4 oz. (114 ml.) of cremomerazine—that is, 16 g. of sulphamerazine—within 48 hours. This drug was then stopped and glucose and an alkaline mixture were prescribed, as on that day he complained of abdominal pain and vomited several times. He was admitted to hospital that afternoon. He passed no urine from admission to hospital on December 3 (except about 30 ml. on December 5) until January 7,

oedema of the lumbar region and legs. Some rhonchi were heard at the bases of both lungs.

Treatment with cortisone was started on December 7, and on that day he was given 500 mg. in two doses (see Table III). Next day he was given 400 mg. of cortisone in two doses, and on the same day (29½ hours after the first dose of cortisone) he passed 240 ml. of urine containing +2 albumin, no sugar, no crystals, an occasional leucocyte, and very numerous erythrocytes, but no casts; the nausea had improved so that he was able to drink a moderate amount of fluid. On December 9 he was given 400 mg.

rhage had by then practically disappeared. He returned to hospital on January 28 and a detailed investigation of kidney function revealed no abnormality.

Case 4

A man aged 64 was studied in co-operation with Dr. B. Mayne in the Meath Hospital, Dublin. He was suffering from symptoms of prostatic enlargement for about one year previous to admission. Prostatectomy was recommended by Mr. Lane, and was carried out by the retropubic method on January 29, 1952.

* Assuming the ammonia present was derived from urea.

of cortisone in two doses, and he passed 4,680 ml. of urine and drank 3,000 ml. of fluid; he had no nausea, vomiting, or oedema, and drowsiness had disappeared. His general condition was improved.

It was decided to reduce drastically the dose of cortisone to see if the diuresis of the previous day was a coincidental phenomenon. On December 10 100 mg. was given twice daily, and on the morning of the 11th 75 mg. No urine was passed from 9 p.m. on December 10 (the day the cortisone dosage was halved) up to 5.30 p.m. on the 11th; 325 mg. of cortisone was therefore given at 5.55 p.m. on December 11 and he passed 390 ml. of urine two hours after this dose (see Table III for details).

On December 19 the urine showed only the faintest trace of albumin and no erythrocytes. The latter never reappeared again up to discharge. On December 24 the urea-clearance figure was 158.

He was discharged from hospital on January 4, 1952, apparently fully recovered. The subconjunctival haemor-

Pre-operative examination had not revealed any other abnormality in the urinary system. The blood urea was 37 mg. per 100 ml. The urine was clear and contained no albumin, cells, or casts. An intravenous pyelogram showed normal outline and concentration in both kidneys. Clinical examination revealed a few scattered rhonchi in the lungs and bilateral inguinal herniae. The heart and blood pressure were considered normal. Blood count, chest x-ray film, and glucose tolerance were also normal.

Some hours after operation his blood pressure was low, and he was given a transfusion of 2 pints (1,140 ml.) of blood, and 40 oz. (1,140 ml.) of normal glucose intravenously. On the following day he seemed well, but his urinary output was only 26 oz. (738 ml.), and his fluid intake (oral and intravenous) was put up to 106 oz. (3,010 ml.). During the next two days his urinary output continued to decrease (see Table IV). On February 1 an exploratory operation was done on the right kidney and ureter. Oedema of the perirenal tissue was noted, and the capsule over the

lower pole was incised. On February 4 his general condition was good and his mind was clear. Except for sighing respiration there was no other clinical sign to indicate the degree to which uraemia had developed. His blood pressure was 160/75 mm. Hg, and there was no oedema. On that date he was put on a high glucose intake (300 g. daily). Treatment with cortisone was started on February 6. This decision was made reluctantly, as there was no clue to the aetiology of the renal failure. He was given 400 mg., which was increased to 500 mg. the next day.

On February 5 his clinical condition was still good, and his electrocardiogram was normal. At that time his serum potassium was 22.7 mg. per 100 ml. The serum potassium subsequently increased further, and on February 17 the electrocardiogram showed the effect on his myocardium of this rise.

His general condition remained very good until February 15, when it became necessary to aspirate his stomach contents because of vomiting; much bile-stained fluid was withdrawn. At this time fluid was given intravenously and during the next three days this increased gradually, and for the first time the blood urea ceased to rise; indeed, the blood urea began to decrease, having reached its peak of 725 mg. on February 14. Meanwhile, however, his general condition deteriorated, and he died on February 18 after a short convulsion.

The post-mortem examination report by Professor R. A. Q. O'Meara on the kidneys, suprarenals, heart, and liver, was as follows:

Macroscopically the liver was enlarged, but no gross lesion was seen in it or in the spleen. The kidneys were swollen and pale, and contained a fair number of cortical cysts about ½ in. (0.6 cm.) in diameter; the pelvis appeared normal. Heart: some hypertrophy of the left ventricle and normal. Suprarenals much auto-atheroma of the ascending aorta. Suprarenals much auto-lysed. Microscopically, the liver showed passive congestion. The kidneys showed: (1) old lesions of chronic glomerulonephritis with hyalinization of glomeruli; (2) recent focal glomerulonephritis; (3) much interstitial oedema; (4) marked congestion of the vasa recta; and (5) some tubules contained pus, others contained blood or altered blood.

Discussion

The onset of anuria in Case 1 appeared to be due to the sudden withdrawal of cortisone, which may have exaggerated an allergic type of reaction in the kidneys following on the throat infection and rash. It was this hypothesis which led us to try the effect of cortisone. The striking improvement in the patient's condition which followed was in agreement with this interpretation. It is debatable whether this patient had an atypical form of acute nephritis, and therefore the possibility that cortisone may be of value in such cases should be considered.

The anuria in Case 2 is difficult to explain and was probably due to mild acute nephritis complicated by pregnancy. Dr. Arthur Barry held the view that it was not entirely a symptom of pregnancy toxæmia for a variety of reasons, including the absence of toxæmia in previous pregnancies and the history of recent sore throats. The response to cortisone was not entirely satisfactory, and it would perhaps be more reasonable to explain, at least partly, the late onset of diuresis by the termination of pregnancy and by the spontaneous recovery which is likely to occur in such cases.

In Case 3 the anuria was interpreted as the result of an acute allergic reaction to sulphamerazine in the urine. The diuresis there was no sulphamerazine crystals in the urine. The diuresis which followed cortisone administration seemed to be attributable to the hormone. This view was substantiated by the recurrence of anuria when the dose of cortisone was suddenly reduced and by the prompt reappearance of diuresis when the dose was increased.

In Case 4 the anuria followed prostatectomy and a moderate degree of glomerulonephritis was found at

necropsy. One apparently contributory cause of death was the high blood potassium.

There are theoretical reasons for caution in using cortisone in cases of acute anuria. One may ignore the well-established fact that cortisone acts in animals as an electrolyte-controlling corticoid causing water and salt retention. In humans this effect is less consistent and even contradictory, depending on the condition of the patient. Thus it has an antidiuretic effect in most normal people if the salt intake is above a certain level; it has a diuretic effect in some cases of nephrosis; whilst in toxæmia of pregnancy it may produce internal fluid transfer, causing ascites with diminution of subcutaneous oedema (Moore *et al.*, 1951).

A more serious objection is that cortisone promotes increased tissue catabolism and is therefore apt to increase the concentration of toxic metabolites in the blood. It is thus possible that some of the increase in blood urea noted in the above cases after cortisone administration could be attributed to this effect. A similar explanation may partially account for the increase in serum potassium noted in Case 4.

Another theoretical objection to using cortisone is suggested by its effect on rats' kidneys, resulting in marked hyperaemia of the glomerular capillaries and a shunting of blood towards the medulla, which becomes greatly congested. This may eventually lead to hypertension and nephrosclerosis. Cortisone is also described as aggravating the renal damage caused by mineral-controlling corticoids. Furthermore, cortisone has not a renotropic effect on the kidney which is characteristic of the anabolic steroids such as testosterone; indeed, it is only the steroids possessing this characteristic which have a protective effect on the kidneys of animals exposed to a wide variety of noxious drugs or violent physical treatment (Selye, 1951). Thomas and Good (1951) reported that cortisone-treated rabbits developed cortical necrosis after intravenous injection of bacterial toxin. Such adverse observations should not be considered decisive for clinical problems, since the reaction of different species is not constant and the doses used are not strictly comparable.

The possibility that an acute allergic reaction in the kidneys to a drug such as the "sulpha" compounds may be controlled by cortisone is of particular interest, as such reactions have often been reported in the literature, especially with sulphathiazole.

Five separate pathological manifestations in the kidney have been attributed to sulphonamide derivatives, and each has been associated with anuria. The best known is mechanical blockage due to crystalluria. The second, that of perifocal tubular nephritis, was recorded by Bergstrand (1946), who also emphasized that the renal findings were essentially the same as those found in the crush syndrome. An acute nephritis resembling the "mercury kidney," with parenchymatous degeneration of the convoluted tubules without inflammatory cell infiltration (More *et al.*, 1946), and a glomerulonephritis have also been described. Finally, a type mainly distinguished by arterial changes and cellular exudate suggestive of an anaphylactic reaction has been defined by Black-Shaffer (1945). That such reactions may arise after even a small dose of a sulphonamide is exemplified by the case of Bakken (1947).

It is evident from the pathological findings in cases of anuria due to sulphonamides that, while the allergic factor may be inhibited by cortisone, the hope of recovery will depend on whether treatment is given before irreversible changes have occurred in the kidneys. Since the type of allergic reaction is variable it remains to be seen if cortisone will be successful in only a limited number of such cases.

According to our limited experience in the treatment of acute rheumatic fever we believe it is probable that cortisone can not only prevent rheumatic carditis but perhaps even abolish it if given in proper dosage and before irreversible cardiac changes have occurred. If also it be true that cortisone is useful in acute diffuse glomerulonephritis due to allergy, one condition for success would seem to obtain in both these conditions: administration should begin early

in the attack and before organic damage is done to the heart or kidneys. This view was expressed over two years ago by one of us (H. M.) as regards the heart when introducing Professor Philip S. Hench for the Honorary Degree conferred on him by the National University of Ireland.

Summary

Four cases of acute anuria treated with cortisone are reported. In two patients an allergic reaction in the kidneys was suspected, and both responded satisfactorily, making a rapid and complete recovery; in one the allergy was attributed to an overdose of sulphamerazine; in the other it was attributed to the sudden cessation of cortisone, which was being taken (100 mg. daily) for rheumatoid arthritis, and to the development of a sore throat, pyrexia, and rash; both factors preceded the anuria.

No definite conclusions can be drawn from the three apparently successful cases, as acute anuria is prone to develop a spontaneous remission.

We are indebted to Professor W. J. E. Jessop, of the Meath Hospital, Dr. Maurice Hickey, of the Mater Misericordiae Hospital, and Dr. Frank Geoghegan, of the National Maternity Hospital, Dublin, for carrying out the biochemical and pathological investigations. The tables were constructed by Mr. Ronan Kieran, of the Department of Anatomy, University College, Dublin.

N,N'-DIBENZYLETHYLENEDIAMINE PENICILLIN: A NEW REPOSITORY FORM OF PENICILLIN

BY

A. P. FLETCHER, M.D., M.R.C.P.

AND

C. R. KNAPPE, M.D., Dip.Bact.

(From the Department of Bacteriology and the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, W.2)

Szabo, Edwards, and Bruce (1951), during a study of the properties of certain penicillin salts, discovered that the coupling of N,N'-dibenzylethylenediamine with penicillin resulted in the formation of a complex only very sparingly soluble in water. These authors described the properties of this complex, its preparation, and the fact that one molecule of base was coupled to two molecules of penicillin. A shortened name for this complex—benzethacil—will be used in this communication. Seifter *et al.* (1951), reporting on the toxicity of benzethacil to animals, found that this compound was approximately 25% more toxic than procaine penicillin to mice by intra-abdominal injection, but was not more toxic when given by intragastric drip, whilst its local analgesic action compared favourably with that of procaine hydro-

chloride. Elias, Price, and Merrion (1951) followed serum penicillin levels in man after the intramuscular injection of this compound, and concluded that it showed no significant toxicity and gave serum penicillin levels of greater duration than any reported with other forms of repository penicillin.

Benzethacil can be administered orally, and shows therapeutic activity by this route (Lepper *et al.*, 1952), but the present communication deals solely with the serum penicillin levels obtained after intramuscular injection.

Materials and Methods

Penicillin assay was performed by the *Sarcina lutea* plate technique (Food and Drugs Administration, Washington), using *Sarcina lutea* C.P.I.-1001. This technique, which uses penicillin dilutions made up in serum, allows adjustment for the influence of protein-bound penicillin, and is thus of considerable assistance in evaluating the significance of low penicillin levels.

With this technique reproducible zones of inhibition were obtained throughout the period of the experiment, as shown by the figures given in Table I. In practice a complete set

TABLE I.—Diameters of Inhibitory Zones of *Sarcina* Plates

Standard Penicillin in Serum (units/ml.)	Mean Diameter of Zone of Inhibition in mm.	Standard Deviation
0.10	23.9	±1.2
0.075	20.0	±0.96
0.05	18.8	±1.25
0.03	12.8	±1.45
0.02	9.1	±1.1

of control plates was run with each set of serum assays. Serum penicillin levels were estimated from a line calculated from the individual control plates (see Ungar, 1951).

Benzethacil was supplied as an aqueous suspension in "tubex" ampoules containing 1 ml. (1 ml. contained 600,000 units of penicillin). The needle provided with the tubex syringe had a diameter of approximately 19 s.w.g.; the suspension could be injected without undue difficulty through this needle.

Nineteen volunteer male subjects took part in this investigation; their ages ranged from 19 to 33 years, and their weights from 10 to 15 st. (63.5 to 95.3 kg.). A single injection of 600,000 units of penicillin contained in one tubex ampoule was given into the gluteal muscles. Blood was withdrawn by venepuncture, and the serum, after being separated by centrifugation, was stored in stoppered bottles over solid CO₂ until used for assay.

Toxicity

Most of the subjects complained of aching at the site of injection for 24 to 48 hours. In no case was this severe. One subject developed a "serum sickness" reaction ten days after the injection. This reaction could not be positively attributed to the benzethacil since another possible antigen had been given shortly before. Despite the lack of positive evidence as to causation, this case is recorded, since benzethacil is excreted extremely slowly, and may give rise to unusual types of sensitivity response.

Results

The serum levels recorded are presented in Table II. It is seen that benzethacil administered by intramuscular injection gives sustained levels of serum penicillin considerably superior to any repository penicillin preparation yet developed. The findings in Table II support the view that even if benzethacil injections were spaced as far apart as 14 days a summation of dose effect might occur.

TABLE II.—Distribution of Serum Levels following 600,000 Units of Benzethacil Intramuscularly

Serum Penicillin Levels (Units/ml.)	Time After Injection												
	3 Hrs.	6 Hrs.	24 Hrs.	48 Hrs.	72 Hrs.	5 Days	7 Days	10 Days	14 Days	17 Days	21 Days	24 Days	28 Days
0.10-0.15	4	3	2	1	5								
0.075-0.099	1	3	2	3	10	1	1		1				
0.05-0.074			2		3	2	8	1	9	7	6	8	3
0.03-0.049					1		7	5	6	5	5	2	5
0.02-0.029							2						
<0.02. No detectable level.													
Total observations ..	5	6	6	6	19	3	18	13	16	12	11	10	8
Range	0.130/ 0.075	0.115/ 0.075	0.115/ 0.070	0.110/ 0.050	0.090/ 0.020	0.050/ 0.035	0.050/ <0.02	0.030/ <0.02	0.040/ <0.02	0.025/ <0.02	0.020/ <0.02	0.025/ <0.02	0.025/ <0.02
Mean	0.104	0.097	0.085	0.076	0.067	0.042							

Though small zones of inhibition were sometimes found at levels of less than 0.02 unit of penicillin, any serum showing less than this level was regarded as showing no detectable amount.

In Table III it is shown that assayable penicillin levels may appear only intermittently in some subjects. This phenomenon is not surprising when the insoluble nature of the preparation and the long duration of action are considered.

TABLE III.—Cases Showing Intermittent Penicillin Levels

Subject No.	Days After Injection							
	3	7	10	14	17	21	24	28

5	0.020	0.025	0	0.025	0.020	0.020	0.025	0

Discussion

This substance is a most interesting addition to the variety of penicillin preparations now available for therapeutic use. It is as yet too early to do more than suggest what place it may come to occupy in the treatment of disease. Venereal disease, since default from treatment is relatively common, would seem to be a promising field for trial. O'Brien and Smith (1952) have reported on the efficacy of this substance in the treatment of gonorrhoea, while preliminary results in the treatment of syphilis (Roberts, personal communication, 1952) have been said to be highly encouraging.

The prophylaxis of haemolytic streptococcal infection in patients who have suffered from rheumatic fever may be improved by the use of benzethacil. Stollerman and Rusoff (1952), who treated 135 convalescent rheumatic children, concluded that in most cases a single injection of benzethacil will clear the throat of haemolytic streptococci, and that with continued administration at fortnightly intervals there will be no recurrence of the carrier state. Unfortunately, low intermittent penicillin levels provide the optimum conditions for the emergence of drug-resistant organisms, and it is possible that the wide use of benzethacil would increase the magnitude of this problem.

The incidence of sensitization to this preparation is not yet known; but theoretically it may be high, owing to the long-continued exposure of the patient to low and at times intermittent penicillin levels. Preliminary data provided by O'Brien and Smith (1952) and Stollerman and Rusoff (1953) with combined series of 1,500 patients suggest that the incidence of significant penicillin reactions is not greater than 0.3%. In addition, O'Brien and Smith, in a study of four patients who developed urticarial manifestations within ten days of the injection, found that the reaction lasted only two to three days and cleared up whilst assayable penicillin was still present in the blood. However, in view of the unusual nature of the penicillin levels produced by

benzethacil further clinical study will be required before the danger of sensitization can be fully assessed.

We are grateful to Wyeth Incorporated, Philadelphia, Pennsylvania, for the supply of "penidural" benzethacil.

CLINICAL TRIAL OF T.B.3 IN SURGICAL TUBERCULOSIS

BY

J. H. MAYER, T.D., M.B., F.R.C.S.

Orthopaedic Surgeon, Pembury Hospital, Kent

AND

P. GOWANS LAING, M.B., F.R.C.S.

Senior Surgical Registrar to the Bradford Group

The thiosemicarbazones have been on trial in the treatment of tuberculosis for several years, principally in Germany, and a fair measure of success has been reported.

This report deals with a short clinical trial of one of the drugs, *para*-ethylsulphonylbenzaldehyde thiosemicarbazone (also known as T.B.3, "ethizone," and 8388), in eight patients suffering from tuberculosis of the spine or sacro-iliac joint whose organism was proved, or strongly suspected, to be resistant to streptomycin and P.A.S. We are concerned here mainly with the toxic effects of T.B.3, which in all our eight cases prevented the administration of the drug for long enough to reach any conclusions about its possible bacteriostatic effect on *Mycobacterium tuberculosis*.

Historical Survey

The use of thiosemicarbazones in tuberculosis was first described by Domagk *et al.* (1946). After trying many of these drugs they concluded that the most useful was *para*-acetamidobenzaldehyde thiosemicarbazone (thiacetazone; also known as T.B.1, "conteben," T.B.1/698); their report stimulated extensive clinical trials in Germany.

Donovick and Bernstein (1949) reported that T.B.1 was more active than P.A.S. but less active than streptomycin in early pulmonary infections, but its activity seemed to decline later in the disease. Karlson *et al.* (1949) found that in guinea-pigs T.B.1 and streptomycin, given together, were more effective than either given alone in ordinary therapeutic doses. Hurni (1949), however, working with mice, reported no additive effect of T.B.1 with either streptomycin or P.A.S. separately, though he found that T.B.1 did have some useful effect if given with both streptomycin and P.A.S. together. Heilmeyer (1949) reported good results in exudative lesions and in bone and joint infections. He noted a frequent fall in the erythrocyte sedimentation rate, which, however, did not correspond to any clinical improvement in the disease. He also recorded many toxic reactions, including liver and kidney damage and anaemia.

Hinshaw and McDermott (1950) and Mertens and Bunge (1950) reviewed German results in 10,000 cases. These workers confirmed the activity of T.B.1 against *M. tuberculosis*, but were unable to reach a definite conclusion about the clinical efficacy of the drug, since the trials had been conducted in Germany at a time when the general nutrition of the patients and the facilities for the general treatment of the disease were constantly improving. Toxic symptoms, consisting mainly of digestive disturbances and albuminuria, were fairly common, while profound anaemia developed occasionally after long courses of this treatment. A further possible toxic effect is mentioned by Stadler and Weissbecker (1951), who report a case of transient Cushing's syndrome in a patient receiving T.B.1.

As early as 1949 Hoggarth *et al.*, reporting trials of about 100 thiosemicarbazones and allied substances in infected mice, stated that T.B.3 seemed to be the most effective of these. In 1950 Hoggarth and Martin showed that T.B.3 was superior to P.A.S., though less effective than streptomycin. Martin and Stewart (1950), however, found T.B.3 superior to streptomycin in the early stages of the disease, but this relationship became reversed in more advanced cases. Bavin *et al.* (1950) and Hamre *et al.* (1950) agreed with other workers that T.B.3 was a more effective agent than T.B.1 in experimental mouse tuberculosis.

Rees and Robson (1951) showed that in experimental corneal tuberculosis T.B.3 with streptomycin was more effective than T.B.3 with P.A.S. or streptomycin with P.A.S. Ross *et al.* (1951) recorded encouraging effects from T.B.1 in conjunction with streptomycin and P.A.S. in human renal tuberculosis, but suggested that T.B.3 might be more efficacious and less toxic.

Little seems to be known about the possible toxic effects of T.B.3 in man. Francis *et al.* (1950) showed in monkeys that a dose of 500 mg. per kg. body weight twice daily produced fatty degeneration of the liver, and that 500 mg. per kg. once daily produced no toxic effects. The therapeutic value of this lower dosage in experimental tuberculosis was about half that of 40 mg. of streptomycin per kg. daily. This is equivalent to comparing a dosage in an average man of 3 g. of streptomycin daily with over 30 g. of T.B.3. From the known toxicity of the thiosemicarbazones such high doses in man would clearly be dangerous. Siebenmann and Zubrys (1952) have shown that the haemolytic anaemia produced by T.B.1 in mice does not occur with T.B.3. Spinks (1951) has shown that T.B.3 in mice and dogs produces blood levels four times as high as the same dosage of T.B.1. Since T.B.3 appears to be a more effective substance in the treatment of tuberculosis than T.B.1, it seems reasonable to hope that an effective blood level can be maintained on T.B.3 with less danger of toxic signs than on T.B.1.

Clinical Material

It was decided to conduct a limited clinical trial of T.B.3 in selected cases of bone and joint tuberculosis whose lesions were failing to respond satisfactorily to other

forms of treatment. All these patients were appropriately splinted and on a general sanatorium routine in hospital, and all had received appropriate surgical treatment where indicated. All were receiving daily 1 g. of dihydrostreptomycin and 15 g. of P.A.S. Three had developed proved resistance to one or both of these drugs, and in the other five the clinical progress led us to believe that such a resistance must be developing, though we were not able to prove this. In six of the eight patients the lesion was proved to be tuberculous; in one there was histological evidence but no bacteriological proof of tuberculosis; in the eighth the clinical and radiological condition was typical though there was no histological or bacteriological proof of its tuberculous nature.

Dosage.—The first four cases started on 50 mg. of T.B.3 a day and the dose was increased gradually over a period of a few weeks to the maximum of 200 mg. a day in divided doses. The later cases started on 100 mg. a day, and the dose was raised more rapidly to 200 mg. a day. This is the dosage advised by the makers, who warn against exceeding 250 mg. a day.

Routine Investigations.—The following investigations were carried out in all cases: daily urinalysis, weekly haemoglobin estimation, red-cell and white-cell counts, and a fortnightly or monthly erythrocyte sedimentation rate. Blood-sugar estimations and glucose-tolerance curves were done in five cases.

Case Records

Case 1.—A woman aged 30. Tuberculosis of left sacro-iliac joint, onset summer, 1948; not proved. Recurrent sinuses despite streptomycin and P.A.S. Arthrodesis October, 1950. Recurrent wound breakdown. T.B.3 was given with streptomycin and P.A.S. from May 28 to August 7, 1951, when intermittent albuminuria and vomiting led to its discontinuation. E.S.R. rose during the course and haemoglobin fell from 102% to 74%.

Case 2.—A boy aged 9. Tuberculosis of dorsal spine; proved. Treated since 1944. Progressive collapse of thoracic spine and recurrent psoas abscess. Aspirations of psoas abscess; local streptomycin and P.A.S. Organism became resistant. T.B.3 was given from May 31 to August 7, 1951. Intermittent albuminuria and reducing substance in urine. Some anorexia. No anaemia.

Case 3.—A woman aged 64. Tuberculosis of right sacro-iliac joint; proved. Treated by plaster bed, streptomycin and P.A.S., and operative fusion. Organism became resistant, and a course of T.B.3 was added from June 5 to September 21, 1951. Discontinued because of severe albuminuria, profound nausea, vomiting, and anaemia. Haemoglobin fell from 96% to 64%, necessitating blood transfusion. E.S.R. rose. Urine occasionally contained a reducing substance.

Case 4.—A woman aged 31. Tuberculosis of thoraco-lumbar spine; proved. Wound broke down after operative excision of the disease in spite of streptomycin and P.A.S. T.B.3 was given from June 5 to September 27, 1951; discontinued because of albuminuria and severe vomiting. No fall of E.S.R. or haemoglobin. A reducing substance was found in the urine.

Case 5.—A man aged 20. Tuberculosis of D.12 and L.1 and os calcis; proved. Wound broke down following excision of spinal lesion while on streptomycin and P.A.S. T.B.3 was given from June 26 to July 13, 1951, when heavy albuminuria led to its withdrawal.

Case 6.—A girl aged 16. Pott's paraplegia; proved. Failed to improve after plaster-bed and lateral rachotomy. T.B.3 added to streptomycin and P.A.S. from August 24 to September 17, 1951, when severe albuminuria and vomiting led to its discontinuation. E.S.R. and haemoglobin percentage unchanged. A reducing substance appeared in the urine.

Case 7.—A woman aged 69. Dorso-lumbar tuberculosis; proved. Lumbar abscess. Organism became resistant to

streptomycin and P.A.S. T.B.3 was given from September 6 to 25, 1951, when severe nausea and vomiting led to its discontinuation. Mild albuminuria. E.S.R. and haemoglobin unchanged. Reducing substance present in urine.

Case 8.—A woman aged 21. Tuberculosis of lumbar spine; proved. Wound broke down following excision of the disease. Course of T.B.3 was given from September 10 to 27, 1951, when albuminuria led to its discontinuation. Moderate nausea and anorexia throughout the course. E.S.R. and haemoglobin unchanged. Reducing substance was found in urine.

Discussion

No attempt has been made to assess the effect of T.B.3 on the tuberculous lesions in these cases. Since only eight patients were given the drug, and some for only a few weeks, any such deductions would be statistically invalid. We confine our remarks to the toxic effects of T.B.3.

None of this series remained free from toxic signs or symptoms while receiving the drug, and in all of them the drug was withdrawn because of this toxicity.

Albuminuria was found in every case at some time during the course, though its severity varied from case to case. Case 4 developed albuminuria while receiving only 50 mg. of T.B.3 a day, and this did not increase when the dose was raised to 200 mg. a day. In Case 5, on the other hand, very severe albuminuria occurred only when this full dose was reached, the course being immediately abandoned. We found no evidence of permanent renal damage following the courses of T.B.3, and albuminuria disappeared a few days after the drug was withdrawn in all cases. We feel, however, that the persistent albumin leak through the kidneys is evidence that the drug has a very definite toxic effect on this organ, and that long courses of the drug might well lead to irreversible changes.

In all but two of our cases a reducing substance appeared in the urine during the course. In Cases 4, 6, 7, and 8 this was a constant finding, while in Cases 2 and 3 it was intermittent. This substance was shown not to be a sugar, and was probably glycuronic acid, which appears in the urine during the detoxication of P.A.S. in the liver. All these cases were receiving P.A.S.

Only one case tolerated T.B.3 without developing anorexia, nausea, or vomiting to some degree. In Cases 1, 3, 4, 6, and 7 these disturbances were severe on a dose greater than 100 mg. a day, and led to a deterioration in the patient's general health. We were unable to reduce the severity of these symptoms by increasing the intake of glucose or by these symptoms by increasing the intake of glucose or by the administration of "avomine" or chlorbutol. We feel that such a disturbance of the general condition of a tuberculous patient can only do harm.

Case 3 showed a gradual fall of the haemoglobin level throughout the course of T.B.3 in spite of the administration of oral iron. The haemoglobin finally reached a level of 63% after nearly three months on the drug. This patient also experienced severe anorexia and vomiting from time to time during the course. No evidence of any haemolytic element could be found, and the anaemia was of the normocytic hypochromic type. After the course of T.B.3 a blood transfusion and the continued administration of iron soon led to cure of the anaemia.

Case 1 developed a similar type of anaemia but of slighter degree. In neither of these two patients was there any local sepsis at the disease site, and the sinus in Case 1 was at all times sterile. It seems probable that the digestive upsets led to deficient absorption of iron from the intestines. No fall of the white-cell count was seen in any of our patients.

The E.S.R. remained substantially unchanged in six cases and rose in two during the administration of T.B.3. We did not encounter the fall reported by other workers. No case developed any allergic manifestations while receiving the drug.

It is possible that our dosage was too high, but it is of interest that Case 2, an undersized boy of 9, tolerated the

full dosage of 200 mg. a day for several weeks a great deal better than most of the adult patients. In view of the work of Francis and Spinks, we felt that no useful therapeutic effects could be expected from a lower dosage.

Conclusions

The serious toxic effects of T.B.3 forced us to abandon this clinical trial in its early stages. Obviously we cannot draw any far-reaching conclusions from this limited experience. We feel, however, that the ill effects of the drug on the general condition of the patients are a very serious contraindication to its use in bone and joint tuberculosis.

The modern combination of a sanatorium regime with the administration of streptomycin and P.A.S. and a planned surgical attack on the disease is in our experience yielding good results. It is important also not to overemphasize the role of chemotherapy in a disease whose basic pathology is the avascular tubercle and caseation, for even the most active antituberculous drug may not reach the living organisms in the centre of the lesion.

The routine use of any fresh chemotherapeutic aids can be justified only if their therapeutic benefits outweigh any toxic effects. The general condition of the patient must not suffer during treatment, and there must be no permanent sequelae.

We believe that T.B.3 fails on the first of these conditions, and that its prolonged administration may lead to failure on the second also. In our opinion its use in bone and joint tuberculosis should be restricted to cases in which other methods are failing to arrest the disease, and in which the situation is becoming so critical that the risks must be accepted.

At a meeting in Edinburgh on January 7 Dr. Charles Hill, Parliamentary Secretary to the Ministry of Food, discussed the possibilities of derationing some foods (*Scotsman*, January 8). Speaking of the shortage of butter, he said that it was not sufficiently realized that it took 20 pints of milk to make 1 lb. of butter, or that 60% more liquid milk was being consumed to-day than before the war. The drive for more meat had also affected production of butter, but it was hoped that Australia would be able considerably to increase supplies of butter to this country, though it would be unduly optimistic to expect a return to the large quantities of cheap butter which were available before the war. Dr. Hill said that there was enough oil and fat in the world to dispense with the rationing of margarine and cooking fat, but our difficulty was to be able to afford to buy the necessary supplies.

TUBERCULOUS MENINGITIS TREATED
WITH STREPTOMYCIN

A FOUR-YEAR FOLLOW-UP

BY

SHEENAH J. M. RUSSELL, M.D., M.R.C.P.Ed.
D.C.H.

Former Clinical Assistant

AND

PATRICK MacARTHUR, M.D., F.R.F.P.S. D.C.H.

Assistant Visiting Physician

Royal Hospital for Sick Children, Glasgow

In 1950 we reported on the various methods of treatment with streptomycin and the results obtained after at least one year in 33 proved cases of tuberculous meningitis in the Royal Hospital for Sick Children, Glasgow (Russell and MacArthur, 1950). Because it has been recognized that certain children with tuberculous meningitis who have been treated with streptomycin and have apparently made a satisfactory recovery may subsequently suffer a relapse of the disease and die, it was thought necessary to watch the progress of these children for some years after the completion of treatment before claiming that they were cured. The present report is a further record of the 15 children who were alive at the time of the first report. The period of follow-up now ranges from 49 to 68 months. Each survivor was examined during the past year and the cerebrospinal fluid of all but one was examined. Details of these children are recorded in Table I and the case numbers correspond with those in our first report.

The main clinical features of the disease in each of the 33 original cases have already been recorded (Russell and MacArthur, 1950). These were the first patients to be treated with streptomycin in this hospital, but they were not consecutive admissions, because the accommodation available and the time required for the detailed investigations necessary ruled out the possibility of treating all cases admitted for diagnosis and found to have tuberculous meningitis. It was the practice to reserve four cots in each of the two medical units for this therapeutic trial, and when one of these cots was vacated the place was taken by the next case diagnosed. No attempt was made to select cases in which a favourable outcome might be anticipated. The results of treatment are not the best that could be obtained, because

the trial was in force at a time when little was known regarding the best method of using streptomycin, and indeed at one stage a number of patients were given only intramuscular injections.

Of the 33 patients, 12 are alive—nine are leading normal lives in their own homes and three are grossly disabled. The cerebrospinal fluid (C.S.F.) is cytologically and chemically normal in 11 of the children. One of the disabled cases (No. 25) has a low sugar content. Table II shows the results obtained in this series and in other published series.

Nine Survivors who are Well

Five of these children were under 4 years old when they developed meningitis. In only one survivor (Case 24) was there a snowstorm appearance on x-ray examination, and in one other (Case 32) there was a single choroidal tubercle, now healed. In three children the disease was in its early stages when treatment was begun, and in the other six it was in an intermediate stage. No child has survived in whom the disease was already advanced at the onset of treatment. Two children have had a relapse of meningitis and have recovered after a second course of treatment. A block in the circulation of C.S.F. from the ventricles throughout the subarachnoid space was present in Cases 14 and 22. In Case 14 the block resolved during the period of observation, while in Case 22 a partial spinal block was still present at the time of writing, although he was very well 55 months after the onset of the disease and 52 months after the block was first detected. The parents of the child with the single healed choroidal tubercle (Case 32) refused to bring him to hospital for review, but he was seen in his own home. It was impossible, however, to examine the spinal fluid or to have a skiagram taken. He appeared to be a healthy, happy boy with no abnormal signs in the central nervous system. During August and September, 1951, the C.S.F. of the other eight children was examined and cultured, and was found to be cytologically and chemically normal and sterile.

While the children were under review special attention was paid to their scholastic attainment, but unfortunately it was not possible to have intelligence tests carried out. One child (Case 14), who is of an affectionate and happy disposition, is definitely backward mentally and attends a special school, while Case 11 is probably of low average intelligence. The remaining seven, however, appear to be making good progress at school and do not exhibit any behaviour problems. Recent skiagrams of the skull show areas of calcification in six of these children.

Three Survivors Disabled

One of these children (Case 2) developed meningitis 68 months ago. Though in an early stage of the disease when treatment was begun, she did not respond satisfactorily, and

* In this series six children treated with intramuscular streptomycin alone have been excluded from the figures quoted.

tubercle bacilli were still cultured from her C.S.F. two and a half months after the start of streptomycin therapy. After six months of intramuscular and intrathecal treatment her clinical condition was deteriorating and she developed convulsions and a right-sided hemiplegia. Treatment was finally stopped after 12 months, when she was hemiplegic and having convulsions. The disease is now quiescent and her C.S.F. is normal and sterile on culture, but the child is a low-grade mental defective with a right-sided hemiplegia and has frequent epileptic fits. Calcification is apparent in a recent skiagram of her skull, and is situated above and anterior to the sella and on both sides of the midline.

Case 15 has been observed for 58 months. He had intramuscular treatment alone for 60 days, after which tubercle bacilli were still cultured from his C.S.F. and he was emaciated and comatose. Ten weeks of combined intramuscular and intrathecal treatment brought improvement in the cerebrospinal-fluid findings, but his clinical disability remained severe. He suffered a relapse of meningitis 15 months after his initial attack and had a further three months of intramuscular and intrathecal treatment. The disease is at present quiescent and the C.S.F. is normal, but he is mentally defective with a right hemiplegia, has epileptic fits, and shows marked sexual precocity. Intracranial calcification began to appear 23 months from the onset of the illness, and there is now a dense mass above the sella turcica and on the left side of the brain.

Case 25 has now been under observation for 52 months. He was 12 months old and was in an intermediate stage of the disease when the diagnosis was made. He had a three-months course of intramuscular and intrathecal treatment, on the completion of which he was blind, he was having convulsions, and his C.S.F. was still abnormal. Six months later, however, his spinal fluid was normal, although he was mentally defective and was still having convulsions. Two years after his initial illness he had a relapse of meningitis, and again tubercle bacilli were cultured from his C.S.F. He was given another three-months course of intramuscular and intrathecal streptomycin with some improvement. At the present time he is mentally defective, has epileptic fits, and his C.S.F. sugar is at an ominously low level.

Changes Since last Report

Comparison of the present state of this series with the state in September, 1949, shows four changes, one for the better and three for the worse. Case 32 was reported as disabled because he was believed to be developing hydrocephalus, but he has completely recovered and attends school regularly, where his achievements are well up to the average standard. One inactive choroidal tubercle is still visible in his right eye.

Case 33, who was disabled at the time of the last report, has since died, 30 months after the onset of the disease. This boy was admitted to the centre with miliary tuberculosis and developed meningitis while on intramuscular treat-

ment. Until his death 30 months later he was under continuous observation and had four relapses, at the onset of three of which tubercle bacilli were cultured from his C.S.F. In the final episode the tubercle bacilli were still sensitive to streptomycin, but he died suddenly on the day after the start of treatment. At necropsy the brain showed hydrocephalus, with a thick gelatinous exudate at the base of the brain, and four small tuberculomata were found in the cortex.

Case 9 was classified as "well" in the original report, although nine months after the completion of treatment his C.S.F. still had a raised cell count. He remained at home, leading a normal life and attaining average success at school, but 45 months after his initial meningitis he had a relapse and in spite of treatment died within two months. This boy showed the most scattered intracranial calcification of the series, the nodules being widely spread on both sides of the brain. The course of the illness during the first six months was stormy, with episodes of convulsions, aphasia, hallucinations, facial palsy, and severe psychological upsets. Three months after stopping streptomycin it was realized that he was deaf, but gradually his deafness diminished, and a year later his hearing, by rough tests, was normal. It seems probable that his deafness was due to the disease rather than to the streptomycin sulphate with which he was treated.

Case 10 was classed as "well" in our 1949 report, but in October, 1949, he was found to have a tuberculous abscess in the anterior end of the left seventh rib. This discharged pus containing tubercle bacilli, and the child was given a four-weeks course of intramuscular streptomycin. The lesion healed completely and permanently within three months. An x-ray film of the skull in February, 1951, showed extensive intracranial calcification at the base of the brain. During 1951 the boy remained apparently well, though there was a mild right-sided hemiplegia, and he attended school regularly. On August 22 a lumbar puncture was done during routine follow-up studies. The C.S.F. was cytologically and chemically normal and he seemed very well, but it was disquieting to culture two colonies of tubercle bacilli from the C.S.F. In May, 1952, he had a relapse of tuberculous meningitis and in spite of intramuscular, intrathecal, and intraventricular treatment he died with gross hydrocephalus eight weeks later. In this relapse, three years after his primary attack, the tubercle bacilli were fully sensitive to streptomycin.

Intracranial Calcification

One of the most interesting features of the follow-up has been the detection of intracranial calcification. This has been present in the skiagrams of 8 of the 12 survivors and also of two children (Cases 9 and 10) who died of a relapse of meningitis in March, 1951, and June, 1952. In every case there have been calcified areas in the vicinity of the sella turcica. In five children central nodules were seen around the sella or just above it. In six cases there were nodules a little above the level of the sella and about one-third of the distance towards the left side of the skull, and in two cases the nodules were on both sides of the film. The majority of calcified foci appeared to be in the vicinity of the cisterna interpeduncularis and cisterna chiasmatica, and in one case the calcification extended up towards the cisterna ambiens. This localization was supported by the findings at necropsy on Cases 9 and 10, whose skiagrams showed widespread intracranial calcification. There were numerous calcified foci in the tuberculous exudate at the base of the brain, often deep in the sulci, but no calcified areas in the brain substance.

Cairns (1951) stated that "in tuberculous meningitis it is probably many months before the subarachnoid spaces are clear of exudate; in some successful cases traces of it persist indefinitely and become calcified." From the present findings it would seem that in the successful cases calcification is the rule rather than the exception, and it is probable that its appearance depends mainly upon the length of time

since active meningitis occurred. The earliest appearance of calcification in the basal cisterns was noted at 23 months from the onset of meningitis. In two of the children the areas concerned may well be within the brain parenchyma. Case 15, who shows signs of precocious puberty, has a dense mass, probably situated in the hypothalamus. Case 14, before the onset of meningitis, was admitted to a neuro-surgical unit for investigation of a cerebral tumour. At that time, in November, 1947, a skiagram of the skull showed an area of calcification in the left temporal lobe. Ventriculography revealed that there was also a large mass in the right frontal area blocking the anterior horn of the right lateral ventricle. A second area of calcification has been present on films dating from 15 months after the onset of meningitis, and the site appears to correspond with the tuberculoma found in the right lateral ventricle. It is not surprising to find that seven of the ten children showing intracranial calcification also show intrathoracic calcification.

Other published accounts of tuberculous meningitis treated with streptomycin have been searched for any reference to the presence of intracranial calcification in surviving patients. Lorber (1951) described intracranial calcification in a girl of 7 years who developed tuberculous meningitis 18 months previously. This girl showed signs of sexual precocity, and in her case there were two small foci of calcification believed to be in the wall of the third ventricle. The demonstration of intracranial calcification which is now possible in so many of these cases is a vindication of the view (Rich and McCordock, 1929) that meningitis is commonly secondary to cortical or meningeal tuberculomata.

Relapse of Meningitis

In this series there have been nine children who suffered recurrence of meningitis at intervals of 3 to 179 weeks after the completion of treatment (Table III). Six children have

TABLE III.—Relapses of Tuberculous Meningitis

Case No.	Interval Since Last Treatment (Weeks)	Last C.S.F. Taken Before Relapse					Present Condition

* Tubercle bacilli cultured. V.P. Ventricular puncture.

died. Only in Case 25 had the C.S.F. been normal before the relapse occurred, but physically he was severely disabled. In Case 10 the C.S.F. was cytologically and chemically normal but tubercle bacilli grew on culture. One relapse which occurred after three and a half years of good health was particularly disappointing. This child (Case 9), in an intermediate stage of the disease when treatment was begun, had intramuscular and intrathecal treatment during a period of three months. Reference has already been made to the severity of the clinical picture. Ten months after the completion of treatment his C.S.F. was still abnormal, although his only physical disability was some impairment of hearing. He remained at home, and was doing well at school until January, 1951, when he had a relapse of meningitis with tubercle bacilli in the C.S.F. In spite of treatment he died six weeks later. A skiagram taken on January 30 showed extensive intracranial calcification, and at necropsy numerous calcified tubercles were found in a dense basal exudate but none were present in the brain substance. The appearance of intracranial calcification is therefore not an

infallible sign of healing of the meningitis; it does not preclude the existence of tuberculous foci which may still contain living tubercle bacilli. Cases 9 and 10 had extensive intracranial calcification when they developed a recurrence of meningitis and died.

Cortical or subcortical tuberculomata have been detected after death in only two of the six children who died after a relapse, and in only 7 of the 20 necropsies performed in the whole series. Hydrocephalus of marked degree was found in five of the six fatal cases of relapse, and the thickness of the basal exudate aroused comment in three. Tubercle bacilli were cultured from the C.S.F. withdrawn at the onset of the relapse in six of the nine children. Unfortunately, it was possible to test the streptomycin sensitivity of only two of these cultures (Cases 10 and 33). The bacilli were as sensitive to streptomycin as at the beginning of treatment more than three years previously, although there had been adequate opportunity for resistance to develop.

Type of Streptomycin and Neurotoxicity

All the children in this series were treated with salts of streptomycin—hydrochloride, sulphate, or calcium chloride complex. During their relapse three children were given dihydrostreptomycin for short periods, but no untoward effects were noted. On the basis of this limited experience of the comparative action of the two drugs we are unable to assess the relative toxicity of streptomycin and dihydrostreptomycin in the present series of cases.

Summary

Thirty-three patients with tuberculous meningitis have been treated with streptomycin and the survivors have been re-examined from four to five and a half years after the institution of treatment.

Nine (27%) are alive and well and leading normal lives, three are gravely disabled, and 21 have died after periods ranging from 2 days to 60 months.

Spinal block occurred in nine of the patients—seven are dead, and a partial block persists in one of the two survivors.

Intracranial calcification as seen in skiagrams has occurred in 10 of the 13 patients who survived long enough for it to develop. Six of these are well, two are disabled, and two have since died.

Relapse of meningitis has occurred in nine cases. Only one of these children is alive and well, two others are disabled, and six have died of the relapse.

We wish to thank the late Professor G. B. Fleming, Professor Stanley Graham, and Dr. James H. Hutchison for access to the case records and for advice in the preparation of this paper; and the staff of the biochemistry, pathology, and radiology departments for their arduous investigations.

The first report of the W.H.O. Expert Committee on Public Health Administration is now available as No. 55 in the *World Health Organization: Technical Report Series*. In the committee's opinion, the main functions of the central authority should be the formulation of policy, the giving of advice and specialized technical assistance to local authorities, and the enforcement of medical legislation and other standards of efficiency; while the main function of the local health administration should be operational

USE OF SUCCINYLCHOLINE IN E.C.T. WITH PARTICULAR REFERENCE TO ITS EFFECT ON BLOOD PRESSURE

BY

D. J. ADDERLEY, M.R.C.S., L.R.C.P.

Formerly Registrar, Springfield Hospital, London

AND

MAX HAMILTON, M.D., D.P.M.

Assistant Psychiatrist, Springfield Hospital, London

In recent years it has been possible to apply electric convulsion therapy to a wider range of cases than previously, with the aid of curare-like substances to weaken the muscular spasms of the convulsion. For the specific requirements of E.C.T. the newly introduced short-acting group of muscle relaxants is particularly appropriate. This paper deals with the practical problems that arise during this type of treatment and the methods of dealing with them. Certain theoretical problems are also discussed.

The contraindications to convulsion therapy, in otherwise suitable patients, are usually classified into two groups: those due to the effects of the convulsion itself—for example, damage to bones, damage to tuberculous lesions in the lung—and those due to the strain on the cardiovascular system, particularly incipient heart failure and hypertension. Since depression, for which E.C.T. is usually given, becomes more common with increasing indication to treatment. There has been much discussion on this problem. Kraemer (1950) measured the blood pressure immediately before the shock, and 2, 5, 10, 30, and 50 minutes afterwards. The average rise of pressure was 40/10 mm. Within 10 minutes it had returned to normal. He concluded that moderate hypertension was not a contraindication to E.C.T. In some preliminary measurements we found that the B.P. is extremely variable, undergoing a number of phasic changes during different stages of the convulsion and immediately afterwards.

Eyman and Morris (1950) discussed fatalities associated with E.C.T., and emphasized the risks of cardiac abnormality. They recommend that an E.C.G. should be taken before treatment is given wherever cardiac involvement is known or suspected. On the other hand, Piette (1950), who agrees that most of the fatalities are due to cardiac failure, thought that in such cases there may often be no clinical or E.C.G. abnormality in the cardiovascular apparatus. This is in agreement with Bankhead, Torrens, and Harris (1950), who state that cardiac reactions are due to overactivity of the vagus, and are of the opinion that they can be eliminated by premedication with atropine. There is no doubt that E.C.T. produces a rise in blood pressure, although this is of fairly short duration. In practice very few fatalities have occurred, but the possibility cannot be excluded that this is partly because of the caution exercised by physicians in the selection of cases for treatment.

The use of relaxants in E.C.T. has been recommended on the grounds that it reduces the strain on the heart produced by the convulsion, so that the presence of hypertension can be regarded as an indication for their use. It was therefore decided to investigate the changes

in blood pressure which occur in E.C.T. when relaxants are used. So far as we are aware, this has not previously been studied; the paper by Davies and Spencer Paterson (1952) dealt with the hypertensive effect of electro-narcosis. Piette (1950) stated that curare does not suppress the rise in blood pressure due to E.C.T., but if it is used with sodium thiopentone, atropine, and oxygen the variations in arterial pressure which normally appear are entirely avoided. Since the shorter-acting relaxants can be used not only to "soften" the convulsion but to eliminate it completely, without at the same time producing respiratory difficulties afterwards, it would seem that they are eminently suitable for this purpose. This investigation is therefore confined to the use of succinylcholine ("scoline").

No attempt was made to select patients, who came from our own wards. They were all women, chiefly elderly, feeble, and hypertensive, with a few younger healthy ones.

Methods

The procedure was as follows. Blood pressures were taken with an aneroid-type sphygmomanometer, because it is speedy and convenient in use. They were taken immediately before the injection of sodium thiopentone, one minute after that injection, again after the injection of succinylcholine had become effective, and, lastly, immediately after the convulsion was over. The moment selected for taking the B.P. after the injection of succinylcholine was when the fibrillation produced by the drug had ceased, and therefore when paralysis was complete. Preliminary trials showed that 0.2 g. of sodium thiopentone was enough to produce unconsciousness in most of our patients, and this amount was always used. It is not often that more would be required, except for very big patients. The recommended dose for succinylcholine is 1.2 ml. of a 5% solution, but we found that 1.5 ml. produced complete relaxation, but we have done so, but, again, More could be given, and we have done so, but, again, The larger dose would in general be required for only very muscular patients. The lungs were inflated two or three times with oxygen containing 5% carbon dioxide, just before a shock of 30 joules was given.

Results

The results of these preliminary trials showed the expected drop of blood pressure after sodium thiopentone medication, but an unexpected rise was almost invariably found after the injection of succinylcholine. This rise was not after the injection of succinylcholine. The accompanying further increased by the convulsion. The rise Table gives the results in 12 consecutive cases. The rise in B.P. demonstrated in the Table is statistically very highly significant. A similar rise after the injection of succinyl-

Blood Pressure in Patients Given E.C.T. After Sodium Thiopentone and Succinylcholine (Recorded to Nearest 5 mm.)

175/105	140/90	195/100	180/100
150/100	150/80	200/150	190/110
140/90	130/80	180/160	200/100
160/90	135/80		

Mean B.P. after sodium thiopentone 130.8/80.4 mm.
 Mean B.P. after succinylcholine 170.8/116.2 mm.
 Difference 40.0/35.8 mm. $\pm$ S.D. 22.6/26.5 mm.
 Number of cases = 12.
 $t = 6.2/4.7$. P is $< 0.001/0.001$.

* Part of the succinylcholine leaked out of the vein in these cases.

choline was found in each of the subsequent experiments. The overall effect of this substance—that is, the change from the initial B.P.—is, of course, not so great, but it is still highly significant statistically.

It is possible that this increase of B.P. might be due to the delayed effects of the sodium thiopentone. A control series was therefore investigated in which succinylcholine was replaced by the same volume of sterile water, and the B.P. taken after the same interval. Subsequently, the normal procedure was completed. It was found that the injection of sterile water had no significant effect on the blood pressure. The results were as follows:

No. of cases	10
Mean B.P. after sodium thiopentone	122.3/75.4 mm.
" " sterile water	121.8/74.5 mm.
Difference: $-0.5/-0.9$ mm. $\pm$ S.D. 7.8/9.1 mm.	

This proves that the rise must be due to the succinylcholine.

This rise in B.P. produced by succinylcholine is not very great, but if the relaxant is to be used for borderline cases in which any strain on the heart might be dangerous it is a matter of practical importance. It was decided to investigate the possibilities of ganglion-blocking agents in preventing this rise. The two substances tested were tetraethylammonium bromide (T.E.A.B.) and hexamethonium iodide ("hexathide").

Preliminary trials showed that both ganglion-blocking drugs achieved their maximum effects in two minutes, and that the optimum dose of hexamethonium iodide was 2 ml. of a 2% solution. The new procedure was as follows. After the first B.P. reading 2 ml. of hexamethonium iodide was injected, followed immediately, through the same needle, by the normal dose of sodium thiopentone. The B.P. was taken one minute after this, the rest of the procedure being identical with that in the first experiment. The results of this new procedure were satisfactory, and demonstrated that this dose of hexamethonium iodide did not produce a profound fall of B.P. and was enough to prevent the B.P. rising above the normal for the patient even after the convulsion. The results were:

No. of cases	10
Mean B.P. at the beginning	171.0/96.0 mm.
" " after fit (preceded by hexamethonium iodide 2 ml., thiopentone, and succinylcholine)	139.0/88.5 mm.
Difference: $-32.0/-7.5$ $\pm$ S.D. 27.3/21.2 mm.	

This procedure was repeated, using T.E.A.B. instead of hexamethonium iodide. It was found that 1 ml. of a 10% solution was just enough for most cases. The results were:

No. of cases	9
Mean B.P. at the beginning	159.4/91.1 mm.
" " after fit, etc.	152.8/92.8 mm.
Difference: $-6.6/+1.7$ $\pm$ S.D. 29.4/22.0 mm.	

The results with 2 ml. are but little more effective for the average case:

No. of cases	10
Mean B.P. at the beginning	184.5/93.5 mm.
" " after fit, etc.	168.0/92.5 mm.
Difference: $-16.5/-1.0$ $\pm$ S.D. 31.4/11.73 mm.	

Discussion

The most important of our observations is the undoubted rise in B.P. following an adequate relaxant dose of succinylcholine. This has previously not been described in the literature; in fact, succinylcholine in clinical doses has been stated to have no effect on the arterial pressure. Experiments on animals have shown that a dose of 25 times the normal, or even higher, is required to produce any increase in the B.P. The difference between this and the results found in our patients is probably a species difference. Since the hypertensive effect of succinylcholine is not eliminated by blocking the autonomic ganglia, either it must be due to an interference with the action of the blocking agent or it acts peripheral to the ganglion. If it be the former, then succinylcholine must have a reaction similar to the "nicotinic" action of acetylcholine. It is evident that the ques-

tion can be settled only by experiment, preferably on human tissue. This is outside the field of this paper, which is restricted to purely clinical matters.

Smaller doses of succinylcholine would have much less effect on the B.P., but then the specific value of this drug would be lost. It can be used to produce a paralysis so complete that no muscular activity can be seen at all during the "convulsion." This eliminates all strain on the cardiovascular system from that particular aspect—which is confirmed by the fact that the patient remains quite pink throughout. Furthermore, recovery from a full dose is just as rapid as from a smaller dose, unlike the longer-acting relaxants. Previous reports have indicated that the latter do not increase the B.P. This would be a contraindication to the use of succinylcholine were it not for the fact that the convulsion itself produces such a rise. If a ganglion block be used to deal with this, it can be used also to cover the hypertensive effect of the succinylcholine.

It was noticed on two or three occasions that after the injection of succinylcholine the pulse became irregular, apparently owing to extrasystoles. It is unlikely that such irregularities are common, and, in any case, they were never observed when the autonomic ganglia were blocked.

We have the impression that the effect of blocking the autonomic ganglia is greater in those patients with the higher blood pressures. This is probably true, but would require a special investigation, with careful standardization of many factors, to test it adequately.

Practical Points

The statistics given are based on a limited number of cases dealt with by the technique described. This, however, is unnecessarily elaborate for routine work, and normally all that would be required would be the following:

1. We consider that an injection of atropine should always be given, to reduce salivation and excessive bronchial secretion. When a relaxant is to be used it is important that the patient should be placed in a comfortable position, to prevent strain on the ligaments when not protected by the tone of the muscles.
2. Sodium thiopentone and succinylcholine may be mixed in the one syringe, provided this be done immediately before injection. This enables a one-syringe technique to be used when no ganglion-blocking agent is given.
3. The ganglion-blocking agent should be given before the mixture of thiopentone and succinylcholine, as the former takes slightly longer to produce its full effect.
4. If a few breaths of oxygen be given before the shock the patient stays pink throughout. In our experience with succinylcholine, running into several hundred administrations, we have never observed prolonged apnoea, which, we think, may be due to an unsuitable technique.
5. It has been our practice to press upon the epigastrium just before the current is passed, to prevent the patient waking with a stomach distended by the oxygen used for inflation.

6. *The Convulsion.*—With complete relaxation it is difficult to determine whether an adequate convulsive dose has been given. We have employed two methods for this purpose: (a) By noting the autonomic component of the cerebral discharge which constitutes the fit; the simplest observation is to look for dilatation of the pupils, and, particularly, injection of the conjunctivae. (b) As this method is not always accurate with ganglion-blocking agents we have devised a specific manoeuvre to demonstrate the presence of the fit. Immediately before succinylcholine is injected a tourniquet or a sphygmomanometer cuff is fixed round the opposite arm. If this be kept tight enough to compress the artery until the current is passed the effects of the shock will be observed in that arm only. Thus the patient may be seen lying absolutely motionless apart from a slightly modified clonic fit in the blocked arm. By this means one is never in doubt about the effectiveness of the current.

Summary

Succinylcholine is a safe relaxant for E.C.T.

It can be used to abolish the convulsion completely; even with the doses necessary to do this the patient's recovery from the fit is always rapid.

Succinylcholine produces a slight rise of blood pressure which is generally unimportant. If necessary, this can be controlled by blocking the autonomic ganglia.

When complete muscular relaxation is advisable succinylcholine can be administered with safety without any elaborate system of dosage. In such cases the presence of a fit can be detected by the simple manoeuvre described.

We wish to thank Dr. H. C. Beccle, physician-superintendent, for his advice and encouragement, and for permission to publish. We are grateful to our nursing staff for their help and forbearance over the additional labour we have imposed on them. We are indebted to Allen & Hanburys Ltd. for the supply of "hexathide" used in this investigation.

CANICOLA FEVER

A HUMAN CASE IN NORTHERN IRELAND

BY

C. COTTON KENNEDY, B.M., B.Ch.

Assistant Pathologist, Northern Ireland Public Health Laboratory, Belfast

T. H. CROZIER, M.D., B.Sc., F.R.C.P.

Physician to the Royal Victoria and Belfast City Hospitals

AND

A. C. HOUSTON, M.D., M.R.C.P.Ed.

Late Senior Medical Registrar, Belfast City Hospital

In 1931 Klarenbeek and Schüffner (1933) isolated *Leptospira canicola* from the urine of a dog. This discovery was soon followed by the recognition of *L. canicola* infections in man (Dhont *et al.*, 1934). Baber and Stuart (1946) reported the first human infection in England; Joe and Sangster (1951) published the first cases in Scotland, although Stuart (1938), in a survey of Glasgow tripe-workers, had found agglutinins in low titre to *L. canicola* in the serum of a woman who gave no history of illness. In the four-year period 1947–50 70 cases were diagnosed in England and Wales (Broom, 1951). Figures given by Alston (1951) show that 25 cases occurred in 1949 and 33 in 1950.

Broom (1951), in a review of leptospirosis in England and Wales, drew attention to the fact that no human case of canicola fever had yet been reported from any part of Ireland, although his survey of the incidence of the disease in Dublin dogs had shown the infection rate in that city to be as high as in England.

The case recorded here is, we believe, the first serologically proved human infection with *L. canicola* reported from Ireland.

Case Report

A muscular and well-nourished man aged 36 was admitted to a surgical unit of the Belfast City Hospital on February 1, 1952. Eight days before admission he complained of feverishness and shivering attacks of abrupt onset. He was forced to give up work six days before admission, and he took to bed one day later. He then developed pains in the legs, lumbar regions, and right renal angle; these were severe and disturbed sleep. Other symptoms were colicky pains in the right hypochondrium and epigastrium, loss of appetite, vomiting, tiredness, photophobia, and very severe frontal headache. Frequency of micturition, dysuria, and oliguria caused him to summon his medical attendant, who visited him on January 29 and found his temperature to be 102° F. (38.9° C.) and the urine to contain a heavy cloud of albumin. A tentative diagnosis of acute pyelitis was made and treatment by oral sulphatriad instituted. The pyrexia promptly subsided, but nausea and vomiting became troublesome, and admission to hospital was arranged.

On admission his temperature was 98° F. (36.7° C.), pulse 104, and respirations 22. Clouding of consciousness was considerable; there was no neck rigidity, and Kernig's sign was negative. The face was flushed and the conjunctivae were markedly congested and suffused. Jaundice was absent. A patchy erythema was noted on the chest, also labial herpes. The tongue was coated. Slight tenderness was elicited over the right upper abdomen, the liver and spleen were not palpable, and the renal angles were free. The urine was acid and contained a trace of albumin with scanty red blood cells but no pus or organisms. On the day after admission the temperature rose to 99.2° F. (37.3° C.), but afterwards remained subnormal.

The patient was seen at this stage by one of us (A. C. H.), and the possibility of leptospiral infection was discussed. He was transferred to a medical unit for further investigation, although clinical recovery was rapid and uneventful. Discovery of a positive leptospiral agglutination prompted an exhaustive inquiry into the history of the case, and it was found that the patient's dog had sickened and died after a few days' illness, during which the patient had tended the animal and handled it a great deal. The patient first felt unwell about three days subsequent to the dog's death. He worked as a labourer in a bakery which was infested by rats and required periodical deratting. One such campaign had occurred about a week before the present illness.

The patient insisted on being discharged on February 11, before an effective penicillin course could be completed. Shortly after leaving hospital the muscular pains reappeared and a pustular rash developed on his face. He returned to hospital on his doctor's advice two weeks after his initial discharge. On this occasion his general condition seemed satisfactory, and the limb pains rapidly subsided. He was given a penicillin course (2,000,000 units daily, intramuscularly, for 12 days) and the laboratory tests were repeated. The leptospiral agglutinins of the other members of the household and of three fellow workers were examined.

Agglutination Tests

The technique of the agglutination tests was Broom's (1948) modification of that of Schüffner and Mochtar (1927). The first specimen of blood, taken on the 12th day of illness, agglutinated *L. icterohaemorrhagiae* and *L. canicola*, both to titres of 1 in 300. (In the early stages of leptospirosis equal or nearly equal titres are common.) Subsequent specimens, taken over a period of weeks, gave agglutinations which showed a falling away of the heterologous titre, while the homologous titre remained high (see Table I).

It will be seen that the second specimen of blood serum (taken on the 19th day of illness) gave agglutination in higher titre for *L. canicola*; this serum was sent to Dr. J. C.

TABLE I.—*Leptospiral Agglutination Tests*

Duration of Illness	Reciprocal of Titres	
	<i>L. icterohaemorrhagiae</i> (Strain Jackson)	<i>L. canicola</i> (Strain Utrecht)
12th day ..	300	300
19th ..	1,000	300. $\pm$ at 1,000. Trace at 3,000
48th ..	300. Trace at 1,000	3,000
66th ..	100	1,000. Trace at 3,000

Broom for confirmation. In view of the nearly equal titres for both *L. icterohaemorrhagiae* and *L. canicola*, a cross-absorption test was carried out. Dr. Broom's result is shown in Table II, clearly demonstrating *L. canicola* as the infecting organism.

In addition, agglutination reactions against *L. icterohaemorrhagiae* and *L. canicola* were performed on blood samples from the patient's wife and eight children, and from three of his workmates. All results were negative.

TABLE II.—*Results of Cross-absorption Test*

	Reciprocal of Titres	
	<i>L. icterohaemorrhagiae</i>	<i>L. canicola</i>
Unabsorbed ..	1,000	1,000. Trace at 3,000
Absorbed:		
<i>L. icterohaemorrhagiae</i>	0	300. Trace at 1,000
<i>L. canicola</i> ..	0	0

0 = Negative in all dilutions from 1/30 upwards.

Other Laboratory Investigations

The blood urea was 100 mg. per 100 ml. on May 4, 44 mg. on May 7, and 38 mg. on May 26. On May 5 the white blood cells numbered 16,300 per c.mm. On May 27 the cerebrospinal fluid (examined after readmission) was normal, and the erythrocyte sedimentation rate 4 mm. in one hour (no E.S.R. done on first admission). On May 28 a blood count showed: haemoglobin, 13.3 g.% (90% Haldane); red cells, 4,400,000 per c.mm.; white cells, 6,600 per c.mm.; haematocrit, 42%; mean corpuscular volume, 96 μ^3 ; mean corpuscular haemoglobin concentration, 32%; normal film. Liver-function tests: serum bilirubin, normal; thymol turbidity, 4 units; alkaline phosphatase, 7 units per 100 ml.; plasma proteins—albumin 5.6 g.%, globulin 2.4 g.%, total 8 g.%; bromsulphthalein, normal (no retention of dye). The Wassermann reaction was negative.

Animal Inoculation.—After the urine had been made alkaline to litmus a guinea-pig was inoculated intraperitoneally with 2 ml. of the centrifugized deposit (33rd day of illness). The animal remained well and was sacrificed 22 days later: no leptospirae were seen by direct microscopy and none were isolated by culture. Failure to isolate the organism was probably due to the fact that the guinea-pig is not highly susceptible to infection with *L. canicola* (Mackay-Dick and Watts, 1949; Whitehouse, 1952, and others). Also, the patient's premature departure prevented the collection of a urine specimen at the optimum time. The patient had earlier received several injections of penicillin, which may have been lethal to the leptospirae.

Summary

The occurrence of a case of canicola fever in Ireland is reported. Infection was probably by dog's urine. The case presented characteristic clinical features—namely, abrupt onset with rigors, muscular pain, headache, photophobia, and gastro-intestinal and renal upset. Jaundice was absent. Recovery was rapid.

We wish to thank Dr. J. C. Broom, of the Wellcome Research Institution, London, for his advice and for carrying out the cross-absorption test. We are indebted to Dr. A. H. Diamond for his help with the early clinical details, and to Dr. Mary Uprichard, resident medical officer, Belfast City Hospital, for her painstaking

work on the case. Acknowledgment is also due to Dr. V. D. Allison, Director of Laboratory Services, Northern Ireland Hospitals Authority, for his interest in the laboratory work.

TWO EXAMPLES OF THE -D/-D- GENOTYPE IN AN AMERICAN FAMILY

BY

R. K. WALLER,* M.D.

Department of Clinical Pathology, Medical College of Virginia, Richmond, Virginia

RUTH SANGER, Ph.D.

Medical Research Council, Blood Group Research Unit, the Lister Institute, London

AND

O. B. BOBBITT, M.D.

Department of Clinical Pathology, University of Virginia Medical School, Charlottesville, Virginia

This report deals with unusual findings in both the red blood cells and serum of a 48-year-old white woman (Mrs. V.W.) suffering from tuberculosis. In 1940 she received one bottle of blood following the first stage of a thoracoplasty. No transfusions were required for the two operations performed several months later. In May, 1952, she submitted to partial lobectomy, during which procedure four bottles of blood were administered. Eight days after the operation her serum was found by one of us (O. B. B.) to be incompatible with 72 random Group O bloods. The only blood found to be compatible was that of the patient's brother, J.C.

The Red Cells of Mrs. V. W.

The blood groups of the patient (Mrs. V.W.) are: O, NsNs, P+, Lu(a-), kk, Le(a- b+), Fy(a+), Jk(a-), Tj(a+), and Mi(a-); the blood groups of her brother (J.C.) are the same save that he is MNSs and Jk(a+). Only the Rh grouping presented any difficulty.

The red cells of Mrs. V.W. and of her brother were strongly agglutinated by anti-D sera; though not agglutinated by anti-c sera they were only weakly agglutinated by a powerful anti-C serum. The clue to the situation was revealed when it was found that saline suspensions of both samples of red cells were agglutinated by incomplete anti-D. This called to mind the remarkable case of Mrs. B., whose genotype was -D/-D- (Race, Sanger, and Selwyn, 1950, 1951).

Subsequent investigation showed that the Rh genotypes of Mrs. V.W. and of her brother were indeed -D/-D-. Saline suspensions of the two samples of red cells were agglutinated by three complete anti-D sera, by 14 incomplete anti-D sera, by five anti-C sera which also contained incomplete anti-D, and by one anti-E serum which also contained incomplete anti-D.

*Dr. R. K. Waller has died since the completion of this report.

Saline suspensions of both samples were not agglutinated by one anti-C serum free from incomplete anti-D, five anti-E sera free from incomplete anti-D, five anti-c sera, three anti-e sera, one anti-Cw serum, and three samples of incomplete anti-D. Neither sample of red cells reacted with two incomplete anti-C sera free from incomplete anti-D (from Rh-positive donors). Neither sample reacted with the serum of the original -D/-D- patient, Mrs. B.: this serum had agglutinated all of more than 1,400 samples of Group O red cells, and was shown to contain anti-C, anti-c, and anti-e (Race, Sanger, and Selwyn, 1950, 1951).

Saline suspensions of red cells of the original -D/-D- patient, Mrs. B., had been agglutinated by 14 out of 16 incomplete anti-D sera. Dr. Philip Levine, of Ortho Research Foundation, has tested saline suspensions of the red cells of Mrs. V.W. against titrations of 13 incomplete anti-D sera; the results are shown in the Table; the cells were agglutinated by 11 of the 13 sera. The agglutination of these cells, however, is not directly related to the titre of incomplete anti-D, as is indicated by the striking differences observed in the behaviour of the five sera of highest titre. Dr. Levine showed that the absence of C from the red cells of Mrs. V.W. could also be demonstrated with the aid of a complete anti-D+anti-C serum; he found that the anti-D component could be successfully blocked by the addition of selected incomplete anti-D (see Table).

Differences in Behaviour of Various Anti-D Sera. Tests by Dr. Philip Levine with 13 Sera Containing Incomplete Anti-D

Titre	No. of sera	Titration with cells of Mrs. V. W. in saline
1/4	1	1/2
1/8	1	1/1
1/16	1	1/8
1/32	1	1/2
1/64	3	1/4, 1/4, 1/64
1/128	1	1/4
1/512	5	0, 0, 1/2, 1/128, 1/256

The Serum of Mrs. V. W.

The serum of Mrs. V.W. has reacted with all of approximately 250 unselected samples of Group O red cells so far tested; it does not react with those of her brother J.C. or with those of Mrs. B. The serum reacts only weakly with cells suspended in saline but strongly by the indirect antiglobulin, the albumin, and the trypsin methods.

Titration of the serum of Mrs. V.W. showed values of 1/128 to 1/256 with the indirect antiglobulin test. Titration with bloods of various genotypes failed to reveal direct evidence of a mixture of antibodies. Absorption experiments now being done present considerable difficulties because of the small quantities of serum available and a gradual diminution of titre in more recent bleedings. So far only anti-e has been isolated, after absorption with cDE/cDE red cells. In view of the parallelism with the blood of Mrs. B. it is very likely that the high incidence of positive reactions is due to the presence of antibodies for both C and c and perhaps E as well as e. Under such conditions all bloods would be incompatible except those with the identical genotype -D/-D-. No atypical antibodies could be demonstrated in the serum of the compatible sibling, J.C.

As in the case of Mrs. B., there is a history of cousin marriage: the parents of Mrs. V.W., each of whom must have contributed the chromosome -D-, were first cousins. Efforts are being made to trace any consanguineous relationship between the British and American families. Further studies are planned on three additional surviving siblings, five others having died—three from tuberculosis, one from influenza, and one from accidental causes.

It may be that the chromosome -D- is not as rare as it was first thought to be; it may, for example, be no rarer than the chromosome CdE. In the heterozygous state the chromosome -D- would usually escape detection, though it can be recognized if it is specially sought for (Race, Sanger, and Selwyn, 1951).

Summary

Two further examples of blood representing the Rh genotype -D/-D- are described. The samples come from a white American woman and her brother, offspring of a first-cousin marriage.

The sister has had five blood transfusions. Her serum is incompatible with all of about 250 unselected samples of Group O blood, but it is compatible with her own red cells, her brother's, and with those of the original -D/-D- British patient. Of the several antibodies which are doubtless present only anti-e has so far been identified. No unusual antibodies could be found in the serum of the brother.

The red cells of the two Americans are the only samples so far found to be compatible with the serum of the British patient, besides her own, though more than 1,400 samples have been tested.

We wish to thank Mrs. V. W.'s physician, Dr. I. N. Hunnicutt, of Virginia, for his active help in this investigation.

Medical Memoranda

Uterine Chorionepithelioma

The possible development of chorionepithelioma following hydatidiform mole is well recognized, although there is a wide variation in estimates of the incidence of the malignant change. In the follow-up of cases of hydatidiform mole the biological tests for the excretion of gonadotrophin in the urine occupy a prominent position, but the interpretation of their results presents problems which are not widely enough understood, despite the excellent summary by Brews (1950). The following case illustrates the difficulty of diagnosis when the Aschheim-Zondek reaction is only weakly positive.

CASE REPORT

The patient, a 1-para aged 32, had had an uneventful pregnancy three years previously. Her last menstrual period began on February 1, 1950, and very early in the pregnancy she attempted to procure a miscarriage by taking a large dose of quinine. At the ninth week of amenorrhoea vaginal bleeding occurred and the case was treated as one of threatened abortion. It was noted at this time that the uterine enlargement corresponded to that of a 12-weeks pregnancy. The diagnosis of hydatidiform mole was made at the eleventh week, when the fundus of the uterus had arisen to midway between the pubic symphysis and the umbilicus. At this stage the early morning urine gave a positive Aschheim-Zondek reaction in a dilution of 1 in 10, but was negative at 1 in 100.

Vaginal evacuation of the uterus was effected on April 22 after dilatation of the cervix by laminaria tents. The tumour removed was a typical hydatidiform mole with characteristic microscopical appearance. There was no evidence of malignancy in the sections. Twenty days later the uterus had involuted satisfactorily and the Aschheim-Zondek reaction had become negative. But further biological tests were made at intervals, and 57 days after evacuation it was found that the Aschheim-Zondek reaction was again positive, though negative in dilution.

The patient was readmitted to hospital and examined under an anaesthetic on July 7. The uterus was bulky, the cavity measuring 3½ in. (9.5 cm.), and the left ovary was

slightly enlarged. With a ring forceps, fragments of apparently typical hydatidiform mole were removed, and then a curettage was performed. Microscopy revealed considerably more trophoblastic activity than in the original specimen, with variations in nuclear size and density, and occasional mitoses. No villi were seen in the curettings. Some bleeding persisted, and one week later the Aschheim-Zondek reaction was still positive, though remaining negative in dilution. X-ray examination of the chest showed no abnormal shadows.

In view of the recurrence of the mole with atypical trophoblastic activity, total hysterectomy with bilateral salpingo-oophorectomy was performed on July 21—that is, 91 days after evacuation of the mole. Both ovaries contained small luteinized and atretic follicles; in the right ovary there was also a recently ruptured small lutein cyst. The uterus was bulky and contained a haemorrhagic tumour approximately $\frac{1}{2}$ in. (1.3 cm.) in diameter near the right cornu. The growth extended from the endometrium through approximately half the thickness of the uterine wall. Microscopically the growth was a typical chorionepithelioma with malignant trophoblastic elements invading the myometrium. Sections of the ovaries and uterine tubes revealed no secondary deposits.

The patient's progress was uneventful; at examinations 7 and 16 weeks after operation there was no clinical evidence of recurrence, and on each occasion the Hogen test was negative. Subsequent direct follow-up has not been possible, as the patient went abroad, but a letter reports that she was well in January, 1952.

COMMENT

In 1939 Brews observed that as a method of absolute diagnosis of active chorionepithelioma quantitative hormone assays had failed to realize initial expectations. By that time cases had been reported in which the biological tests for urinary gonadotrophin had remained negative in the confirmed presence of a tumour. Cuscaden and Bettinger (1940), in describing a case in which certain features closely resembled that now reported, refer to the possible fallacies of the biological tests and maintain an attitude of great caution in accepting reports of cases of chorionepithelioma without a positive Aschheim-Zondek reaction. The possibility of a negative pregnancy test in the presence of chorionepithelioma is mentioned by Baird (1950) and Browne (1950), while Sutherland (1951) has collected 19 reports of such cases from the literature, and Richli (1950) describes another in detail.

In trying to explain the negative and only weakly positive reactions the factors to be considered include haemorrhage, necrosis, thrombosis, and fibrous reaction; all of these may separate the tumour from healthy maternal tissue and so limit the absorption of gonadotrophic hormone. Browne (1950) suggests that the degree of anaplasia present in the cytotrophoblast may determine the strength of the Aschheim-Zondek reaction. Sutherland (1951) attempts to relate the very weakly positive reaction to an almost complete absence of syncytium, although he admits that this is not in accordance with the experimental evidence of Jones, Gey, and Gey (1943), who found that the Langhans cells were apparently responsible for the production of chorionic gonadotrophin.

The cases described by Browne (1950), Ehrhardt and Bureck (1939), Scott (1939), and Brews (1950) illustrate the dangers of waiting to establish a firm histological diagnosis in the presence of a persistently positive pregnancy reaction after evacuation of a hydatidiform mole. When the reaction has become negative soon after expulsion of the mole, and later in the absence of a new pregnancy it again becomes positive, radical treatment is indicated. This view, however, is not shared by Siegler, Ravid, and Tobin (1950), who, in presenting a review of 12 cases of chorionepithelioma and acknowledging the fallibility of the biological tests, advise that, "so long as the titre is decreasing or at least remaining constant, watchful conservatism may still be

applied." Such a recommendation appears highly dangerous, bearing in mind the fatal cases of Brews and of Ehrhardt and Bureck, referred to above.

Shively (1950) assesses the reliance to be placed upon quantitative urinary gonadotrophin determinations by saying that, because of the variations encountered, they should be used only as confirmatory evidence in the diagnosis of these neoplasms and should not be regarded as necessary diagnostic criteria.

Publication of this case report has been approved by the Director-General, Army Medical Services.

Traumatic Encephalopathy from Boxing

The risk of serious intracranial damage occurring in boxing is well known, and the following account may be of interest to those concerned with the welfare and medical examination of boxers.

CASE REPORT

A miner aged 26 had boxed on numerous occasions since the age of 15 and as a professional from the age of 20. An ample history, obtained from various sources, failed to reveal evidence of previous mental disorder or any other abnormality, except a minor degree of mental dullness indicated by his school work and Army records. His I.Q. was reported to have been 90 on the Stanford-Binet scale (Form L) when he was tested at some unspecified time before leaving school at the age of 14.

Two years ago, after becoming cruiser-weight champion of his area, slight changes in character became apparent, shown in the form of egocentricity and of monopolizing the conversation with accounts of the various opponents whom he had knocked out. Soon he was knocked out himself after only 18 seconds in the first round, and three months later, in an encounter with a boxer thought by all to be inferior, he took so much punishment that the fight was stopped in the fourth round. His friends were now finding him more quarrelsome and garrulous; he often complained of headaches, and he expressed mild paranoid ideas about his wife which eventually resulted in his admission to a mental hospital a year ago, after he had made threats to kill her with the carving-knife.

He was then found to be slightly confused, was alternately excited or unduly reticent, and had also a slight spatial and temporal disorientation, misidentification of persons around him, confabulation with an associated patchy memory defect for events of the preceding four months, and fleeting olfactory hallucinations. Abnormal physical signs were slurred speech, absent abdominal reflexes on the left side, and a slightly ataxic gait of cerebellar type. The cerebrospinal fluid and an x-ray film of the skull were normal.

Gradual improvement took place over a period of six months with sedation and rehabilitation, and he was then

discharged from hospital and obtained work as an unskilled labourer. Residual signs then were amnesia for events over a period of one to two weeks at the time of his last two fights, and what appeared to be a reduction in intellectual capacity. His I.Q. on the Stanford-Binet scale (Form L) was 65. On Raven's progressive matrices and on Kohs's blocks test he was at the 5 percentile and on the Mill Hill vocabulary scale at the 10 percentile level. There were now no abnormal signs neurologically. The E.E.G. showed reduced activity in all leads.

COMMENT

The difficulties in the diagnosis of this type of case have been summarized by Bremner (1950) and one has to admit that the difference in the I.Q. may be wholly or partly due to other factors, and also that further improvement might have been found had examination at a later date been possible.

One hesitates to go as far as Carroll (1936), who believes that every knockout is likely to cause irreparable damage, although the boxer intellectually below average is more likely to show persistent clinical abnormality. A further difficulty is the fact, as observed by Jokl (1941) and others, that severe cerebral injury may occur without anything unusual being observed by spectators at the time, and medical elimination of a contestant in such circumstances may be strongly opposed. Romino (1949) puts forward various suggestions to make boxing safer, such as equality of matching, medical records of each fight, and no fights for three months after being knocked out, to which might be added the use of psychometric tests at intervals and the search for minimal neurological abnormality.

Comparison of Treatment of Haematemesis by Drip Transfusion of Stored Blood and by Direct Transfusion

The aim of treatment of haematemesis is to produce haemostasis; where a large artery is eroded this can be achieved only by surgery, but haemorrhage from small arteries and veins is stopped by the natural process of vasoconstriction and thrombosis. That repeated transfusions of stored citrated blood may inhibit this natural process, whereas small direct transfusions aid vasoconstriction and thrombosis, is suggested by the histories of the following three cases.

CASE 1

A married woman aged 52 was admitted to hospital on June 24, 1952. She was well until 12 hours previously, when there was a sudden onset of diarrhoea followed by melaena.

On admission her general condition was good, the haemoglobin being 73%. Nine hours later she passed a tarry stool and became pale. Systolic blood pressure was 70 mm. Hg and haemoglobin 44%. A drip transfusion of stored blood was begun, and 3 bottles (each 500 ml.) were given over a period of four hours, followed by 1 litre of normal saline, then 2 bottles of blood at a slower rate. Three hours after the transfusion had finished, haematemesis recurred and the patient became shocked. A surgeon advised medical treatment. A drip transfusion was begun, being continued for two days, during which period further repeated attacks of haematemesis and melaena occurred and 7 bottles of blood and 2 litres of saline were given.

Three days after admission the patient's condition was so low that surgical operation was hazardous, and it was decided to try direct transfusions. Three were given at intervals of approximately four hours, and her condition

improved. Twenty-four hours later haematemesis recurred and a drip transfusion of 6 bottles of blood and 1 litre of saline were administered. This transfusion continued over 35 hours, during which period melaena and haematemesis occurred repeatedly.

Her condition was again desperate, and two further direct transfusions were given at intervals of four hours. Although several melaena stools were passed there was no further evidence of severe haemorrhage.

On July 1 the haemoglobin was 48%; two direct transfusions were given to raise the haemoglobin, which on July 15 reached 70%. At this stage a generalized erythematous rash developed, labelled the Stevens-Johnson syndrome, which delayed her discharge from hospital until August 9. X-ray examination of the stomach and duodenum was reported as N.A.D. All told, the patient was given 19 bottles of stored blood and 6 direct transfusions.

CASE 2

A man aged 36 was admitted to hospital on December 27, 1951, suffering from haematemesis and melaena.

On admission he was in a shocked state, and a drip transfusion was begun; 4 bottles of bank blood were given, and his condition improved. Within nine hours further haematemesis occurred, and the drip transfusion was recommenced. During the next five days the transfusion was continued and 29 bottles of blood and 9 litres of glucose-saline were administered. During this period the patient repeatedly vomited blood and passed melaena stools.

On January 3, 1952, he was seen by me. His general condition was very low; systolic blood pressure was 90 mm. Hg and haemoglobin 38%. During a period of two days he was given five direct blood transfusions. His condition improved, and no further bleeding occurred. X-ray examination showed no abnormality of the stomach or duodenum. He had been given 34 bottles of blood, 9 litres of glucose-saline, and five direct transfusions.

CASE 3

A man aged 28 was admitted to hospital on March 10, 1951. He was suffering from haematemesis and melaena, which occurred on the day of admission.

On examination his skin was pale and he was in a shocked condition. He was immediately given a transfusion of 4 bottles of stored blood by the drip method. The next day he vomited blood and the haemoglobin was 52%. Another drip transfusion was started, and during a period of 17 hours 6 bottles of stored blood were given; but during the transfusion further haemorrhages occurred and on March 13 the haemoglobin was 42%. Another 3 bottles of stored blood were transfused. On March 14 there was severe melaena, and the haemoglobin was 40%. Two bottles of bank blood were given, but again there was haematemesis.

The patient was seen by me at this stage. Three direct transfusions, each of 500 ml., were given on the 14th, 15th, and 16th. Subsequently there was no further bleeding. On March 24 the haemoglobin was 83%. X-ray examination on March 27 showed evidence of duodenal ulceration. He had been given 15 bottles of bank blood and three direct transfusions.

COMMENT

In these three cases severe haemorrhage occurred during the prolonged transfusion of large quantities of stored blood and ceased when fresh blood was transfused at short intervals by the direct method. Further investigation, such as a planned research project, would be necessary to establish the validity of this observation as indicating an untoward effect of stored blood transfusions when given to excess, and the purpose of recording these cases is to suggest that such an investigation would be worth while.

Recent work on blood coagulation and thrombosis emphasizes the importance of blood platelets in the natural

This large volume is the second edition of a treatise that enjoys a considerable reputation. It is the work of 87 authors, distinguished for their contributions to paediatrics and allied subjects, and they deserve congratulation for their industry in producing, under the leadership of Grulee and Eley, a reference book of much merit. It is only natural that the chapters should vary in quality and that there

pathognomonic. When the child is awake there is a low-pitched inspiratory stertor in the early stages, with a louder and lower-pitched coarse expiratory rattle, resembling a snore. Later, when oedema is marked, the inspiratory stertor is replaced by a somewhat muffled high-pitched stridor, or the inspiratory stridor disappears, the expiratory component remaining unchanged. He emphasized that these were dry sounds and had to be distinguished from the "ruttling" produced by mucus. If the epiglottitis could not be seen by tongue depression or laryngoscopy, or if laryngoscopy was thought inadvisable, a lateral radiograph of the throat was sometimes useful in showing the narrowing and obstruction of the airway above the vocal cords. Camps described similar cases in Britain, but *H. influenzae* Type B was recovered in only two, though in the earlier cases seen by him this organism was not specifically looked for. The mortality in these cases is quite high. In Rabe's series it was 18%.

The treatment is basically the same for both types—the relief of anoxia, the provision of an airway, and the combating of infection. Humidification of the atmosphere by a steam kettle or aerosol vaporizer seems to be beneficial. Briggs and Heseltine, in common with other workers, strongly advocate that tracheotomy should be performed as an elective procedure, not as a last desperate measure in a moribund child. If the child with restlessness and severe stridor does not rapidly respond to rest in bed, or if there are cyanosis, extreme fatigue, increasing restlessness, pallor, and stridor, with decreasing air entry, tracheotomy should be performed without delay. In the "virus" type this is essential to secure an airway, and to enable the thick tenacious secretions, which are the principal cause of death, to be sucked out of the bronchi. For this purpose they found that an electrical sucker with polythene tubing was needed: the water suction apparatus was not adequate. Rotation of the head combined with twisting of the curved tubing allowed easy passage of the tube into either main bronchus, and down distally to a distance of 4 to 6 in. (10 to 15 cm.) in a child aged 3 to 6 months. Suction was repeated in most cases every three to four hours on the first post-operative day. A soft rubber catheter was used to keep the tracheal tube clear of mucus. They emphasized that a special nurse is essential for each child, that the patient should not be hidden in a canvas tent, and that lighting at night should be adequate for inspection of the child. If there is sudden deterioration, the nurse is told to remove the inner tube immediately and

apply suction to the outer tube while another nurse sends for medical help. They thought that intubation or bronchoscopy should be an emergency procedure only: repeated bronchoscopy would do more harm than good by damaging the inflamed cords. Of Rabe's 347 cases, 35 (12%) required tracheotomy. Of the 39 cases described by Briggs and Heseltine, 9 needed it.

The use of antibiotics is strongly advocated by many workers, but it is not clear which is the best one to use. Penicillin is undoubtedly effective in many cases, but *H. influenzae* Type B is only moderately sensitive to it and is more likely to respond to chloramphenicol, in a dose of 100 mg. per lb. (220 mg. per kg.), or to terramycin or aureomycin, in a dose of 50 mg. per lb. (110 mg. per kg.). In the "virus" type it is probable that only secondary invaders respond to the drug, whichever is used. Some clinicians also give a sulphonamide (such as sulphamezathine). In America type-specific rabbit serum is given for the cases due to *H. influenzae*, but the exact role of this is uncertain, and it is not normally available in Britain. Whatever antibiotic or other "specific" treatment is given, it must always be remembered that the relief of mechanical obstruction is essential, and that death is much more likely to result from suffocation than from the actual infection.

It is clear that "infectious croup," which includes epiglottitis and laryngotracheobronchitis, should be treated with the greatest respect by the family doctor. If there is a sudden onset of stridor, or if there is an insidious onset of stridor which becomes progressively worse, the child should be sent to hospital without delay. Serious harm is done by waiting until the child is cyanosed, has severe intercostal recession, or is otherwise seriously ill before he is sent in. Furthermore, hospitals which admit small children should have an emergency tracheotomy set ready at all times, so that acute emergencies due to laryngeal or bronchial obstruction can be dealt with immediately.

NOTIFICATION OF PUERPERAL PYREXIA

When child-bed fever was a scourge methods were needed of estimating its frequency, investigating its source, and determining how its spread could be controlled. As knowledge of the bacteriology and the modes of transmission of puerperal sepsis increased, there was a decline in the mortality rate in the first 35 years of this century. The introduction of the sulphonamides caused a further rapid decrease in the death

rate, and when this fall had largely lost its impetus the discovery of penicillin and other antibiotics effected a further decline. In Britain a maternal death from sepsis is now a rare occurrence. But the improvement in the mortality rate is not due to chemotherapy alone: better antenatal care, improved methods of prophylaxis, and increasingly high standards of obstetrical and nursing practice have all contributed, and this is reflected in the fact that the mortality from post-abortion infections has not fallen equally with that from puerperal sepsis.

Because of the decline in morbidity as well as mortality, the puerperal pyrexia regulations were amended in England and Wales in 1951, so that any fever of 100.4° F. (38° C.) or more in a woman within 14 days after confinement or miscarriage became notifiable. Under the previous regulations the temperature of 100.4° F. had to be maintained over or recur within 24 hours; the period covered was 21 days, and the first 24 hours after delivery were excluded. One reason given for supplanting these older regulations was that the use of newer drugs reduced the temperature promptly and so prevented an infection from becoming notifiable. This seems peculiar reasoning when it is considered that puerperal pyrexia is not a specific entity like measles or mumps. Moreover, a single innocent spike of temperature is common within 24 hours of delivery and is almost the rule after caesarean section or other operative delivery.

The 1951 regulations were therefore not received without some criticism, and in his health report for 1951 the Medical Officer of Health for Ilford, Dr. I. Gordon, asks some pertinent questions about what is being notified and who is doing the notifying. The object of the regulations is to control infections of the genital tract, but the cause of the pyrexia is not required to be stated on the notification form. Dr. Gordon therefore obtained information on the cause of the fever in 62 of the 65 cases notified to him in the last five months of 1951. In 50 of the 62 cases the fever was unconnected with any genital infection, and in more than half of all the cases it was ascribed to some disorder of lactation. It is possible that in some, perhaps many, of the cases notified the exact cause of the pyrexia was not known but was imputed to engorgement of the breasts. Dr. Gordon also found that in Ilford 89% of the notifications came from hospitals, although only 63% of deliveries took place in hospitals. He reasoned from this that, even though the complicated cases might have gravitated to hospital, the busy family doctor might omit to fill in yet another

form, while the hospital officer, more conscious of temperature charts and of regulations, notified every case of pyrexia. Dr. Gordon therefore concluded that, in his borough at any rate, the notification of puerperal pyrexia bore little relationship to infection of the genital tract and could be dispensed with.

It is indeed doubtful whether the notification of puerperal pyrexia still serves the public health purpose for which it was originally introduced. Maternal mortality from puerperal sepsis is now so low in this country that it is no longer a reliable index of the efficiency of the maternity services or of the state of maternal health after confinement. Yet compulsory notification, if less valuable to the community as a whole, may still be of benefit to the individual woman, for it ensures that the midwife, whose statutory period of attendance on the puerpera is 14 days, summons medical aid at the first possibility of infection. But in their present form the regulations do not provide a satisfactory maternal morbidity index, and, as Dr. Gordon points out, may produce inaccurate statistics, especially in regard to domiciliary confinements. Any system of notification of disease is enhanced in value if the need for flexibility in its application is appreciated. For instance, in the light of present views on the connexion between maternal rubella in early pregnancy and congenital malformations there is much to be said for the compulsory notification of that infectious fever throughout the country. Again, while retaining the present puerperal pyrexia regulations as a rule of the Central Midwives Board, a system of notifying specific complications of labour and abortion, irrespective of the presence of pyrexia and with a more generous time limit, might be useful in evaluating both prophylactic and curative measures in this sphere. Indeed, much could be learnt by making notifiable not only maternal complications such as venous thromboses but also foetal abnormalities the origin of which remain obscure, such as congenital malformations and retrolental fibroplasia. Such notification, if not of purely public health interest, would serve to bring closer together the interests of the community and the interests of the individual.

PROPHYLAXIS OF RHEUMATIC FEVER

It has long been known that the daily administration of a small dose of a sulphonamide, usually sulphadiazine, can be continued without harm for many months, and that it will usually prevent streptococcal throat infection and thus recurrences of rheumatic fever. More recently penicillin has been used for this purpose,

and has usually been given by the mouth. Owing to the very high sensitivity of *Str. pyogenes* of Group A to penicillin the low and variable concentrations resulting from this method of administration are nevertheless enough to keep this organism in check. A course of injections continued throughout the winter is obviously impracticable, particularly in a child, but if the interval between injections could be greatly lengthened this alternative would be worth considering for the increased certainty of its effect. One line of progress has been the development of preparations which in single doses will act for longer and longer periods. One- and two-day effects have been commonplace for some time, but a preparation of which the effect is measured in weeks is now available in N,N'-dibenzylethylene-diamine dipenicillin G, known as "bicillin" or benzethacil. The first full account of this substance was given by Elias, Price, and Merriam,¹ of the Wyeth Institute of Applied Biochemistry. Its outstanding property is the very low solubility of only 200 units per ml.: it is also tasteless, which is claimed as an advantage for oral administration. Injected intramuscularly merely as an aqueous suspension a dose of 300,000 units gave detectable amounts in the blood for five days, and one of 2,500,000 units for as long as 15 days. Admixture with a non-aqueous base can prolong these times further, although presumably amounts in the blood will then be lower and perhaps less constant. The first account of work done with benzethacil in this country is published in this issue of the *Journal* (p. 188). The authors of the report, Drs. A. P. Fletcher and C. R. Knappett, have found that the intramuscular injection of an aqueous suspension of benzethacil "gives sustained levels of serum penicillin considerably superior to any repository penicillin preparation yet developed," though in some subjects assayable amounts of penicillin appeared in the serum intermittently.

Several important uses can be thought of for a form of penicillin possessing such remarkable properties, and it is not surprising that among these the possible prophylaxis of rheumatic fever has been studied. Stollerman and Rusoff² have administered benzethacil to 143 rheumatic subjects (all but eight being children) for periods of 2 to 10 months. It must be said at once that they obtained no proof of its efficacy in preventing rheumatic fever, since although no recurrences took place in treated subjects there was only one in an untreated patient in the same institution during the period of observation. The drug was injected first in simple aqueous suspension and later in a "polyvinylpyrrolidone vehicle." Patients were given 300,000 units weekly, 600,000 units bi-weekly, or 1,200,000 units monthly, and an extensive series of blood assays showed that each of these systems can be depended on to maintain continuously an assayable level (0.02 unit/ml. by the method used) in the blood of most patients. Some even had detectable penicillin in the blood 40 days after the largest dose. Ten patients on admission and three members of the staff were found to have Group A streptococci in the throat, and daily swabs after an injection of benz-

ethacil showed that the organism disappeared in every case within one day. It reappeared in four days in one patient, and another became a carrier during treatment, but later injections abolished the carrier state in both and no patient had a rise in antistreptolysin titre. The drug was well tolerated, and the results of a study of the penicillin resistance of *Str. viridans* from treated patients' throats suggested that no highly resistant strains were being bred, although comparison with similar studies by another author who gave penicillin orally indicates that both methods may have at least some effect in this direction. It may be assumed with some confidence that infrequent injections of benzethacil will be at least as effective as giving penicillin in moderate doses orally in preventing throat infections. To continue either method of treatment for the greater part of a year must necessarily be costly, and in the choice between them the operation of this factor may well be decisive.

APES AND MEN

"*Ex Africa semper aliquid novi.*" For some years past the scientific world has become accustomed to learning every so often of the discovery in increasing numbers of fossil higher primates in Transvaal caves. Mr. J. T. Robinson, of the Transvaal Museum, Pretoria, recently announced the discovery at Swartkrans¹ of some remains, including a fragmentary maxilla with some teeth, of *Telanthropus capensis*. The type is apparently transitional between the still ape-like Australopithecinae and undoubted men, such as the *Pithecanthropus* group (including *Sinanthropus*) of Java and North China. *Telanthropus* was hitherto represented only by a mandible, considered by Broom and Robinson² to be clearly distinct from the *Paranthropus crassidens* (Australopithecinae) remains obtained at the same site. Dr. K. P. Oakley, of the British Museum (Natural History), is now in the Transvaal in the hope of discovering satisfactory geological and palaeontological evidence on the date of the finds. Meanwhile it is worth considering the possible implications of the new discovery to existing ideas about the course taken by human evolution from the ape stage.

Our nearest living relatives, the great apes, have certain features—among others the "simian shelf" in the section of the mandibular symphysis—which were until recently held to be primitive. The Miocene of Kenya, however, yielded to Dr. L. S. B. Leakey in 1948³ an almost complete skull of a chimpanzee-like ape (*Proconsul*) without the simian shelf and with other features of skull and dentition more closely resembling the condition seen in man than do those of any of the surviving great apes. It is therefore thought probable that *Proconsul* stands close to the common ancestor of ape and man, and that human and simian stems have pursued separate courses at least since the Miocene, about 15 million years ago.

⁴ Zeuner, F. E. *Dating the Past*, 3rd ed. Methuen, London, 1953.

The South African Australopithecinae seem to represent an early branch of the distinct human stem. In brain capacity they were not yet men by any standard that we have learnt to use, but they had already developed the erect posture and possessed a remarkably human type of dentition. Their small brains, prominent muzzles, and enormous jaws and teeth nevertheless betray a not very remote simian ancestry.

The *Telanthropus* mandible was less heavily built. The teeth were large by modern standards, but markedly smaller than those of the Australopithecinae; the mandible lacked some typical australopithecine characters, but showed the beginnings of a mental eminence where none is to be seen in apes or Australopithecinae. The new maxillary fragment enables comparison to be made with those of the Australopithecinae and a modern Bushman. It shows that, in *Telanthropus*, the muzzle was markedly shortened, with reduced procumbence of the upper incisors and a right-angled section at the inferior margin of the nasal aperture instead of the smoothly curving transition between the subnasal region of the muzzle and the floor of the nasal cavity seen in the Australopithecinae. Despite their differences, the remains show other features in common with the Australopithecinae, so that the direct relationship of *Telanthropus* to these can hardly be doubted. Mr. Robinson claims that we have here a form transitional between the Australopithecinae and true hominids, though it would be helpful if we could also know something about the cranial capacity of the new species.

Much hangs on the date which may be assigned to *Telanthropus* and the Australopithecinae. It now appears that it may be necessary to regard them as approximately contemporary. The Swartkrans limestone (travertine) is considered to be late Pliocene. The next evolutionary stage is represented by the *Pithecanthropus* group of fossils, found at the eastern extremities of Asia. If the Transvaal specimens can confidently be dated to the Pliocene (at least one million years ago) it is possible to envisage the further development of the types they represent, their diffusion to the Far East, and their reappearance, perhaps half a million years ago, as the *Pithecanthropus* group. The dating of this group to a period more than 400,000 years ago is based on good palaeontological evidence.⁴

We may then regard the possible steps of human evolution as represented by: *Proconsul*, the Australopithecinae, and *Telanthropus* in Africa; the *Pithecanthropus* group, and the late Middle Pleistocene (about 180,000 years ago) palaeanthropic men of Asia and Europe. Should the Swartkrans finds prove to be only half a million instead of a million or more, years old, as is quite possible, we should be obliged to seek for the Far Eastern *Pithecanthropus* fossils some progenitor other than the Australopithecinae or *Telanthropus*.

Whatever the outcome of further investigations into the dating of the particular specimens concerned, their interest will remain paramount for students of human evolution. Morphologically the Australopithecinae represent an evolutionary stage which would readily be acceptable as essentially Pliocene, and therefore potentially a direct forerunner of the *Pithecanthropus* stage.

Even if it should prove that the individuals known to us are late survivals, they must resemble more or less closely earlier members of their species or genus, who could have been the ancestors of *Pithecanthropus*, thus bridging the gap between undoubted apes and undoubted men.

PSITTACOSIS

It has long been known that human beings are susceptible to an infectious disease of parrots, which was given the name psittacosis. The disease is caused by infection with a virus, and in addition to birds of the psittacine group—which includes parrots, cockatoos, and budgerigars—canaries, pigeons, domestic fowls, and ducks all harbour these organisms and have been responsible for infection in man.¹ There are a number of closely related viruses, rather than a single strain; they are called viruses of the psittacosis-ornithosis group, which includes those causing psittacosis, acquired from contact with infected parrots, and ornithosis, which results from contact with pigeons² or other domestic birds. Man can be infected in various ways. The droppings of diseased birds and carriers contain the virus, which may be inhaled by people cleaning the cages or handling the birds. Bites by infected parrots may also convey the disease. Infection with viruses of this group is widespread in susceptible birds, but newly imported birds of the parrot family are a specially dangerous source of human infection.

In 1930, following a serious outbreak of psittacosis, with many deaths, a complete ban was imposed on the importing of parrots into this country. The ban was raised in December, 1951, and it is likely that a number of infected parrots have since been introduced. Indeed, the death on December 4, 1952, of the manager of a pets' corner in a department store was shown at the inquest at Birmingham to be caused by psittacosis acquired from infected parrots in a consignment of birds which he had received in November.

The onset of the disease is usually fairly acute and follows an incubation period of about 10 days. The symptoms are general malaise, severe headache, pains in the back and limbs, and sometimes nausea, vomiting, epistaxis, and photophobia. The patient is febrile, and often no other abnormal signs are found on physical examination. In a number of cases the condition remains a general febrile illness without localizing signs, and after lasting a few days the temperature falls and the patient recovers. In more severely ill patients evidence of pulmonary consolidation is found towards the end of the first week. Cough develops, but sputum is scanty or absent. The spleen is sometimes palpable. With suitable treatment the course of the illness can be shortened and the outlook greatly improved, but without modern chemotherapeutic agents the severe form of the disease carries a high mortality rate.

It is clear that there are no features of the illness

which point specifically to the diagnosis. Laboratory tests are of great interest and importance, but are not likely to provide immediate help. It is possible to isolate the virus from the patient's blood in the early days of the infection and from the sputum when lung involvement has occurred. A more generally applicable test is the demonstration of psittacosis antibody in the patient's serum. For this test two specimens of serum are required, one in the acute stage, ideally before the fifth day, and the second about the twenty-first day.³ Although the finding of antibody in high titre (1:32 or over) in the first specimen is suggestive, a fourfold or greater rise in the second specimen is required for a firm diagnosis. At least 1 ml. of serum, preferably sterile and not haemolysed, is required for each specimen.

Psittacosis has been successfully treated with large doses of penicillin,⁴ but the virus is more sensitive to the newer antibiotics. In view of the dangers of chloramphenicol, it would seem that aureomycin is the drug of choice, and if this is not tolerated terramycin, or large doses (2 million units or more a day) of penicillin, may be used. Because of the impossibility of diagnosing the disease early, it seems reasonable to regard as possibly psittacosis any illness starting acutely and being either influenzal in type or apparently a virus pneumonia in a person who has been exposed to ill birds of any species, and in particular recently imported parrots. Suitable treatment should be begun at once and the first of the two serum specimens taken. Specimens may be sent for investigation to the laboratories of the Public Health Laboratory Service in Cambridge, Cardiff, Exeter, Hull, London, Manchester, Newcastle, Northampton, and Nottingham.

ANGIOSPERMS AGAINST VIRUSES

The isolation of a substance from the seeds of the Norway maple which has an action against phage and vaccinia virus has recently been announced by Fischer.¹ The seeds were boiled with alcohol and ether, and the ground residue was extracted with dilute alkali, neutralized, and purified further by various procedures. The extract inactivated *in vitro* a phage of *Bacterium coli*, so that no phage multiplication took place when the host organism was added subsequently; the bacteria themselves were not affected by concentrations which were sufficient to inactivate the phage. Fischer also claimed that the extract inactivated phage after it had entered the host cell, but the evidence in support of this is open to question. The extract was not active against a staphylococcus phage, but inactivated vaccinia virus *in vitro*. The active principle in the extract was named acerin. The work reported is in no way unusual, and no exceptional claims are made for acerin by the author, who is rightly concerned to give a bare account of his findings. Observations of a similar nature are commonly made in virus laboratories all over the world.

It cannot be emphasized too strongly that *in vitro* tests are useless for detecting potential antiviral agents.

The agents which inactivate viruses *in vitro* are many and varied, and range from the common antiseptics on the one hand to such innocuous materials as lipids,² physiological saline, and even distilled water on the other. Moreover, those few antiviral agents which are known seem to be active *in vivo* but not *in vitro*, and would thus have escaped detection in tests of the latter type; for instance, benzaldehyde thiosemicarbazone confers significant protection to mice inoculated intracerebrally with vaccinia virus, but does not destroy the virus when incubated with it in the test-tube,³ and the growth of influenza virus in tissue culture is inhibited by certain amino-acids which do not inactivate the virus *in vitro*.⁴ The method of preparation of acerin suggests that it may be a pectin, and the antiviral action of pectins has been known for some time. Thus Green and Woolley found in 1947 that the growth of influenza virus in fertile eggs was inhibited by apple pectin,⁵ yet this discovery has not led to any development of clinical importance. It may thus be concluded that acerin, even if active *in vitro*, does not afford any easy solution to the virus problem nor even an important clue to it.

What hope does acerin hold for the future? Control of vaccinia-variola probably lies in the development of a thiosemicarbazone with a somewhat greater antiviral activity and a much lower toxicity, but Fischer's work on acerin will nevertheless be of importance if it directs attention to the possibility of finding antiviral agents in the angiosperms (that is, the flowering plants other than conifers). The storage organs of the flowering plants contain many compounds of a complexity such as to render them inaccessible by the methods of organic synthesis, and it might well be that some of these compounds might have by chance some activity, as for example against viruses, other than that which they exert naturally.

The Norway maple (*Acer platanoides*) is commonly used in this country for park and street planting, and the purple-leaved var. *Schwedleri* is a familiar object in suburban gardens. Abundant crops of seed are borne every autumn and there is thus no scarcity of material for anyone who wishes to confirm Fischer's observations and extend them by *in vivo* tests. The field maple (*Acer campestre*) and sycamore (*Acer pseudo-platanus*) also provide material for examination. The scope of such an investigation is almost unlimited, since it could be extended to cover the commoner members of the British flora, and it might well afford a better chance of a discovery of major importance in the field of virus chemotherapy than the methods which are being pursued at present. Much labour is required to produce a new synthetic compound, and the substances produced by plants in the course of their metabolism can be extracted at the cost of far less effort. If the report on acerin does nothing more than arouse an interest in flowering plants as a source of potential antiviral agents, it will at least have justified the attention which it has attracted.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

ANTENATAL CARE—I. CLINICAL EXAMINATION

BY

W. C. W. NIXON, M.D., F.R.C.S., F.R.C.O.G.

Professor of Obstetrics and Gynaecology, University College
Obstetric Hospital, London

The half-century has turned since Ballantyne, of Edinburgh, published his article—"A Plea for a Pre-Maternity Hospital"—containing the first suggestion of an antenatal clinic or hospital. During these fifty years opinion and practice have changed, in some instances swinging a full circle. Maternity care is now accepted in this country as part of the Health Service that must be provided by the State. In England and Wales in 1951 there were 695,446 births (679,497 live births and 15,949 stillbirths). The number of mothers (new out-patients) who attended antenatal clinics attached to hospitals was 413,805, and 256,931 attended local health authority clinics. The total attendances made by expectant mothers (new and old patients) during 1951 was 2,333,902 at hospital clinics, and 1,450,097 at local health authority clinics. These figures, kindly supplied by the Ministry of Health, serve to indicate the magnitude of the service required for these expectant mothers.

The most striking recent trend in antenatal care is the increasing emphasis that is being placed on function as distinct from structure. The mechanistic approach to the parturient woman is to be deplored: the woman must be taken as a whole; her psyche and soma are so interwoven that neither can be neglected, especially at this most critical time of her life. In view of the ana-improved physique of women in this country the anatomical emphasis that it has had in the past. The emotional aspect of pregnancy and labour is as important as the physical, but it has been neglected by doctors and midwives.

History

In addition to obtaining the history of general illnesses, operations, and so forth, it is of value to know something of the psychological background of the woman and her own mother's obstetric history. One should always inquire whether the mother has had any virus infection, particularly rubella, during the first trimester of pregnancy. It has now been established that there is an added risk of congenital malformations (deaf mutism, cataract, heart disease) when a woman has been exposed to such infection in the very early weeks of pregnancy. Severe vomiting early in pregnancy should be noted, since this is sometimes followed by pre-eclamptic toxæmia in the later months.

In a multipara a full history must be taken of the previous pregnancies and labours, including the puerperium. The weight, health, and method of feeding the baby must also be noted.

Physical Examination

Auscultation of the heart should always be performed. In about 50% of women attending an antenatal clinic a soft murmur will be heard towards the end of pregnancy. This is due to organic disease in only about 1% of cases.

The blood pressure should be taken at every visit, before any physical examination and after the mother has rested and been engaged in conversation for a few minutes. The limit of normal blood pressure in pregnancy is usually taken as 140/90, but as the result of Professor F. J. Browne's

researches at University College Hospital it has been suggested that this ceiling should be dropped to 120/80. He has shown that a rise of blood pressure above this level has been present early in pregnancy in about 65% of cases of pregnancy toxæmia. It is to be regarded as an early warning sign of a future toxæmia of pregnancy.

The urine should be tested for albumin at each visit; if this is found, a catheter specimen must be obtained, since the original specimen may have been contaminated by vaginal discharge. If albumin is present in the catheter specimen then the urine should be examined bacteriologically. It is usual to examine for sugar at the first visit, and in some clinics this is repeated at each subsequent visit.

The height and the rate of increase in weight can provide useful information. Recent studies at Aberdeen by Professor Dugald Baird and his co-workers have revealed a relationship between the stature of a woman and the shape of her pelvis. In some of the small women (under 5 ft.—152 cm.) there was evidence of pelvic flattening as shown by x-ray pelvimetry. In women of normal and adequate stature the pelvic brim was gynaecoid (round) or anthropoid (long oval). When growth was stunted as the result of poor nutrition the pelvis was small and contracted, either android or platypelloid. The tall women in the Aberdeen investigation had no difficulties in their first labour. It has long been known that in the absence of a hereditary factor the stature of individuals is a measure of the nutrition of a community. If a woman is under 5 ft. (152 cm.) in height a careful assessment of her pelvic capacity must be made. A survey in 1940 of 500 London women attending University College Obstetric Hospital revealed a significant tendency for those of shorter stature to have a flatter pelvis.

Regular weighing at each visit is becoming the practice in more and more clinics. In the United States considerable importance is attached to the control of weight as a means of reducing the incidence of toxæmia. This will be referred to in more detail in Part II.

A vaginal examination should be made in all primigravidae, but not at the first visit. It should be postponed till after the sixteenth week, when the risk of abortion has diminished. If an ovarian cyst or other tumour is detected at this time the hazard of removal is minimal. In multiparae who have had normal deliveries there is no need to assess the pelvic outlet.

Pelvimetry

External pelvic measurements as a means of diagnosing pelvic contraction no longer occupy the hallowed place they held two or more decades ago. Nowadays they are taken routinely by medical students and midwives, and serve more as an anatomical exercise than anything else. This does not apply, however, to a woman of small stature (under 5 ft.—152 cm.), since in her case external pelvic measurements when carefully estimated may be a guide to the size of her pelvis.

There is a fairly high correlation between the greatest transverse diameter of the pelvic inlet (5½ in.—13.3 cm.), and the intercrural diameter, which can be measured clinically with callipers with a fair degree of accuracy. Thus this measurement is more reliable in predicting the corresponding internal measurement than is that of the external conjugate in predicting the internal conjugate measurement. The intercrural diameter is measured between the widest points on

the outer borders of the iliac crests, and the average is usually considered to be between 10 and 11 in. (25 and 28 cm.).

A male distribution of pubic hair and hirsuties does not seem to be related to a masculine type of pelvis. The architecture of a female pelvis indicating a masculine tendency is a relatively narrow brim, a narrow sacrospinous notch, a highly curved sacrum, a small subpubic angle, and an unusual degree of convergence of the side walls, or funnelling, leading to a narrow outlet.

The Diagonal Conjugate.—The majority of clinicians agree that this is the most important of all internal measurements. It is a digital measurement taken from the mid-point of the sacral promontory to the subpubic angle and is of value in estimating the internal conjugate. When there is cephalo-pelvic disproportion, and it is necessary to obtain this measurement with accuracy, then an anaesthetic will be needed, since the resistance of the perineum in some primigravidae will make the sacral promontory inaccessible to the examining finger. In the normal pelvis the promontory cannot be reached, and if it cannot be felt at 4½ in. (12 cm.) from the lower border of the symphysis then the pelvic brim is usually adequate. Half an inch (1.3 cm.) is subtracted from this measurement in order to estimate the length of the true conjugate (4½ in.—11.4 cm.). When the angle of inclination of the plane of the brim is greater than usual the promontory will be difficult to "tip" even in the presence of brim contraction.

Pelvic Outlet.—Much can be learnt from a careful digital examination of the outlet. The perineum should be palpated to ascertain its length and rigidity. With two fingers in the vagina the ischial spines, sacrospinous ligaments, lower end of the sacrum, and the subpubic angle can all be examined. The "knuckle" test (intertuberal) is familiar to all, but the measurement across one's own knuckles must be known. A rough estimate of the intertuberal diameter can be gained by pressing the clinched fist between the ischial tuberosities at the level of the anus. This intertuberal measurement is usually reckoned as 4½ in. (11.4 cm.). If the subpubic angle is normal two fingers of average size can be placed within the pubic arch under the subpubic angle. With experience it is possible by these somewhat crude digital methods to detect the type of pelvic outlet that may give rise to difficult delivery.

X-ray Pelvimetry.—Routine radiographic pelvimetry of every primigravida is to be deprecated. There are enthusiasts who would like every pregnant woman to have her pelvis measured with radiological precision. They forget the expense incurred, the time consumed, the fallacies, and, last but not least, the danger with repeated exposures of radiation damage to the foetal gonads. Radiological methods should be used to supplement—not displace—the clinical examination, and x-ray pelvimetry should be considered only in the following clinical categories: (1) primigravidae with a height of 5 ft. (152 cm.) or less; (2) primigravidae with the foetal head not engaged at term and with variation in the anatomy and capacity of the bony pelvis as detected by digital examination; (3) primigravidae with a breech presentation in which external version has failed; and (4) multiparae with a bad obstetric history.

Dental Examination.—It is not sufficient for the doctor or midwife to make a perfunctory examination of the teeth and gums. The mother should be under the care of a dental surgeon as early as possible in pregnancy. He will advise on oral hygiene, further visits, and treatment.

Routine Chest Radiography.—Since 1947 every mother attending the antenatal clinic at University College Obstetric Hospital has had a radiological examination of her chest. The incidence of pulmonary tuberculosis detected early in pregnancy in this way has been about 1 in 200. All these patients had had the usual chest examination by the medical officer and in only one out of 27 were any abnormal signs discovered by this physical examination. Routine chest radiography of pregnant women should be obligatory, and, where it is available, miniature radiography might well be used for this purpose.

Preparation for Lactation

The clinical studies of Dr. Harold Waller at the British Hospital for Mothers at Woolwich have been a major contribution to this subject. He has shown that a defect can be found in one or both nipples in about 40% of women in their first pregnancy. Inspection is not enough, and he has devised a simple test which will reveal tethering of the nipple. Such fixation of the nipple interferes with sucking. Waller's test consists in placing the forefinger just above and the thumb just below the nipple's base at its junction with the areola. The finger and thumb are then pushed a short distance into the breast and squeezed together in imitation of the baby's bite. If the nipple retracts then the baby will have difficulty in feeding.

When this defect is present Waller recommends the use of a shield or "shell" made of glass or plastic.* The nipple projects through the hole in its base and the apparatus is kept in position by a well-fitting brassière. At first it is worn for a few hours daily and then throughout the day. It can be applied from the twentieth week onwards.

Waller has also shown how daily expression of the colostrum during the last eight weeks of pregnancy helps to eliminate lactation difficulties. All primigravidae and all who have had difficulty or have failed in previous lactation should be given prenatal tuition. Attempts to "harden" the nipple are to be condemned.

Special Examinations

As early as possible in pregnancy a sample of blood should be taken and sent to a laboratory for ABO blood-grouping, and Wassermann (Kahn) and Rhesus-factor testing. The haemoglobin should be estimated at the same time and again at the thirty-fourth week.

The simple haemoglobin test may lead to the detection of one of the more serious anaemias of pregnancy.

What is the lower limit of normal for the haemoglobin level during pregnancy? This is a controversial question, since there is a progressive increase in blood volume as pregnancy advances. The dilution of the circulating blood reaches a maximum of about 25% early in the last trimester of pregnancy. This physiological hydraemia results in a fall in the red-cell count and thus in the haemoglobin concentration. In a young woman during the last month of pregnancy 80% haemoglobin may be taken as the lower limit of normal; in an older woman (over 30) this figure is lower, about 76%. With increasing parity the haemoglobin level drops.

For many years the Tallqvist method of estimating haemoglobin has been used by general practitioners. Recently it has been criticized because of its unreliability. It is a useful procedure for the approximate estimation of haemoglobin. Although seemingly a somewhat crude procedure, the Tallqvist method has yielded results which are of about the same accuracy as those obtainable with most dilution haemoglobinometers, such as the Haldane and Sahli.

Frequency of Examination

It is usual to see the mother at monthly intervals until the thirty-second week, then again at the thirty-fourth and thirty-sixth weeks, and then weekly until the delivery. It is quite unnecessary to do an abdominal palpation at every visit. Provided there are no untoward symptoms, this examination should be done at the twenty-eighth, thirty-second, thirty-fourth, and thirty-sixth weeks. If the head is well engaged at the thirty-sixth week there is no need to do another abdominal palpation until term. The urine and blood pressure must be examined and the mother weighed at every visit. There is no doubt that many mothers are subjected to much purposeless palpation during antenatal supervision.

[Part II will appear in our next issue.]

CENTRAL PUBLIC HEALTH LABORATORY MINISTER OPENS NEW BLOCK

The Minister of Health, Mr. Iain Macleod, opened a new block of laboratories at the Central Public Health Laboratory, Colindale, on January 15. Mr. Macleod, who was introduced by Lord Limerick, Chairman of the Medical Research Council, paid a tribute to all who worked in the Public Health Laboratory Service.

He recalled that, before the war, there had been a very haphazard service in this field. It had needed the whip and spur of war to start the story, another page of which was turned on this occasion. It was on the recommendation of the Committee of Imperial Defence that an emer-

gency public health service had been set up. Although fears of bacteriological warfare and widespread epidemics were falsified, it had been realized that in peace as well as in war there was an essential need for such a service. It was a strange, casual, but very English way of meeting a great need in the ordinary life of the country.

Mr. Macleod spent an hour inspecting the building and learning about the work which was being carried out. He said that he was most interested to see the various reference laboratories. Some were main centres not only for this country but for Europe, the Commonwealth, and even the world—for example, the Enteric Reference Laboratory. "It is in such places as this," continued the Minister, "that the weapons against disease are to a large extent fashioned and sharpened. It is strange, when so many new diseases which used to be the scourge of this and other countries have yielded their secrets, there are still diseases like the common cold which defy us."

"A Microbiological Palace"

Colonel H. J. Bensted, Director of the Central Laboratory, said that the service had first been established, seven years ago, on the upper floor of a small Edwardian building. Later it extended to the lower floor, but even so its cramped

conditions for working contrasted remarkably with the present "microbiological palace."

The new building has been completed in two years. It has enabled all departments to expand considerably, including those which remain in the old building (occupied before 1946 by the Government Lymph Department). Each floor is provided with sterilizing and wash-up kitchens, preparation rooms, and hot and cold rooms. There are special experimental rooms for the investigation of air-hygiene problems, and there are facilities for sterilizing the air intake of some of the rooms and the air exhaust from others where it may be contaminated by pathogenic bacteria or viruses. One entire floor is devoted to the study of virus diseases. This includes a special low-temperature suite consisting of chambers at 4° C., -30° C., and -70° C.

The following reference laboratories and special departments are contained in the new block and other buildings: the Standards Laboratory for Serological Reagents and the National Collection of Type Cultures (originally established as M.R.C. units many years ago); the Central Enteric Reference Laboratory; the Virus Reference Laboratory; the Salmonella Reference Laboratory; the Food Hygiene Laboratory; the Streptococcal and Staphylococcal Reference Laboratory; the Air Hygiene Laboratory; the Dysentery Reference Laboratory; the Epidemiological Research Laboratory; the Routine Department.

THE TECHNIQUE OF MEDICAL TEACHING

Another highly successful Conference-Course on the Technique of Medical Teaching was held at the Postgraduate Medical School, Hammersmith Hospital, London, on January 9 and 10. At the first session, presided over by the Dean of the School, Dr. C. E. NEWMAN, methods of group teaching were discussed in contrast to the formal lecture.

Group Teaching

Dr. L. J. H. BURTON, medical adviser to the Central Council for Health Education, offered some criticisms of the formal lecture. Sir William Hamilton Fyfe had said, for instance, "The lecture system has survived because it is cheap and easy. The stimulating effect of the lecturer fades away as soon as the lecture is over." And Sir John Simon, 75 years ago, declared that education was not something which one man could receive passively from another, but something which his own nature must grow forth most actively to meet. Dr. Burton pictured the lecture-theatre situation—the 40 minutes' lecture delivered behind the barrier of a rostrum, the front seats of the theatre empty and the back seats occupied by some whose interest was obviously in other things. In contrast with this was the discussion around the table, with its exchange of experiences and information and with each person in the group thinking actively in order that he should not disappoint the others.

Group discussion was partly interpretative and partly informative. It ensured that facts and opinions were scrutinized from many different points of view. Each student could fit his information into his own particular frame of reference. Everybody learned in a different way, and unless a teacher saw a problem in two or three different ways he would miss at least nine-tenths of the audience. Referring to the technique of group leadership, Dr. Burton said it would generally be found that questions which started with "How?" "Why?" or "What?" stimulated more useful discussion than vague questions which began with "Do you think?" The leader's main concern was to encourage all members of the group to participate and avoid the discussion being dominated by one aspect or one personality.

Miss M. L. JOHNSON, of the department of anatomy, University College, London, added some further observations on the value of group discussion. In practice, students selected from the lecture just what they could assimilate or what would fit in with the ideas they already possessed. In the discussion group, on the other hand, students were continually comparing and contrasting views, and examining the facts in their various relations. At a former conference the need to train students to treat patients as anxious and frightened people had been stressed. She thought that teachers should assume also that students are anxious, frightened people, and this was one of the golden rules of teaching.

At a later session, with Professor JOHN McMICAL in the chair, a number of practical demonstrations were given of class teaching. The students taken were in their first, second, or third clinical years, and the teachers were for the most part junior teachers or senior registrars. However, from a conference point of view the result was not wholly successful, because the replies and observations of the students were in almost every case inaudible.

The Overburdened Curriculum

Professor G. PAYLING WRIGHT spoke of the growing size of the medical curriculum, and the need to relieve the burden on the student. Not all students of medicine ought to be forced into the same Procrustean bed. Medical education should be on less rigid lines than at present and try to adapt itself to providing the best fits for the widening variety of professional activities now available to young qualified people. At present, all medical students went through the same formal course irrespective of the branch of medicine in which they would ultimately be engaged. He believed that it would be possible to hold examinations in the preclinical subjects of anatomy, physiology, and biochemistry at two levels, one requiring a general and the other a more advanced knowledge. Every student should take all at the general and one, of his own choice, at the higher level. The load would be lightened and the educative value of the course improved. He thought it unsound psychologically so to arrange the course in some universities that students fatigued by the heavy strain of the second M.B. examination were precipitated after a wholly inadequate vacation into the "bridge term" of pathology and introductory clinical studies. As a result, many students failed to benefit as much as they should from this critically important few months of their training.

In the first clinical year the student had to absorb an enormous array of new facts, and much help could be given him by systematic didactic lectures. But during the remaining years, not only the subject-matter but the manner of its presentation should undergo evolution. With the increasing maturity of the student, the didactic lectures should be superseded by others of a less systematic and more stimulating kind. The aim of the educator should be to encourage mental independence in the student—to replace his natural desire to be "taught" by a capacity to "learn." He recommended that more attention should be directed to helping students to make use of libraries, because after leaving his medical school the reading of periodicals and monographs would be the main means by which a young doctor could improve his professional powers. The student should be introduced to the *Index Medicus* and the *Surgeon General's Catalogue*, and encouraged to use them to amplify his knowledge on interesting cases. Professor Payling Wright also suggested that some simple weekly or fortnightly "journal club," covering a few of the more important medical journals, and led perhaps by a registrar, might help the more senior students to bridge the difficult gap between textbooks and periodicals. Such discussions would ensure the active participation of the better students and train them to the critical appreciation of new advances in medicine.

The Museum in Teaching

Dr. KEITH SIMPSON said that many museums in medical schools and elsewhere had a constant and unchanging character; they were in the worst sense of the term "museums," often lacking reasonable comfort and adequate lighting. The museum at Guy's, of which he was curator, was a very large one, with about 8,000 specimens, but the size of a museum need have no bearing on its general practicability. Dr. Simpson showed examples of many ways in which the teaching facilities of a museum might be furthered, such as the use of photography, or of an artist, or by collating different stages in a condition or process, and by special methods of mounting. Specimens of use to elementary students on the one hand and to advanced students on the other could be marked accordingly, or collected into groups, and the artist could help to co-ordinate the clinical and pathological teaching in the museum by means of diagrams and cartoons. Lecture demonstrations on recent additions might be given as well as routine courses in medical or surgical pathology. No museum should ever appear to the student as an archaic, out-of-date collection of material, but as something abreast of the times and bearing upon the study which the student was making in other departments of the hospital.

Research and the Queue for Security

The last session of the course, with Professor IAN AIRD in the chair, was devoted to the question of how to introduce students to research.

Professor MAX ROSENHEIM stressed the value of research in producing a critical outlook in medicine, and discussed how students might be made more aware of the research in progress in their schools. He said that one of the principal dangers in medical practice to-day was the development of a stereotyped pathway to consultant posts. In America a period spent on investigation was regarded as an essential part of the training of the consultant, but in this country it was possible and even usual for a man to spend five or six years as registrar and senior registrar entirely at the bedside and in the out-patient clinic. Facilities for research existed, but were not fully used. There was lack of encouragement from above, and the young registrar was beset by the fear of turning away from the recognized pathway lest he lose his place in the queue for security. In his opinion every registrar should be given a research problem, however simple, and it should be possible for him to spend a period in a clinical or preclinical laboratory. It must, however, be made clear from the start, whenever a registrar was seconded for research purposes, that if eventually he found himself unsuited for a research career his time would not have been wasted. He should be able to return to clinical medicine not frustrated but enlightened and stimulated by his experience.

SIR LEONARD ROGERS, F.R.S., AT 85

The good wishes of many friends will have gone out to Sir Leonard Rogers on Sunday last, when he celebrated his eighty-fifth birthday. When he left India in 1921 after 28 years' service in that country the *Indian Medical Gazette* described him as "a prince of science." But the word "prince" suggests ease and glamour, which have been far from Sir Leonard Rogers's experience. No man has laboured more unremittingly, pursued research with a more ardent and inquisitive mind, braved with more unconcern the discomforts of climate and the occasional perils of the jungle or the laboratory. His energy and initiative have been unabated, whether in tracking down the causes of tropical disease to their lair or enlisting the help of business and official people in the beneficent projects he had at

heart. His work as professor of pathology at the Medical College, Calcutta, laid India and the East under his debt.

Those who know anything of the history of tropical medicine since the last decade of the nineteenth century will not need to be reminded of Sir Leonard Rogers's great work on amoebiasis and the placing of emetine treatment on a scientific basis; on cholera, with the working out of treatment by intravenous hypertonic saline; on the investigation of epidemic kala-azar in Assam and the application of antimony treatment; on the pathogenesis of sprue; above all on leprosy, whereby both the standard of treatment of that disease and the social lot of the leper have been extraordinarily improved.

When he came back from India he was still at the zenith of his powers. His labours, begun in Calcutta, were con-

(Walter Stoneman, London)

tinued in London with equal zest. As physician to the Hospital for Tropical Diseases, as medical officer and afterwards president of the Medical Board of India, as founder of the British Empire Leprosy Relief Association, as author of a continual stream of papers and books on tropical diseases, as a vigorous fighter in the cause of freedom for research, his second career has been as strenuous as his first. Many of the present generation will have heard his occasional addresses to the Royal Society of Tropical Medicine or the Research Defence Society, but his work now goes back for 60 years.

When, a year or two ago, he published his autobiography, dedicated to his wife, "the best and most unselfish of women," he gave it the title of *Happy Toil*. The secret of the happiness was to be found, not principally in the ennobling nature of his researches, but in the religious faith which has sustained him through many difficulties and disappointments in accomplishing something for the relief of suffering. His work has gone on into old age: the publication in this *Journal* a few weeks ago of a contribution from his pen on progress in the control of cholera in India shows that he is as eager as ever to promote the welfare of mankind.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

"There is No Pathology"

SIR,—When a suspect organ or tissue is found to be normal reports about it sometimes state: "There is no pathology." Recently a candidate in an answer to a question in an examination paper stated that "one cause of torticollis was spinal pathology." There is an increasing use of the word pathology (which the *Oxford Dictionary* defines as "the science of diseases") when lesion or disease is meant. I would ask the courtesy of your columns to make a plea for the correct use of the word.—I am, etc.,

Cardiff.

LAMBERT ROGERS.

Elliptocytosis

SIR,—May I ask, through the courtesy of your columns, that any pathologist who finds a case of elliptocytosis should be kind enough to let me know? A family has been found in which the gene determining this anomaly is on the same chromosome as the genes of the Rh blood group system (Goodall *et al.*, *Ann. Eugen. (Camb.)*, 1953, in press). I am therefore anxious to do blood typing in some more families showing the same anomaly.—I am, etc.,

Galton Laboratory,
University College,
London, W.C.1.

SYLVIA D. LAWLER.

The Climacteric and Oestrogen Therapy

SIR,—Your timely annotation, "The Climacteric and Oestrogen Therapy" (January 3, p. 37), will have encouraged many gynaecologists who are so often presented with problems associated with the menopause. Too frequently we see cases where indiscriminate use of preparations containing oestrogens, or a combination of hormones, has been made, and even more often cases of irregular and post-menopausal bleeding are sent to out-patient clinics without any information from the family doctor about previous hormone treatment. Close questioning may reveal that "pink pills" have been taken for some months "off and on," but apparently the patient has not realized for what periods of time they should have been taken. These things, as you have so wisely said, should not be.

I rather suspect, Sir, that I am not alone in regretting that all synthetic preparations of oestrogens are not subject to the Poisons Schedule; such a measure of control might discourage the casual use of these potentially dangerous remedies. Used properly and intelligently, these remedies can, as we know, be of immense benefit to suffering women (and men). But there is far too much careless and, in my view, dangerous prescribing of these things, and it is time indeed that the association of prolonged trickle-dosage with oestrogens and carcinoma in women of menopausal age should be recognized as a real danger.

Your article touches on the use of combined oestrogen-androgen therapy. It is true that extravagant claims have been unwisely made for such preparations, but I should like to put forward the suggestion that this combination may well be given a more extended trial in the suppression of unwanted lactation. Our experience in the Bath hospitals is that it is superior in action to testosterone; we long ago gave up the use of oestrogens alone for this purpose chiefly on account of their undesirable side-reactions.—I am, etc.,

Bath.

A. LEECH-WILKINSON.

SIR,—In your annotation on "The Climacteric and Oestrogen Therapy" (January 3, p. 37) you rightly object to the indiscriminate use of oestrogen in menopausal disturb-

Pain in the region of the second and third metatarsal heads was the cause of symptoms in 20 cases (30%). There was no efficient action of the small toes in these cases, and dorsal dislocation of one or more toes was found in four feet.

Results

Grade	Subjective Function	No. of Feet	Percentage
4	No symptoms. No disability	44	66
3	Intermittent symptoms. No significant disability	18	27
2	Persistent symptoms. Occasional disability	4	6
1	Persistent symptoms. Constant disability	1	1

Analysis of Results

Grade	Cause of Symptoms	Feet
3	Tender operation scar in cold weather	1
	Pain in longitudinal arch or ankle	2
	Intermittent metatarsalgia	15
2	Persistent metatarsalgia	4
1	Severe metatarsalgia	1

Metatarsal bars had been provided in five cases, four of whom at examination were free of symptoms: these cases are, however, included in Grade 3.

In conclusion, Keller's arthroplasty can give a reasonable proportion of good results. When there is no efficient action of the small toes, some form of forefoot support should be prescribed post-operatively.—I am, etc.,

Oxford.

G. P. MITCHELL.

Ageing Cartilage

SIR,—There is no doubt that purely chemical analysis of body tissues has yielded much valuable information. The paper contributed by Dr. B. F. Matthews (December 13, 1952, p. 1295) draws attention to the inconstancy of the collagen/chondroitin sulphate ratio in certain joint cartilages, and differences in the composition of the articular cartilage of different joints. From what is known of collagen gels, and in view of the unequal distribution of force, both muscular and gravitational, such differences may be expected and have also been shown to occur with advancing age and in degenerative processes of cartilage.

It should, however, be emphasized that the matrix of articular cartilage of at least the juvenile and middle-aged subject is a complex gel in which there is a coarse, but relatively uniform, network of fibre-protein which one may regard as the disperse phase. The continuous phase is water, and the physical properties of the cartilage matrix may be modified by changes in the relative amounts of all three major components—water, collagen, and ester mucopolysaccharide. There are also small amounts of other compounds in the gel, some non-ionic, which may also influence the response of the gel to physical factors such as pressure and friction. A simple illustration of the importance of the water component of the gel is the changes which take place in a thin slice of cartilage upon dehydration. Toughness and rigidity are markedly increased and there is the concomitant optical change from opacity to transparency. This modification implies reduction of the "pore size" of the protein network, and is associated with markedly increased molecular orientation as shown by the enhanced birefringence and bireflection.

It is therefore suggested that the application of chemical analytical methods to the separation and estimation of the solid components of the matrix gel may confuse the picture when taken alone, since an appreciation of the physical chemistry of protein gels indicates clearly that the characteristic behaviour of the gel is not only concerned with the type and number of molecules present but also with their mode of association—i.e., linkages by primary valence bonds, Van der Waals forces, or longer-range ionic forces. The physical features of any gel substance and its *in vivo* function should therefore not be considered without due regard being given to the degree of hydration of the gel, as well as to the relative proportions of the two major organic constituents.—I am, etc.,

Bristol.

C. H. G. PRICE.

The College of General Practitioners

SIR,—During the festive season our thoughts were wafting to the distinguished sponsors whose report adorned the front pages of the *Journal* of December 20, 1952, and firmly implanted the embryonic college in the history of British medicine. Nor do we forget, Sir, your words of blessing in the leading article (p. 1344). Among the college objectives the prestige of general practice takes precedence. Our president uttered auspicious words in his annual address: "The general practitioner should occupy a position second to none in the profession." But does the opening statement under "Conclusions"—"General practice is the oldest branch of medicine"—do justice to the noble cause that the college represents? May we more aptly conceive it as the parent of medicine—the "root and trunk" of the "tree of healing" with the specialties among its fruitful branches?

Conditions have changed in this half-century, and greatly to the disadvantage of the family doctor. The ethical core of medicine is the doctor-patient relationship. This intimate social bond has deteriorated gravely. Happily it is receiving signs of solicitude; but equally impeded is the mediatory function of the doctor in the extending specialist-patient relationship. The latter is causing dissatisfaction in the ranks of general practice, curbs the comity of the profession as a whole, and deserves a high place on the college agenda.

The profession falls into three groups: (a) general practitioners, (b) pre- and non-clinical laboratory staffs and research workers, and (c) specialists. The G.P.'s relations with group (b) are remote, affected little in the present issue, and need no more comment. It is regarding groups (a) and (c) that elucidation is urgently needed. Clear orientation of their relative positions is the first step in relieving the doctor of a grievous sense of lost terrain and caste. That he is too busy battling in the front line with the grim realities of human suffering to protest vehemently about his own degradation does not mean he lacks the sensibility of common humanity. Apparent indifference instead of vocal sympathy on the part of his colleagues makes him fret the more. But a manifestly intact professional camaraderie would confirm his determination to fight on until the good conditions in practice essential for decent professional work are won, and with them the final objective—prestige.

Encircling the layman nowadays is an assembly of diverse specialists with daunting polysyllabic titles. They are of two kinds, (a) "Harley Street," (b) "public health." Members of group (a) hold clinical positions, and it is to them the title of specialist ordinarily applies. Their variety has multiplied greatly owing to the advances of medical science. Group (b) embraces preventive medicine generally and includes those engaged at schools, factories, etc. Their notable increase is due to the urbanization of society. Humanity—already belonging to a general practitioner—now tends to congregate for its various occupations; there are often M.O.s attending who are engaged solely on specialist aspects of hygiene. Their contacts with patients are light and rather *ex officio*.

Despite the specialist's rather impersonal relationship his brilliant achievements capture public imagination, and the family doctor, who bears the major load of healing, is apt to lose in favour. In so many directions there have been encroachments on his province, although the most exacting parts of general practice remain his. Keeness suffers *pari passu* with loss of hold over his patients and increasing sense of detachment from his specialist brethren and hospital. The balance needs redress urgently—analogy points the way.

In his nuclear role the G.P. should be related to his specialist neighbour like a nucleus to nucleoli in the cell, and co-ordinate the team-work for the good of his patient. Someone must be captain, and, as he is primarily responsible for his patient's health, he is the obvious intermediary. He knows of each illness, the whole history, the personality and home background, and is honoured by the implicit trust of the patient. At the same time, aware of things from the consultant's angle, he must loyally represent his colleague's interest. Because society respects individuality and health is at stake, an adaptable service is vital. This ideal is attained by a harmoniously integrated group with the general practitioner pivotal. Judgment is constantly called for when dealing with suffering humanity—rigid regulations of commerce are out of place.

Why is the pre-eminence of the G.P. in the patient's purview indispensable? Because the patient who refers with assurance and confidence to "my doctor" is the most content; and the

doctor, conscious of such regard, is put on his mettle. *Per contra*, everybody's patient is nobody's patient. Again, the higher the esteem of the patient for his doctor, the earlier does he take his troubles to him and thence to the specialist, whose unceasing warning is, "The earlier the intervention the greater the chance of success." The patient, guided by his G.P., gets to the right specialist(s); unaided he would usually fail. From his viewpoint the young consultant needs to recognize that it is from the G.P. that there come the patients who add to his technical skill, the experience by which he rises to the top of his specialty and carries on the good work of riper years. Thus, in an evolving professional structure the G.P. remains on firm ground regarding status, and the debt due to him by his specialist colleagues is clearly manifest.

Prestige is a foremost topic in general practice to-day and of primary concern for the college, and is within as well as without the profession. Less dramatic as the domestic sphere may be, prudent reformers will first redress the lost balance there. Having consolidated their professional base, they will extend with unmitigated assurance on the wider public front.—I am, etc.,

A. WILFRID ADAMS.

Bristol, 8.

SIR,—I am sure that I will not be alone in wishing to reply to the letter of Dr. Bernard Kendrick (January 10, p. 97), and would be grateful if you would accept a few observations on his diatribe. First, the college has been formed to satisfy the wishes and needs of a large body of general practitioners. Those, like Dr. Kendrick, who are self-sufficient in matters of clinical research and postgraduate education, and who do not feel that they have anything to offer or gain from their colleagues, will remain aloof. In other words, there are already a sufficient number of interested doctors to form the college and they have every right to do so, just as Dr. Kendrick has the right to remain an individualist and plough his furrow alone. The suggestion that "it is hoped to thrust upon us" such a college is quite erroneous. The college has in fact been formed by those interested, and the latter have no wish to thrust it upon anyone who prefers to remain without.

Dr. Kendrick calls for "a body of doctors who are persistent in helping to improve the medical service." What is the medical service if not the doctors who serve in it, together with their ancillary colleagues? If the aim is to improve themselves, how better could the general practitioners seek to improve the service as a whole? It is interesting to learn that principals do not need help in finding suitable assistants. I had always been under the impression that to sort and evaluate 50 applications for a post was a very difficult task when the applicants' previous experience might be to a large extent unsuitable for the type of practice in question and, in some cases, their interest superficial and pecuniary. If Dr. Kendrick wishes to devote his energies to "helping assistants to become principals"—a very laudable aim—the various medico-political organizations offer suitable channels, and in the meantime the College of General Practitioners will carry on with the work of giving them every opportunity, if they wish to accept it, of becoming good or even better principals.

As for the suggestion that the college may restrict entry into general practice, I am sure that the sponsors have never dreamed that such power might one day be theirs—and when that time comes I am sure that they will be content to allow the law of supply and demand to remain unaltered.—I am, etc.,

H. H. PILLING.

Sheffield.

SIR,—With reference to the proposed College of General Practitioners, I would like to support Dr. A. G. Cruikshank (January 10, p. 98) in his proposal for membership examination. Membership is worthless while it can be obtained for 10 guineas and a promise to do three days' "refreshing" a year.

Twenty years' successful doctoring does not always prove a high standard. A large "successful" practice means little more than an ability to please the patient—and this

not by good doctoring in every case. Examinations, for all their defects, are the only practical way to assess one's knowledge. Let us combine, say, five years' general practice with an examination on the most general and practical lines—eliminating as far as possible theoretical questions.

As to functions of the college, not the least should be teaching and research. In general practice one often recognizes unrecorded epidemics, unrecorded because the cases never reach hospital; to mention a few—Bornholm disease, streptococcal infections, often followed by epidemics of fibrositis, herpes zoster, urticaria, and minor "influenza" infection. Even cystitis seems to be epidemic at times. One of the faults of the present system is that each consultant has such a limited field of knowledge that he is unable to weigh up the importance of his own special findings in the picture of the patient as a whole. Who is to assess which is the most important factor in, say, a case of mitral stenosis, pregnancy, and anxiety neurosis? The college might encourage the emergence of a consultant general practitioner of wide knowledge, whose function would be to assess the importance of all the specialist findings.

We would then arrive at the position where the reflections on general practice would be replaced by, "Poor old Smith has failed his M.C.G.P. so he will probably have to specialize."—I am, etc.,

Dundee

RONALD A. B. RORIE.

Emphysema

SIR,—The report of the erudite address by Dr. A. G. W. Whitfield (December 6, 1952, p. 1227) has raised some important issues. Dr. Whitfield refers to the use of morphine in patients with cardio-respiratory failure, and rightly asserts that its dangers are "well, but not sufficiently well, known." However, your correspondent Dr. W. N. Leak (December 27, 1952, p. 1416) appears to hold the view that morphine can sometimes be used with benefit in such cases. Unfortunately, he made no attempt to define the clinical criteria which would enable the practitioner to decide which of these cases could be given morphine with "safe and useful" results. On the contrary, there is a wealth of evidence to show that the use of morphine in cases of the asthma-emphysema complex, etc., is fraught with grave danger. This drug not only depresses the respiratory centre, but also inhibits the cough reflex. In the case of status asthmaticus the patient's very life depends on the untrammelled activity of these physiological mechanisms. Furthermore, morphine is an addicting drug which should not be given to those suffering from a chronic, painless malady. The fact that many patients survive an injection of morphine is no justification for its use, since others are less fortunate. The value of morphine in so-called cardiac asthma is, however, generally accepted.

The use of ephedrine is logical in cases of emphysema with marked bronchospasm. Nevertheless, I have seen the rapid onset of congestive heart failure immediately following the use of ephedrine in a case of cyanotic emphysema with minimal bronchospasm. The patient improved somewhat on withdrawal of the drug, and made further progress with its substitution by thiouracil. The increased metabolic rate produced by ephedrine may be dangerous to these precariously situated (cyanotic) patients.—I am, etc.,

Littlemore, Oxon.

J. TODD.

Post-epileptic Automatism

SIR,—I am grateful to your correspondents who have expressed their views regarding post-epileptic automatism. It is significant that no one has produced any evidence to support the idea originally put forward by Mercier and repeated by Norwood East. This is that the automatism repeats some previous behaviour: the woman wringing out washing has a fit and wrings her child's neck, the man peeling potatoes cuts someone's throat, and so on. Such a theory is too good to be true and is obviously erroneous.

of the more important references of Jawetz *et al.*^{1,2,3} His work is confirmed by Lepper and Dowling,⁴ who have shown definite antagonism between penicillin and aureomycin in the treatment of meningococcal meningitis.

Our patients who received mixed antibiotics were treated in this manner before we were aware of antagonism—that was in 1950. They only received one dose of crystalline penicillin, and I feel that it is unlikely to have caused a resistance, but this statement is made purely on impression.—I am, etc.,

Winnipeg, Manitoba.

J. NIXON BRIGGS.

Foetal and Neonatal Death

SIR,—The memorandum "Neonatal Death due to Ligation of Umbilical Cord by an Amniotic Band," by Drs. F. O.K. Craven and C. J. M. Geddes (January 10, p. 81), contains an unfortunate example of confused terminology.

The memorandum begins: "The following case of neonatal death is interesting enough to be placed on record. So far as we can ascertain no previous foetal death due to this exact cause has been published." This wording suggests that neonatal death and foetal death are the same thing, but this is not so. *Neonatal death* means death within the first 28 days after birth of a child that had been born alive, whereas *foetal death* means that the child had died before or during birth. It is important in many ways that this distinction be understood and maintained.

It is stated later in the memorandum that "a dead baby had . . . been delivered." This being so, the use of the term "neonatal death" is quite inappropriate in this case.—I am, etc.,

W. P. D. LOGAN,
Chief Medical Statistician,
General Register Office.

London, W.C.2.

POINTS FROM LETTERS

The College of General Practitioners

Dr. D. D. MACDONALD (London, N.1) writes: The College of General Practitioners has been launched and looks gay in the paint of good intention, rich in the promise of high performance. One watches with the interest of good will from the bank and hopes the correct solution will be available, in full measure, to resolve its problems to come. In wishing this great venture, this New Elizabethan vessel, all success in real usefulness, the words of Samuel Langhorne Clemens (Mark Twain) come welcome to mind: "Diligently train your ideals upwards and still upwards towards a summit where you will find your chiefest pleasure in conduct which, while contenting you, will be sure to confer benefits upon your neighbours and the community. This has been taught by all the great religions for ten thousand years. The only thing new about it is that this time it has been candidly stated. That has not been done before."

Dr. A. E. STEVENS (Jersey) writes: "The College and the Hall" (M.R.C.S., L.S.A.) were good enough for our medical forebears. To-day we have the Royal College of Physicians and the Royal College of Surgeons, which are surely sufficient seeing that so many of us derive our registration on the strength of their diplomas. The Royal College of "Accoucheurs" is quite redundant and unnecessary; and now there is a demand for a College of General Practitioners. If it has to be, why not indicate from its name that it is at least connected with medicine? Why not College of Medicine, or better still College of Apothecaries? But it should be borne in mind that such a college is tantamount to the acceptance of our lowered status.

Otitis and Ear Syringing

Dr. W. STANLEY SYKES (Morley, near Leeds) writes: Mr. A. Tumarkin (December 20, 1952, p. 1361) recommends that cases requiring ear syringing for wax should be sent to an E.N.T. specialist. Surely, Sir, there should be two groups of specialists or operations of this magnitude—one for the right ear and one for the left.

Obituary

F. E. SAXBY WILLIS, M.C., M.D., M.R.C.P.

Dr. F. E. Saxby Willis, who died on January 2 in Hampstead General Hospital, had been the senior physician there for many years.

Frederick Edward Saxby Willis was born in London on October 21, 1889, the son of Frederick and Alice Willis, and received his early education at Dulwich College. He then entered St. Bartholomew's Hospital Medical College and qualified M.R.C.S., L.R.C.P. in 1913. On the outbreak of war in 1914 he enlisted in the South Staffordshire Regiment and was severely wounded at Ypres in 1915. On recovering from his wounds he entered the R.A.M.C. and was attached to the Seaforth Highlanders until the end of the war, being awarded the Military Cross in 1917 for attending to wounded under heavy fire. After demobilization he obtained the degrees of M.B., B.S. of the University of London in 1920 and became casualty physician and chief assistant in the children's department at St. Bartholomew's Hospital, a position he held for several years. In 1922 he proceeded M.D. and took the M.R.C.P. In due course he was elected to the honorary staff of the Royal Chest Hospital and the Hampstead General Hospital. Despite the handicap of his war wounds and, later, diabetes, he refused to allow them to interfere with his daily activities, and he built up a large consulting practice in lung diseases and general medicine. At the time of his death Dr. Saxby Willis was senior physician to Hampstead General Hospital and to the Royal Chest Hospital. He was also physician to the Weir Hospital and consulting physician to the Metropolitan Ear, Nose, and Throat Hospital, to Yateley Cottage Hospital, and to the Alexandra Orphanage.

With the advent of the National Health Service in 1948 he became a member of the teaching staff at the Royal Free Hospital School of Medicine and gave clinical lectures to students and postgraduates there. He contributed many papers on diseases of the lungs to the medical journals, and his joint contribution on cystic diseases of the lungs has been included in Davidson's *Practical Manual of Diseases of the Chest*. At the time of his death he was keenly engaged in a research survey of "atypical pneumonia" for the Royal Free Hospital School of Medicine, and it is to be regretted that his personal conclusions on the aetiology and clinical aspects of this syndrome will not be available to the profession.

Saxby Willis's sympathetic manner and genial personality endeared him to his many patients. His colleagues also had a deep affection for him, and, whether at hospital board meetings, clinical lectures, or social functions, he was the centre of attraction. He leaves a widow and two sons and two daughters, to whom we offer our deepest sympathy.—J. V. A.

B. L. JEAFFRESON, M.D., F.R.C.S., F.R.C.O.G.

Mr. B. L. Jeaffreson, well known in Leeds as a gynaecological and obstetric surgeon, died at his home at Leeds on January 7 at the age of 56.

Bryan Leslie Jeaffreson was born in London on August 29, 1896, the son of Mr. H. J. Jeaffreson. Several of his forebears, who came from Framlingham, in Suffolk, were eminent surgeons in their day. He was educated at Hurstpierpoint College, and at St. Bartholomew's

Hospital Medical School, which he entered in August, 1914. A year later, having passed the first M.B. examination of the University of London, he enlisted as a private in the Honourable Artillery Company and served as a combatant in France. In 1917 he was invalided out of the Army and returned to the study of medicine at St. Bartholomew's Hospital, graduating M.B., B.S. in 1921 and winning the Willett Medal for operative surgery in the same year. He held successively the posts of house-surgeon and resident intern midwifery assistant at St. Bartholomew's Hospital, and then, having proceeded M.D. in 1924, he became house-physician at the London Chest Hospital.

In 1926 Jeaffreson went to the Jessop Hospital for Women, Sheffield, where he worked for two years under Professor Miles Phillips and where he began in earnest his career in obstetrics and gynaecology. In 1928, while working in Birmingham as assistant to the late Sir Beckwith Whitehouse, he obtained the F.R.C.S., and in 1930 he went to Leeds as tutor in obstetrics and gynaecology, later becoming senior clinical lecturer in gynaecology in the university. He told, always with amusement, how a lay member of one of the committees which appointed him at Leeds gave voice to her thought that his travels had made him a rolling stone and that soon he would be moving on again. But he settled down to a brilliant career in Leeds, being appointed honorary assistant surgeon to the Hospital for Women in 1930 and becoming honorary surgeon to the Maternity Hospital in 1934. Jeaffreson was admitted a Member of the Royal College of Obstetricians and Gynaecologists in 1936, becoming a Fellow in 1950, and he served on the council of the College from 1942 to 1949. The work which interested him most was teaching, and indeed he was a great teacher. His lucid exposition and infinite patience endeared him to a large number of Leeds students. He himself had remarkable diagnostic powers, and he insisted on the painstaking elicitation of physical signs by his juniors. But his modesty in that, as in other respects, made the lesson on each occasion the more telling. If he will be honoured as a teacher, he will be remembered, particularly by his junior colleagues, as a kindly chief and an approachable friend.

He was a good organizer, and the success which attended the thirteenth British Congress of Obstetrics and Gynaecology, held at Leeds last year, was in no small measure due to his efforts as senior secretary. Many were looking forward to his term of office this year as president of the North of England Obstetrical and Gynaecological Society. He leaves a widow, and a son and a daughter.—A. V. G. B.

Sir T. DRUMMOND SHIELDS, M.C., M.B., Ch.B.

A. B. W. writes: "T. D." as he was known to many of us who graduated with him at Edinburgh, had something about him which drew us to him. Perhaps it was his seniority in years and his wider background of experience, but in those early days we recognized those sterling qualities of heart and mind—his humanism, his kindly sympathy and understanding, his quiet courage and patience, his intellectual endowments, and his dry humour—which he put to such good use later in the service of his profession, his country, and the Commonwealth. His concern was never for himself but for others, especially those struggling with ill-health or adversity. He was a fearless espouser of lost causes, like that of Oscar Slater, if he felt that a wrong had been committed. A devoted husband, a loving father, staunch and true to his many friends, "T. D." was indeed one of Nature's "veray parfit" gentlemen. He passes to his rest leaving the world better and nobler by his efforts.

Dr. E. G. L. GOFFE, who practised for many years in Kingston-upon-Thames, died at Ferring, in Sussex, where he had lived in retirement for only a few months, on November 28, 1952, at the age of 85. Ernest George Leopold Goffe was born in Jamaica on September 12, 1867, the son of Mr. J. B. Goffe, J.P., and received his early education at York Castle High School, Jamaica. He then came to London and entered University College as a medical student, distinguishing himself as an athlete and as a rugby footballer. He graduated M.B. in 1897, and proceeded M.D. two years later. After holding a number of house appointments at University College Hospital he became assistant medical officer and later assistant medical superintendent at Lewisham Infirmary, subsequently holding posts at other hospitals in the London area. He then settled in practice at Kingston-upon-Thames and continued his hospital association by joining the staff of the Kingston Victoria Hospital, where his charm of manner and vast store of knowledge and experience endeared him to all his colleagues. The closure of the hospital to general practitioners in 1951 greatly saddened him. Dr. Goffe gave up general practice in June last year to enjoy a well-earned retirement, a retirement which proved to be tragically short. A member of the British Medical Association for 56 years, Dr. Goffe was chairman of the Kingston-upon-Thames Division in 1924-5, and he represented his constituency at the Annual Representative Meeting on six occasions. He married Edna Mary, daughter of the Reverend E. Pierce Powell, and she survives him, together with three sons. Mrs. Goffe is herself a member of the medical profession, and one of the sons is Dr. Alan Powell Goffe, also a medical practitioner.—T. W. M.

We are greatly indebted to Dr. DAVID NABARRO for the following appreciation: I first met Leopold Goffe more than 60 years ago, when I entered University College as a medical student in October, 1890. He had a fine physique which made him very noticeable in any assembly. A friend once remarked of him that he resembled a Greek god. His infectious laugh and his good humour made him a valuable acquisition to any company. In his student days he was a great athlete, and in 1892-3 he won the Quain challenge cup for athletic sports. He also played rugby football for University College Hospital from 1892 to 1894. Goffe was a great altruist. As an undergraduate he was very interested in the University College Boys' Club Society and attended the club every week to give the boys instruction in athletic sports. In the summer he helped to take them on their annual trip on the Norfolk Broads. He was also the honorary treasurer of the society. Further examples of his altruism in setting up and managing trusts for the sons of deceased colleagues will be well remembered by some of his friends. Goffe took the London M.D. in 1899, and at the presentation for degrees in May, 1900, at which the Prince of Wales—afterwards King Edward VII—distributed the prizes, I well remember the applause which greeted Goffe when he ascended the platform, a striking figure in scarlet and purple gown, to receive his degree from His Royal Highness. He was a most lovable man, and his patients must be considered fortunate to have had so good a doctor and so sympathetic a friend as their medical adviser. It was remarkable how he retained his interest in medicine to the end. Each year he attended the course for old students at University College Hospital, and 1952 was no exception. For several years we sat beside one another at the annual dinner, and it was only a few weeks ago that we sat alongside for the last time. And now this great man has gone to his rest, but his personality will endure. Our sympathy is extended to his widow and three sons in their bereavement, but theirs is the satisfaction of knowing that Leopold Goffe's name will live for many years in the affection of his multitude of patients and friends.

Dr. HILARY LEDGERWOOD, who died in London on December 6, was born on December 7, 1890, and was educated at Queen's University, Belfast, where she graduated M.B., B.Ch. in 1921. After holding a house appoint-

Universities and Colleges

UNIVERSITY OF LONDON

The following candidates have been approved at the examinations indicated:

M.D.—*Branch I (Medicine)*: P. J. Banks, A. F. Barnett, H. Barrie, B. Bass, Mary Bateman, S. I. Cohen, Phyllis M. E. Cook, Betty B. Dyer, F. R. Ellis, D. G. Evans, D. M. D. Evans, D. D. Felix Davies, I. T. Gabe, P. J. D. Heaf, Cherry D. Heath, B. W. Jaslowitz, R. P. V. Jayewardene, A. M. Johnson, J. C. Leonard, W. E. Medd, L. P. A. Newborne, C. P. Newcombe, B. E. C. Nordin, M. A. Pears, Betty E. Powe, S. J. G. Semple, R. G. Shorter, K. A. Sowden, C. J. Stevenson, F. Taylor, W. B. Thomson, Brenda D. Van Leuven, B. W. Webb. *Branch II (Pathology)*: A. Bernstein, J. L. Brennan, Patricia C. Brown, L. H. Collier, H. R. Colquitt, J. C. Crook, Phyllis Dagnall, D. Marrack, D. J. O'Brien, F. R. Philips, K. A. Porter, J. I. Pugh, M. V. Salmon, W. J. L. Sladen, C. S. Treip, S. P. B. Way, W. J. Williams, A. L. Woolf, E. A. Wright. *Branch III (Psychological Medicine)*: A. A. Cashmore, J. Denham, A. Folkson, W. P. Gurassa, J. Merry, D. J. Parr (Mark of Distinction, University Medal), H. P. Tarnesby, D. L. C. Thomas, G. C. Turle. *Branch IV (Midwifery and Diseases of Women)*: J. C. Brace, S. Burke, F. Denny, J. Elstob, G. W. Garland, D. W. S. Gordon, J. M. Holmes, R. Moolan-Feroze, Elsie M. Sibthorpe, N. G. G. Talbot. *Branch V (Hygiene)*: J. D. B. Andrews, J. R. Mayers, Anita J. Thomas. *Branch VI (Tropical Medicine)*: J. C. L. Adams, P. B. Adamson, A. C. S. Hobson.

The following candidates at the London School of Hygiene and Tropical Medicine have been approved at the examination indicated:

ACADEMIC POSTGRADUATE CERTIFICATE IN PUBLIC HEALTH.—I. Ash, Dorothy J. Ball, S. Bano, Mary M. M. Boyd, D. E. Boye-Johnson, R. Bradley, J. H. Brodie, P. P. M. Browne, Gwen S. Clark, J. Clearkin, C. Eid, A. J. Essex-Cater, R. S. Gibson, L. P. Harington, I. K. Hay, G. B. Hopkins, I. A. Hussein, Dorothy D. Jones, F. R. S. Kellett, A. J. I. Kelyack, S. Khuri-Otaqui, J. H. Lewis, K. H. Lim, B. Mahadevan, Mavis H. Mortimer, H. Mowchenson, A. Natarajan, F. G. Neild, B. Nicholson, W. L. Palmer, G. A. Real Jimenez, E. P. Rigby, W. F. Ross, M. C. Sanyal, J. H. Taylor, M. Tha Tun, D. E. Thompson, A. M. Thomson, D. R. Thomson, G. F. Willson, A. B. Wittek, C. H. Wood, A. Zahra, A. A. Zaki.

Dr. Mary F. Lockett has been recognized as a teacher of physiology and pharmacology in the University at the Chelsea Polytechnic. (Corrected announcement.)

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on January 8, with Sir Cecil Wakeley, President, in the chair, the Cecil Joll Prize for 1953 was awarded to Mr. Geoffrey Keynes. A Laming Evans Research Fellowship was awarded to Dr. Angus McPherson for his research into the blood-flow changes in the limbs in poliomyelitis. A Hunterian Professorship was awarded to Professor H. R. Dew for a lecture to be delivered during his visit as Sir Arthur Sims Commonwealth Travelling Professor in 1953. Erasmus Wilson Demonstratorships were awarded to Mr. V. E. Negus, Sir Frank Colyer, and Dr. B. E. Heard, and an Arnott Demonstratorship to Mr. L. E. C. Norbury.

The following were elected to the Fellowship of the Faculty of Anaesthetists: Dr. J. G. Bourne (Salisbury), Dr. H. G. Epstein (Oxford), Professor Fernando Hudon (Quebec), Dr. J. V. Mitchell (Oxford), Dr. G. Jackson-Rees (Liverpool), Dr. Arnold Robertson (Brisbane), Dr. A. Slater (New Zealand), Dr. B. N. Sircar (Bombay).

Diplomas of Membership were granted to A. G. N. Calder (Middlesex), K. G. Lupprian (St. Thomas's), and N. E. Pitts (Sheffield).

Diplomas were awarded, jointly with the Royal College of Physicians of London, as follows:

DIPLOMA IN ANAESTHETICS.—D. E. Argent, A. Banerjee, D. W. Barron, M. McC. Burrows, K. B. Chambers, C. C. D. Chandler, H. S. Cohen, E. A. Cooper, J. S. Crawford, D. W. J. Cullingford, L. D. Davidson, B. H. Egerton, S. Galloen, Rosalinde J. Harrison, Pamela M. Hellings, Frances S. Huxley, E. G. A. Jackson, J. W. Latham, R. A. L. Leatherdale, S. McKechnie, A. V. McVey, A. H. B. Masson, R. A. Millar, A. C. Milne, P. R. H. Molesworth, Ruth Molphy, E. J. O'Mullane, Doreen B. Pallot, J. Parkhouse,

C. Pearce, D. J. Pearce, S. Ponnambalam, L. T. Rees, P. W. H. Robinson, F. M. Sandford, P. H. Simmons, W. D. Turner, D. C. White.

DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.—T. L. Bradbeer, D. C. J. Carter, G. O. Clark, D. A. Clements, J. B. David, J. W. T. Dixon, A. K. Ghosh, H. V. Jones, K. V. Krishnamurthy, J. Lapper, J. Littlejohn, A. Majali, J. S. Martin, H. W. H. Shepherd, D. W. Stuart, J. K. Suryodayam.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—R. H. Boardman, K. N. Kothaneth, T. R. Malloy, T. L. Pilkington, J. W. Warboys.

DIPLOMA IN TROPICAL MEDICINE AND HYGIENE.—H. Barakat, M. S. Boparai, T. Mirza.

DIPLOMA IN PATHOLOGY.—J. N. Dearnaley, J. S. Elwood, M. M. Friedman, E. M. Stirk, Jean E. D. Taylor.

DIPLOMA IN CHILD HEALTH.—A. Banerjee.

Hospitals were recognized under paragraph 23 of the F.R.C.S. regulations as follows: Royal Hospital, Wolverhampton, *Paragraph 23c*, senior registrar (senior house officer); house officer. Doncaster Royal Infirmary, *Paragraph 23c*, ear, nose, and throat house-surgeon (senior house officer). Barnet General Hospital, two house-surgeons (general surgery); house-surgeon (orthopaedics), all for six months. Haywards Hospital, Bishop's Stortford, senior house officer (surgical) for six months. Royal Surrey County Hospital, Guildford, *Paragraph 23b*, ophthalmological and neurological senior house officer. Harrogate and District General Hospital, *decennial revision*, registrar, general surgery; registrar, orthopaedics; two house-surgeons, all for six months. Croydon General Hospital, principal surgical officer (or senior surgical registrar); surgical registrar, both for one year. St. Bartholomew's Hospital, Rochester, casualty house-surgeon (January 1, 1954). Gravesend and North Kent Hospital, casualty officer (January 1, 1954). St. Mary's Hospital, Portsmouth, *extension of temporary recognition until January 1, 1954*, senior surgical registrar; surgical registrar, each for 12 months; house-surgeon (general surgery and orthopaedics); house-surgeon (general surgery), each for six months. Clare Hall Hospital, Barnet, registrar (surgical); senior house officer (surgical), each for six months. Southport General Infirmary, *revision*, registrar (in place of senior registrar); two house-surgeons for six months (until January 1, 1954). Queen Elizabeth Hospital, Gateshead, house officer; surgical registrar, both for six months. Sunderland General Hospital, *additional recognition*, first house-surgeon for six months. Ryhope General Hospital, Sunderland, first house-surgeon; senior house-surgeon, both for six months. Mayo Hospital, Lahore, three registrars and six house-surgeons for six months (for one year). Central Middlesex Hospital, *decennial revision*, two registrars (general and neurology); one registrar (general and urology); one registrar (general and orthopaedics), all for one year; three house-surgeons (general and neurology); two house-surgeons (general and urology); one house-surgeon (orthopaedics), all for six months. *Casualty posts*, two senior house-surgeons, casualty, from January 1, 1954. Doncaster Royal Infirmary, *Paragraph 23b*, ophthalmic house-surgeon. Royal Homoeopathic Hospital, London, *decennial revision*, house-surgeon (general) for six months. St. Martin's Hospital, Bath, *additional recognition*, orthopaedic house-surgeon for six months. Cheltenham General Hospital, *decennial revision*, resident surgical officer, two house-surgeons, all for six months. King Edward VII Hospital, Windsor, *decennial revision*, surgical registrar for one year; first, second, and third house-surgeons for six months. *Casualty posts*, casualty officer (senior house officer), from January 1, 1954.

Vital Statistics

Infectious Diseases

A large rise occurred in the incidence of infectious diseases in England and Wales during the week ending January 3. The numbers of notifications always rise in the week after Christmas, compensating for the fall recorded in the preceding week, but the rise recorded this year is larger than usual. The increase included 16,308 for measles, from 14,189 to 30,497, 1,048 for whooping-cough, from 1,117 to 2,165, 597 for acute pneumonia, from 826 to 1,423, 358 for scarlet fever, from 1,358 to 1,716, and 78 for dysentery, from 184 to 262.

The rise in the incidence of measles was mainly concentrated in and around London. The largest increases were

London 1,709, from 996 to 2,705, Middlesex 1,723, from 784 to 2,507, Essex 1,347, from 1,415 to 2,762, and Kent 1,282, from 771 to 2,053. The largest rises in the number of notifications of whooping-cough were 137 in Essex, from 41 to 178, and 106 in Middlesex, from 31 to 137. The only large rises in the incidence of scarlet fever were Lancashire 60, from 170 to 230, and Essex 41, from 85 to 126. 25 cases of diphtheria were notified, one fewer than in the preceding week.

No case of paratyphoid fever and only 1 case of typhoid fever were notified during the week. This is the lowest level of the enteric fevers for almost three years.

During the week 37 cases of acute poliomyelitis were notified. These were 3 fewer for paralytic and 7 more for non-paralytic cases than in the preceding week. The largest returns were Sussex 5 (Chichester R.D. 3), Berkshire 3, Nottinghamshire 3, and Derbyshire 3.

The largest centres of infection for dysentery were Lincolnshire 53 (Grimsby C.B. 47), Lancashire 39 (Liverpool C.B. 19), Surrey 36 (Carshalton U.D. 32), London 26, and Warwickshire 14.

England and Wales in 1952

The chief feature of the returns of infectious diseases during 1952 was the absence of an outbreak of influenza in the spring. In the first 13 weeks only 485 deaths were recorded in the great towns from this disease, compared with 7,859 in the first quarter of 1951. The incidence of with 7,859 in the first quarter of 1952, but the rate of diphtheria continued to fall during 1952, but the rate of decline was slower. The notifications of diphtheria in 1952 were only 2.9% of the notifications in 1941. The total notifications of acute poliomyelitis were 46% above the half of 1951. The notifications of dysentery were about half of 1951, but the incidence remained high. The total of 1951, but the incidence was mainly due to the high level of the enteric fevers was mainly due to the persistent outbreak in South Wales during the third quarter. A comparison of the notifications with those of the four preceding years is given below:

	1948	1949	1950	1951	1952
Scarlet fever	75,460	71,753	66,852	49,431	69,091
Whooping-cough	145,878	102,516	157,714	169,394	116,311
Diphtheria	7,903	4,929	2,858	1,969	1,473
Measles	396,841	384,361	366,116	615,332	400,838
Acute pneumonia	31,096	34,624	30,714	43,181	31,403
Meningococcal infections	1,971	1,586	1,745	1,956	1,687
Acute poliomyelitis	2,175	6,850	8,699	3,093	4,504
Dysentery	5,587	4,819	18,135	29,488	15,665
Typhoid and paratyphoid fevers	873	1,138	654	1,438	1,190
Deaths from influenza in the great towns	?	?	2,052	8,338	1,019

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1943-51 are shown thus ————, the figures for 1952 thus ————. Except for the curves showing notifications in 1952, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

DEATHS in Great Towns	1952					1951				
	Eng. & Wales	Lond.	Scot.	N. Ire.	Eire	Eng. & Wales	Lond.	Scot.	N. Ire.	Eire

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
§ Includes puerperal pyrexia.

Nuffield Lodge.—The removal of the headquarters of the Nuffield Foundation, the Nuffield Provincial Hospitals Trust, and the National Corporation for the Care of Old People to Grove House, Regent's Park, London, N.W.1, takes place on January 24 (see *British Medical Journal*, September 6, 1952, p. 571). Grove House, which is the large mansion opposite St. John's Wood Church, has been renamed Nuffield Lodge with the consent of the Commissioners of Crown Lands. The telephone number is Primrose 8871-5. The address of the Trust's Investigation into the Function and Design of Hospitals will be 33, Doughty Street, London, W.C.1 (Terminus 5288).

Sir Allen Daley, medical officer of health to the London County Council from 1939 to 1952, has gone to Australia for an eight-weeks tour of the State health services. The Nuffield Foundation is sponsoring the tour. Sir Allen will lecture to medical audiences and advise on public health problems. He is due to arrive at Melbourne on February 6.

Emergency Bed Service: Applications and Admissions.—During the seven days ending January 19 the number of applications made by doctors to the London Emergency Bed Service for admission of patients was 1,700, of whom 83.97% were admitted. A white warning, indicating that the percentage of admissions fell below 85, was issued on January 6.

COMING EVENTS

The British Council for Rehabilitation has arranged a one-day conference on "Speeding recovery through the closer co-operation of hospitals and industry," which will be held at the Royal College of Nursing, Henrietta Place, London, W.1, on February 4. The conference is intended for industrial medical officers and nurses. The fee is 15s., and bookings should be made in advance with the general secretary, British Council for Rehabilitation, Tavistock House (South), Tavistock Square, London, W.C.1.

Oxford Graduates Medical Club.—Sir Rudolph Peters, F.R.S., will take the chair at the winter dinner of the Oxford Graduates Medical Club at the Royal College of Surgeons on January 30 at 7 p.m. Tickets (price 30s.) may be obtained from Mr. Selwyn Taylor, 3, Roedean Crescent, Roehampton, S.W.15.

The Psychology of Eating.—The Scottish Group of the Nutrition Society will hold a conference on "The Psychology of Eating" in the Anatomy Lecture Theatre, Marischal College, Aberdeen, on January 31 at 1.20 p.m. Professor Rex Knight will be in the chair, and other speakers will include Professor W. M. Millar, Professor C. F. W. Illingworth, Dr. C. F. Rolland, Dr. J. M. Walker, and Dr. C. G. Kennedy.

SOCIETIES AND LECTURES

Details in this column are necessarily brief. Further information and tickets where required (marked ●) should be obtained from the institution concerned.

Monday, January 26

INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: Lecture-demonstration for postgraduates.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., discussion to be introduced by Mr. W. J. Dempster, Mr. B. W. Rycroft, and Mr. A. L. Schofield: Present Status and Future Prospects of Homologous Tissue Transplantation.

Tuesday, January 27

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Sir Frederic Bartlett, F.R.S.: Nature and Place of Thinking in Medicine.

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. Wade: Treatment of the Epithelioma.

LONDON UNIVERSITY.—At London Hospital Medical College, 5.30 p.m., Professor A. Claude (Brussels): Technical Aspects of Cell Research.

WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Mr. J. Minton: Ocular Manifestations in Nervous Disease: Part II.

Wednesday, January 28

CAMBRIDGE MEDICAL SOCIETY.—At Addenbrooke's Hospital, 8.15 p.m., A.G.M. Professor J. Dixon Boyd: "Pigment Cells" in Man.

EDINBURGH CLINICAL CLUB.—4 p.m., visit to Experimental Practice Dispensary, Richmond Street.

●ILLUMINATING ENGINEERING SOCIETY.—At Royal Institution, 6 p.m., Second Trotter-Paterson Memorial Lecture by Dr. E. D. Adrian, O.M., F.R.S.: Nervous Reactions of the Retina.

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Precancerous Conditions of the Skin.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, W.C., 4.30 p.m., Dr. R. Thomson: Laboratory Aids to Diagnosis.

RENAL ASSOCIATION.—At 41, Portland Place, W., 4 for 4.30 p.m., Mr. A. W. Wilkinson: Biochemical Changes after Transplantation of the Ureters; Mr. D. Innes Williams: Long-term Results of Transplantation of the Ureters for Ectopia Vesicae.

ROYAL EYE HOSPITAL CLINICAL SOCIETY.—At Royal College of Surgeons of England, 8 p.m., demonstration of work of Ophthalmological Research Unit, Royal Eye Hospital, and Royal College of Surgeons of England.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Finlayson Memorial Lecture by Professor E. J. Wayne: The Heart in Endocrine Disease.

SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP—NUTRITION PANEL.—At Burlington House, W., 6.15 p.m., Dr. G. A. C. Herklots and Professor J. Yudkin: Food and the Future—Present Methods of Attack on the Problem.

Thursday, January 29

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Sir Alexander Fleming, F.R.S.: Recent Progress in Antibiotics.

EDINBURGH UNIVERSITY.—At University New Buildings, 5 p.m., Professor Jean Fiolle (Aix-Marseille): Diagnosis and Treatment of Embolisms of Arteries of the Limbs.

EPSOM AND SUTTON INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At St. Ebbas's Hospital, 6 p.m., clinical meeting. Dr. H. H. Robinson: Combined Insulin Coma and E.C.T. Treatment; Dr. D. E. Sands: Some Observations on 200 Patients Treated by Leucotomy with the Use of Three Forms of Operation.

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—At Glasgow University Union, 7.30 p.m., Mr. A. W. Kay: Ulcer Problem: The Quest for Achlorhydria.

●INSTITUTE OF CHILD HEALTH.—5 p.m., Mr. H. S. Sharp: Upper Respiratory Tract Disorders.

LONDON UNIVERSITY.—At London Hospital Medical College, 5.30 p.m., Professor A. Claude (Brussels): Morphological and Biochemical Aspects of Cell Structure and Function.

OXFORD UNIVERSITY.—5 p.m., Dr. G. W. Corner (Washington): Anatomical Illustration and the Fine Arts.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Sir Geoffrey S. Todd: Modern Methods in the Treatment of Pulmonary Tuberculosis.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor J. M. Mackintosh: Medical Care To-morrow.

Friday, January 30

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. G. B. Mitchell-Heggs: Acne Vulgaris, Acne Excoriata, and Dermatitis Attracta.

ROYAL INSTITUTE OF PHILOSOPHY.—At University Hall, 14, Gordon Square, W.C., 5.15 p.m., Mr. D. A. Rees, M.A.: Greek Views of Nature and Mind.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Dr. K. W. Miller: Allergy. UNIVERSITY COLLEGE.—At Physiology Theatre, 5.30 p.m., Professor F. Bergel: Some Chemical Aspects of Normal Growth.

APPOINTMENTS

EYTON-JONES, JACK, M.B., Ch.B., D.Obst.R.C.O.G., Obstetrical and Gynaecological Registrar, Scarsdale Hospital, Chesterfield, Derbyshire.

HAMMOND, GEOFFREY T., M.D., M.R.C.O.G., Consultant Obstetrician and Gynaecologist to Winchester Group of Hospitals.

NOTTINGHAM, CITY OP.—Elspeth M. Warwick, M.B., Ch.B., D.P.H., Deputy Medical Officer of Health; Patricia H. S. Shaw, M.D., D.P.H., Senior Medical Officer.

O'RIORDAN, J. P., M.B., B.Ch., D.P.H., D.C.H., Lieutenant-Colonel, I.M.S.(ret.), Port and Airport Medical Officer, Dublin.

RICE-OWLEY, J. M., D.M., M.R.C.P., Consultant Physician to the Chesterfield Royal Hospital and hospitals at Worksop and Retford.

ST. HILL, CHARLES A., M.B., Ch.B., Home Office Pathologist (Liverpool Region), attached to Forensic Science Department, Preston.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—A. E. Fyfe, M.B., B.S., Registrar in Obstetrics and Gynaecology, Southmead Hospital, Bristol; Z. L. Szur, M.B., B.Ch., D.M.R.D., D.M.R., Assistant Radiotherapist, Exeter Clinical Area; J. B. Gordon-Russell, M.B., Ch.B., M.R.C.P., D.P.M., Consultant Psychiatrist to South Somerset Clinical Area; R. J. Hart, M.B., B.S., Orthopaedic Registrar in North Gloucestershire Clinical Area.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Lewis.—On January 11, 1953, at The Maltings, Boars Hill, Oxford, to Dr. Evelyn, wife of Dr. Charles Lewis, a sister for Alexandra—Joanna Augusta.

DEATHS

Atkinson.—On January 14, 1953, Wilfred Percy Tindal Atkinson, M.R.C.S., L.R.C.P., of Old Manse, Fair Green, Sawbridge, Herts, aged 68.

Browne.—On January 13, 1953, at the Bristol Royal Infirmary, Frederick William Browne, M.B., B.Ch., of Penhill, Shirehampton, Bristol.

Cooper.—On January 15, 1953, at Packhorse Cottage, Bessels Green, Sevenoaks, Kent, John Gerald Cooper, M.B., B.Ch., aged 78.

Cuthbert.—On January 17, 1953, at Dundee, James Arthur Cuthbert, M.B., Ch.B., D.P.H., of 247, Strathmartine Road, Dundee.

Elsner.—On January 12, 1953, at Desmesne House, Heighington, Darlington, Co. Durham, Otto William Alexander Elsner, C.B.E., D.S.O., L.R.C.P.&S.I. & L.M., D.P.H., Colonel, R.A.M.C., retired, aged 81.

Fowler.—On January 14, 1953, Henry Fowler, L.R.C.P.&S.Ed., L.R.F.P.S., of 160, Chislehurst Road, Orpington, Kent.

Grant.—On January 14, 1953, at his home, Hazel Coppice, West Mersea, Essex, Alexander Smeaton Grant, M.R.C.S., L.R.C.P., aged 83.

Hayman.—On January 9, 1953, at his home, Royden House, Sharnbrook, Beds, Frank Keith Hayman, M.B., F.R.C.S., formerly of Great Yarmouth, Norfolk, aged 59.

Lee.—On January 7, 1953, at his home, 7, Upper Maze Hill, St. Leonards-on-Sea, Sussex, James Carrel Lee, M.D., C.M., J.P.

McGregor.—On January 12, 1953, at the Princess Royal Hospital, Halifax, Yorks, Robert McGregor, L.R.C.P.&S.Ed., L.R.F.P.S., of Moor View, Walsden, Todmorden, Yorks.

March.—On January 14, 1953, Charles March, M.B., Ch.B., of The Little House, Gerrards Cross, Bucks, aged 40.

Martin.—On January 6, 1953, at Hampstead, London, N.W., Alfred John Martin, O.B.E., M.R.C.S., L.R.C.P., D.P.M., of Norgrove, The Bishops Avenue, London, N., aged 43.

Mosse.—On January 7, 1953, Cotton Grimley Tenison Mosse, M.R.C.S., L.R.C.P., of Southminster, Essex.

Robertson.—On January 6, 1953, at Banbury, Oxon, James Fenwick Robertson, M.R.C.S., L.R.C.P., aged 76.

Scott.—On December 8, 1952, at the National Hospital for Nervous Diseases, Queen Square, London, W.C., Philip Dennis Scott, M.B., B.S., of Clifton Hill, London, N.W., aged 61.

Wilson.—On January 14, 1953, at her home, Roseneath, Fairmount Road, Cheltenham, Glos, Sarah Wilson (formerly Kaye), M.B., aged 85.

Williamson.—On January 18, 1953, at 11, Chaffer's Mead, Ashted, Surrey, John Rutter Williamson, M.D., aged 81.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Malaria Prophylaxis during Pregnancy

Q.—What is the best malaria suppressive to use during pregnancy?

A.—Chloroquine is probably the best suppressive for all forms of malaria during pregnancy. Proguanil and mepacrine are likely to be equally active against the parasites, but in the former case there is the possibility of having to deal with a proguanil-resistant strain of falciparum malaria, and in the latter the skin is stained yellow. If falciparum infection is suspected a full therapeutic course of chloroquine, mepacrine, or proguanil should be given before starting on the suppressive regime. None of these drugs is likely to affect the pregnancy. Quinine should be avoided because it is less efficient than the other drugs; in the dosage used for therapy or suppression it is not likely to affect the pregnancy.

Ellis Classification of Nephritis

Q.—Is the Ellis classification of nephritis now universally accepted or is one still justified in using the old acute, sub-acute, chronic, etc.? Could you give me a résumé of the Ellis classification, including percentage of recovery or ultimate fate in each group? What is Ellis's view on "nephrosis," and is his view generally accepted?

A.—The Ellis classification of nephritis has been widely accepted both in this country and abroad. It is more popular, on the whole, with clinicians than with pathologists. Reference to current textbooks shows that many pathologists still make use of the time-honoured terms: acute haemorrhagic glomerulo-nephritis, subacute and chronic nephritis, and so forth. This is due not to a reactionary bias on their part but to a certain scepticism arising from the frequent difficulty in reconciling the histological appearances with the clinical diagnosis of Ellis's Types I and II. In particular they observe, from time to time, that a nephritis may appear to start as Type I but proceed later to the clinical manifestations of Type II with retention of the glomerular features of Type I; there are many transition forms, histologically, between the two.

Ellis described his classification in his Croonian lectures on "The Natural History of Bright's Disease," which he gave in 1941. Type I nephritis mostly affects young subjects and corresponds to the "acute haemorrhagic nephritis" of older classifications. It is generally reckoned that from 80-85% recover completely; of the remainder a few die in the acute stage or the rapid progression of this to a "subacute stage." The remainder do not clear up completely but enter a latent stage, which may last for several decades, ending with contracted kidneys, secondary hypertension, and uraemia. Type II nephritis occurs over a wider age range, is of insidious onset, and characterized by the "nephrotic syndrome." The disease is steadily progressive, and recovery is rare. If death does not occur at an early stage from secondary infection the condition may progress, over months or years, to a stage of renal failure with secondary hypertension. If of renal failure with secondary hypertension "lipoid nephrosis" is taken to signify the "lipoid nephrosis" of Munk, Volhard, and Fahr and others this would be included in Type II nephritis, but other forms of nephrosis such as the amyloid and mercurial forms are included in Ellis's "miscellaneous conditions." Apart from Type I

and Type II nephritis Ellis also recognized a hypertensive group, in which "essential hypertension" is subdivided into "benign" and "malignant" groups. One does not speak of recovery in these, but the prognosis differs widely. In the malignant form the course is usually rapid, with death in less than two years; the benign is compatible with a normal life over many years, especially in women.

Slow Convalescence after Virus Infections

Q.—To what is attributed the slow rate of recovery to full vigour from virus infections, such as pneumonia treated with chloramphenicol or similar antibiotics? What is the prognosis and treatment of protracted insomnia with which this prolonged convalescence is sometimes associated?

A.—The rapid response of the toxæmia in virus infections of the lung following therapy with the new antibiotics makes it important to realize that return to normal vigour depends upon structural recovery of the affected part, a process which takes some weeks. The patient has had a severe illness, and convalescence should never be cut short however dramatic the initial response seems to be.

Protracted insomnia following these illnesses is part of a general state of depression, which is especially common after infection with the influenza virus. It is best treated by giving a mixture of amylobarbitone 1 gr. (65 mg.) and amphetamine sulphate 5 mg. in the morning and at mid-day, and an adequate dose of barbiturate at night. Quinalbarbitone 1½ gr. (0.1 g.) with amylobarbitone 3 gr. (0.2 g.) is generally suitable. The condition clears up as a rule within a few weeks.

Anaesthesia for Cataract Operations

Q.—What is the best general anaesthetic for cataract operations?

A.—It is difficult to lay down hard-and-fast rules about any anaesthetic—the choice depends so much on the patient, and the result on the skill of the anaesthetist. As post-operative vomiting, and straining and coughing, must be avoided the operation is usually performed under local analgesia; but general anaesthesia can be wholly satisfactory. For an "average" patient, 0.5 g. thiopentone and 40 mg. gallamine triethiodide can be given; the pharynx, epiglottis, and larynx are sprayed with 3 ml. of 4% cocaine by a Macintosh spray; a pharyngeal airway is inserted and nitrous-oxide-oxygen is given. The anaesthesia may be reinforced with a small quantity of trichlorethylene or intermittent doses of thiopentone, but if the customary local analgesic is given after the patient is asleep the depth of narcosis need not be deep.

Anosmia and Cacosmia

Q.—What are the likely causes of loss of the sense of smell gradually following its perversion? This has occurred in an elderly man who has always been troubled with nasal catarrh. Now he cannot smell creosote or bonfires; formerly he thought he could smell fat frying and burning pastry when there was none. What investigations and treatment are advised?

A.—Anosmia and cacosmia are usually the result of some local disturbance of the olfactory area of the nose itself. The commonest cause of anosmia is inability of the vapourized substances to reach the olfactory cells in the lining of the upper third of the mucous membrane lining the nasal cavity. It is usually a temporary accompaniment to the common cold and fortunately lasts only a few days. Sometimes it follows a very severe upper respiratory infection of the influenza type. Anosmia also occurs in cases where the nose is full of polypi. Some patients with allergic rhinitis, where there is much swelling of the mucosa, may also be unable to smell.

Cacosmia, or an abnormal olfactory sensation, is fortunately unusual. It may follow an upper respiratory infection or may appear for no reason at all. A few cases have been recorded in which it has followed the use of tyrothricin locally. An olfactory aura is not uncommon in epilepsy. Very occasionally tumours involving the olfactory tracts in the brain may give rise to abnormal olfaction or to loss of the sense of smell. In the case in question a full nasal and neurological examination is recommended. Apart from dealing with any disease in the nose no other form of local treatment is advised.

Risk of Transmitting Trichomonal Infections to Children

Q.—A girl of 18, who is being treated for a *Trichomonas vaginalis* infection with a heavy purulent discharge, is in charge of a baby girl aged 1 year. Is the child likely to become similarly infected, and, if so, what precautions should be taken?

A.—There is a good deal of evidence to show that trichomonal infection is transferred from one individual to another, but the exact mode of transfer is in most cases unknown. Newly born babies of infected mothers occasionally have *Trichomonas* in the vagina (R. E. Russell *et al.*, *Amer. J. Obstet. Gynec.*, 1942, 44, 292), and trichomonal vaginitis does occur in infancy and childhood. Nevertheless, considering how widespread is trichomonal vaginitis in adults, there are remarkably few cases of this infection in infancy. Even when groups of cases of vulvovaginitis in infancy are analysed, trichomonal vaginitis is a rare cause. Thus, although there is a risk of transfer of infection in a case such as the one described it must be extremely small.

As regards precautions, the first essential is to institute treatment for the nursemaid. The risk should also be explained to her, and she should be given strict instructions about always washing her hands thoroughly before handling the child, its clothing, and its napkins. The nurse's bedding, underclothes, and bath-towels should be kept separate, even during laundering, and she should not use the same bath as the baby—even though it is scrubbed out after use.

Disturbed Menstruation after Parturition

Q.—Since the use of oestrogens to inhibit lactation a multipara of 30 has had irregular periods. There have been two peculiarities; a period has started the day following intercourse on each of the only three occasions since the birth when it has been practised, and the periods have been associated with breast engorgement and the secretion of milk. What is the explanation of these associations?

A.—Assuming that oestrogens were given only for the usual period of four to eight days and have long been discontinued, their use can be dismissed as having no bearing on the present symptoms. The data imply that the confinement occurred only a few months ago, and it is common enough to see some disturbance when menstruation is resumed—especially if the woman does not breast-feed the baby. Absence of lactation tends to delay involution and to result in a return of menstruation at a time when the uterus is still large and vascular. Extreme congestion of the uterus could result in bleeding after coitus, although the relationship of coitus to menstruation in this case might be coincidental.

Some enlargement and tenderness of the breasts is also common at the time of menstruation, and especially premenstrually. It takes months and sometimes years before secretion disappears entirely from the breasts after pregnancy, and it is likely to be more noticeable at the time of premenstrual engorgement.

The clinical features of this case do not suggest anything which could not be regarded as a minor functional disturbance which is frequently seen after pregnancy—and especially

ally if breast-feeding is avoided. They should settle of their own accord within a few months; if they do not, further investigation will be required.

Medical Hazards of Sand-pits

Q.—What are the medical hazards of children's sand-pits in public parks? How seriously should such hazards be taken, and what preventive measures are worth while?

A.—The medical hazards of children's sand-pits are that infections may be spread from pollution of the sand, and that the sand itself may cause injury to the eyes through being blown or thrown about.

Pollution would occur from excretion either by the children themselves or by dogs and cats. The risk of infection being spread from child carriers is very small indeed. The diseases most likely to be involved are the enteric fevers and dysentery. In the former, young children are very rarely found to be carriers, and in the latter a child carrier would almost certainly be a clinical case and would therefore be unlikely to be playing in a sand-pit. Other infections which might be spread through children playing in sand-pits would be due more to the circumstances of their aggregation than to the conditions of the sand-pit itself.

The hazard, though small, should not be neglected. The sand-pit should be adequately fenced and animals rigorously excluded. There should be sanitary accommodation close at hand. The sand should be raked daily to remove surface debris and turned regularly in order to bring moist sand to the surface and to disperse sand that has been polluted. In hot dry weather the sand should be sprayed to reduce the risk of eye injury. Treatment with rock salt has been employed to increase the cohesion of the sand. It is inadvisable to have trees overhanging the sand-pit, as they are likely to reduce the bactericidal action of sunlight, while the fallen leaves tend to produce a compost. Finally, whenever the sand shows signs of becoming dirty it should be removed.

Alcohol and Barbiturates

Q.—In cases of "drunk in charge" the accused sometimes says that he has taken barbiturates as well as alcohol. Do alcohol and barbiturates potentiate each other?

A.—Barbiturates and alcohol are both cerebral depressants. Consequently the effect of one will certainly be potentiated by a dose of the other. Whether they are pharmacologically synergistic to one another is more controversial. This question is discussed by Dille and Ahlquist¹ and by Ramsey and Haag.²

SUBDURAL EFFUSIONS IN INFANCY: 24 CASES

BY

A. N. GUTHKELCH, M.Ch., F.R.C.S.

(From the Royal Manchester Children's Hospital and the Department of Child Health, Manchester University)

Subdural effusions in infancy have received little attention from British writers. Brief communications have been made by Northfield (1939, 1 case), Hinden (1939, 1 case), and Gimson (1945, 3 cases); while Wolfe (1948) has reported two cases of subdural haematoma treated successfully by operation, and Fine and Herson (1951) a fatal case. While this paper was in preparation Everley Jones (1952) recorded six cases of subdural effusions complicating purulent meningitis.

It should be emphasized that infantile subdural effusion is not a rare condition. Study of the records of the Royal Manchester Children's Hospital for the four years covered by this series shows that, of all surgical conditions of the central nervous system occurring in the first two years of life, only spina bifida and hydrocephalus were seen more often than subdural haematoma. Tumours and abscesses of the central nervous system in infants were much less common. Similarly, Smith and her co-workers (1951) have reported finding subdural effusions in almost a half of their cases of bacterial meningitis in infancy, and Everley Jones's (1952) figures are similar. To paraphrase Ingraham and Heyl (1939), the frequency with which these effusions are found is proportional to the intensity with which they are sought.

The series here reported comprises 24 cases—18 cases of subdural haematoma in infancy; 5 cases complicating purulent meningitis; and 1 case of subdural effusion in a patient with sagittal sinus thrombosis. These groups are considered separately.

SUBDURAL HAEMATOMA IN INFANCY

The recognition of the importance of this condition is virtually the work of one man—Franc Ingraham, of Boston, whose classical papers with Matson (1944, 1949) record a much larger series of cases than any other writer. A further 55 cases are reported by Elvidge and Jackson (1949). Their series includes 10 cases of birth trauma treated by immediate operation and 9 cases of severe post-natal head injury, both of which groups had a very high mortality—even in the more chronic group 19.2% died. Statten (1948) reported 13 cases treated by miscellaneous methods and compared them with 15 cases treated by the regime advised by Ingraham and Matson (1944). He showed that in the former group inadequate treatment led to many deaths and to mental deficiency among the survivors; in the latter, 10 cases were normal.

Age and Sex.—Most cases occur in the first few months of life. Of the series reported here 11 developed

symptoms before the age of 3 months, five between 3 and 6 months, and only two thereafter (Table I). Ingraham and Matson (1949) found a preponderance of males over females in the ratio of 5:3. In this series the preponderance is even more striking, being 5:1.

Aetiology and Pathology

Ingraham and Matson (1949) found evidence of birth trauma in about a quarter of their cases. In the present series a comprehensive history was available in 16 cases. Eight of these sustained definite birth trauma with a history of obvious damage to the head, difficulty in resuscitation, or a bloody cerebrospinal fluid in the neonatal period. Two infants were members of twin pregnancies and two were born prematurely (at 30 and 34 weeks respectively). In a further two cases the baby had sustained a definite head injury a fortnight before the onset of symptoms, though no sign of fracture of the skull was found on x-ray examination. In only two cases was the antecedent history completely negative.

Obviously, therefore, subdural haematoma is very often associated with an abnormal or difficult labour (75% in this series). Furthermore, the fact that it most frequently presents in the first months of life also suggests that the cause is to be sought at or near the time of birth; finally, the preponderance of males might be explained on the basis that male infants have bigger heads than females, and are therefore more likely to sustain intracranial injury at birth.

There is no evidence that the haemorrhagic diseases play much part in the aetiology of the condition. Ingraham and Matson have noted that 31.5% of their cases showed some anaemia, but this is a common finding in infants who have been ill for long, whatever the cause. In the present series haemoglobin estimations were made at the beginning of treatment in 14. Nine of these infants had been ill for 14 days or less; only two of them showed some anaemia, while in seven the haemoglobin was within the normal limits for age. Of the five infants who had been ill for more than 14 days three showed a haemoglobin of less than 60%; in the other two it was 68%.

Much has been written on the pathology of subdural haematoma. The conventional theory is that the original haemorrhage occurs from a cortical vein, probably in many cases one crossing the subdural space to reach a major venous sinus. This haemorrhage clots, and the clot then liquefies and eventually becomes surrounded

cough for eight days. On examination the head circumference was as before, the fontanelle tense. His temperature was 101° F. (38.3° C.) and there was slight meningism. An immediate subdural tap yielded 8 ml. of very deeply blood-stained fluid on each side. The subdural taps were repeated daily for a further 18 days, 850 ml. of fluid being removed. The composition of this was similar in all respects, at first, to that obtained before. Later the fluid became almost clear yellow.

First Operation.—On June 13, under general anaesthesia and with a blood transfusion from the beginning, a right temporal osteoplastic flap was turned down. There was found to be a large cavity lined with a thin membrane in the subdural space extending mainly anteriorly over the frontal lobe of the brain. Most of the membrane was dissected away, the cavity filled with saline, and the wound closed. Convalescence was uneventful except for a considerable recurrence of effusion on the operated side during the next 14 days, a total of 210 ml. being aspirated.

Second Operation.—On June 27, again under general anaesthesia and with continuous blood transfusion, a left temporal osteoplastic flap was turned down. This time the haematoma was found to be mainly over the post-frontal, parietal, and temporal regions, and was easily dissected away.

The child again made a smooth recovery, and this time further aspirations of the subdural spaces were negative. He left hospital on July 20. He has since been seen at intervals of a few months in the out-patient department and is developing normally in all respects.

Case 17. Neglected Subdural Haematoma

This baby was admitted at the age of 14 months. His had been a very difficult forceps delivery, and he sustained a depressed fracture of the left side of the skull. At 4 days he had several fits (right side). At 10 weeks he had a febrile illness with screaming attacks and vomiting which lasted a week. Since then he had had repeated generalized epileptic attacks, and occasional projectile vomiting. He had not sat up or begun to play with toys.

On examination he was found to be very backward, paying no attention to sounds or to objects moved in front of him and making no effort to sit up. There was a gross depression of the left fronto-parietal region of the skull; the head circumference was normal. The pupils reacted briskly to light, the fundi were normal, and there was no obvious hemiparesis. Lumbar puncture showed 5 white blood cells per c.mm. with a normal chemistry.

First Operation.—Under general anaesthesia an exploratory burr-hole was made over the site of the depressed fracture, but nothing abnormal was found. A burr-hole over the left parietal eminence, however, revealed a rather tough subdural membrane, densely adherent to dura and brain, from which a small piece was removed for biopsy. It showed mature fibrous tissue with no evidence of calcification.

Second Operation.—A week later, under general anaesthesia, a small bone flap was turned down over the site of the biopsy. The dura was lined with a tough fibrous tissue several millimetres thick, adherent everywhere to the arachnoid. The subarachnoid space was abnormally deep, the cerebral cortex yellow and tough, with small atrophic gyri and wide sulci. In one area it contained multiple small cysts. There seemed no point in dissecting away the subdural

membrane in the presence of such severe brain atrophy, so the bone flap was replaced in the usual way.

This child has not been seen recently, but was making little progress during the few months after his operation.

Comment

Case 14 shows how with early diagnosis one can hope to achieve a rapid and smooth recovery without recourse to major surgery. If the subdural spaces can be emptied early enough no membrane is allowed to form and there need be no craniotomy.

Case 6 taught a lesson which has since been emphasized by Ingraham and Matson (1949). The majority of these haematomas extend into the temporal region and will be found by the diagnostic burr-holes already recommended. From time to time, however, a case occurs in which the clot is situated elsewhere, so that, if the suspicion of subdural haematoma is very strong but temporal exploration is negative, further burr-holes should be made in the frontal and parietal regions. The sudden "drying-up" of the subdural spaces should have suggested that there was still some effusion, but in a situation not accessible to needling through the fontanelle. The recurrence of symptoms 12 weeks after the first admission was doubtless due to the further expansion of a haematoma which had been only partially aspirated before. It is fortunate that the delay has had no permanent effect on the child's mental development.

It would be wrong to claim that Case 17 could necessarily have been saved by prompt treatment. Although there was certainly an old subdural haematoma, the atrophy and sclerosis of the underlying cortex may well have been the end-result of contusion, laceration, and vascular disturbance occurring during the actual birth trauma.

SUBDURAL EFFUSION IN PURULENT MENINGITIS

There are several different circumstances in which infection and subdural effusion can be associated. Spitz *et al.* (1945) pointed out the fundamental distinction between subdural effusion complicating purulent meningitis and a collection of pus in the subdural space complicating osteomyelitis of the skull. Schiller *et al.* (1948) noted that the latter condition might be either localized or spreading. If it were spreading they preferred to call it "purulent pachymeningitis." They also mentioned the possibility of subdural abscess occurring as a complication of cerebral abscess or through the infection of a subdural haematoma. Finally, as is reported in the next section, a subdural effusion may complicate cerebral thrombophlebitis.

The complete classification of subdural effusions associated with infection is therefore:

- | | | |
|--------------|----|--|
| A. Localized | .. | (1) With osteomyelitis of the skull.
(2) With cerebral abscess. |
| B. Spreading | .. | (1) With osteomyelitis of the skull—"purulent pachymeningitis."
(2) Due to infection of a subdural haematoma.
(3) With purulent meningitis.
(4) With cerebral thrombophlebitis. |

Of the spreading effusions, purulent pachymeningitis has a strong tendency to localize, and therefore presents a surgical problem of great difficulty. We are here concerned only with the meningitic variety, the five examples being shown in Table II.

TABLE II.—Clinical Features in Five Cases of Subdural Effusion Complicating Purulent Meningitis

Case No.	Sex	Age on Admission	Infecting Organism	Presenting Symptoms	Time from Onset of Meningitis	Site of Effusion	Craniotomy	Result
19	F	4 months	Not identified	Fits	4 weeks	L. and R.	L. and R.	Fits continued; died a year later
20	M	12 "	Streptococcus	Vomiting	1 week	"	No	Developing normally (2½ years)
21	M	8 "	Pneumococcus	Fits	3 weeks	"	L.	Behaviour disturbed (2 years)
22	F	6 "	Staph. pyogenes	"	2 "	"	No	Appears well (2 months)
23	F	12 years	Pneumococcus	Fits. Right hemiparesis	5 years	L.	L.	" " (6 ")

Incidence.—Most of these cases occur in the first year of life (McKay *et al.*, 1950; Smith *et al.*, 1951; Everley Jones, 1952), but cases may be found in adults (Spitz *et al.*, 1945). The incidence between the sexes seems to be about equal, in contrast to the marked preponderance of males in subdural haematoma.

Aetiology and Pathology

The causative organism of the initial meningitis is most commonly *Haemophilus influenzae* or a pneumococcus, but several others have been recorded. In this series two were pneumococcal, one was staphylococcal, one streptococcal; and in one no organism was isolated. The reason for the effusion is obscure. McKay *et al.* mention the possibilities of exudation or haemorrhage into the subdural space as a complication of either antibiotic therapy or of repeated lumbar puncture, or of "minimal trauma in a critically ill infant"; Smith *et al.* postulate a transudation of fluid containing cells and bacteria across the inflamed arachnoid into the subdural space, where the lysis of the cells produces a fluid of high protein content, and osmotic processes subsequently cause the effusion to enlarge until it produces symptoms. It is known that an effusion can occur without intrathecal administration of antibiotics, while the fact that it does not complicate tuberculous meningitis must surely nowadays exclude lumbar puncture as a cause. There may in fact be two separate conditions. The minimum protein content in the nine cases of McKay *et al.* was 700 mg. per 100 ml. The 20 cases of Smith *et al.*, however, showed a variation between 40 and 1,920 mg. of protein per 100 ml. In Everley Jones's series there were four cases with a protein content of 1,000 mg. or more, and two in which it lay between 150 and 250 mg. per 100 ml. In the four patients now reported in whom the estimation was made, the reading was between 1,000 and 5,000 mg. per 100 ml.

It is tempting to suggest that the lower-protein group represent cases of simple transudation across the arachnoid, while in the high-protein group some additional element exists. A suggestion about the nature of this additional factor is made below. The difference is not due simply to the age of the effusion, for a high reading was found by Everley Jones in his Case 6 on the eighth day of the illness, and a low one in his Case 4 on the sixteenth day.

Whatever the reason, it is certainly unexpected and interesting to find in the present series that the protein content of the fluid is exactly the same as it is in subdural haematoma (1–5 g., average 2 g., per 100 ml.), nor were the white cell counts very dissimilar (30–2,500, usually 400–600, per c.mm.).

Diagnosis and Treatment

It is generally agreed that a subdural effusion should be suspected, and diagnostic subdural taps made, in any infant with meningitis whose clinical progress is unsatisfactory after three days' treatment, or who has persistent fever, vomiting, convulsions, or a tense fontanelle.

The routine of daily subdural taps, exactly as advised for subdural haematoma, should be followed. After 10 days, at any rate in all but the smallest effusions, bitemporal burr-holes should be made and the subdural space inspected. Where membrane formation has occurred, craniotomy with removal of the membrane is indicated.

In Case 20 the fontanelle had closed and the diagnosis was made by exploratory burr-holes. Here membrane formation was minimal and a good result was obtained by simple tube drainage for four days.

Results

No one yet knows the long-term results in these cases. Case 23 (this patient is older than the others, but is included here because her condition was the same as that of the infants) the membrane was too adherent and wide-spread to be totally removed. Of the two cases in which a very thin membrane was present, Case 20 has been

followed for 2½ years and is developing normally, and Case 22 seems well but not enough time has elapsed for assessment. Of the two with membranes requiring craniotomy, Case 19 was always backward, suffered from fits, and died a year after operation from a further attack of meningitis. Case 21 has been followed for two years, and is a bad-tempered and intractable child.

Nevertheless, from the literature referred to previously one gets the general impression that with early diagnosis the results may approach those obtained in infantile subdural haematoma.

Case 20. Effusion without Membrane Formation

A male baby aged 12 months was transferred to the Royal Manchester Children's Hospital with a seven-day history of streptococcal meningitis complicating a left otitis media. He was pyrexial and vomited repeatedly. There was a left external rectus palsy, the head circumference was 20½ in. (51.5 cm.), and x-ray films of the skull showed gross separation of the sutures. There were no localizing neurological signs. The lumbar cerebrospinal fluid contained 110 mg. of protein per 100 ml. and 33 cells per c.mm. Bitemporal burr-holes made under general anaesthesia revealed large collections of turbid yellow subdural fluid. This contained 3.75 g. of protein per 100 ml. and 2,500 white blood cells (80% polymorphs). As there was only a very thin membrane craniotomy was not performed. Instead the subdural spaces were drained by rubber tubes for four days. The child made an uninterrupted recovery, and aspiration of the burr-holes seven days after the removal of the tubes showed no evidence of recurrence of the effusion. As noted above, he is developing normally.

Case 21. Subdural Effusion with Membranes

A male infant of 8 months was admitted to the Royal Manchester Children's Hospital on March 13, 1950, with a history of vomiting and a squint for three days, followed by convulsions within the last 24 hours. On examination he was having frequent right-sided epileptic attacks, there was no meningism, and the fundi were normal. There were rales over both lung fields. Immediate lumbar puncture yielded a turbid fluid containing 500 white cells per c.mm. and many Gram-positive diplococci, later established as pneumococci; the protein content was 300 mg. per 100 ml. Treatment with penicillin intramuscularly and intrathecally together with sulphadimidine was begun at once. By March 30 the cerebrospinal fluid showed 45 cells (all monocytes) per c.mm., 110 mg. of protein per 100 ml., and sterile culture, but the child was still irritable and pyrexial, and was developing a right hemiparesis. As the fontanelle was closed and the diagnosis was uncertain, bilateral occipital burr-holes were made on March 30 with a view to ventriculography if necessary. These showed the presence of large subdural effusions on each side, the fluid being xanthochromic and slightly turbid, with a protein content of 5,000 mg. per 100 ml. The wounds were closed and a further 80 ml. of similar fluid was aspirated during the next week from the left side. The right side produced only a further 20 ml. of fluid.

Craniotomy.—On April 10, under general anaesthesia, a left temporal osteoplastic flap was turned down and a rather thin but tough subdural membrane dissected away. The cavity was filled with saline and the flap replaced and sutured.

During the immediate post-operative period there was some pyrexia and swelling of the scalp, but no frank sepsis developed. Further aspirations of the left subdural space were negative. On May 1 a right temporal burr-hole was made, but there were no signs of effusion or membrane formation on this side. Meanwhile, the right hemiparesis had almost completely cleared, and the child was discharged a week later. Two years later he was bad-tempered, destructive, and dirty in his habits. There was still slight stiffness of the right arm and leg.

Case 23. Neglected Subdural Effusion

A girl aged 12 years was admitted some five years before with a history of pneumococcal meningitis which had been complicated by the development of a right hemiparesis, dysphasia, and fits. Cerebral thrombophlebitis had been suspected at the time. When seen at the Royal Manchester Children's Hospital she was having about one major and one minor epileptic fit per week, the right face and limbs twitching more than the left. She had some difficulty in speech and definite clumsiness of the right hand, but a normal gait. Air encephalography showed a gross dilatation of the posterior part of the left lateral ventricle.

Operation.—Under general anaesthesia a left-sided posterior osteoplastic flap was turned down. The dura was found to be everywhere densely adherent to a membrane about 1 cm. in thickness. This in turn was very adherent to the underlying cortex, and only a limited amount could be dissected away. There was also, on the other hand, a well-localized cerebral scar; this was excised down to the ventricle, leaving healthy white matter on all sides. The usual closure of the wound was made.

The child made a good recovery. There has been no increase in her neurological signs and so far (six months after operation) she has had no further fits.

Comment

In Case 21 the relatively poor result may be due either to the severity of the original infection or to the fact that diagnosis was somewhat delayed. In Case 23, which closely resembles the neglected case of subdural haematoma (Case 17) there was so typical a sheet of fibrous tissue lying in the subdural space and extending far beyond the bounds of the cerebral scar that the diagnosis of old encapsulated subdural effusion can hardly be doubted. It is conceivable, however, that the findings represent spontaneous resolution of a cerebral abscess with a subdural effusion overlying it.

The high proportion of cases with membrane formation recorded by McKay *et al.* (1950) and in this series, both from neurosurgical clinics, contrasts with the very much lower figures of cases submitted to operation from paediatric clinics: Smith *et al.* (1951)—two cases in twenty—and Everley Jones (1952), one in six. The explanation is doubtless that if subdural effusions are sought for early in cases of meningitis they will rapidly respond to treatment, without need for major neurosurgical intervention. But where they are not so sought, though a proportion may resolve spontaneously, the others will become encapsulated. These latter, if untreated, may cause either a fatal issue or (as in Case 23) serious disability later.

CEREBRAL VENOUS THROMBOSIS WITH
SUBDURAL EFFUSION

The whole question of the importance of cerebral thrombophlebitis as a cause of neurological symptoms and signs in infancy is a somewhat controversial one. The condition is rarely fatal, and even modern cerebral angiography with special methods designed to demonstrate the venous sinuses has failed, both in cases investigated by me and in those of others (Logue, 1952, personal communication), to demonstrate an obstruction with any regularity. None the less there are certain forms of illness in infants, particularly with a sudden onset of fits and a varying degree of hemiplegia associated with fever and moderate increase in the cells and protein content of the cerebrospinal fluid, in which the diagnosis of cerebral thrombophlebitis provides an acceptable explanation. The occurrence of a subdural effusion in such a case has some theoretical importance.

Case 24.—A female infant aged 4 months was admitted to Booth Hall Hospital under the care of Dr. W. H. Patterson, by whose kindness I record this case. She was the daughter of an epileptic mother and suffered from congenital heart disease. The immediate reason for admission was a history

of five convulsions in the past ten days, with irritability and vomiting. On examination the child was severely dehydrated, but with a tense bulging fontanelle. Lumbar puncture showed a faintly xanthochromic fluid under a pressure of more than 300 mm. It contained 40 mg. of protein per 100 ml. and 12 leucocytes, 50% being lymphocytes and 50% endothelial cells. Subdural taps yielded 5 ml. on the left side and 3 ml. on the right of a dark-brown slightly blood-stained fluid containing 110 leucocytes on the left and 60 leucocytes on the right. The child was not improved by this procedure, and died within 48 hours. Necropsy showed a thrombosis of the sagittal sinus and of its tributary veins on both sides, together with pulmonary stenosis and a patent interventricular septum.

Comment

The similarity, already noted, of the fluid found in cases of infantile subdural haematoma to that found in the majority of cases of subdural effusion complicating purulent meningitis suggests that a similar cause is responsible for both. The haematomas are generally believed to arise from haemorrhage from a vein bridging the subdural space from cortex to venous sinus, so that it would seem reasonable to suppose that a similar effusion in purulent meningitis might arise from necrosis of the wall of a vein involved in a process of thrombophlebitis. Spitz *et al.* (1945) have already made this suggestion, claiming indeed to demonstrate in their necropsy material a "necrotizing involvement of the bridging veins which had allowed their contents to escape through their damaged walls." But as their case was also suffering from purulent meningitis the transudation theory previously mentioned might still conceivably have accounted for the effusion observed.

In Case 24 no such explanation is possible because there was no evidence of meningitis. The objection that the effusion was small can be answered in two ways. On the one hand, the thrombosis was so massive that the infant died before the effusion could grow to any size. On the other, there is a case in the literature (Penfield, 1923) in which a boy of 16 months was found to have huge bilateral subdural effusions after a febrile illness with otitis media. Penfield observed this boy for many weeks and noted further febrile episodes accompanied by a lymphocytic reaction in the cerebrospinal fluid. At that time little was known of the cause of "otitic hydrocephalus," as it was then termed, but Penfield obviously leans to this diagnosis in his discussion. The case would probably be regarded now as one of cerebral thrombophlebitis, and there is therefore no reason to regard Case 24 as unique.

Accordingly it may be concluded that cerebral thrombophlebitis, whether it occurs from extension of infection from purulent meningitis or from a focus elsewhere, may give rise to a subdural effusion, and that the likely mechanism is the giving way of the necrotic walls of veins crossing the subdural space.

Finally, now that we know (Symonds, 1952) how commonly an intracranial venous thrombosis may complicate any infective focus, however trivial and wherever situated in the body, it is tempting to attribute to the same process those cases of infantile subdural effusion in which convincing evidence of either trauma or intracranial suppuration is entirely absent.

Summary

A series of 18 cases of subdural haematoma of infancy is presented. The clinical features of the condition are described and the method of treatment is indicated. There is reason to suppose that nearly 70% of these children will grow up normally.

Five cases of subdural effusion complicating bacterial meningitis are described. The clinical details are given, and the similarity of the effusion to that found in subdural haematoma is noted.

A case of subdural effusion complicating sagittal sinus thrombosis is also described. On the basis of this case and of those of other workers it is concluded that certain types of subdural effusion complicating purulent meningitis may be due to a leakage of blood from the necrotic wall of a vein involved in thrombophlebitis.

It is a pleasure to acknowledge the co-operation of all the paediatricians in the Manchester Region in collecting the material for this paper. I am also indebted to Mr. L. P. Lassman and Mr. A. Jolleys, and to many residents at the Royal Manchester Children's Hospital, for help in the documentation and management of the cases, and to Sister N. Kewley for devoted nursing care. There is no doubt that the credit for the low operative mortality recorded in this paper belongs very largely to Dr. Tom Dinsdale, who gave the anaesthetics for almost all the operations.

THE TREATMENT OF STEATORRHOEA
IN CROHN'S DISEASE

BY

JOYCE BURKE, M.D., D.Obst.R.C.O.G., D.C.H.
(From the Royal Infirmary, Sheffield, and the Department
of Pharmacology and Therapeutics, University
of Sheffield)

During recent years it has been recognized that Crohn's disease, or regional ileitis, is not always confined to the terminal ileum, but may be widespread, involving the proximal ileum, jejunum, colon, and even the duodenum. Surgery is definitely indicated for the relief of intestinal obstruction, and possibly for treatment of localized forms of the disease, when the affected portion of bowel may be excised. Patients with widespread disease present a difficult therapeutic problem. Surgery has proved disappointing, as complete extirpation of the affected bowel is seldom possible and recurrence after operation is common. In such circumstances therapy is directed towards improving the general nutrition of the patient and correcting deficiencies of vitamins and minerals. The main purpose of this paper is to describe the effects of a high-protein diet and intravenous iron, observed in three patients suffering from Crohn's disease with steatorrhea, and to draw attention to the beneficial result that may accrue from a carefully planned diet.

Case 1

A schoolboy aged 12 was admitted to hospital on April 4, 1948, complaining of diarrhoea and of colicky pain in the right iliac fossa. Intermittent slight pyrexia was present, but otherwise his general condition was good. He passed several loose green stools daily, from which no pathogenic organisms were isolated. Agglutination reactions to the

typhoid and dysentery groups were negative. A barium enema revealed nothing abnormal. After treatment with sulphonamides and penicillin he was discharged home on May 27. His symptoms persisted and his weight fell from 7 st. 3 lb. (45.8 kg.) to 4 st. 10½ lb. (30.2 kg.). He was readmitted to hospital on July 2. Apart from his wasted appearance clinical examination was negative. A hypochromic anaemia was present: Hb, 13.6 g. per 100 ml.; red cells, 4,300,000 per c.mm. The E.S.R. was 28 mm. in one hour (Westergren). Agglutination reactions were again negative, including those to *Brucella abortus*. The diagnosis of Crohn's disease was considered at this time, but attempts to demonstrate the terminal ileum radiologically failed. A low-residue diet was prescribed and his weight had risen to 5 st. 1 lb. (32.2 kg.) when he returned home on August 19. He remained under observation until March, 1949, when he weighed 6 st. 11½ lb. (43.3 kg.), and although his stools were still loose he was free from pain and attending school regularly.

In September the diarrhoea became worse and colicky abdominal pain returned, accompanied by vomiting. In April, 1950, examination by barium enema and sigmoidoscopy was normal. His condition deteriorated steadily until he was admitted to hospital on February 7, 1951, weighing 4 st. 3 lb. (26.8 kg.). He was passing about 10 loose offensive stools daily and vomiting most of his food shortly after it was eaten. He also complained of numbness and paraesthesiae in the extremities. Clinical examination revealed gross emaciation and faint brown pigmentation of the skin. The blood pressure was 110/75. No mass could be felt in the abdomen.

The results of laboratory investigations at this time are summarized briefly: E.S.R., 40 mm. in one hour (Westergren); Hb, 63% (9.3 g. per 100 ml.); red cells, 3,350,000 per c.mm.; C.I., 0.95; M.C.D., 7.2 µ; white cells, 12,000 per c.mm. The iliac marrow showed a marked normoblastic reaction of iron-deficiency type; macronormoblasts were also present, but no megaloblasts were seen. Microscopy of the stools showed no exudate; a few undigested meat fibres were seen. No faecal pathogens were isolated. Blood culture was negative. The titre of serum agglutinating *Br. abortus* was 1:640 ± 1:1,280, and *Br. melitensis* 1:320 ± 1:640. The total serum proteins were 5.4 g. per 100 ml. (albumin 3 g., globulin 2.4 g.). The average daily output of fat in the faeces was 7 g.; full details are given in the Table.

Radiological examination of the bowel showed marked narrowing and irregularity of the terminal ileum. There was narrowing in the middle of the transverse colon, with destruction of normal mucosal pattern, continuing to half-way down the descending colon.

As a result of the above findings a clinical diagnosis of chronic ileocolitis due to Crohn's disease was made.

The temperature varied between 99 and 100° F. (37.2 and 37.8° C.) for the first six weeks in hospital. The agglutination reactions to *Br. abortus* and *Br. melitensis* were still at the same high titre a week after admission. Blood cultures for these organisms were negative. A course of aureomycin was given, 60 g. in 21 days. There was little effect on the temperature, but the titres fell to 1:80 to both organisms four days after starting the drug and to 1:20 one month later, and have remained at this level. In view of the rapid fall in titre of agglutinins, it was unlikely that active brucellosis was present.

Feeding presented a great problem at first, owing to vomiting and anorexia. The patient was given a low-residue, high-protein, low-fat diet, containing daily two or three eggs, liberal helpings of meat and fish, and 75 g. of protein in a proprietary preparation. Bread-and-butter, small quantities of sieved vegetables, and boiled potatoes were included. His condition improved rapidly, and at the end of three weeks his weight was 5 st. 5 lb. (34 kg.), a gain of 16 lb. (7.3 kg.). The hypochromic anaemia responded to iron, 30 ml. of "ferrivenin" being given intravenously in the week before he was discharged from hospital.

As his appetite improved, his stools increased greatly in bulk and it was even more evident that steatorrhoea was present than on admission. Estimations in April showed the average daily output of fat in the stools over four days to be 36 g. The fat intake was approximately 90 g. daily during the period of collection (see Table). A glucose-tolerance test was normal.

When the patient returned home on April 27 he weighed 7 st. 6 lb. (47.2 kg.).

Subsequent progress has been excellent. After three weeks' convalescence he returned to school, and has attended regularly for nine months. His activities are not restricted. He plays games, swims, and rides a bicycle for the first time since the start of his illness in 1948. His basic diet consists of an egg for breakfast with bread-and-butter, banana or cheese sandwiches for lunch, and a meal at night of meat or fish, potatoes, and a milk pudding. Milk is not restricted and fats are allowed in moderation. His mother has been advised to add different articles to the diet, one at a time, noting the effect on the stools. It has been found that he can tolerate boiled carrots, stewed apples, and fresh oranges. Most other foods cause an increase in the number of stools. This diet is supplemented by oral iron, vitamins of the B group, and ascorbic acid.

The patient was reassessed in January, 1952. His weight was then 10 st. (63.5 kg.), a gain of 81 lb. (36.7 kg.) in 11 months. He had grown taller and secondary sexual characters had appeared. He was passing two or three semi-formed stools daily, as compared with six stools at the time of discharge from hospital, in spite of the fact that he was taking most of his fat ration. The average daily output of fat in the faeces over three days was 8 g., on a measured intake of 100 g. daily (see Table). A barium enema showed normal haustration and outline as far as the middle of the transverse colon, where persistent narrowing was still present. The proximal part of the transverse colon, ascending colon, and caecum showed a normal outline, as in previous studies. The terminal ileum remained narrowed, with a distorted mucosal pattern. Healing of the lesion in the descending colon and splenic flexure had undoubtedly taken place.

Case 2

A man aged 20 began to have attacks of right-sided abdominal pain and occasional diarrhoea in 1945. Three months after the onset of symptoms appendicectomy was performed, but no report on the condition of the bowel is available. He was in bed for six weeks after the operation and then returned to work. Symptoms recurred two years later. The pain increased in severity, and was accompanied by abdominal distension and the passage of flatus. Four loose stools were passed daily. He lost 3 st. (19 kg.) in weight before admission to hospital in May, 1948. A tender mass was palpable in the right iliac fossa. The blood count was normal. A diagnosis of regional ileitis was made. This was confirmed at laparotomy in August, 1948, and was treated by resection of 4 ft. (1.2 metres) of terminal ileum, ileo-colostomy, and right hemicolectomy. The histological appearance of the diseased ileum was that of Crohn's disease. He was discharged from hospital in October, 1948, and was well until February, 1950, although he continued to pass loose stools three or four times daily. Abdominal pain then returned and the diarrhoea became worse. A barium meal in February, 1950, showed recurrence of the disease, just distal to the anastomosis. In September, 1950, a fistula appeared at the upper end of the abdominal scar and discharged intermittently.

He was readmitted to hospital on May 1, 1951. Examination revealed a pale, wasted young man, with early finger-clubbing. A tender mass was palpable in the right iliac fossa, deep to the discharging fistula. He was passing three or four bulky offensive stools daily. The results of laboratory investigations are summarized as follows: Hb, 63% (9.3 g. per 100 ml.); red cells, 3,750,000 per c.mm.; C.I., 0.88; M.C.D., 7.2 μ ; white cells, 15,000 per c.mm. The blood film showed a simple polymorphonuclear leucocytosis. Two types of red cells were seen: (1) microcytic and slightly

hypochromic, and (2) macrocytic and normochromic. The iliac marrow showed a normoblastic reaction of iron-deficiency type, along with megaloid cells and macro-granulocytes which suggest liver-factor deficiency. Free hydrochloric acid was present in the stomach. The urine was normal. Microscopy of the stools showed scanty leucocytes only. No faecal pathogens were cultured. The total serum proteins were 7 g. per 100 ml. (albumin 3.4 g., globulin 3.6 g.) Culture of the pus from the fistula grew *Staph. pyogenes*, sensitive to penicillin. The average daily output of fat in the stools was 38 g. measured over three days, while the intake was approximately 70 g. daily (see Table).

There was continuous pyrexia for the first four weeks in hospital, the temperature varying between 99 and 101° F. (37.2 and 38.3° C.). Sulphadimidine, penicillin, and chloramphenicol were prescribed in turn. The abdominal mass finally became fluctuant. It was incised, and approximately 500 ml. of thick pus drained. Thereafter he was afebrile.

A diet similar to that given to Case 1 was prescribed. He also received iron intravenously—90 ml. of "ferrivenin" being given in 10 days—and folic acid, 15 mg. daily by mouth. When he left hospital on June 20 his weight was 8 st. 8 lb. (54.4 kg.). The abdominal fistula had closed by August and he returned to work. In November he weighed 10 st. 2 lb. (64.4 kg.), a total gain of 23 lb. (10.4 kg.). His haemoglobin was 110% (16.3 g. per 100 ml.), and the red blood cells numbered 5,200,000 per c.mm.

A full assessment was made in February, 1952. By this time he had worked regularly for six months, had married, and was feeling extremely fit. His weight was stationary and the fistula had remained healed. For the first time since the start of his illness in 1945 he was passing only one stool daily, and this was usually formed. His basic diet resembled that of Case 1. He said that as fats precipitated diarrhoea he avoided them, but he tolerated fruit and vegetables quite well so long as they were taken with meals. He continued to take ascorbic acid, yeast tablets, and small doses of iron by mouth. Folic acid had been discontinued four months previously.

The average daily output of fat in the stools, on a fat intake of 100 g. daily, was 32 g. (see Table). A glucose-tolerance test was normal. The blood count was as follows: Hb, 95% (14.1 g. per 100 ml.); red cells, 4,100,000 per c.mm.; C.I., 1.15; M.C.D., 7.4 μ ; white cells, 11,000 per c.mm. Slight macrocytosis persisted and megaloid cells were still present on examination of the iliac marrow. Folic acid, 15 mg. daily for 21 days, failed to correct this abnormality.

Case 3

A man aged 39 first complained of colicky pain in the right iliac fossa in 1945. It was relieved by the passage of flatus. Diarrhoea was noticed at the same time and the stools remained loose. In November, 1949, he had to give up work as he was passing up to 20 loose stools daily. His weight had fallen from approximately 10½ st. (66.7 kg.) to 7 st. 10 lb. (49 kg.). He was admitted to hospital in February, 1950, and a diagnosis of Crohn's disease was made, narrowing of the terminal ileum being demonstrated radiologically. At laparotomy the disease was confined to the terminal ileum, but there was a fistula into the upper ileum. Three feet (0.9 metre) of terminal ileum was resected and ileocolostomy and right hemicolectomy were performed. The diagnosis of Crohn's disease was confirmed histologically.

The patient returned to work in May, 1950. He gained weight and remained well until November, 1951, although mild diarrhoea persisted. At that time the number of stools increased to four or five daily and slight abdominal pain had returned.

In January, 1952, he was admitted to hospital. Clinical examination showed obvious recent loss of weight and considerable pallor. His tongue was normal. No abdominal mass was felt. He weighed 8 st. 3 lb. (52.2 kg.). Laboratory findings were as follows: Hb, 48% (7.1 g. per 100 ml.);

red cells, 3,270,000 per c.mm.; C.I., 0.73; M.C.D., 7.3 μ ; white cells, 7,000 per c.mm. The iliac marrow showed a normoblastic reaction of iron-deficiency type, along with macronormoblasts. Scanty leucocytes were seen in the stools; no faecal pathogens were isolated on culture. The glucose-tolerance test was normal. The total serum proteins were 6.2 g. per 100 ml. (albumin 3.5 g., globulin 2.7 g.). No abnormality was found in the urine. The average daily output of fat in the faeces was 41 g., on a measured intake of 100 g. daily (see Table).

He was started on the same diet as the other two patients and received iron intravenously, 100 ml. of "ferrivenin" being given in 14 days. After six weeks he had gained 14 lb. (6.4 kg.) in weight and his haemoglobin had risen to 78% and his red cells to 4,500,000 per c.mm.; C.I., 0.86. He was able to return to work.

Discussion

It is fully appreciated that regional ileitis is characterized by remissions and relapses. During a remission rapid gain in weight is common. Crohn (1949) mentions figures of 15, 25, and even 50 lb. (6.8, 11.3, and 22.7 kg.). Case 2 was undoubtedly benefited by the evacuation of a large abscess, and all three patients were at rest in hospital for several weeks. All received intravenous iron, and two of them were given antibiotics. However, it is believed that the rapid improvement was largely due to the diet, especially in Case 1, this patient having already gained 14 lb. (6.4 kg.) in weight before aureomycin was started. He was well and had gained 38 lb. (17.3 kg.) before intravenous iron was given to correct a persistent hypochromic anaemia. During the year on the high-protein diet he gained 81 lb. (36.7 kg.) in weight. Case 3 did not receive antibiotics. In all three cases diarrhoea was controlled for the first time after institution of the diet.

Steatorrhoea, which was present in the three cases, has been observed previously in regional ileitis (Bockus, 1945; Frazer, 1949), and Crohn (1949) mentions tropical sprue in the differential diagnosis. The high incidence of malnutrition, vitamin deficiencies, and anaemia is well recognized, and the great importance of a high-protein diet, with supplementary minerals and vitamins, is stressed by Brown and Donald (1942), Bockus (1945), Crohn (1949), and Kiefer *et al.* (1950).

In order to obtain the extra meat rations granted to patients with steatorrhoea in this country at the present time the diagnosis must be established by analysis of the stools. It is therefore worth while having this carried out. Steatorrhoea can easily be overlooked if the stools are inspected shortly after admission to hospital, when the food intake is often reduced, or if only a single specimen of faeces is sent to the laboratory for routine examination. The diagnosis of steatorrhoea is most readily established by investigating the response of the patient to an increase of dietary fat. In normal subjects the fat excretion shows a minimal change even when the intake of fat is raised as high as 200 g. daily. Thus Cooke *et al.* (1946) found that with a 50-g. intake the maximum fat excretion was 4.5 g. daily. Fourman *et al.* (1948) state that the output of fat should not exceed 23 g. in four days on a fat intake of 70 g. daily. Wollaeger *et al.* (1946) gave 13 subjects 208 g. of fat daily, and the average output in the stools was 8.7 g., the range being 5.5 to 13.6 g.

On the other hand, when steatorrhoea is present the total fat excretion is within limits proportional to the fat intake, and defective fat absorption can be made more obvious by increasing the dietary fat (Fourman *et al.*, 1948). It is accordingly suggested that patients be given 70 to 100 g. of fat daily two days before and during the time that the stools are being collected, instead of 50 g. as often recommended (Cooke, 1952). By this means more elaborate balance studies using coloured markers may be avoided. These points are clearly shown in the Table, where the measurements of the faecal fat excretion of the three cases of Crohn's disease are summarized. In addition, for com-

parison, there are included observations on a case of idiopathic steatorrhoea and on four subjects with normal intestinal function.

Details of Fat Intake and Output

Diagnosis	Date of Faecal Fat Estimation	Daily Fat Intake in g.	No. of Days of Stool Collection	Average Daily Weight of Faeces in g.	Total Fat Percentage of Dried Faeces	Average Daily Output of Fat in g.
Crohn's disease (Case 1)	23/2/51	Very small owing to anorexia and vomiting	5	302	32	7
	11/4/51	90	4	820	32	36
Crohn's disease (Case 2)	9/1/52	100	3	200	39	8
	28/5/51	70	3	461	73	38
Crohn's disease (Case 3)	18/2/52	100	4	391	48	32
	12/2/52	100	4	649	67	41
	29/2/52	70	3	264	51	19
Idiopathic steatorrhoea	7/3/52	50	3	285	35	9
	17/10/51	70	3	96	38	10
Convalescent pneumonia	29/10/51	150	3	179	56	22
	12/11/51	100	3	44	58	5
Treated Addison's disease	20/11/51	150	3	60	41	5
	14/3/52	150	3	61	37	2
Normal	14/3/52	150	3	179	24	3
	19/3/52	150	3	55	43	2

It will be seen that when the faecal fat was first estimated in Case 1 the daily output just exceeded the upper limit of normal. However, when the fat intake was increased gross steatorrhoea was evident. When the third estimation was done the daily output of fat was only 8 g., although the intake was 100 g. for two days before and during the time the faeces were being collected. The capacity to absorb fat had clearly increased. In Case 3 the faecal fat was estimated on intakes of 100, 70, and 50 g. during the patient's first admission to hospital. The fat excretion increased with the fat intake. The findings were similar in the case of idiopathic steatorrhoea. In contrast to this the excretion of fat in the normal subjects did not exceed 5 g. a day even when the intake was as high as 150 g. The total fat content of the dried faeces was, however, over 30% in three of the normal subjects, and it is clearly fallacious to base a diagnosis of steatorrhoea on this figure alone.

Davidson and Fountain (1950) reviewed all patients with the sprue syndrome who applied for extra rations between January 1, 1943, and December 31, 1948. These included 1,303 cases of coeliac disease, 311 cases of idiopathic steatorrhoea, and 403 cases of tropical sprue. Among the 58 cases of steatorrhoea due to causes other than the sprue syndrome there were only five cases of regional ileitis. In addition there were 15 in which the diagnosis was uncertain; 12 of these had undergone resection of gut or short-circuiting operations. Even if it is assumed that all these patients had regional ileitis, this only makes a total of 20 applying for extra rations. No information is available regarding the incidence of steatorrhoea in a large series of cases of regional ileitis, though it is probably high, especially if the disease is extensive. It was certainly present in all the three cases of regional ileitis that we have investigated during the last two years. It accordingly seems improbable that steatorrhoea, either due to sprue or of the idiopathic variety, is over 30 times commoner than that due to regional ileitis, as is suggested by the figures of Davidson and Fountain.

In an effort to ascertain the relative frequency of steatorrhoea due to regional ileitis and other causes the records of cases admitted to the Royal Infirmary, Sheffield, have been studied during the two years 1950-1. There were 10 cases of steatorrhoea. These included five cases of idiopathic steatorrhoea, one case following gastro-enterostomy and vagotomy, one due to carcinoma of the suprarenal gland

with infiltration of the pancreas, and the three cases of regional ileitis mentioned in this paper. These findings suggest that steatorrhoea due to regional ileitis is commoner than is generally appreciated. This may be because estimations of faecal fat are not regularly carried out in these cases, and so steatorrhoea is overlooked. Alternatively, Davidson and Fountain suggest that doctors fail to realize that priority rations are available to all patients with steatorrhoea, whatever the cause.

Anaemia, which may be hypochromic, megalocytic, or dimorphic in type, is a well-recognized complication of steatorrhoea (Barker and Hummel, 1939; Bennett and Hardwick, 1940; Cooke *et al.*, 1948). Hypochromic anaemia was present in the three patients described. The value of intravenous iron in the treatment of refractory hypochromic anaemia has been mentioned by Hawkins *et al.* (1950). It is particularly useful in regional ileitis, in which large doses of oral iron are apt to aggravate the intestinal disturbance. Cases 1 and 2 now tolerate a small maintenance dose of iron by mouth. In Case 2 there was also evidence of liver-factor deficiency, and he received folic acid. No effects were observed on the macrocytosis present in the peripheral blood or on the megaloid changes in the iliac marrow.

The patients found that with the five extra meat rations allowed weekly it was possible to have an appetizing and varied diet, although many articles of food had to be excluded to avoid diarrhoea. Their daily protein intake is estimated to be approximately 130 g. Bread, sugar, bacon, cheese, milk, fish, and eggs were not restricted. Fats were allowed in cooking and bread was thinly buttered. They were advised, however, to avoid fried foods. For the rest they were encouraged to find out for themselves the foods that caused diarrhoea by adding different articles to the basic diet one at a time. In addition, they received vitamins of the B group, ascorbic acid, and small doses of iron by mouth.

It is difficult to say for how long the diet outlined above should be continued, for the cost of the extra meat is considerable. Nevertheless, it would seem advisable to continue the high-protein intake so long as there are signs of activity of the disease or of persisting steatorrhoea. Indeed, one of these patients commented that the extra expense of the diet was repaid many times by his restoration to full earning capacity.

The presence of steatorrhoea in regional ileitis suggests that the disease is widespread, and this is of grave prognostic import, but complete clinical recovery has been recorded with medical treatment alone (Crohn, 1949). The regime outlined above is simple and worth a trial in the type of case described. It is probable that there are many patients with steatorrhoea, malnutrition, and anaemia due to this disease attending the out-patient departments of hospitals in this country. With treatment on the lines indicated, particularly by the provision of extra protein rations, they may be restored to reasonable health and normal activity, and even be spared extensive resection of the bowel.

Summary

Detailed case histories of three patients with Crohn's disease are given. Steatorrhoea, considerable malnutrition, and anaemia were present in all.

A high-protein diet led to great improvement, indicated by a considerable gain in weight and restoration to normal activity. The value of intravenous iron for the correction of hypochromic anaemia in these patients was demonstrated.

Faecal fat estimations are recommended in patients with this disease, as steatorrhoea is often overlooked. If the presence of steatorrhoea can be established patients are eligible for extra meat rations in this country at the present time, and by this means they can obtain an appetizing high-protein diet.

I wish to thank Professor E. J. Wayne for permission to publish these cases; Professor R. S. Illingworth, Mr. J. Lytle, and Mr. C. Jones for access to their records; Dr. E. K. Blackburn for the haematological reports; Mr. D. A. Podmore for carrying out the faecal-fat estimations; and especially Dr. G. M. Wilson for his encouragement and advice.

A NEW LONG-ACTING INSULIN A PRELIMINARY TRIAL OF "LENTE" NOVO INSULIN

BY

R. D. LAWRENCE, M.D., F.R.C.P.

AND

WILFRID OAKLEY, M.D., F.R.C.P.

The Novo Laboratories, in Copenhagen, have recently produced a series of three new insulin preparations whose composition and action have been described by Hallas-Møller, Petersen, and Schlichtkrull (1952). The makers have kindly provided us with a supply of these insulins on which to carry out a therapeutic trial, and the results obtained justify the publication of this preliminary report.

New Insulin Preparations

In 1934 Scott, of Toronto, found that various metals were of importance for the formation of insulin crystals. This led to a study of the influence of zinc on the insulin effect. This research resulted in the discovery that small quantities of zinc (1-2 mg. per 1,000 units) fail to retard the action of soluble insulin, whereas large amounts increase its length of action. It was further found that the effect of protamine insulin and similar combinations was substantially protracted by the addition of small quantities of zinc (2 mg. per 1,000 units). The practical outcome of these investigations was protamine zinc insulin.

Subsequent research has been largely directed towards the discovery of new and more suitable preparations, new substances being tried to replace protamine. The idea of increasing the zinc content alone was regarded as impracticable, because of the local reactions produced when sufficient zinc is added to prolong the action of insulin.

Novo Laboratories were, however, aware that different anions influenced the reaction between insulin and zinc. Hallas-Møller and his co-workers in Copenhagen found that insulin, in the presence of a very small quantity of zinc (1 mg. per 1,000 units) was less soluble at the pH of the blood than protamine insulin, provided that anions such as phosphate and citrate were not present. Phosphate buffer has been thought the most suitable at pH 7, and is normally

used to adjust insulin preparations to that figure. This may explain why more than 15 years of research failed to lead to the simple discovery that if a different buffer is used it is wholly unnecessary to add such materials as protamine, globin, surfene, etc., to make insulin insoluble at the pH of the blood.

With the use of acetate buffer, Hallas-Møller was able to prepare a suspension of pure insulin in media at the pH of the blood in the presence of very small quantities of zinc. Further work led to the discovery that the length of action of such preparations varied with the form of the insulin, whether pure amorphous, amorphous and crystalline, or pure crystalline. This apparently minor difference in the form of insulin would seem to determine the range of activity of the preparations, varying from 12 to 36 hours. The action of amorphous insulin is shorter than that of crystalline, the larger the size of the crystal the greater being the length of activity. Three such insulins have been produced and given the names of "semi-lente," "lente," and "ultra-lente," the first having the shortest and the last the longest range of activity, lente being intermediate in duration. These insulins are miscible to produce preparations of intermediate ranges of activity. They cannot, however, be mixed with the present soluble insulin.

Our present trial has been carried out mainly on lente insulin, the intermediate preparation, and the one which seems the most promising of the three for treatment. The number of diabetics to whom lente has so far been given is very small—some 11 cases—and before briefly describing

the results obtained the conditions necessary for the therapeutic trial of any insulin preparation will be considered:

(1) In view of the variability of diabetes at the onset of the disease only those patients whose diabetes has been controlled for a reasonable period of time can be considered suitable.

(2) The diabetes should be of the severe type which relapses heavily when insulin action is finished.

(3) There must be no intercurrent complicating disease.

(4) The patient must be in hospital long enough for good control on existing methods to be compared with that obtained with a new type of insulin in similar dosage.

These essential requirements are often forgotten and explain, in the present shortage of our hospital beds, so occupied by acute work, the few cases on which we have so far been able to carry out therapeutic trials.

Clinical Material

The therapeutic trial of lente insulin was carried out on 11 adult diabetics, 6 of whom were men and 5 women, their ages varying between 25 and 92. They all fulfilled the conditions of suitability described above, and were in-patients in the diabetic department of King's College Hospital.

The patient's diabetes was controlled on two injections of S.I., P.Z.I. alone, a combination of the two given as a single mixed injection before breakfast, or a single injection of globin insulin. When adequate control was established,

FIG. 1.—Case 1. Comparison between equal doses of a mixed injection of S.I. and P.Z.I., and lente insulin.

FIG. 2.—Case 2. Comparison between equal doses of a mixed injection of S.I. and P.Z.I., and lente insulin.

FIG. 3.—Case 7. Comparison between two doses of S.I. and a single dose of lente insulin of same total amount.

FIG. 4.—Case 8. Comparison between two doses of lente insulin of slightly different sizes to show regularity of action. The noon blood sugar on 76 units of S.I. to be compared with that on 76 units of lente insulin.

FIG. 5.—Case 9. Comparison between a single dose of P.Z.I. and the same dose of lente insulin given on two occasions. Note the regularity of action of lente insulin.

blood-sugar determinations were made before breakfast, at noon, at 6 p.m., and at 9 p.m.; the patient was then changed over to a single dose of lente insulin, given before breakfast, and equal in amount to the total quantity of insulin required to stabilize the diabetes. When the patient had been on lente insulin for not less than two days the blood-sugar estimations were repeated at the same times and the results plotted in the form of graphs (Figs. 1 to 5). In addition to blood-sugar determinations, seven daily urine sugar tests were made at informative times. In two cases the blood-sugar estimations on lente insulin were repeated in order to see whether consistent results could be obtained with this insulin.

Results

In six cases comparison was made with mixed doses of S.I. and P.Z.I., the total dose varying from 36 to 60 units. In two cases the patients were previously stabilized on 68 and 76 units of S.I. respectively, given in divided doses, before breakfast and the evening meal. Two cases received single injections of 52 units of P.Z.I. and one of 28 units of globin. It will be seen that in all 11 cases lente insulin produced fasting blood sugars of the same order as those obtained with the other insulin preparations, the figures varying between 70 and 200, being 150 or less in eight. At noon lente produced a degree of control as good as, or better than, that obtained with the other insulins in all but two cases. At 6 p.m. the blood sugar on lente was comparable with but tended to be slightly higher than that produced by the other insulins, but at 9 p.m. the reverse was seen to be the case in most instances (see Table).

Comparison of Blood Sugars in the Six Cases Not Shown in Figs. 1 to 5

Case No.	Insulin	Blood Sugar in mg./100 ml.			
		8 a.m.	Noon	6 p.m.	9 p.m.
3	44 S.I.+16 P.Z.I.	165	260	140	118
	60 Lente ..	200	375	260	255
4	20 S.I.+16 P.Z.I.	168	238	95	190
	36 Lente ..	105	100	155	155
5	24 S.I.+20 P.Z.I.	110	155	130	195
	44 Lente ..	130	105	110	95
6	24 S.I.+16 P.Z.I.	155	210	170	—
	40 Lente ..	140	180	135	—
10	52 P.Z.I.	190	178	195	250
	52 Lente ..	95	140	175	180
11	28 Globin ..	155	245	165	—
	28 Lente ..	165	205	170	250

It would appear, therefore, from this small series of experiments that lente insulin possesses the prolonged action claimed by the manufacturers, and also that it exerts a shorter hypoglycaemic action, comparable with and equal to that of soluble insulin alone or mixed with P.Z.I. Throughout the course of these and other experiments with

lente insulin, hypoglycaemia occurred only two or three times and was never severe. There were no local reactions or undesirable side-effects. In the few cases in which tests were repeated with lente insulin the results obtained were remarkably constant.

We hope to carry out further trials on lente insulin in order to determine: (1) the length of action and time of maximum action of lente insulin in varying dosage; (2) whether there is significant variation between different batches of the same preparation; (3) whether lente insulin produces satisfactory control in ambulatory cases; (4) the arrangement of diet best suited to the action of these insulins; the diet of the cases reported was kept constant, and the carbohydrate content was arranged to suit the insulin or insulins with which comparison was made; (5) the suitability of the new insulins for initial stabilization of severe diabetics.

Summary

A preliminary trial of the new Danish lente insulin supports the claim that it exerts a prolonged hypoglycaemic action, lasting at least 24 hours, which is strong enough to control the blood sugar of moderately severe diabetics throughout the day without causing hypoglycaemia during the night. It has not in our experience produced either local or general reactions and appears to be no more likely to produce hypoglycaemic reactions than the insulin preparations at present in use.

ACUTE BENIGN PERICARDITIS

A REPORT OF FOUR CASES IN CHILDHOOD

BY

B. D. BOWER, M.B., M.R.C.P.
Paediatric Registrar

JOHN GERRARD, D.M., M.R.C.P.
Lecturer in Paediatrics

(Department of Paediatrics and Child Health, University of Birmingham)

AND

M. E. MacGREGOR, M.D., M.R.C.P., D.CH.
Consulting Paediatrician, South Warwickshire Area

Acute benign pericarditis has been recognized more often in America than in Europe, and its existence in Britain has even been denied (Andrews *et al.*, 1948). Having recently seen two typical cases, we decided to examine the notes of all children with pericarditis treated at the Birmingham Children's Hospital between 1942 and 1951, and thus discovered two other probable examples of the condition.

Case 1

Both parents of an 8-year-old boy had a feverish illness, one a week before and the other a week after their son was taken ill with shivering and left-sided chest pain. Penicillin and sulphonamides in adequate dosage had no effect on his high temperature or irritating cough. A week later he developed severe abdominal pain and was transferred to hospital. He was then only moderately ill; temperature 103° F. (39.4° C.), pulse 124, and respirations 28. Fine crepitations and distant bronchial breathing were heard at the left base; clinically the heart was normal. Chloramphenicol—40 mg. per lb. (88 mg. per kg.) per day—reduced the temperature, but pain increased and the child developed both a loud pericardial friction rub and an apical systolic murmur. Yet he was not critically ill. The E.C.G. strongly

suggested pericarditis, with raised RS-T segments in Leads I and II and P-R interval 0.18 second. An x-ray film showed a wide heart shadow with a trace of fluid at the left base (Fig. 1).

After five days aureomycin was substituted for chloramphenicol, and in the following week there was a fall in temperature and the pericardial friction disappeared. On the day after stopping aureomycin the boy complained of right shoulder pain. Apical gallop rhythm together with venous congestion and bronchial breathing at the left base suggested, and x-ray examination confirmed, the presence of a pericardial effusion, areas of consolidation in the lower lobes, and a small right pleural effusion. All these signs disappeared without treatment, and after a week the heart size was almost normal (Fig. 2).

A month after admission there was another relapse, with pain in the left shoulder, chest, and abdomen, a raised temperature, and signs of pericardial effusion. A second course of aureomycin, lasting two weeks, led to improvement, and after three weeks' freedom from symptoms he was discharged from hospital on the 59th day. There was a further relapse two and a half weeks later, but recovery was spontaneous.

The Mantoux test, cold agglutinins, streptococcus MG antibodies, Q fever complement fixation, and examination

for antibodies to four strains of Coxsackie viruses were negative repeatedly throughout the illness. A typical blood count showed white blood cells, 12,500, 83% polymorphs.

Case 2

A boy aged 9 walked into the out-patient department after two weeks' illness with fever, anorexia, and chest pain. He was pale but not ill; temperature 102° F. (38.9° C.), pulse 100, respiration 20, blood pressure 105/65. The heart was large, and there was pericardial friction but no evidence of valvular disease, nodules, or joint involvement. Blood-stained, sterile serous fluid was obtained by paracentesis of the pericardium. The Mantoux test was repeatedly negative; white blood cells 14,500, with 90% polymorphs.

Penicillin and sulphadiazine were given in adequate doses, but the friction rub persisted for a week. There was no evidence of endocarditis or persistent cardiac enlargement when discharged two months afterwards, nor when he was examined again clinically, electrocardiographically, and radiologically four years later.

Case 3

A boy aged 3½ years had central abdominal pain and anorexia, and vomited once, and three days later developed a painful cough. On the seventh day of his illness he looked moderately ill, and was orthopnoeic; temperature 98° F.

FIG. 1.—Case 1. Radiograph showing wide heart shadow with trace of fluid at left base.

FIG. 2.—Case 1. Radiograph showing return of the heart to normal size.

FIG. 3.—Case 3. Radiograph showing pericardial effusion.

FIG. 4.—Case 3. Radiograph taken five years after Fig. 3.

(36.7° C.), pulse 140, respirations 44. There were no nodules or joint changes. Venous congestion, hepatic enlargement, increased cardiac dullness, and muffled heart sounds suggested a pericardial effusion, which was confirmed by x-ray examination (Fig. 3), and 210 ml. of fluid was aspirated. The fluid was blood-stained, contained a few polymorphs, and was sterile. Relief was great, but, although receiving penicillin, the child relapsed within a week and further aspiration was required. Guinea-pig inoculation was negative.

The temperature was raised for three weeks, and, although the pericardial effusion was resolving by the end of the second week, fluid appeared at the right base. He was discharged after three months and his heart has remained normal in size, with no E.C.G. or radiological evidence of disease, for five years (Fig. 4). The Mantoux reaction was then, and is still, negative.

Case 4

An 11-year-old boy developed a temperature of 102° F. (38.9° C.) with pain in the front of the chest and abdomen aggravated by breathing. His symptoms subsided, but soon returned with such severity that he had to be propped up in bed. A week after the onset his temperature was 100° F. (37.8° C.), pulse 100, and respirations 20. There was no venous congestion or liver enlargement; the blood pressure was 120/78. His heart was enlarged, with normal sounds but loud pericardial friction, and a pleural rub at the left and later at the right base posteriorly. There were no nodules.

A week later x-ray examination showed considerable cardiac enlargement and the E.C.G. revealed a raised S-T segment with upright T in Lead II, suggestive of pericarditis. Within a week the x-ray picture was normal and the E.C.G. showed an iso-electric S-T segment with inverted T₂, which a week later had returned to normal. The white cell count was 7,600 per c.mm., with 77% polymorphs, and the E.S.R. was raised to 70 mm. in one hour (Westergren) at the height of the illness. The Mantoux test was repeatedly negative. He was discharged from hospital after five weeks, free from all symptoms and clinically normal.

Diagnosis

In America acute benign pericarditis seems to be as common in young adults as rheumatic pericarditis, though less frequent than coronary artery disease (Logue and Wendkos, 1948); in this country it may be commoner than is generally realized. Among 40 cases of pericarditis seen in the past ten years at the Birmingham Children's Hospital, 27 were rheumatic, 8 were pyogenic, 1 was tuberculous, and 1 was uraemic. The remaining three (Cases 1, 2, and 3 above) were thought to be due to acute benign pericarditis. Other examples may have been missed, for pericardial friction and/or effusion are by no means invariable in acute benign pericarditis, and in patients with atypical pneumonia pericarditis may be recognized only if serial E.C.G.s are taken (Levy and Patterson, 1950). Other cases might well be sought among children with acute unexplained abdominal pain, especially when accompanied by fever and a painful cough.

We based the diagnosis on exclusion of other recognized causes of pericarditis with effusion. Rheumatic fever was regarded as unlikely because there was no joint involvement, there were no nodules, there was no permanent damage to the heart or its valves, and the patients were not as ill as children with rheumatic pericarditis are. A tuberculous origin was rejected because Mantoux tests, carried out repeatedly for at least four months, were constantly negative, guinea-pig inoculation was negative in one case, there was no evidence of a tuberculous focus in any other part of the body, and the recovery was relatively rapid. Pyogenic pericarditis was thought to be improbable in view of the relatively low white-cell count (the highest being 14,500 per c.mm., with 90% polymorphs), the relative mildness of the illness, a failure to culture organisms from the pericardial

fluid in Cases 2 and 3, the ineffectiveness of penicillin, sulphadiazine, and chloramphenicol, the spontaneous recovery of Case 4 without specific therapy, and the absence of a primary septic focus such as osteomyelitis. There were no reasons to believe that any of the patients had renal disease, cardiac infarction, disseminated lupus erythematosus, Still's disease, myxoedema, or traumatic pericarditis.

Each of the four patients had illnesses which corresponded with that recorded for acute benign pericarditis.

1. The illness was relatively mild, and one child actually walked into the out-patient department, although he had a pericardial rub at the time. Three of our children had an obvious friction rub, but only one was critically ill, and in this case aspiration of a large pericardial effusion immediately transformed his general condition. Large effusions are uncommon, although they may occur (Levy and Patterson, 1950).

2. The pericardial fluid may be straw-coloured or haemorrhagic; it is conceivable that trauma may have been responsible for the blood-staining in our two cases.

3. Pain, a striking feature in adults, affected all four children, and in two was severe enough to simulate appendicitis.

4. Each child had associated pleurisy, and in Cases 1 and 4 it was bilateral.

5. A relapsing course such as that observed in Case 1 sometimes occurs (Taubenhaus and Brams, 1950), but the ultimate prognosis is good. All our patients have remained well, and none has any residual abnormality, but the longest follow-up period is only five and a half years.

Aetiology

Although the cause of acute benign pericarditis is unknown it has been recognized in patients with primary atypical pneumonia (Finkelstein and Klainer, 1944), a condition usually due to a virus infection. The disease has many features in common with acute benign dry pleurisy (Scadding, 1946) or Bornholm disease, and the latter is often associated with, if not always caused by, the Coxsackie group of viruses (Findlay and Howard, 1950). Friedman *et al.* (1952) examined sera of five cases of acute benign pericarditis, but found no evidence that there had been recent infection with two strains of Group A or one strain of Group B Coxsackie virus. In one case we also failed to demonstrate infection by any of four different strains of the virus. However, there are many strains of Coxsackie virus, and it remains tempting to link acute benign pericarditis with Bornholm disease even though there are minor differences in the seasonal incidence. Both diseases run a benign, sometimes relapsing, course with severe abdominal, thoracic, and even shoulder pain, which may lead to suspicion of appendicitis or coronary occlusion. Pleural friction may be present in both. Pericarditis may complicate Bornholm disease; one case of this kind reported by Heckscher (1933) and six described by Bing (1933) seem to have been very like cases of acute benign pericarditis. Our fourth patient was taken ill during an outbreak of epidemic myalgia, and during this same outbreak Dr. S. R. F. Whittaker had under his care two adults with acute benign pericarditis. Another of our patients (Case 1) developed his illness within a week of a vague febrile illness in both parents.

Treatment

It is difficult to assess response to treatment in a disease with a uniformly good prognosis and a natural tendency to relapse. Sulphonamides, penicillin, and streptomycin (Levy and Patterson, 1950) are almost certainly valueless. In one of our patients a pericardial rub developed during treatment with chloramphenicol, but this child later responded twice, though only temporarily, to aureomycin. Taubenhaus and Brams (1950) have reported favourably on the effects of aureomycin, but Friedman *et al.* (1952) state that neither aureomycin nor any other antibiotic has any effect on the illness. These last authors report that either A.C.T.H. or cortisone will lead to prompt and dramatic improvement. It seems, however, scarcely justifiable at the moment to use these agents for a disease with no apparent sequelae.

Summary

Four cases of acute benign pericarditis in childhood are recorded.

It is suggested that this disease may sometimes be a complication or manifestation of Bornholm disease.

We are grateful to Professors A. V. Neale and J. M. Smellie for permission to record details of cases under their care, to Dr. S. R. F. Whittaker for access to his cases, to Dr. F. O. McCallum for the serological investigations, to Dr. Clifford G. Parsons for his interest and advice, and to Mr. J. G. Williamson for the illustrations.

AN INVESTIGATION INTO STERILITY AFTER LUMBAR GANGLIONECTOMY

BY

S. S. ROSE, M.B., F.R.C.S.

First Assistant, Surgical Professorial Unit, Manchester
Royal Infirmary

"We are obtaining increasing evidence that males may not be sterile or have any alteration of sexual function after bilateral excision of the first lumbar ganglion or even the upper three ganglia." This observation of White and Smithwick (1942) crystallizes a belief contrary to the usual teaching and supports a view held in this clinic for some time. Professor A. M. Boyd instigated this work because of a clinical impression arising out of and sustained by a follow-up of several hundred cases of bilateral lumbar ganglionectomy in which there was every reason to believe that the first lumbar ganglion had been removed on both sides.

Before proceeding with a discussion on sterility following this operation it is important that a clear distinction should be made between sterility and impotence. Many patients arrive at this clinic under the impression that the two terms are synonymous, and alarm and despondency are created on these grounds. No one has ever suggested that an impairment of gross sexual function follows this operation, and this should be emphasized to the patient at the outset. Furthermore, the substitution of the term "seminal anorrhoea" for sterility conveys to the practitioner a full understanding of the symptom under consideration.

For many years there has existed a widespread belief that the bilateral removal of the first lumbar ganglion results in sterility. This belief has been based on experimental evidence which has implied a loss of ejaculatory function and clinical evidence which has perhaps been given undue prominence by the fact that only the patients in whom this symptom has occurred return to complain of sterility.

During the course of this investigation it has become increasingly clear that sterility, far from being a common post-operative complication, is only rarely encountered, and even then, as is shown later, is usually the

result of a much more extensive sympathetic denervation. The present communication is in the nature of a progress report, and the work is by no means complete. The conclusions drawn from the data at present available may be modified by further evidence.

Method of Investigation

The problem has been approached by posing the following questions: (1) Is there a failure of seminal emission after bilateral removal of the upper three lumbar ganglia? (2) If so, what is the mechanism of this failure? (a) Does the semen fail to reach the posterior urethra? Or (b) is it due to reflux of the semen into the bladder through a lax internal sphincter?

The subjects of this research have been divided into three groups: patients who have been subjected to bilateral lumbar sympathectomy; patients who have had a much wider sympathetic interruption for hypertension; and patients who have had an operation of similar or greater degree of severity to act as a control of sexual resilience.

In the sympathetomized patients the level of denervation has been ascertained by the use of the electrodermometer, an electronic apparatus devised by Hall Ratcliffe and Jepson (1950) for measuring the alteration in surface resistance consequent on drying of the skin. The constancy of the post-ganglionectomy skin-resistance patterns has been described by the same authors, and when a pattern showing an upper-thigh distribution is obtained (Fig. 1) it is safe to assume that the first lumbar ganglion has been included in the section of chain removed. It is certain that when the lumbar chain is followed under the internal arcuate ligament with division of the diaphragmatic crus if necessary, and the ganglion thus exposed is removed, this pattern is obtained. The high lumbar ganglionectomy is performed as a routine at this centre, for it is only by this means that an adequate sympathetic denervation of the lower limb can be achieved (Boyd *et al.*, 1949).

The purpose of the investigation has been carefully explained to the patients, and there has been no lack of co-operation. They were instructed to obtain a specimen of semen at a convenient time, a few hours before the proposed examination, and immediately afterwards two specimens of urine. The first specimen was to wash out the urethra, and the second specimen contained the rest of the bladder contents—making a two-glass test. The volume of semen was noted, a sperm count was carried out, and centrifuged specimens of the urinary samples were examined for the presence of spermatozoa. In addition the urinary specimens were tested for fructose by the Selivanoff test.

A questionnaire was also submitted with regard to the pre-operative and post-operative sexual function, with particular reference to any alterations noticed.

This simple routine has given the answer to Question 1 without difficulty—that is, does sterility occur in these cases? There is no doubt that in the majority of them the bilateral removal of the upper three lumbar ganglia does not cause sterility. If, however, a more extensive

FIG. 1.—Pattern shows area of sympathetic denervation achieved by bilateral removal of L1, 2, and 3.

sympathectomy is carried out sterility will almost certainly occur. The cases in the three groups were as follows.

Group I.—Thirty cases of bilateral lumbar ganglionectomy.

Group II.—Ten cases of various surgical procedures 21 days after operation. These consisted of three partial gastrectomies, two perforations, one ureterolithotomy, one pyelolithotomy, one bilateral inguinal hernia, one intestinal obstruction with gut resection.

Group III.—Eight cases of hypertension in which some extensive form of sympathectomy had been carried out. In this series the segment of sympathetic chain removed extended from T9 to L3 at least, and in all cases the splanchnic nerves were removed in addition.

The groups of cases are further analysed in the Table.

Group Analysis of Cases

	Normal	Sterile with Reflux	Sterile No Reflux	Total
Group I	27*	1	2	30
Group II	10	—	—	10
Group III	Nil	3†	5	8

* One case had no emission for three months and then gradually recovered.
† One case of this group has now a small seminal emission.

Results

Group I

Of these 30 cases 27 had normal ejaculation. One of this number, however, stated that he had no ejaculation for a month after operation, while noticing no abnormality in other respects; but at the time of examination four months later he was found to be quite normal. He had also noticed that there was some post-coital cloudiness of his urine during the first post-operative month. Another patient in this series had passed the acid test and become a father since the operation.

Of the three patients who showed no ejaculation one was a young man of 28 with a history of congenital syphilis and recent gonococcal infection. Unfortunately, no pre-operative test was carried out, but there was reason to believe that his functions were already considerably impaired. The second patient was a healthy man of 50 who had lost all seminal emission up to the time of examination 15 months post-operatively. There was no evidence of bladder reflux in his case. The third patient was a young man of 26 referred from another clinic on account of a post-operative loss of seminal emission. There was definite evidence of reflux of semen into the bladder when he was examined after a year.

It is seen, therefore, that there was no ensuing abnormality of seminal emission in 27 out of 30 cases of high bilateral lumbar ganglionectomy in which there was every reason to suppose that the first ganglion was removed. Furthermore, one of the cases regarded as sterile had an intercurrent disease which may have been responsible.

It should be added that many other cases of bilateral lumbar ganglionectomy in which there was a detectable failure to remove the first lumbar ganglion on one or both sides were subjected to post-operative examination, and all of these were perfectly normal in every respect.

Group II

Tests were carried out on these widely differing cases of general surgical procedures on about the twenty-first post-operative day; it was apparent that, normally, the function of ejaculation was not impaired and no case of lack of emission was found at this early period.

Group III

These are the most interesting patients of all, and it is here that some light is thrown on the ejaculatory mechanism.

In striking contrast to the simple bilateral ganglionectomy, seven out of eight of these extensive sympathectomies

resulted in complete absence of ejaculation, while there were no other sexual abnormalities. The eighth case was remarkable in that, after several months of failed ejaculation, there was a gradual return of this function, albeit to a diminished degree. It is seen, therefore, that the more radical procedures nearly always result in lack of seminal emission. How, then, is this form of sterility brought about? The answer lies obviously in the study of the anatomy and physiology of the sympathetic chain, the splanchnic nerves, and the musculature of the bladder-neck, vas, vesicles, and ejaculatory ducts.

The occasional occurrence of seminal anorrhoea after a high lumbar ganglionectomy would seem to indicate that the critical level is close to the first lumbar ganglion, and a working hypothesis to explain these cases must postulate an abnormally high removal of the chain, an abnormally low exit of the ejaculatory pathway, or a coincident removal of important medial branches.

Modern knowledge of the function of the ganglionated chain and its branches is based largely on the classical work of Professor Learmonth carried out at the Mayo Clinic in 1930-1, and this has supplanted and supplemented the somewhat fragmentary information gained earlier in this field by other workers (Budge, 1858; Langley and Anderson, 1895).

Learmonth took a unique opportunity of studying these nerves at operation, and systematically stimulated the individual roots of the presacral nerve while recording the effects on the prostate, posterior urethra, and bladder-neck.

He proved without doubt the sympathetic origin of the innervation of the accessory genital apparatus, and put forward the denervation theory of post-sympathectomy sterility. He also produced an unrivalled description of the roots of the presacral nerve, which is diagrammatically represented in Fig. 2. For the sake of clarity multiple branches arising from the same nerve have their course demonstrated by a single line. An abnormally high removal of the chain may be brought about by extensive upward dissection or by the removal of a fused first lumbar and twelfth thoracic ganglion, thus interrupting the ejaculatory pathway before it leaves the sympathetic chain. The important medial branches carrying this pathway probably leave, in the majority of cases, just above the L1 level, as removal of the lumbar chain and therefore its splanchnic branches does not usually interfere with ejaculatory function. Reference to Fig. 2 reveals a possible route for the fibres under discussion—namely, from the region of the twelfth thoracic ganglion through the renal and possibly the aortico-

FIG. 2.—Formation of presacral nerve (after Learmonth). (1) Greater splanchnic nerve; (2) lesser splanchnic nerve; (3) least splanchnic nerve; (4) coeliac plexus; (5) aorticorenal plexus; (6) renal plexus; (7) pre-aortic plexus; (8) inner part of lateral root of presacral nerve; (9) outer part of lateral root of presacral nerve; (10) lateral root of presacral nerve; (11) presacral nerve. It is postulated that (8) may carry the ejaculatory pathway.

renal and coeliac ganglia to the nerve or bundle of nerves which run down the aorta lateral to the pre-aortic plexus. This bundle forms an inner part of the lateral root of the pre-sacral nerve and should normally escape damage during lumbar ganglionectomy. The pre-aortic plexus is not regarded as an alternative pathway, for, as Learmonth pointed out, it is largely vasomotor in function. Possible avenues of escape through aberrant ganglia have been suggested, and these merit further consideration, but the part played by sympathetic filaments accompanying the testicular vessels is thought to be of little importance.

It is seen, therefore, that a high or extensive sympathectomy such as is undertaken for hypertension will produce sterility, while removal of L1, 2, and 3 with the intervening chain should leave intact the ejaculatory function.

Sterility after Extensive Sympathectomy

The patients in whom extensive sympathectomy has been carried out show interesting variations in the manner in which sterility has been produced. (1) Five patients have no evidence of sperm entering the urethra at all; (2) three have evidence of reflux of semen into the bladder; and (3) one patient, although sterile for six months after operation, now has a small seminal emission.

De Takats and Helfrich (1941) report a similar case of recovery of seminal emission after extensive sympathectomy, and Lake (1944) describes two more.

In the first group (1), without seminal emission, if there are no urethral sperm, no bladder sperm, and no urethral fructose, ejaculation into the urethra has not taken place, and it must be assumed that denervation of the vas, vesicles, and ejaculatory ducts has occurred.

This is the first mechanism by which post-operative seminal anorrhoea is brought about, and there is a considerable amount of clinical and experimental evidence to support this view. Experimental evidence brought forward by Simeone (1933) confirmed the innervation of the vas, by the sympathetic in the guinea-pig; and those vesicles, etc., by the sympathetic in the guinea-pig; and those findings which are of especial interest from the point of view of this investigation are summarized below. It was found that (1) the normal vas deferens and epididymis undergoes peristalsis; (2) sympathectomy abolishes this movement and substitutes a segmentation movement; (3) spermatozoa float inertly along the vas while reaching maturity; (4) sympathectomy slows the passage of spermatozoa by four-fifths and many degenerate by the time they reach their destination; (5) motility of spermatozoa occurs only at ejaculation; (6) sympathectomy abolishes prostatic contraction and secretion, and therefore limits the production of the activating hyaluronidase; (7) the vesicles become enlarged after sympathectomy.

These effects were not usually permanent in the guinea-pig, and recovery tended to occur after several weeks. It is true, however, that considerable caution must be used in the application of these findings to man, but investigation of those cases which showed no evidence of ejaculation into the posterior urethra suggests that in man, under these circumstances, there is also no prostatic secretion or these circumstances, further work is in progress on the size of contraction. Further work is in progress on the size of the seminal vesicle after sympathetic block, and there is reason to believe that there is an increase.

Seminal emission following bilateral vasoligation does not become completely absent for almost three months post-operatively (Wells, 1948), while it disappears immediately after an extensive sympathectomy, as would be expected following a sudden denervation of the ejaculatory organs.

Seminal Reflux into Bladder

The second mechanism to be discussed is that of seminal reflux into the bladder, and, of the patients under review, five are considered under this heading. In Group I—that is, after high bilateral lumbar ganglionectomy—one patient is, after high bilateral lumbar ganglionectomy, but no had definite ejaculation into the posterior urethra, but no external emission; while the other, although functioning normally at the time of examination, had a history which

suggested that regurgitation had occurred during a period in which ejaculation had failed. In Group III—that is, after extensive sympathectomy for hypertension—two patients showed definite evidence of seminal reflux, and one who had complete seminal anorrhoea for six months post-operatively now had a small seminal emission, coupled with some degree of bladder reflux.

In cases in which all the emission regurgitates into the bladder, it would seem that, although the vas, vesicles, and prostate are still able to act normally, there is a free communication between the posterior urethra and the bladder at the moment of ejaculation. A consideration of the neuromuscular arrangement at the bladder-neck throws some light on this mechanism.

The internal sphincter is an arrangement of muscular loops curving round the anterior aspect of the bladder-neck and continuous below with the inner circular muscle of the prostate. It is supplied by both sympathetic and parasympathetic fibres, the former carrying motor impulses and the latter inhibitory impulses.

The mode of opening of this sphincter has been the subject of much controversy, and the part played by the trigonal muscle alternately magnified and minimized.

This broad triangular band of fibres runs immediately beneath the mucosa from the inter-ureteric bar and converges on the internal meatus to plunge through the internal sphincter and to be inserted at the base of verumontanum. Contraction of this muscle, or, as some authorities believe, its inherent elasticity combined with inhibition of the internal sphincter, causes opening up of the bladder-neck and posterior urethra in the manner shown (Fig. 3). The relative importance of the component parts of this action has been variously stressed by different authors, but it is felt that the conception of a balance between the two is more in keeping with physiological principles.

FIG. 3.—Mode of opening of internal sphincter. (a) closed; (b) open. (After Young.)

The Internal Sphincter after Denervation

It is now necessary to consider the effect of sympathectomy on micturition, and in particular on the behaviour of the internal sphincter after denervation.

Although it has been reported that a funnel bladder-neck may occur after sympathectomy, it is certain that if any permanent loss of tone did occur one would expect rather more than just a few days' post-operative frequency of micturition; and if it is argued that the external sphincter takes complete control—undoubtedly true after prostatectomy—it can be stated with equal confidence that no case of frequency or incontinence has developed after radical sympathectomy in parous women—that is, those patients whose external sphincters are notoriously unreliable. Furthermore, the results of investigation of the pre-operative and post-operative pressures of the sphincters, although, it is admitted, carried out with a crude home-made instrument, lead us to the opinion that normal resting tone is quickly recovered. A new instrument is at present being devised, and the experiment will be repeated.

It is probable, then, that the competence of the internal sphincter is dependent on a certain basic tone which is inherent in the muscle itself. Its competence during ejaculation, however, depends on superadded spasm, which is achieved through its sympathetic nerve supply. The simplest possible explanation of post-operative reflux, therefore, is the failure of this superadded spasm to occur. This will

explain all our cases of seminal reflux except the case in which a return of ejaculatory power occurred after a six-months interval. This patient had noticed a post-coital cloudiness of the urine at first—a sign common to the other cases which showed reflux—although there was no actual emission. Later, with the return of emission, the cloudiness had become less obvious. A further point of extreme interest was the fact that he believed the return of seminal emission coincided with a much more virile erection. He was one of the few patients who thought he had not been quite normal in this respect after operation.

This case raises the point of production of urethral obstruction by erection. Apart from the narrowing produced by the erect corpus spongiosum, it is obvious that if the erectile verumontanum enlarges proportionately it would help to block the posterior urethra. This would account for the well-known difficulty of micturition in full erection, and is beautifully illustrated, for example, by a case reported by Swift Joly (1929).

FIG. 4.—(a) Tight internal sphincter. The dotted line represents shortened trigonal muscle, and the verumontanum is pulled up to plug the internal meatus. (b) Lax internal sphincter. The dotted line represents straightened-out trigonal muscle with open bladder-neck. The verumontanum is not pulled up.

unyielding ring of a spastic internal sphincter, expends its energy in shortening its fibres as it is prevented from straightening itself out. It therefore pulls up the erect colliculus, thereby shortening the posterior urethra and plugging the bladder-neck (Fig. 4, a). This renders doubly secure the closure of the internal meatus, and possibly even opens the ejaculatory ducts. If this theory is correct it is easy to visualize how the denervated internal sphincter now yields to the contracting trigonal muscle, so that shortening of its fibres fails to occur. The verumontanum is not elevated, therefore, and seminal reflux occurs into the bladder (Fig. 4, b).

This hypothesis postulates that in normal ejaculation the internal sphincter is of predominant importance, thoroughly able to resist the antagonistic attempt of the trigonal muscle to open it, and indeed assisting in the action of this muscle to elevate the verumontanum. The combined tight spasm of the internal sphincter aided by the obstructive effect of the erect colliculus seminalis serves to prevent seminal reflux. If, however, the sympathetic denervation of these muscles occurs, the internal sphincter, although it may recover sufficient tone to remain closed under normal conditions, cannot undergo the accentuated spasm which normally occurs at ejaculation and therefore fails to resist even the weakened attempts of the trigonal muscle to open it. The resulting incompetence is aggravated by failure of the plugging action of the verumontanum secondary to the shift in the balance of muscular power.

Summary

Thirty cases of bilateral lumbar ganglionectomy in which the first, second, and third lumbar ganglia had been removed have been followed up with regard to post-operative sterility (seminal anorrhoea). Only three of this series were found to be sterile.

Eight cases of extensive sympathectomy for hypertension were followed up, and seven were found to be sterile.

The sterility in 11 of the above 38 cases was due in seven cases to complete failure of ejaculation to occur, while four cases showed that there was reflux into the bladder. There was no obvious reason for the difference in these two groups.

The mechanism of sterility in these cases is discussed and a theory of normal ejaculation is advanced.

This paper is regarded as a report on work that is as yet incomplete, and further investigation is in progress. I am grateful to Professor A. M. Boyd for his constant stimulation and advice and for his original idea which initiated this investigation.

COMBINED USE OF HEXAMETHONIUM BROMIDE AND PROCAINE AMIDE IN CONTROLLED HYPOTENSION

A PRELIMINARY REPORT

BY

A. A. MASON, M.B., B.S.

Senior Anaesthetic Registrar,
Queen Victoria Hospital, East Grinstead

AND

JOHN F. PELMORE, M.R.C.S., L.R.C.P., D.A.

Consultant Anaesthetist,
Queen Victoria Hospital, East Grinstead

Despite increased experience in the use of hexamethonium bromide it was felt that this drug was not of itself wholly satisfactory, and there still remained the small percentage of patients in whom it seemed impossible to produce a blood pressure low enough to achieve the required ischaemia for relatively "bloodless field" surgery. Successes had risen from 50% (Enderby, 1950) to 85% (Enderby and Pelmore, 1951). Failures were almost always in the younger age group of patients, and it was observed that such patients often responded to the administration of hexamethonium bromide by an increased pulse rate (up to 120–140 a minute) and a small and often inadequate fall in blood pressure.

A constant search has been maintained for a drug which would either replace or enhance the action of hexamethonium bromide. Procaine amide appeared likely to achieve the latter for two reasons: (1) its vaso-

dilatory action would enhance the similar vasodilatory action of hexamethonium bromide; and (2) its effect in increasing the refractory period of the heart muscle might prevent the tachycardia which usually occurred and which may well be the cause of failure when using hexamethonium bromide.

Pharmacology of Procaine Amide

Procaine amide hydrochloride is *p*-amino-N-(2-diethyl-aminoethyl) benzamide hydrochloride, with the empirical formula $C_{13}H_{21}N_3O.HCl$, and the molecular weight of 271.79. Its structural formula is:

It differs from procaine only by the substitution of the amide group for the ester group. The structural formula of procaine is:

Procaine is a more potent local analgesic than its amide (Newman and Clark, 1950), but it causes much more central stimulation (Kayden, Steele, *et al.*, 1951). Both drugs are slight respiratory depressants, procaine having the greater effect. Both drugs produce hypotension when administered intravenously, but in conscious patients this is only a temporary effect.

Bradycardia is a feature of the action of both drugs, with depression of the T wave and QRS complex. Such production of bradycardia may well be one of its important features in its power to enhance the action of hexamethonium bromide.

Joseph *et al.* (1951) studied the mechanism by which procaine amide is believed to influence ventricular arrhythmias, and suggested that by some means, not yet satisfactorily determined, it depressed ventricular irritability—specifically the refractory period, as measured by the Q-T interval.

Whether the effect of procaine amide was due to the direct action of the circulating drug, or whether its effect was mediated through either the nervous system or some humoral mechanism, or both, has not yet been clarified. In view of the observation at operations, that inadequate ventilation was associated with most of the ventricular arrhythmias was encountered, it was thought possible that the efficacy of procaine amide lay in the diminution of the oxygen requirement of the ventricular musculature, and the cardiac component of the intracellular oxidative processes to participate in the intracellular oxidative processes to increase the oxygen utilization of the tissues (Kayden, Steele, *et al.*, 1951).

Procaine amide is absorbed rapidly and completely from the gastro-intestinal tract, permitting oral dosage when such is desirable. It is excreted in the urine, approximately 60% being recovered unchanged (Mark *et al.*, 1951). Plasma levels decline slowly, approximately 10–20% an hour after intravenous administration (Mark *et al.*, 1951). The amide of procaine is not hydrolysed by the enzyme which affects procaine, and hence is relatively stable *in vivo* (Brodie *et al.*, 1948).

Procaine has been used for the correction of cyclopropane-induced cardiac arrhythmias during anaesthesia (Burststein, 1949). He claimed satisfactory results in 50 cases. Joseph (1951) and Joseph *et al.* (1951) had similar results with procaine amide. No toxic effects of procaine amide have been produced, as evidenced by haematological, renal, and hepatic studies in dogs (Mark *et al.*, 1951).

Effect on Ventricular Arrhythmias

Ventricular fibrillation is usually rapidly fatal, and search has long been made for a drug which will prevent its onset. Among the drugs that have been used are diethylaminoethanol, potassium chloride, quinine, "dibamine," procaine, and procaine amide. Intravenous procaine has been the most widely used during anaesthesia, and has provided the best results (Burststein, 1949).

Ventricular arrhythmias leading to fibrillation may occur under the following conditions: (1) If the patient has pre-existing ventricular extrasystoles, which may be occasional or paroxysmal. (2) With direct mechanical stimulation of the ventricle such as occurs in cardiac catheterization, or operations on the heart itself. (3) The administration of drugs which have a tendency to produce ventricular irregularities—for example, chloroform, cyclopropane, trilete, and adrenaline. (4) Ventricular arrhythmias are sometimes produced for no apparent reason. Stimulation of the larynx, peritoneum, or pleura, and section of the vagi have all been implicated.

Effect on Supraventricular Arrhythmias

Kayden, Steele, *et al.* (1951) stated that the effectiveness of procaine amide in auricular arrhythmias may be influenced by the duration of the arrhythmia. Chronic auricular flutter (10 cases) and chronic auricular fibrillation (14 cases) failed to respond, whereas auricular fibrillation of recent origin (4 cases) responded and reverted to normal rhythm (Kayden, Brodie, and Steele, 1951). Auricular premature contractions were eliminated by procaine amide, although its effect was of shorter duration than in ventricular premature contractions.

Schaffer *et al.* (1951) treated 14 patients with procaine amide and found the drug clinically effective in the treatment of auricular extrasystoles, tachycardia, flutter, and fibrillation. They observed that procaine amide had a depressant influence on abnormal auricular stimulus formation and on normal conduction, as well as having an atropine-like action.

Procaine amide, while protecting the heart from arrhythmias, has been shown to be less toxic than procaine (Mark *et al.*, 1951). It is therefore the drug of choice when treating arrhythmias from any of the above causes. One side-effect of both procaine and its amide is the production of hypotension. In view of the increasing use of hexamethonium bromide for the deliberate production of hypotension in all branches of surgery, the possibility of a series of conditions occurring which necessitate the use of both these drugs in the same patient is becoming more likely—for example, one of us (A. A. M.) was recently faced with the problem of anaesthetizing a patient who showed pronounced irregularity of the pulse. Ventricular extrasystoles were diagnosed, and the control of these with procaine amide during operation was thought advisable. The operation was for removal of a retrobulbar tumour, and because of the ease with which these tumours are removed under the hypotensive technique the surgeon requested that if possible hexamethonium bromide should be used.

It was not known whether the hypotensive action of hexamethonium bromide would be further potentiated by the previous or simultaneous use of procaine amide. The result of this first case encouraged us to study a series of cases using hexamethonium bromide following the previous administration of procaine amide.

We have compared this series with figures taken from 50 unselected cases in which hexamethonium bromide alone was used. Anaesthesia in the two series was exactly the same—namely, induction was with a mixture of thiopentone and gallamine triethiodide, and maintenance was with nitrous oxide and oxygen (2:1), in a semi-closed absorber system, together with intermittent thiopentone or pethidine.

Present Series

Table I shows plainly that after the previous administration of procaine amide a blood-pressure fall to below 60 mm. Hg occurs in more than twice the number of cases

TABLE I.—The Blood-pressure Levels in 50 Unselected Cases Using Hexamethonium Bromide Alone, Compared with the Levels Achieved when Hexamethonium Bromide is Given After 1 g. of Procaine Amide

Control Series: Hexamethonium Bromide Alone; Average Dose, 95 mg.		Hexamethonium Bromide; Average Dose, 65 mg., after Procaine Amide, 1 g. Given in Two Divided Doses of 500 mg.	
Average Blood-pressure Level during Operation	No. of Cases	Average Blood-pressure Level during Operation	No. of Cases

70-80	21	70-80	15
60-70	10	60-70	23
50-60	3	50-60	7
	50		50

(30 against 13 in the control series) in which hexamethonium bromide alone was used. It is also evident that the dose of hexamethonium bromide needed to produce a similar fall in blood pressure is reduced by about 30 mg. after the administration of procaine amide. From this we may conclude that the drugs show a true potentiation of each other's hypotensive effects.

In the case of retrobulbar tumour mentioned both procaine amide and hexamethonium bromide were used in the following manner.

Case A.—A woman aged 42 had a neurofibroma of the left orbit. Her general condition was good. "Omopon," $\frac{1}{2}$ gr. (22 mg.), and scopolamine, 1/150 gr. (0.43 mg.), were given one hour pre-operatively. Her pulse was 84 and irregularly irregular; and blood pressure 130. Anaesthesia was established with a mixture of 0.9 g. of thiopentone and 80 mg. of gallamine triethiodide. An oral tube was passed and anaesthesia was maintained with N_2O+O_2 (2:1) and intermittent thiopentone. The table was then tipped to a 35-degree foot-down position. Her blood pressure was 110, pulse 86 and irregular. Procaine amide was injected intravenously as two doses of 500 mg. each. The pulse became regular two minutes after this and remained so throughout the remainder of the operation. The blood pressure fell to 80 and the pulse rate to 82. Surgery was begun and after only three minutes the blood pressure began to rise, reaching 100 mm. in six minutes. Hexamethonium bromide was then administered intravenously, 20 mg. at a time. After 60 mg. had been injected the blood pressure fell to 60 mm. and remained steady at this level until the operation finished 35 minutes later. The colour remained excellent throughout, the surgical field was clear of blood except for the merest ooze, three swabs only being used. Respirations were unlaboured at 24 a minute. Post-operatively the patient was levelled to a 5-degree foot-down tilt. The blood pressure rose to 100 mm. and the pulse rate was 86. She was transferred at this tilt to her bed. Recovery was uneventful.

It may also be said that cases with a blood pressure of over 80 mm. Hg are often unsatisfactory from an ischaemic point of view. The number of such cases was reduced from 16 with hexamethonium bromide alone to 5 when procaine amide had first been administered. We did not, however, find that all cases with a blood pressure of 80 or over were necessarily unsatisfactory. In fact, many were relatively bloodless, and did not require the pressure to be taken any lower in order to facilitate surgery.

It must be emphasized that the primary object of the anaesthetist is to produce a field which is satisfactory to the surgeon, and not necessarily to produce a particular level of blood pressure. The optimum blood pressure for any particular case varies enormously with the age of the patient, the site of operation, the state of the blood vessels, the pulse rate, and probably many other variables which have not yet been fully assessed. Many cases—for example, excision of a rodent ulcer of the face in a patient of over

70—are virtually bloodless with a pressure of 80-85 mm. Hg, while a young patient may bleed profusely from any site with a blood pressure as low as 65 mm. Hg.

It is estimated that in approximately 85% of all cases in which hexamethonium bromide is used alone a satisfactory surgical result is achieved. That being so, it would be unnecessarily wasteful and troublesome to administer procaine amide to every case, in an attempt to avoid the small number of failures (15%) (Enderby and Pelmore, 1951) which occur when hexamethonium bromide is used alone.

It was therefore decided to restrict the use of procaine amide to cases in which the use of hexamethonium bromide alone had failed to produce adequate ischaemia. A series of 17 such cases were subsequently treated with 1 g. of procaine amide. It will be seen (Table II) that in all except one of these cases a satisfactory operative level was achieved. In no case was any toxic effect seen, and in no case was the blood-pressure fall so severe as to cause concern. The maximum fall occurred within five minutes of administration.

TABLE II.—Blood Pressure in Cases of Failure with Hexamethonium Bromide (H.M.B.), Showing Subsequent Levels Following the Use of Procaine Amide (P.A.)

Case	Age	Dose of H.M.B.	B.P. after H.M.B.	B.P. after Addition of P.A.	Dose of P.A.

Cases Illustrating Response to Procaine Amide

Two case histories show the type of response to procaine amide.

Case B.—A boy aged 10 had an operation for the removal of a neurofibroma of the orbit. Premedication was with omopon, $\frac{1}{2}$ gr. (11 mg.), and scopolamine, 1/300 gr. (0.22 mg.). Induction was with 3 ml. of thiopentone (0.15 g.) and maintenance was with N_2O+O_2 and ether, using an Ayre's T-piece. An endotracheal tube was passed and the table tipped to a 35-degree foot-down position. The systolic blood pressure was 110 mm. Hg, and pulse 120. Hexamethonium bromide, 100 mg., was injected intravenously. After five minutes the pulse rate had risen to 140, and the blood pressure had dropped only 5 mm. Hg. Positive pressure could not be used because of the Ayre T-piece. Procaine amide, 800 mg., was given intravenously. The blood pressure fell in five minutes to 60 mm. Hg and the pulse rate resumed its original level of 120. Operation was begun and the field was virtually bloodless. Four swabs only were used during the entire operation, and these only to mop the merest ooze. The pulse remained steady up to the completion of the operation 50 minutes later, and the blood pressure climbed slowly to 80 mm. Hg. On levelling the patient the blood pressure rose to 95 mm. Hg and subsequently recovery was uneventful.

Case C.—A girl aged 18 had an operation for nasal reduction. Premedication was with omopon, $\frac{1}{2}$ gr. (22 mg.), and scopolamine 1/150 gr. (0.43 mg.). The pre-operative blood pressure was 120 mm. Hg, pulse 84. Induction was with 0.9 g. of thiopentone and 80 mg. of gallamine triethiodide. The blood pressure was then 110 and the pulse 80. An oral tube was passed and anaesthesia maintained with N_2O+O_2 in a semi-closed circle system. Intermittent thiopentone was used. The patient was tipped to a 35-degree foot-down tilt, and hexamethonium bromide, 100 mg., was injected intravenously. After five minutes the blood pressure became 110 and the pulse 116. A second dose of hexamethonium bromide, 100 mg., was then injected and positive pressure respiration began. After five minutes the blood pressure became 85 and the pulse 118. The operation was started and after ten minutes the bleeding was brisk. The blood pressure was 100

and pulse rate 124. Procaine amide, 1 g., was injected intravenously. Within five minutes the blood pressure became 65 and pulse fell to 90. The bleeding stopped. The operation was continued uneventfully, there being only three swabs used, and the sucker was discontinued completely once the blood pressure had fallen to 65 mm. The blood pressure gradually rose to 75 mm. after 70 minutes, but no further bleeding occurred. The pulse was 92. On levelling, the blood pressure rose to 100 mm. Hg. Recovery was uneventful.

Discussion

Cases B and C show an interesting relationship between pulse rate and blood pressure. On the administration of hexamethonium bromide the pulse rate is seen to rise, and the fall in blood pressure is only slight. The injection of procaine amide causes both the blood pressure and the pulse rate to fall. It seems highly probable that the main action of the procaine amide is on the pulse rate, and that the fall in blood pressure is secondary and due to the prevention of this tachycardia.

It would seem reasonable to suppose that the rise in pulse rate following hexamethonium bromide is an effort by the body to compensate for the fall in blood pressure, and occurs possibly through the secretion of adrenaline. The prevention of this compensatory tachycardia seems to be a necessary concomitant of a successful hypotensive anaesthetic, for it has long been observed that almost all the unsuccessful cases have an elevated pulse rate.

It may well be that the omission of gallamine triethiodide, with its tendency to produce tachycardia, will further increase the success rate. This substance was used in our first hexamethonium bromide/procaine amide series so as to make it strictly comparable with the 50 control cases to which it has been added. Enderby has omitted using hexamethonium bromide recently, but continues to use of gallamine triethiodide in cases in which a compensatory tachycardia detracts from a good ischaemic result.

Another point of interest is the age group of the 17 cases in which the addition of procaine amide was deemed advisable. Thirteen of the total were under 30 years of age, and this strengthens our previous view that the failures were mostly in the younger age group of patients. Thus the anaesthetist who deals more with the older age group will have greater success with hexamethonium bromide alone and less need for an adjuvant in order to achieve hypotension.

Conclusions

If it is deemed advisable to use hexamethonium bromide and procaine amide together—for example, with ventricular arrhythmias and maxillo-facial operations—no toxic effects occur. The blood pressure, however, does fall more than with either one of these used separately, and also with smaller doses. The drugs show a true potentiation of each other's hypotensive effects. The anaesthetist must use supreme caution and vigilance when using them together.

If hexamethonium bromide fails to bring the blood pressure down to a level in which bleeding is negligible the result will almost always be safely and quickly achieved by the subsequent addition of 1 g. of procaine amide intravenously. Failure of hexamethonium bromide alone seems to occur with the greatest frequency in patients under the age of 30, and it may be anticipated that procaine will be required most often in this age group.

Summary

A series of 50 cases is reported in which procaine amide was used before the administration of hexamethonium bromide, and the results are compared with a control series.

A further series of 17 cases is reported in which hexamethonium bromide failed to produce a sufficient fall in blood pressure, and which responded after the administration of procaine amide.

The effect on the pulse rate and its relationship to the hypotensive effect of these two drugs are clearly demonstrated.

We wish to thank our colleagues for their encouragement and assistance with these investigations and their permission to use some of their records, and Messrs. Squibb for generously supplying procaine amide ("pronestyl"). We are also indebted to Dr. D. A. Robertson, cardiologist at this unit, for his help and advice.

[ADDENDUM.—Since completing the foregoing article in February, 1952, work has gone forward with procaine amide, and 150 additional cases have received this drug. Careful observations have been made and records kept. So far no cases of allergy or untoward side-effects have been noticed. The pulse rate has almost invariably been reduced, with resulting benefit. The drug is being used by us in doses of 0.5 to 1 g. in those cases in which the pulse rate remains higher than 110. An additional paper is being produced on this series.

We are indebted to Messrs. May and Baker Ltd. for supplying the entire requirements of this later series of cases.]

TREATMENT OF ACUTE MALARIA
WITH PYRIMETHAMINE

BY

T. WILSON, M.D., D.P.H.

AND

J. F. B. EDESON, M.B., Ch.B.

Institute for Medical Research, Kuala Lumpur,
Federation of Malaya

Pyrimethamine, which is 2:4-diamino-5-p-chlorophenyl-6-ethylpyrimidine, is the latest of the new synthetic anti-malarial drugs to be tested by us in the Malaria Research Division of this institute. This compound is produced by Burroughs Wellcome & Co. under the trade name "daraprim," and was formerly known by the experimental number B.W. 50-63.

Falco *et al.* (1951) found that pyrimethamine was active in very small doses against *Plasmodium gallinaceum*, *P. berghei*, and *P. cynomolgi*, and its toxicity was slight. Rollo (1951) reported that proguanil-resistant strains of *P. gallinaceum* and *P. berghei* were susceptible to pyrimethamine, and found that *P. gallinaceum* could not readily be made resistant to pyrimethamine by the usual methods. Archibald (1951) gave the first account of the effect of pyrimethamine in human malaria. Single doses of as little as 5 mg. cleared *P. falciparum* trophozoites from the blood of Nigerian schoolchildren; his patients, however, seem to have been parasite carriers rather than sufferers from acute malaria.

Through the kindness of Brigadier J. S. K. Boyd, Director of the Wellcome Laboratories of Tropical

Medicine, we obtained a supply of pyrimethamine, and have used it to treat 126 patients with acute malaria. This paper includes the results up to June, 1952.

Experimental Methods and Standards

Our patients were drawn from the Asian population of the Kuala Lumpur and Tampin districts of the Federation of Malaya. They may be regarded as semi-immunes; but they came to hospital seeking treatment for fever, and were admitted to the General Hospital, Kuala Lumpur, or the District Hospital, Tampin, where they were under the personal supervision of one or other of us. The cases here recorded were previously untreated and uncomplicated infections due to a single species of malaria parasite, and usually with fever and other symptoms of acute malaria.

Parasite counts were made daily on all patients, using the Dreyer-Sinton fowl-cell technique, and thick blood films stained by Field's rapid method were also examined once or twice daily to check progress. A film was reported negative if no parasites were seen in 100 thick film fields. Pulse rates and temperatures were charted four-hourly.

The doses of pyrimethamine were given to each patient by one or other of us, and were seen to be swallowed along with a drink of water. The drug was supplied in tablets of two sizes, containing respectively 10 and 25 mg. of pyrimethamine base, and all doses are stated in terms of base.

At the start of our trial little was known about the effectiveness of pyrimethamine in the treatment of acute malaria or what the optimum dose should be. Treatment was therefore restricted to patients in good physical condition whose parasite counts were relatively low. After a single dose of 20 mg. had proved ineffective in one falciparum and one vivax infection, we decided to begin with single doses of 50 mg.

Results

(1) *Acute Falciparum Malaria*.—Fifteen patients were treated with a single dose of 50 mg. of pyrimethamine; 39 received 100 mg., in divided doses of 50 mg. each at intervals of 4 to 12 hours, and 26 received a total dose of 300 mg. in five days—100 mg. on the first day, followed by 50 mg. daily for the next four days. The results are summarized in Table I. They were disappointing. The

TABLE I.—Average Duration of Asexual Parasitaemia and Fever after Treatment of Acute Falciparum Malaria with Pyrimethamine

Dose of Pyrimethamine Base	No. of Cases	No. of Failures*	Average Duration of Parasitaemia and Fever in Days (Excluding Failures*)		Average Asexual Parasite Count per c.mm. Before Treatment	Range of Parasite Counts
			Parasitaemia	Fever		
50 mg. × 1	15	2	1.9	2.0	16,400	1,000–92,600
100 mg. in 12 hours	39	4	2.4	2.1	9,200	600–27,400
100 mg. × 1 50 mg. × 4	26	7	2.6	2.3	12,600	2,100–46,400

* Failure means that asexual parasites were still present on the seventh day, or that therapeutic intervention with another drug was necessary before the seventh day.

most disturbing feature was the failure to cure so many of the patients. But, apart from these failures, the clinical action of the drug was slow, and more than one-third of the successfully treated patients had persistence of fever and symptoms for a day or two after trophozoites had disappeared from thick blood films. A similar delayed action on fever is often seen when treating falciparum malaria with proguanil, but is rare with other synthetic drugs. In a comparable series of 25 patients treated with single doses of 300 mg. of chloroquine base there were no failures; the average duration of parasitaemia was 2.3 days, but the average duration of fever was only 1.2 days.

Many of our patients came from areas where proguanil-resistant strains of *P. falciparum* were known to exist. It was possible that such strains were also resistant to pyrimethamine, and that this would explain the failures and indeed the persistence of symptoms in so high a proportion of our patients. We tested this hypothesis by giving pyrimethamine to patients whom proguanil had failed to cure.

(2) *Treatment of Proguanil-resistant Falciparum Infections with Pyrimethamine*.—Twenty-four patients with acute falciparum malaria had responded little or not at all to doses of 300 mg. of proguanil daily for an average of 3.7 days; they were then given 100 mg. of pyrimethamine in two doses of 50 mg. each. The results are summarized in Table II. Apart from the two immediate failures, one

TABLE II.—Average Duration of Parasitaemia and Fever in Proguanil-resistant Falciparum Infections Treated with 100 mg. Pyrimethamine

No. of Cases	No. of Failures*	Average Duration of Parasitaemia and Fever in Days (Excluding Failures*)		Average Asexual Parasite Count per c.mm. on Day Pyrimethamine was Given	Range of Parasite Counts
		Parasitaemia	Fever		
24	2	1.9	1.8	7,814	200–54,700

* Failure means that asexual parasites were still present on the seventh day, or that therapeutic intervention with another drug was necessary before the seventh day.

TABLE III.—Average Duration of Parasitaemia and Fever after Treatment of Acute Vivax Malaria with Pyrimethamine

Dose of Pyrimethamine Base	No. of Cases	Average Duration of Parasitaemia and Fever in Days		Average Asexual Parasite Count per c.mm. Before Treatment	Range of Parasite Counts
		Parasitaemia	Fever		
50 mg. × 1	11	3.1	2.0	5,470	600–14,600
100 mg. in 12 hours	11	3.4	1.9	5,640	400–18,600

patient treated with pyrimethamine on day 4—that is, after three full days' treatment with proguanil—and discharged from hospital apparently cured on day 12, returned six days later with a temperature of 102° F. (38.9° C.) and falciparum trophozoites in his blood. Excluding the two failures and two afebrile patients, only 2 patients out of 20 had persistence of fever and symptoms after trophozoites had disappeared from their peripheral blood. These results are so similar to those in Table I as to suggest that resistance to proguanil plays little part in determining how falciparum malaria will respond to treatment with pyrimethamine.

(3) *Acute Vivax Malaria*.—Eleven patients with acute vivax malaria were treated with the 50-mg. single dose, and 11 with the 100-mg. dose. The results are summarized in Table III. Parasite clearance was slow, but there were no failures; fever and symptoms did not persist after trophozoites had disappeared from the peripheral blood.

Discussion

Comparison with Results from Elsewhere.—During the progress of this work accounts of therapeutic trials of pyrimethamine in other countries became available. One, by Schneider *et al.* (1952), was from Tunisia and Indo-China; another, by McGregor and Smith (1952), was from the Gambia. More recently still, Goodwin (1952) has reviewed these results, and has also given details of other clinical trials in Assam. The general tenor of these reports is favourable, yet occasional failures appear in the records, and Schneider *et al.* make special mention of the slow clinical response, and of the fact that results were not improved by using more than a 50-mg. single dose. More

work is needed before the value of pyrimethamine in the treatment of malaria can be assessed. Our own results indicate that it is unsuitable for the treatment of acute malaria caused by Malayan strains of *P. falciparum*; its effect on parasitaemia is so uncertain that it could not be relied upon in a heavy infection.

Drug-resistance.—In recent years, and particularly since the advent of proguanil, the problem of drug-resistance in malaria parasites has assumed a new importance. Not only must the ability of parasites to develop resistance against a drug be investigated, but also the possibility of cross-resistance between different drugs. Schmidt (1953) found that *P. cynomolgi* in monkeys could quickly be made resistant to pyrimethamine, that the resistant quality was transmissible through the mosquito, and that resistant trophozoites were also refractory to treatment with proguanil. Rollo (1952) produced resistance to pyrimethamine in *P. gallinaceum* and *P. berghei*, but found that the drug was almost as active against proguanil-resistant strains in the laboratory as against normal strains. We are still uncertain whether falciparum infections which fail to respond to pyrimethamine are also resistant to proguanil; but the figures in Table II suggest that proguanil-resistant strains of *P. falciparum* behave similarly to unselected Malayan strains of falciparum when treated with pyrimethamine.

Summary

Pyrimethamine, a new antimalarial drug of the 2:4-diaminopyrimidine series, has been used in Malaya for the treatment of 126 patients with acute malaria.

Eighty patients had previously untreated acute falciparum malaria. A single dose of 50 mg. of pyrimethamine failed to cure 2 out of 15 patients; a dose of 100 mg. (in two doses of 50 mg. each) failed to cure 4 out of 39; and a total dose of 300 mg. (100 mg. on the first day and 50 mg. daily for the next four days) failed to cure 7 out of 26 patients. Apart from the failures, the action on fever and symptoms was usually slow.

Twenty-four patients whose falciparum infections had proved refractory to treatment with proguanil were given 100 mg. of pyrimethamine. Results were so similar to those described above as to suggest that resistance to proguanil does not affect the response to pyrimethamine, and is therefore unlikely to have been responsible for the failures in the other groups.

Workers in other countries have obtained better results than these, but occasional failures have been encountered, as has also the slow action on fever and symptoms. Whatever the verdict elsewhere, pyrimethamine must be regarded as unsuitable for the treatment of acute malaria due to Malayan strains of *P. falciparum*.

Eleven patients with acute vivax malaria were treated with the 50-mg. single dose, and eleven with the 100-mg. dose. Disappearance of parasites was slow, but there were no failures.

We are greatly indebted to Brigadier J. S. K. Boyd, Director of the Wellcome Laboratories of Tropical Medicine, for the supply of pyrimethamine and for information about its properties.

USE OF LOCAL ANALGESIA IN SEPTIC-FINGER SURGERY AT A TEACHING HOSPITAL

BY

P. E. B. HOLMES, M.B., B.S., B.Sc.
Senior Casualty Officer, King's College Hospital

AND

D. J. C. GRAFF, M.R.C.S., L.R.C.P.
Late Second Casualty Officer, King's College Hospital

The purpose of this limited survey is to ascertain whether local analgesia is an advantage over general anaesthesia in septic-finger surgery. The operations have been performed by the casualty officers and the casualty dressers; although the latter change once a week, they have operated on two-thirds of the cases. Each new dresser has one or two practical demonstrations of the technique of analgesia and the principles of drainage; he is then allowed to operate single-handed, but with a casualty officer present.

The investigation began in February, 1952, and covers 256 patients operated on between that time and July, 1952. In the final analysis the case records are complete enough in only 209. The youngest patient was 3 years old and the eldest 85.

For the most part we have followed the terminology used in Professor Pilcher's clinic at University College Hospital (Pilcher *et al.*, 1948; Bailey, 1952). We have used local analgesia for the fingers and thumb. The types of infection classified are: (1) Acute paronychia (40.2%). (2) Pulp abscess: this includes the terminal pulp only (24.2%). (3) Apical abscess: the "apex" being that space lying between the true pulp and the end of the finger (9.3%). (4) Subcutaneous abscess, both volar and dorsal (17.9%). (5) Subungual abscess: we use this group to include sepsis following on splinters under the nail (8.2%).

Method of Treatment

Most cases were operated on at their first attendance. When pus has not been obvious on examination we have found that throbbing pain and loss of sleep are the symptoms which are most suggestive of its presence.

Analgesic.—2½% procaine solution without adrenaline was used. For the first two months the injections were given at the sides of the proximal phalanx—but later the nerves were injected as they leave the palm, just distal to the deep transverse metacarpal ligament. After cleansing with tincture of cetrimide, the dorsal skin between

FIG. 1.—Sites for injection of the various fingers.

the knuckles is stretched and a very fine needle introduced here (Figs. 1 and 2). It is directed distally and forwards—fairly near to the proximal phalanx. Before withdrawal the needle is directed across the knuckle to block the dorsal nerves and the site for injection of the opposite side of the finger: the second injection is then made. In all, 6 ml. is usually more than enough. At this stage we allow at least five minutes, preferably ten minutes, for the block to become effective.

FIG. 2.—A longitudinal section at the level of a metacarpophalangeal joint; for the sake of clarity, the other structures at this level have been omitted.

A tourniquet of thin rubber is placed on the finger at its base. This is essential, since the extent of dead tissue and "collar-stud" sinuses cannot be seen without a bloodless field. We stress to students that (1) incisions must be adequate in extent, placed if possible over dead skin, and in the direction of Langer's lines; (2) all slough must be removed and the cavity mopped out; (3) deep extensions must be carefully sought with a probe; and (4) drainage must be ensured by the use of a small piece of tulle gras (which serves solely to hold the edges of the incision apart) and often by the excision of a narrow diamond of skin.

We have not used "through-and-through," "hockey-stick," or "alligator" incisions for pulp lesions. For paronychia we used the classical lateral incision, as merely elevating the nail-fold has not been found effective. When possible, distal healthy nail has been left *in situ* as protection. For infections at the side of the nail we have removed a strip wide enough to ensure drainage rather than the whole nail.

After operation a dry dressing is applied and the tourniquet removed; the circulation is checked and a tubular bandage applied. This has been found much more useful than the orthodox finger bandage. The affected arm is rested in a sling for at least two days. The patient is given a small supply of codeine tablets.

Dressings.—These are done as infrequently as possible. The patient attends the day after operation, but if, as expected, he has had a good night and the dressing is comfortable it is not touched for 48 hours. Then the wick is removed and suitable dressings are continued. These are performed in a morning hand clinic, where the same casualty officer and nurses deal with the cases daily. There is also a physiotherapist in attendance. For certain cases we have soaked the wound in chloramphenicol solution (24% in propylene glycol) for five minutes. Otherwise we have kept the wounds dry and have instructed the patients to do likewise.

Chemotherapy and Bacteriology.—In all but nine cases penicillin (300,000 to 600,000 units of procaine penicillin daily) has been given. Five patients received systemic chloramphenicol because of the isolation of penicillin-resistant organisms and a tendency to chronicity. Bacteriological sampling was not undertaken as a routine measure except for a short period during April, May, and June, 1952, when bacteriological swabs were taken from the lesions of all patients at the time of incision. In 100 consecutive cases comprising all types of hand infection, cultures were sterile on two occasions; in the remaining cases the organisms isolated were: *Staphylococcus aureus*, 94 cases (in pure culture, 88 cases); *Streptococcus pyogenes*, 7 cases (in pure culture, 2 cases); coliform bacilli, 4 cases (in pure culture, 2 cases). Infections with two or more organisms were found in six cases. Of the staphylococci 77% were sensitive to penicillin.

Results

The results are expressed in days of disability from the first symptoms until operation and from operation until the end of treatment, and of total disability. The pulp abscess is the most common type of infection to become chronic. We have had 12 such complicated cases in this series; in these, the total disability has been over 14 days. In Table I are shown separate results for the straightforward cases and for the 12 cases with complications. In the last column are shown the results achieved by Bailey.

TABLE I.—Disability Times from Onset Until Operation and from Operation until Discharge

No. of Cases	Type of Infection	Average Disability Time in Days			Total Time U.C.H. Series
		Pre-operative	Post-operative	Total	
85	Paronychia	4.7	8.4	13.1	14.3
48	Pulp abscess (total)	5.0	12.5	17.5	18.7
36	Pulp abscess (uncomplicated)	4.9	6.9	11.8	
12	Pulp abscess (complicated)	7.6	30.9	38.5	
37	Subcutaneous abscess	4.3	8.0	12.3	14.5
21	Apical abscess	4.9	11.1	16.0	11.0
18	Subungual abscess	4.8	10.1	14.9	

From the point of view of this investigation it is necessary to compare local analgesic with general anaesthetic cases as regards post-operative time. This has been done from the records of this hospital for 1951, when general anaesthetics were used. The cases were selected according to letters A-L of the names record. The unbiased comparison is shown in Table II.

TABLE II.—Comparison Between the 1951 and 1952 Series

	Type of Infection	Post-operative Time in Days	Type of Infection	Post-operative Time in Days
1951 series (G.A.)	Paronychia (80 cases)	11.6	Pulp abscess (50 cases)	15.0 (22 cases >14 days)
1952 series (L.A.)	Paronychia (85 cases)	8.4	Pulp abscess (48 cases)	12.5 (12 cases >14 days)

The results reveal that: (1) The figures for disability time are similar for the large University College Hospital series and this small series; in both, local analgesics were used. (2) The figures at this hospital are better when a local analgesic has been used. We are convinced that the reason for this is unhurried careful operation in a bloodless field. (3) The disability time for "simple" pulp abscesses (three-quarters of the cases) is seen to be about the same as that for paronychia. (4) Failure to obtain a quick recovery has been due to osteitis (three cases); inadequate drainage by doctors outside the hospital (three cases); inadequate drainage at the hospital (four cases); far-advanced initial lesions (four cases); fracture of terminal phalanx (two cases); and lack of co-operation (one case). (5) The difference in disability time between the local and general anaesthetic cases may seem slight; however, for the cases in Table II alone it represents one man's work for 18 months. (6) It would seem from Table I that the average patient, no matter what type his infection, lingers about five days before coming to hospital; this time allows for the formation of pus.

Discussion

As a result of the investigation we are of the opinion that local analgesia is definitely superior to general anaesthesia for infections of the fingers. The reasons are:

From the patient's point of view.—We have found that the majority prefer an injection to a "whiff" of gas, with its attendant period of starvation and the chance of post-anaesthetic debility and vomiting.

From the surgical point of view.—The advantages are many. They are summarized thus: Local analgesia has

been objected to because it is said to endanger the blood supply of the finger. We do not use adrenaline, and if the injection is given as above there is no mechanical constriction except by the tourniquet. We have watched the colour of the finger-tips post-operatively and found it normal in all cases. Another objection is the injection of fluid into potentially infected tissues—making them oedematous and thereby risking spread of infection. We have met neither of these complications, nor sensitivity to procaine. General anaesthesia involves a small risk and, in addition, a wait until the statutory four hours has passed since a meal. Its possible unpleasantness has been mentioned.

Above all, it is preferable to be able to operate with care on a stationary finger rather than to make a quick incision on a patient who is perhaps not too well anaesthetized. This type of operation leads inevitably to inadequate drainage.

The knowledge that operation can be performed immediately under local analgesia is of great value; there is no temptation to defer operating should the patient attend in the evening, nor are superficial pustules opened without anaesthesia and without proper exploration.

Local analgesia can be attained by anyone working alone, and from the point of view of casualty officers in small hospitals it is excellent; in fact, it has been practised in many such hospitals for some years. It is a better method for teaching purposes, since the student learns to work with care and sees the lesion clearly. There is also the extra time which the inexperienced operator needs.

In conclusion, we would stress that students under supervision have performed most of the operations; the results indicate that this is a satisfactory method.

We thank Mr. E. G. Muir for his helpful criticism and permission to publish these cases, also the other casualty officers, Sister Doris, the nursing staff, and the students who have done most of the operating. We also acknowledge the help we have received from the Bacteriology Department, and in particular thank Mr. K. Tippet and Mr. L. Rutty, who undertook the cultural investigations.

SOME ASPECTS OF CATHETERIZATION IN RETENTION OF URINE

BY

J. A. LLOYD DAVIES, M.B., B.S., F.R.C.S.

The closed methods of prostatectomy introduced by Harris (1934), Hey (1945), and Millin (1945) require the absence of urethral and urinary sepsis for their safe performance. The undertaking of these closed operations on patients with urinary-tract infection offends surgical principles, and may lead to ascending pyelonephritis, wound sepsis and diastasis, and suprapubic urinary leak, despite the use of chemotherapy and antibiotics. It is clear that previous catheterization jeopardizes the patient's recovery if infection has been introduced with the catheter. This is particularly so in cases of acute on chronic retention of urine, in which immediate closed prostatectomy is now so often feasible. The advantages of this procedure need no emphasis when compared with the alternative of catheter drainage until urethral and bladder infection are well established, followed by suprapubic cystostomy, and transvesical prostatectomy at a later date.

Present Investigation

With this factor of urinary infection in mind, an investigation was carried out into a series of 117 consecutive patients admitted to hospital for the treatment of retention of urine caused by prostatic enlargement, fibrosis, or neoplasm. A history of any catheterization prior to admission was obtained, and the first specimens of urine collected in hospital were examined. In some cases these samples were midstream specimens, some were from suprapubic drainage of the bladder, others were obtained at prostatectomy or cystoscopy, while in a small group specimens were collected by catheterization when the patient's general condition precluded any other manoeuvre. A specimen of urine in which pus cells were seen on microscopy of the centrifuged deposit and from which pathogens were grown on culture was regarded as infected. The following results were obtained:

Total No. of cases	117	No. infected	31 (26%)
No. uncatheterized	86 (73%)	"	15 (17%)
No. catheterized	31 (27%)	"	16 (52%)

A further review with regard to frequency of catheterization disclosed the following:

No. catheterized once	13 (11%)	No. infected	3 (23%)
" repeatedly	18 (15%)	"	13 (72%)

In those patients who had been catheterized *Bact. coli* was present in only four, while the remaining 12 cases had mixed infections of two or more of the staphylococcal, coli, *Sr. faecalis*, pyocyanus, or proteus groups. The corresponding figures for the uncatheterized showed a *Bact. coli* infection in ten and mixed infections in the other five cases.

It is not surprising that retention is sometimes associated with urinary infection even when no urethral instrumentation has taken place, for the stasis of urine in the bladder provides a relatively undisturbed haven for the growth of bacteria.

That previous catheterization in retention of urine should raise the numbers infected from 17% to 52%, and, in addition, noticeably increase the proportion of mixed infections is of grave significance. Particularly is this so in view of the relative insensitivity of many strains of these organisms to antibiotics and chemotherapy. It is not only in the patient's home but in the hospital out-patient clinics and wards that urethral catheters are passed. How may such catheterization be avoided?

The discomfort of acute on chronic retention is often such as to lead to urgent demands from the patient for relief. In these circumstances there are several courses open to the practitioner. The time-honoured method of trying to get the patient to micturate while he is sitting in a warm bath with the taps running is rarely of avail, and recourse is generally had to one of the following procedures: (a) giving the patient morphine and transferring him to hospital; (b) the passing of a rubber catheter, partial or complete decompression of the bladder, removal of the catheter, and the transfer of the patient to hospital; (c) catheterization and decompression, removal of the catheter, and the hopeful waiting for return of spontaneous micturition—this happy occurrence is by no means usual, and the catheter may be passed again and thereafter repeatedly; (d) the passing of a catheter and tying it in.

The Best Course

Which course should the practitioner adopt? Although the arranging of a patient's admission to hospital nowadays is sometimes a difficult and exasperating matter, there is no doubt that generally, so long as there is no excessive delay, this is the best course, with the patient adequately sedated and with no catheter passed. It is felt that, normally, recourse should never be had to repeated catheterization or the tying in of a catheter. The safe performance of a closed prostatectomy, in itself necessitating an indwelling catheter

MACHINE AND BRAIN

Design for a Brain. By W. Ross Ashby, M.A., M.D. (Cantab.), D.P.M. (Pp. 260. £1 16s.) London: Chapman and Hall. 1952.

One of the methods by which we try to understand biological processes is that of seeking a model or artifact which imitates the process we are studying. In the past almost every known mechanism—clocks, pulleys, levers, pumps—has been fruitfully used in physiology to this end. Recent developments in mathematics and in electrical engineering, based on the principle of "feed back" (which created guided missiles, automatic aeroplane pilots, and giant computing machines), have given a fresh impetus to the interpretation of the activities of mind in terms of machines—and, it must be added, the activity of machines in terms hitherto reserved for minds, such as memory, purpose, and intelligence.

Dr. Ashby's book is a remarkable contribution to this field. Its major extravagance is its title *Design for a Brain*, for the thesis it presents is much narrower. It is indeed confined to the answer to the questions: Can a machine learn from past experience? Having erred, can it so adjust itself that its next effort is likely to be more successful than its last?

To these questions Ashby's machine, the homeostat, supplies an affirmative answer. He describes in detail the data of its construction and discusses, first in non-mathematical language and then in appendices with the full panoply of advanced mathematical symbolism, the concepts and principles which lead him to suggest that these may "account fully for the development of adaptive behaviour even when the adaptation is as complex as that of man." The crucial criticism of all the ingenious artifacts which mimic vital behaviour lies in the validity of the analogy. Although Ashby has shown that his homeostat acts like the living organism in that it can adapt itself to its environment, learn from experience, and even repair itself when damaged, what evidence is there that the organism acts like, or has a similar structure to, the artifact? Ashby concedes that such evidence is almost entirely lacking, but says that it has never been searched for systematically. He candidly admits, however, that the behaviour of the homeostat differs markedly from that of brain. Among the differences are, first, the absence of gradation of success in the homeostat; it either fails or it succeeds—unlike living organisms, in which adaptation becomes "better and better every day." Secondly, the homeostat cannot conserve its learning; the readjustments necessary for a second adaptation destroy those which brought about the first; except in very primitive organisms learning does not destroy what was earlier learnt. And, thirdly, if the time factor in adaptation in the homeostat is analysed, it will be found that, "if we were like homeostats waiting till one field gave us, at a stroke, all our adult adaptation, we would wait for ever." Yet, on theoretical grounds, Ashby postulates that by increasing the number of fields and using repeated partial systems, the objection to the time factor is not insurmountable. But conceptual possibilities do not always emerge as physical realities!

Ashby's work and that of others interested in the field of cybernetics raise issues which are relevant to at least two currently important problems: first, the relationship between the concept of mind and the percept of brain; and, secondly, the nature of neurophysiological mechanisms and its therapeutic implications. The latter tends to be approached by all with commendable objectivity; the former still gives rise to intemperate comment. The mechanists in an orgy of unrestrained extrapolation tend to exaggerate the implications of machine behaviour, and to press too far on present evidence its analogy with brain. The vitalists seek to mask these achievements by a cloud

of fervent and emotionally toned appeals to faith and mysticism. But the scientist will acknowledge Ashby's work as a significant though difficult contribution to the analysis of the problem it tackles—namely, adaptive behaviour in machines—even if he is not prepared to accept on the evidence Ashby adduces all the suggested inferences.

HENRY COHEN.

CLINICAL EXAMINATION

The Essentials for Medical Diagnosis. By the Rt. Hon. Lord Horder, G.C.V.O., M.D., F.R.C.P., and A. E. Gow, M.D., F.R.C.P. Second edition, revised with the assistance of Ronald Bodley Scott, D.M., F.R.C.P. (Pp. 462; 6 colour and 17 black-and-white plates, 22 figures in text. £1 2s. 6d.) London: Cassell and Company. 1952.

Methods of clinical examination tend to have a local flavour. That must be the reason why Messrs. Cassell, who already publish Hutchison and Hunter's *Clinical Methods*, have now, after an interval of 25 years, issued a second edition of this very similar book from St. Bartholomew's Hospital. In writing the book in the first place, and in revising it for a second edition, Horder, Gow, and Bodley Scott reacted against the modern tendency to parcel out the patient to a number of ancillary investigations, biochemical, radiological, and the like, and tried to secure that the student should approach clinical problems by the application of his trained senses. Normal anatomy and physiology are emphasized, and the book is essentially a textbook of physical diagnosis, attention being concentrated on physical symptoms such as cough, dyspnoea, and vomiting, and on objective findings. There are some excellent x-ray photographs, but the section on the E.C.G. is too brief to be instructive.

The charm of the book lies in the numerous aphorisms with which it is studded, for they are of a kind likely to stick in the student's head. That is not to say that one agrees with all of them. One could certainly produce examples to disprove the statement that an enlarged spleen does not cause eversion of the lower ribs. Indeed, in a book of this kind it might be well to warn the student of the wide range of error of physical signs and laboratory data which has been revealed by C. M. Fletcher and other workers in this country and the U.S.A. In fact, one of the jobs for this generation of clinical teachers is to work through the classical physical signs and divide them into the reliable and the unreliable.

The book is well produced at a most reasonable price. It is handy in size and has a useful appendix of tables of normal data, such as the circumference of the head at different ages and the commoner biochemical findings. Bart's students and others will be well catered for now for some years to come.

L. J. WITTS.

THE UNIVERSAL SEROLOGICAL REACTION

Serology with Lipid Antigen: With Special Reference to Kahn and Universal Reactions. By Reuben L. Kahn, M.S., D.Sc. (Pp. 328. £2 6s. 6d.) London: Baillière, Tindall and Cox. 1950.

An Introduction to Universal Serologic Reaction in Health and Disease. By Reuben L. Kahn, D.Sc. (Pp. 155. £1 2s. 6d.) London: Geoffrey Cumberlege. 1951.

There must be few workers who have spent so much time and energy on the investigation of one test as Dr. Kahn. When such a test has a world-wide reputation, and has proved its worth over a period of more than 25 years, it is surprising that Dr. Kahn's investigations concerning the "universal serologic reaction" as revealed by the application of the Kahn test have not received more attention. This interesting work, the results of which may explain the occurrence of some of the troublesome non-specific reactions obtained with serum tests for syphilis, has not been investigated with sufficient zeal by serologists in general. Perhaps this is due in part to Dr. Kahn's method of presenting the results of his researches. Thus his book entitled *Serology with Lipid Antigen* is a hotchpotch of the universal sero-

logical reaction (Part I), the serology of syphilis with Kahn procedures, including the use of cardiolipin antigens (Part II), the technique of Kahn procedure (Part III), and the "Practical Aspects of the Kahn Universal Reaction" (Part IV).

Part I is interesting and contains sufficient evidence to warrant the investigation of the universal serological reaction by other serologists. Part II is disappointing, as for example when the author fails to indicate whether it is an advantage to use cardiolipin or the original Kahn antigen in the test. Part III gives much that has already been published, and it might well have been omitted. Part IV is mainly a recapitulation of, though adding a little to, the information contained in Part I.

Clinicians and serologists might benefit from reading Parts I and IV of this book, but are recommended to study Kahn's next book entitled *An Introduction to the Universal Serologic Reaction in Health and Disease*. This is written in a much happier vein and consists of some 155 pages of subject-matter profusely illustrated with graphs. He discusses the universal serological technique with lipid antigen, and serological reactivity in normal human beings, in different animals, in syphilis, yaws, leprosy, malaria, and tuberculosis. Curiously enough no mention is made of the reaction in pregnancy, virus diseases, and people immunized against enteric fever or smallpox. Because these conditions are the most frequent causes of non-specific reactions with serum tests for syphilis in Britain the omission may cause some comment, but no doubt Dr. Kahn or some other worker will remedy this defect in due course. The last two chapters (11 and 12) deal with technical studies on, and the nature and significance of, the universal serological reaction.

This book should be read by clinicians as well as serologists, who will find much food for thought, the digestion of which will help them in the interpretation of some of the results of serum tests for syphilis obtained with "problem" sera.

I. N. O. PRICE.

CONTRAST PSYCHOLOGY

Contrast Psychology: A Concept of the Movements of the Human Spirit. By Murdo Mackenzie, M.D., M.R.C.P. (Pp. 304. £1 1s.) London: George Allen and Unwin. 1952.

There must now be almost as many systems of psychological explanation as there are shades of religious belief, and with those which are to be taken seriously there is no alternative to learning the terminology and basic tenets of each and applying these sympathetically to a variety of known situations. Only then is it possible to hold an opinion on its validity. Contrast psychology is worth this effort because its originator has tried to subject his experiences as a psychotherapist to a philosophical scrutiny. From this process he has derived certain basic principles, and in this book he applies them to problems of the behaviour of communities, both historical and contemporary. Briefly, he discounts the possibility of a psychological universal and interprets the activities of mind in terms of dissimilarity and polarities. His schema is a tetrad: immediacy in the individual outlook is opposed to deliberation, and amplification in the outlook of the community in contrast to simplification. The uneasy personality created by an anxious mind can reveal itself in four ways only: by assertion, depression, hysteria, and the obsessional ritual.

Armed with this schema, contrast psychology proceeds to explain the attitudes of civilizations and the groups within them in its own terms. The theme is traced from Pericles through Karl Marx to Franklin D. Roosevelt, whose personalities represent deliberation, and from Lynders to Churchill, both of whom the author regards as immediates—thinking solely in terms of the here and now. Freud and Adler, Communism and Fascism, are polar opposites with minimal emphasis on similarities. The hormic view, with the driving force, is taken for granted, together with the Freudian theory of intrapsychic conflict. The solution to community problems lies in psychological awareness

and recognition of the significance of contrast. Whether this must necessarily be in terms of contrast psychology is not made clear.

Dr. Mackenzie is not lacking in confidence in his system and its applicability to the problems of civilization in its widest sense, and there is no middle to his road. Deeply influenced by Hegel and A. N. Whitehead, and assuming what he calls "modern psychological concepts," he has leaped to some interesting conclusions. Whether he has over-simplified or over-amplified his basic system or not, his asides are readable and his logic challenging to anyone who will give the time to learn the terminology of one more system of explanation of the behaviour of mankind having its origins in the autisms of the psychotherapist's consulting-room.

ALEXANDER KENNEDY.

THE KNEE

The Knee and Related Structures: Injuries, Deformities, Diseases, and Disabilities. By Professor Philip Lewin, M.D., F.A.C.S., F.I.C.S. (Pp. 914; 333 figures and 2 coloured plates. £6.) London: Henry Kimpton. 1952.

The author states in the preface that "I am determined to present the matter as it has never before been presented." Certainly no such complete summarization of the views of all possible lesions related to the knee-joint has been produced before, though one feels that his determination to include everything has occasionally got the better of his judgment. It is perhaps a misfortune that Dr. Lewin has been the orthopaedic editor of the *International Abstracts of Surgery* for 35 years. His encyclopaedic knowledge of the works of others has studded the volume with names known and unknown. Pages read like an abstract of abstracts. As a result, the quick decision of the practical surgeon is hidden in a mass of facts and often difficult to find; nor is it always entirely satisfactory. The discussion on total removal of a meniscus versus partial removal is summarized by this final sentence: "Improve your technique to the point where complete removal can be accomplished without undue prolongation of the operation or added trauma during the procedure." This to most readers will seem to be begging the question. Where the subject is obscure or largely academic—for example, intermittent hydrarthrosis—the summary of viewpoints given is excellent.

As neither the initials nor dates are given with names referred to in the text (for example, King), a search of the bibliography at the back will give a choice of Don King, Byron King, and E. S. J. King as the possible author. Nor are all the names referred to in the text—for example, Pulvertaft—included in the bibliography.

In order to vary the format of his pages, certain lists are enclosed in frames. This naturally emphasizes them, and, if this is intended for the uninformed, equal weight is given to each statement and the student may therefore be misled. If it is intended for the knowledgeable, many of the statements included seem unworthy of their place—for example, "Treat the periosteum as gently as you would the eye-ball." The "Ten Commandments," "Ten Simple Analogies," and "Wise Words" offer little pungency. Hiding in the appendix are those orthopaedic dodoes, rupture of the plantaris muscle and rupture of the plantaris tendon.

Although the book on the whole is well illustrated, it is remarkable that no illustrations of arthrography of the knee-joint are included. While the technical varieties of arthrography are well described, and there is some discussion of their theoretical helpfulness, no practical guide to their use is given, and it can only be concluded that the author has not handled the method himself. Its value may be limited but ought not to be as completely underestimated as it appears to be here.

The author's volume in similar format on *The Foot and Ankle* has now run into its third edition, and I have no doubt that this volume will do the same, but it is a volume primarily for reference and not for easy reading.

J. G. BONNIN.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 31 1953

SIX GUINEAS' WORTH

A letter in this week's *Supplement* draws attention to two prevailing misconceptions. The first is that six guineas a year is a large subscription for belonging to the B.M.A., and the second is that the increase this year is, in our correspondent's words, due to "the increased expenditure now necessary to produce the *British Medical Journal*." The annual subscription to the B.M.A. must be among the smallest of subscriptions paid by doctors anywhere in the world for belonging to a voluntary national medical association. Corresponding rates are, for example, much higher in the Scandinavian countries and in the U.S.A. The "ordinary" subscription of six guineas is in fact paid by little more than one-third of the 68,000 members of the Association, in view of the many concessions made to various groups and of the fact that overseas members pay only two guineas a year. But some members forget how greatly the B.M.A.'s obligations and responsibilities have increased since 1939, when membership was little over half what it is now. There is, for example, the valuable work now done by the Medical Practices Advisory Bureau, and by the Empire Medical Advisory Bureau, neither of which was in existence in 1939: these are services to members and have to be paid for. The N.H.S., it should hardly be necessary to point out, has put an enormous burden of work on those in the Association who have to negotiate constantly and continuously on behalf of various groups of doctors. The Treasurer, it may be recalled, informed the Representative Body at Dublin¹ that in 1951 expenditure in connexion with central meetings had increased by over £4,000 above the previous year's level to a total of £22,400. He reminded them, too, that the cost of maintaining B.M.A. premises in 1951 had risen by over £4,500. The implications of all this, surely, should be self-evident. The B.M.A.'s experience reflects that of every householder in the country, and every institution. Costs have risen by 100% in this item and by more in that. It is surprising, not that the "ordinary" subscription has risen to six guineas, but that it has not risen sooner than this.

¹ *British Medical Journal Supplement*, July 12, 1952, p. 25.² *Ibid.*, p. 21.

The cost of producing the *B.M.J.* has increased two- or three-fold since 1939, but increased revenue from sales to non-members and from advertisements has, coupled with prudent management, kept its financial position fairly stable. Even in 1951, when the price of paper soared to previously unknown heights, the *B.M.J.* cost each member only just on 9s. for the whole year, or £30,000 out of the total membership subscription of £196,000; in 1938 the cost of the *Journal* to each member was 10s. As the Chairman of the Journal Committee, Dr. O. C. Carter, further explained to the Representative Body at Dublin last year,² surpluses earned by the *B.M.J.* in the previous nine years had been used for the general purposes of the Association: it was these surpluses that made it possible for the Association to delay raising the subscription. Dr. Carter also pointed out that the publication of quarterly journals on various medical specialties enabled the Association to fulfil its principal object—"to promote the medical and allied sciences." These publications not only do this; they are a service to members and to British medicine. But they, too, cost money to produce. The publishing crisis of two years ago subjected the publishing activities of the Association to a severe strain, which is being successfully borne. Members should realize, and most doubtless do, that the increase in the subscription is not the result of a costly *B.M.J.* The present subscription is a realistic assessment of the cost of the whole range of the Association's activities on behalf of its members, and, if it may be stated in these columns, it seems a small price to pay when so much is received in return.

TOXICITY OF CHLORAMPHENICOL

During last summer a sudden spate of papers appeared in the *Journal of the American Medical Association* describing aplastic anaemia, often fatal, in patients who had been given chloramphenicol.¹ The same condition was described in two reports^{2,3} in this *Journal*. Since then the medical profession in both countries and indeed throughout the world may well have been uncertain how to regard this drug and what indications to recognize for its use. Opinions have varied widely; some workers have looked on these findings as rare pathological curiosities; others have condemned chloramphenicol for any purpose except the treatment of typhoid fever, the single serious disease for which no equally effective alternative form of chemotherapy has been available. It was evidently necessary that extensive inquiry should be made into the frequency of this complication,

which had been recognized only by a few astute observers or by physicians who happened to have given exceptionally long courses of the drug. Such an inquiry has been undertaken in the U.S.A., and its results have now been published as a report⁴ from the Food and Drug Administration in Washington. This is an interesting but inconclusive document, and its recommendations are little more than such platitudes as might have been voiced about the proper use of any antibiotic suspected of causing some toxic effect.

The scope of the "nation-wide survey" on which the report is based is not clear, but it was carried out "mainly, but not entirely, in cities of more than 100,000 population." Inquiries addressed to an unstated number of hospitals for information about cases of aplastic anaemia, granulocytopenia, and related blood disorders occurring since 1949 produced information about 539 such cases. In only 55 of these, of which 44 had aplastic anaemia (fatal in 23), was chloramphenicol the only drug used. A second group of 143 patients, mostly with aplastic anaemia, had received other drugs in addition to chloramphenicol. Out of this group 83 patients died. The other drugs included antibiotics, sulphonamides, arsenicals, analgesics, anticonvulsants, barbiturates, and antipyretics. It is perhaps not surprising that this group was considerably larger than the first, since in any severe illness more than one drug is usually prescribed. No details about these other forms of therapy are given, and some would have been helpful. For example, sulphonamides and at least one analgesic, amidopyrine, have been known to damage the bone marrow, and it would have been useful to know how many of these patients were given any other drug known to be capable of causing such damage and how many had adjuvant treatment which, so far as is known, is blameless in this direction. The third and largest group of patients—341 in all, of whom 157 had aplastic anaemia, 80 granulocytopenia, and the remainder various other blood disorders—had received no chloramphenicol: 133 had had various drugs or been exposed to x rays, and in 208 the condition was termed "idiopathic." It is interesting that inquiry should bring to light so many cases of blood disorders of obscure aetiology. The possible significance of this part of the report depends much on how searching were the inquiries into these patients' drug-taking histories. Many had granulocytopenia, and it is not to be forgotten that 25 years ago people were dying with agranulocytic angina in this country for

some time before it was recognized that the cause was amidopyrine in a widely advertised patent medicine described as a "tonic."

Age distribution, which was wide, did not differ significantly in the three groups of patients, but analysis by sex reveals the unaccountable fact that in the group with blood disorders due only to chloramphenicol females were affected three times as often as males. Analysis of dosage systems is singularly unhelpful in indicating a safe system of administration. Of all patients in whom chloramphenicol could be incriminated, 73 were given a single course, 53 two courses, and 28 had intermittent and 61 prolonged therapy; but nothing is said about how often these different systems were used. If, for instance, in the practice of the hospitals studied "single" courses were ten times as common as "prolonged," it would have been evident that a prolonged course involved a greater risk. No analysis of total dosages is given, but it appears from earlier reports that very small amounts of the drug may suffice to affect the marrow.

The conclusions reached by the authors of the report are that a warning of this possible complication should appear on packages of the drug; that it should not be used indiscriminately or for minor infections; that prolonged administration should be controlled by blood counts; and that further study of marrow damage caused by this and other drugs should be pursued. The report leaves the impression that something remains to be discovered. It is still not clear why it should apparently be possible on the one hand to point to thousands of cases treated with chloramphenicol with no ill effects, whereas in the practice of other physicians or institutions substantial numbers of disasters have occurred. The true incidence of this complication has yet to be determined, and on it a final assessment of the place of chloramphenicol in therapeutics must depend.

BREAD

It is now more than ten years since the Government of the day ordered that the extraction rate of flour should be increased from the prevailing 70% up to 85%. This step was mainly taken to save shipping space, but the new, somewhat coarser kind of flour had long been advocated by most dietetic experts. Thus it was much richer than the old fine white flour in most vitamins of the B complex and was also superior in iron. Typical values of 0.35 i.u. per gramme for vitamin B₁ and 0.85 µg. for riboflavin in the old flour were raised to 1.15 i.u. and 2.0 µg. in the new variety. Although there was some apprehension that the much higher concentration of phytic

¹ *J. Amer. med. Ass.*, 1952, 149, 912, 914, 918, 1293, and 1301.² Hawkins, L. A., and Lederer, L., *British Medical Journal*, 1952, 2, 423.³ Wolman, B., *ibid.*, 1952, 2, 426.⁴ Lewis, C. N., et al., *Antibiot. and Chemother.*, 1952, 2, 601.

acid in the new flour might depress the absorption of calcium and so cause rickets, this danger was averted by fortifying the flour with chalk. Throughout the intervening years there have been many minor variations in the extraction rate, which has sometimes reached 90%, but the general procedure in flour milling has not been changed. The national "off-white" flour seems indeed to have stood the test of time without any serious criticism of its nutritional qualities—apart from the vexed question of the use of "agene" and other so-called improvers. Many have regarded it as one of the mainstays of the official food policy which has seen us through difficult times.

For every virtue it is usually possible to find a corresponding vice. Wheat offals make an important contribution to the feeding of pigs and poultry, and the adoption of a more nutritious loaf has been at least one of the causes of our reduced home production of bacon and eggs. The millers also argue that the average Briton prefers white flour when he can get it, and that its use allows the production of more attractive cakes and pastries. By fortifying white flour with synthetic vitamins the manufacturers should have no difficulty in endowing it with the nutritive virtues which are at present the chief argument in favour of a coarser flour, and it would then seem quite reasonable to leave the public to make their own choice between faithfulness to the old "off-white" bread and the attraction of a new vitaminized white loaf, offered with the additional inducement of better supplies of bacon and eggs.

A White Paper¹ on the decontrol of cereals and feeding-stuffs shows that the choice will soon be offered to the public. After consultations with farmers and with representatives of many trades the Government has decided that the present feeding-stuffs rationing scheme is unsatisfactory. By removing the present controls on the prices and supplies of all cereals and feeding-stuffs, and by returning imports to private trade, the Government expects to make economies and to increase efficiency. The existing subsidy on flour is to cease, and millers will be allowed to produce any flour they choose, provided it is fortified with the nutrients which are known to be lost in the processes of refining. But a national flour of 80% extraction will continue to be made, and the subsidy on bread made from this flour will be continued and modified to take account of the disappearance of the flour subsidy. The national bread, moreover, will still be controlled in price. Bread made from the new white flour will be neither subsidized nor subjected to price control.

¹ Cmd. 8745, H.M.S.O., London.

These changes will come into force at the end of the next harvest. In the meantime we may speculate, perhaps with a little anxiety, on how the farmers, the millers, and the general public will react to the new conditions. Dietitians may worry whether the vitamins which are to be added to the new flour will give complete compensation for the losses incurred during refining. Is vitamin E to be added? Can we overlook the danger that coarse flour may contain important dietary factors which have not yet been recognized? Doubts about the answers to these questions will make many dietitians hope that white flour will be used only for the special purposes for which it is suited, and that it will not displace the present coarser flour as our main material for making bread.

KINDNESS TO PATIENTS

Earlier this week the Minister of Health sent out to hospital management committees and boards of governors a report of the Central Health Services Council entitled "The Reception and Welfare of In-Patients in Hospitals." This document owes much to a similar report of the Scottish Health Services Council published in 1951. Among the more important recommendations are the following:

Meal times should be spaced so that patients have no long fasts; a serious effort should be made in all hospitals to reduce noise to the absolute minimum; ear-phones or pillow-phones should replace loud-speakers in wards; patients should not be wakened earlier than 6 a.m. and later if possible; in all their dealings with patients and their relatives, members of the staff should find time to show consideration and understanding of their point of view.

If there are many hospitals which need to be given these elementary instructions it is surprising that the reputation of the hospital service stands as high as it does with the public. Perhaps the dangerous notion that the Health Service is free has something to do with it. Most patients have a deep sense of gratitude to doctors and nurses and would feel it was hardly sporting to complain about anything except life-and-death matters, especially when their hospital treatment apparently costs them nothing. Perhaps the putting on of a hotel charge would make patients more effectively critical: so long as they suffer in silence their recovery will continue to be hindered in the sort of hospitals, mentioned in the report, where sheets must be tucked in tightly over their feet, where the tea is sugared whether they like it or not, and where the wards are cleaned and painted with the patients still in occupation.

The great majority of hospitals must obviously be well aware of their responsibilities to patients and anxious to make them as happy as possible. Those in charge of these hospitals can skip the depressing parts of this report and turn to the constructive suggestions. Lack of information probably causes patients and their relatives more worry than anything else, but, as the report shows, only a little extra thought and effort are required to banish the bewilderment and apprehensiveness of the ordinary patient. In our correspondence columns this week Dr. G. Roworth describes how a simple printed sheet of information has changed the atmosphere of his ward greatly for the better.

The interval between entering the hospital doors and getting safely into bed in the ward is an anxious time for most patients. Some may have to find their own way along confusing and ill-lighted corridors, others are trundled about like sacks of potatoes on noisy trolleys which look as though they had seen their best days at Paddington. The Central Health Services Council, attaching "great importance to the personality and suitability of the person who first receives the patient," makes the excellent suggestion that hospitals should employ receptionists as hotels do. The sooner some hospitals try this idea out the better. The best nursing-homes and private hospitals long ago adopted to good effect some of the principles of hotel management. The majority of ill people attach very great importance to their meals, but it is doubtful whether the time will ever come when the hospital chef accompanies the matron on a morning round and presents an *à la carte* menu to each patient. Such was the admirable practice in one well-known nursing-home some years ago.

The report also has some useful things to say about the handling of relatives and about visiting. It appears that in hospitals where daily visiting has been introduced the initial doubts of the ward staff have changed to wholehearted support. Not long ago Mr. David Patey, speaking at the annual dinner of the Middlesex Hospital Medical School, mentioned that a special room had been set aside for the relatives of patients who were seriously ill. This is only one of the many ways in which the anxieties of relatives can be eased. Mr. Patey also raised, with some delicacy, a matter which concerns only the teaching hospitals. He suggested that more consideration might be given to the dignity of the patient as a human being. The report of the Central Health Services Council puts it even more plainly: "The welfare of the patient must never be subordinated to the needs of teaching."

PROCAINE AMIDE

Procaine amide has been used during the last few years in the treatment of arrhythmias and other irregularities of the heart. It is a substance with properties similar to those of quinidine and procaine, and these are also similar to one another. Quinidine is ordinarily thought of as a drug for treating auricular fibrillation and procaine as a local analgesic. But quinidine differs very little in action from quinine, and solutions of quinine-urea were used, and perhaps still are used, to produce local analgesia. Again, procaine is known to prevent the ventricular fibrillation caused by adrenaline in dogs anaesthetized with chloroform. Procaine amide is a slightly different chemical substance with properties of this kind. The Council on Pharmacy and Chemistry¹ of the American Medical Association, whose reports are usually conservative and trustworthy, points out that it depresses the irritability of ventricular muscle, having a more prolonged action than procaine and one-half to one-third the toxicity. It can be taken by mouth, and it is useful for the treatment of ventricular arrhythmias and extra systoles occurring in heart disease or during general anaesthesia. When given intravenously it causes a fall of blood pressure.

On another page Drs. A. A. Mason and J. F. Pelmore describe a new use of procaine amide in conjunction with hexamethonium to lower the blood pressure in maxillo-facial and other operations, and so to allow the surgeon an unobscured field. The depressor effect of hexamethonium is often counteracted, especially in younger patients, by a reflex increase in heart rate, and the authors find that when procaine amide is given in conjunction with hexamethonium a satisfactorily low blood pressure is obtained in a much larger proportion of patients than when hexamethonium is used alone. However, they say that "the anaesthetist must use supreme caution and vigilance when using them together." In the two cases they describe in detail, when procaine amide was given after hexamethonium, the effect they obtained was a slowing of the pulse rate, which might have been due to a direct action on the heart or to exclusion of the rise in rate caused by the fall of blood pressure. It will be interesting to learn whether this procedure is adopted by other anaesthetists.

On the use of procaine amide for cardiac irregularities papers have appeared recently by Shack, Hoffman, and Vesell² and by Lucas and Short.³ The authors of the latter paper found that intravenous administration was more effective than oral, and by the intravenous route they were successful in arresting ventricular tachycardia in four out of five cases, and ventricular extra systoles in five out of five. Supraventricular tachycardia and extra systoles were controlled in about half the cases, while auricular fibrillation was rarely benefited. Toxic effects were confined to gastro-intestinal disturbances and hypotension.

⁴ New Engl. J. Med., 1952, 247, 673.

⁵ Amer. J. med. Sci., 1952, 224, 573.

Davis⁴ has described the successful treatment of a patient with angina pectoris which was brought on by exercise and was accompanied by pulsus bigeminus. The patient was given 0.25 g. of procaine amide at four-hour intervals and remained free from attacks of angina during 16 months. Finally, Goldman⁵ has treated hereditary or Huntington's chorea with procaine amide. Its use in this condition was due to the chance observation that a patient sitting in a dentist's chair had little or no choreiform activity after receiving an injection of procaine for removal of a tooth. The effect of procaine amide varied with different patients, though all benefited to some extent and a few were almost completely relieved from symptoms of chorea. A large dose, 1.0 g. four or five times a day, was used, and this amount was tolerated only by raising the dose gradually during two or three weeks from an initial dose of 0.25 g. The immediate use of a large dose caused somnolence and feelings of faintness and numbness. Since there has been no treatment for this form of chorea hitherto, these results sound hopeful.

A NEW LONG-ACTING INSULIN

Since the original discovery of insulin in 1921 great improvements have been made in its manufacture. The ordinary insulin now in use is very pure and has a quick action which is over in eight to ten hours. This necessitates, in most cases, a second dose of insulin to control the blood sugar after the evening meal and during the night. Many attempts have been made to prolong the action of insulin, and the two best-known preparations are the protamine and globin insulins, both of which are combined with zinc. In many patients the action of these insulins is too slow at the onset but may last 20 to 26 hours, so that the fasting value of the blood sugar may be within normal limits. The slow onset of the action of protamine zinc insulin may be overcome by mixing it with some of the ordinary quick-acting insulin. This often gives good results but does entail either two injections or measuring the two insulins in one syringe. Some patients find difficulty in doing this. In November last Hallas-Møller, Petersen, and Schlichtkrull¹ described a new modification of insulin which seems to have many advantages. They found that the addition of protamine or globin to make the insulin insoluble was unnecessary, since this could be done by using a neutral acetate buffer with the addition of 2 mg. of zinc per 1,000 units. Crystalline insulin cannot take up more than 0.8 mg. zinc per 1,000 units, but this new insulin in some way is made to take up 2 mg. Its action seems to depend on the amount of amorphous insulin which is present, since this has a quick action, on the amount of the crystalline insulin, which has a slow action, and on the size of the crystals, since large crystals have a long-delayed action. Three preparations have now been made by the Novo Laboratories in Copenhagen: the "semi-lente," "lente," and "ultra-lente." Elsewhere in this issue Drs. R. D.

¹ *Science*, 1952, 116, 394.

Lawrence and Wilfrid Oakley describe the results of giving lente insulin to eleven adult patients who all had a severe type of diabetes. Some of these patients were having two doses of soluble insulin, some one dose of protamine zinc insulin or globin insulin, and some a mixture of soluble and P.Z. insulin. When the diabetic condition was reasonably stable under this treatment the blood sugar was estimated four times a day. The patients were then changed over to a single daily dose of lente insulin (the amount of insulin remaining the same), and two days later the blood sugar was estimated at the same times as before. The figures differed from case to case, but in the individual patients the blood-sugar values after injection of lente insulin were roughly similar to those obtained with the other insulins. The injections were well tolerated and the liability to hypoglycaemia was slight. Lawrence and Oakley have thus confirmed the observations of Dr. Jersild of the Hvidøre Hospital in Copenhagen.

As only one injection a day of this new insulin is needed it is certainly worthy of further trial; and if it produces more constant results than mixtures of protamine zinc insulin and soluble insulin it will be much appreciated. A minor drawback is the introduction of one and perhaps three more insulins to those already available. Doctors who seldom have to treat diabetes and patients new to insulin, are occasionally confused by the varieties at present in use. However, if the new insulins give a better control of the disease this is a difficulty which must be faced and which experience will soon eradicate. It is to be hoped that the new lente insulin will soon be available for general use.

THE CATHETER AND PROSTATIC RETENTION

In days past the need for operation in prostatic disease was determined by the onset of retention of urine or by the amount of residual urine. To estimate the latter a catheter was passed, as it was, too, for the immediate treatment of retention. But it has long been recognized that repeated catheterization in the presence of residual urine leads to infection, and this alone may undo the advantages of modern methods of prostatectomy by which the bladder can be closed completely and convalescence made shorter and sweeter. Wilson Hey¹ went so far as to condemn catheterization entirely in prostatic cases, and the ardour of his advocacy as well as the excellence of his results led many surgeons to follow his practice. While the dangers of sepsis are now fully recognized, the problem of retention from prostatic obstruction remains, and the conflicting opinion on its management have been debated in our correspondence columns recently—as they were before a smaller audience at the meeting of the Association of Surgeons in Cardiff last year.

The problem concerns the general practitioner first and the urological surgeon second. If the best result are to be obtained, agreement between them is much to be desired. The patient with chronic retention may not know that his bladder is distended; the condition

is usually painless, and no good and possibly much harm is done by emptying his bladder by catheter. He should be sent into hospital as soon as possible. Acute retention on the other hand can be a most painful condition, and the doctor's first desire and duty is to relieve the pain. The rational treatment is to remove the immediate cause of it by emptying the bladder. But this is only a small part of the doctor's duty. If the retention is due to prostatic obstruction, hospital treatment is necessary, and the doctor should see that his patient agrees to having it, preferably before the bladder is emptied.

If the doctor is skilled in the use of a catheter and can work aseptically, he should pass it and empty the bladder. If he has no suitable catheter available, or if he is sending the patient to a surgeon known to object to its use, he would do better to adopt the more tedious process of emptying the bladder by suprapubic aspiration. The danger of the catheter lies in lack of skill or practice in its use, and urethral trauma must be avoided at all costs. The patient in whom catheterization has failed is even worse off than the one who has been catheterized repeatedly.

The surgeon's problem is rather different from the family doctor's. When taking charge of a case of prostatic retention he has to decide whether to drain or not, and, if so, by what route. Followers of Wilson Hey or Wells will doubtless do an "immediate" prostatectomy with the minimum of investigation and pre-operative treatment. This entails, as Fergusson² has pointed out, "a full-time urological service backed by radiological and pathological facilities throughout the 24 hours." It also tends to exclude full medical assessment and treatment of an elderly man about to undergo what is still a major operation. Allanby³ has stressed the advantages of operating on these patients at leisure after an interval when they could be taught breathing exercises and generally made as fit as possible.

If the surgeon decides to drain the bladder, he must choose between the urethral catheter and the suprapubic tube. The urethral catheter will cause urethritis if used repeatedly or left indwelling for more than two days, and it is usually impossible at the outset to forecast how long drainage will be needed. The formal suprapubic long drainage will be needed. The formal suprapubic cystostomy mars the field for the subsequent prostatectomy and makes closure of the bladder without leakage more difficult. The small suprapubic catheter⁴ does not have this disadvantage. If drainage is deemed necessary—whether because the patient is in general unfit or shows extreme renal deterioration—it can safely be used provided the bladder is fully distended. The same conclusion seems to be indicated by the ingenious method described by Mr. Lloyd Davies at page 257 of this issue. A fine polythene tube is passed into the distended bladder through a cannula inserted above the pubes; the procedure would be safer and even less likely to cause extravasation if the track were made oblique. The figures quoted by Lloyd Davies for infection after

urethral catheterization are illuminating. Of the patients catheterized only once 23% were infected, an even smaller proportion than those not catheterized at all, although the numbers are small. Of those catheterized repeatedly 72% were infected.

The problem of when and how to relieve retention has arisen because it is now possible, in skilled hands and with a clean field, for the convalescence after prostatectomy to be as easy as that after interval appendicectomy. The difficulties could be avoided by treating patients at an earlier stage—before the onset of retention. That they are not treated earlier is due more to lack of hospital beds than to lack of knowledge by their medical attendants.

RISKS OF BUTAZOLIDIN THERAPY

The need for caution in administering "butazolidin" is emphasized again by the death of a Nottingham woman from agranulocytosis caused by the drug.¹ This is the third death attributed to butazolidin, the other two having occurred towards the end of last year.² And a paper³ from the U.S.A. now reports five more cases of agranulocytosis, ending in recovery, in addition to those recently referred to in a leading article in this *Journal*.⁴ Clinical trials, the first of which was reported by Currie⁵ (not by American workers as was inadvertently stated⁴), have shown that it may have a useful part to play in the treatment of patients with various types of arthritis; and so common are these disabling conditions that doctors in every part of the country are now being posed the problem whether or not to administer butazolidin to their patients. According to reports reaching us many patients, too, are well aware of the benefit that the drug may confer and are pressing their doctors to prescribe it. This is partly the result of some ill-judged publicity in a Sunday newspaper article, and many doctors will echo the words of Dr. H. M. Rice, who gave evidence at the Nottingham inquest, that "whoever was responsible for that article cannot have been aware of the implications."

Butazolidin bears a structural similarity to amidopyrine, a drug known to have caused agranulocytosis many times. Though the evidence so far accumulated does not indicate that butazolidin is too dangerous a drug to use, there is no doubt that certain precautions should be taken when it is administered, and contraindications to it borne in mind. A history of peptic ulcer or dyspepsia should put the physician on guard, because of the risk that butazolidin may induce gastrointestinal haemorrhage, and special care against precipitating heart failure is also indicated. The patient must be warned to watch for and to report immediately to his doctor the onset of purpura or any signs or symptoms that may herald agranulocytosis. These include malaise, fever, dryness of the mouth, and sore throat. The dose should not exceed 0.6 g. in one day.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

ANTENATAL CARE—II. ADVICE FOR THE EXPECTANT MOTHER

BY

W. C. W. NIXON, M.D., F.R.C.S., F.R.C.O.G.

Professor of Obstetrics and Gynaecology, University College Obstetric Hospital, London

The subject of diet in pregnancy is so important that it is considered in a separate section. Alcohol and tobacco need not be vetoed provided moderation is practised.

Exercise.—There is no harm in cycling, gardening, or swimming, provided it is not vigorous. Some miscarriages have been directly attributed to the lifting of heavy weights or to turning of a mattress. Walking, if possible for an hour a day, is the best exercise. Driving a motor-car can be allowed, but long journeys are not desirable. High-heeled shoes should be changed during pregnancy for those with heels not more than 1½ in. (3.8 cm.) high. Employment involving much standing should be given up, at least during the last two months of pregnancy.

Rest.—A mother who is learning how to relax is usually advised to practise this after the midday meal. In any case she should at this time take a rest with her shoes off. When sitting down the feet should be raised whenever possible. Sleep at night can be helped by taking a hot drink.

Clothes should hang loosely, and any constricting bands—garters, rolled stockings, tight belts—should be avoided. A brassière that lifts the breasts up but does not compress them should be worn.

Bathing.—If a daily bath is impossible, then the mother should have a sponge down. Personal hygiene is of particular importance during pregnancy. Douching should never be performed.

Bowels.—A daily bowel action can be maintained by attending to diet. Fresh salads, fruit eaten with its skin (plums, prunes, tomatoes, apples), wholemeal bread, and hot water all help to ensure a regular bowel action. The ritual of purgation and the taking of laxatives should be avoided. It should also be remembered that the bowel is a creature of habit. When there is obstinate constipation then a bran recipe will be helpful.

Diet in Pregnancy

During recent years diet has become a subject of universal interest, and from the spate of scientific and lay publications it might be concluded there is something novel about it. Yet since the dawn of history food has played a dominant part in the survival and evolution of man. Pregnancy is a "diet-efficiency" test, and during this period of physiological strain borderline states of malnutrition may be revealed which otherwise would have remained latent.

In a community in which diet is faulty or restricted the children and mothers, expectant and nursing, suffer first. This does not mean, however, that the baby born of an undernourished woman is necessarily small and feeble, for it is a common experience in obstetrics to see ill-fed and unfit women give birth to babies who are apparently healthy and of average weight. At present we are fortunate in not having in this country the severe degrees of malnutrition seen in Asia and the Middle East. But no one can deny that there are groups in our population who do not enjoy

optimum nutrition—that is, a state of well-being in which improvement cannot be effected by a change in diet.

A doctor is sometimes asked by an expectant mother if she can affect the weight of her baby by dieting. Normally there is no correlation between maternal diet and the birth weight of the baby or between maternal gain in weight and birth weight. It is only under famine conditions, with the maternal diet dangerously restricted for a long time, that the baby's weight will be significantly reduced. This was seen in Holland and in the sieges of Leningrad, Budapest, and Vienna in the last war.

It is well known that during pregnancy—and still more during lactation—a woman needs to pay careful attention to her diet. In 1933 Sir Edward Mellanby chose as his Lloyd Roberts Lecture the subject of "Nutrition and Child-bearing," and it is interesting to compare the advice he gave then with the modern view. There has been little change.

"Proper nutrition is essential to healthy child-bearing, and the diet should include throughout pregnancy and lactation a sufficiency of what are known as protective foodstuffs. When plenty of these are taken there is every reason to believe that the rest of the diet will take care of itself.

"As a general guidance, the diet of pregnancy and lactation ought to include:

- 2 pints (1.1 litres) of milk daily.
- 1 or 2 substantial servings of green vegetables—cabbage, spinach, or lettuce—daily.
- 1 or 2 eggs or egg-yolks daily.
- An apple or orange or some fresh fruit daily.
- Sea fish twice or more a week.
- Calf's liver once a week.
- If cod-liver oil can be taken, 2 teaspoonfuls (7 ml.) daily is advisable.

"The rest of the diet can be made up as the woman wishes."

The extra rations and allowances for expectant mothers (milk, eggs, meat, orange juice, vitamins A and D, ferrous sulphate) go a long way in 1953 to supplementing what might be thought a meagre diet.

Should calcium be prescribed in pregnancy? This element is best obtained from food. Milk and cheese are the best sources of calcium, green vegetables less so. The ideal amount of milk is a quart (1.1 litres a day), since this would meet all requirements for calcium and phosphorus. Some women find difficulty in drinking raw milk. For these there are different ways in which the daily milk ration can be taken—soups, gravies, milk puddings, hot drinks, including coffee, milk shakes, cereal. The administration of iron should be regulated by the haemoglobin level, and the Tallqvist test is a simple and quick way of doing this.

Control of Weight

In the United States much importance is attached to controlling the weight of a woman during pregnancy. At every visit her weight is accurately measured, and if there is an increase of more than 1 lb. (0.45 kg.) a week her diet is then restricted. Some obstetricians in that country view even an increase of more than ½ lb. (0.23 kg.) as abnormal and try to limit the total gain to 20 lb. (9 kg.). The reason for the attention to this aspect of pregnancy during recent years is the recognition that a sudden and rapid increase of weight may herald toxæmia of pregnancy. On the other hand, there are some women who put on many pounds in weight yet pass through pregnancy and labour normally;

this group usually remains overweight after the pregnancy over. By regular weighing it is possible to detect the sharp rise of weight which sometimes occurs before the classical signs of toxæmia present themselves.

During the first trimester there is little gain in weight, in fact there may be a loss. It is during the second and third trimesters that the weight increases. In the last trimester about half the total gain takes place, and for the last 24 weeks of pregnancy there is an average gain of about 1 lb. (0.45 kg.) a week. Of this 24 lb. (10.9 kg.) increase, 14 lb. (6.4 kg.) is distributed as follows:

Baby	7 lb. (3.2 kg.)
Placenta	1 lb. (0.45 kg.)
Amniotic fluid	1½ lb. (0.68 kg.)
Increase in weight of uterus	2 lb. (0.9 kg.)
Increase in blood	1 lb. (0.45 kg.)
Increase in weight of breasts	1½ lb. (0.68 kg.)

(Taken from *Expectant Motherhood*, by Professor Nicholson Eastman, Johns Hopkins University, Baltimore, 1948.)

The 10 lb. (4.5 kg.) that remain are accounted for by increased deposit of fat and fluid. A very real attempt should be made to keep the total weight gain between 20 and 24 lb. (9.1 and 10.9 kg.) for two reasons: (1) the risk of toxæmia, particularly of the fulminating type, can be lowered; and (2) most women are sensitive about their body curves not turning to normal after pregnancy.

In many women the abnormal weight gain is due to reversion of appetite and the excessive ingestion of food of high caloric value (carbohydrate and fat). There is, on the other hand, a physiological reason for the increase in weight apart from "the reproductive weight gain" of the products of conception. During pregnancy there is much later elaboration of those hormones—oestrogen and other steroids—that are responsible for sodium and fluid retention.

Below is a diet which should be taken when there has been a rapid increase in weight. This can be taken as an alternative for some weeks provided vitamins and minerals are prescribed as extras.

Low-sodium Reducing Diet for Pregnancy*

1,800 calories. Sodium intake, 0.8 g. daily. Total of 1½ pints skimmed milk daily.

Breakfast

- Tea or coffee, milk, no sugar.
- 2½ oz. salt-free bread.
- ½ oz. salt-free margarine.
- 1 egg.
- 4 oz. orange or juice.

Mid-morning

- Tea or coffee, milk, no sugar.

Dinner

- 2 oz. lean beef or lean mutton, lean veal, liver, heart, rabbit, chicken, rationed cheese (Cheddar type).
- 6 oz. green vegetables.
- 6 oz. potato.
- ½ oz. rice with milk.
- 4 oz. fruit.

Tea

- Tea, milk, no sugar.
- 2 oz. salt-free bread.
- ½ oz. salt-free butter.
- 4 oz. fruit.

Supper

- 4 oz. white fish.
- 5 oz. root vegetables.
- Salad—e.g., 2 oz. lettuce, 3 oz. tomato, 1 oz. watercress.
- 2½ oz. salt-free bread.
- ½ oz. salt-free butter.
- 4 oz. of fruit.

Bedtime

- Any milk left from 1½ pints.

½ oz. salt-free butter or margarine may be added daily to complete the ration of 4 oz. of each per week. In the above table this is calculated as butter.

*1 oz.=28 g. 1 pint=0.57 litre.

Calcium and iron supplements are necessary as well as vitamin supplements (A, B complex, C, D). The actual vitamin content of fruits and vegetables is always doubtful. Food yeast, which is a good source of vitamin-B group, might be used to improve the flavour of the skimmed milk.

Drugs and Pregnancy

It is surprising how seldom drugs harm the foetus. When given in therapeutic doses during pregnancy, even those with a known oxytocic effect—for instance, ergotamine tartrate for migraine—need not be contraindicated. Quinine in the treatment of malaria will even prevent an abortion or maceration of the foetus by destroying the parasites. It has been suggested that sulphonamides might interfere with foetal development if prescribed in large doses for longer than 14 days. In the case of streptomycin, a report has been published in which a woman with pulmonary tuberculosis was treated with this drug in the early months of her pregnancy up to a dosage of 75 g. The baby was normal and on follow-up has not revealed any damage to its auditory system.

Antenatal Preparation

Increasing attention is being paid to the psychological preparation of the mother and the elimination of the fear of delivery which affects most expectant mothers, especially primigravidae. The mother must be considered as a person. The family doctor is in a favourable position to give the mother this confidence by explaining the process of birth and the changes that take place during pregnancy. He can train the mother in muscle control, breathing, and relaxation. The publications of Dr. Grantly Dick Read are familiar to all, and the late Helen Heardman's monograph, *A Way to Natural Childbirth* (Livingstone, 1948), gives useful advice. It is, of course, understood that the attendants during labour have more influence on a mother's happiness than antenatal training.

The expectant father has been too long neglected and relegated to a back place. He should be brought much more into the picture and told how he can help his wife during pregnancy and labour. An advantage of home delivery is that the husband can be present during most or all of his wife's delivery if both of them wish it. Unfortunately, the rigid regimentation so often seen in hospitals precludes husbands seeing their wives till after delivery. A husband can quickly become an adept "back-rubber" and give his wife much support, both psychologically and physically.

It is not possible in the scope of this article to give details of what should be included in a programme of antenatal preparation. The emotional aspects of pregnancy and labour have been neglected in the past. They should receive much more attention in the future.

Next Refresher Course Article.—"Chest Pain," by Dr. Howard Nicholson.

The American Army Medical Service has started an influenza vaccination programme to protect military personnel against a mild form of the disease occurring both in the United States and abroad. All American troops in Korea, and those under orders for Europe or the Far East, are receiving a one-injection vaccination which has proved effective against the A-prime virus of influenza in previous trials. Military personnel in Europe will also be vaccinated if the situation warrants. Major-General George E. Armstrong, Army Surgeon General, said all Continental armies and major overseas commands are making detailed reports on the occurrence of influenza in their areas and are submitting estimates of their probable requirements of vaccine. The A-prime virus, believed responsible for the current influenza outbreak, is related to strains which accounted for the disease in 1950-1. The virus was identified at Fort Leonard Wood, Missouri, on December 31, 1952.

blood from the back of the hand or front of the wrist when nothing can be felt or seen in the antecubital fossa. Within the limits of the diameter of the vein, the wider the bore of the needle the easier it is to withdraw blood without frothing or clotting.—I am, etc.,

Edinburgh.

W. H. F. BOYD.

SIR,—May I be permitted to supplement your answer to the question ("Any Questions?" January 10, p. 115) raised under this heading? Many other simple precautions will help. Preferably the patient should be recumbent in bed or on a couch. The arm selected should be warm, and those with very difficult veins can be warmed either by hot towels, a hot-water bottle, or other suitable means, and should be kept out of a draught. The arm should be extended, since any flexion at the elbow slacks the tension on veins and allows them to move; hyperextension tends to flatten veins. The hand and elbow should be lower than the shoulder so as to prevent gravitational drainage. Light, preferably daylight, should fall transversely across the arm, preferably from without inwards. This tends to give slight shadows with even the smallest veins. Instead of the broad band you recommend, a sphygmomanometer cuff on the upper arm is much to be preferred, the pressure being raised to 60–80 mm. of mercury—that is, just below the diastolic. With the sphygmomanometer so used the operator can work single-handed and has complete control over the distension of the veins.

Attention should be given to the selection of syringe and needle. A syringe with a well-fitting plunger and needle should be used, preferably of the all-glass type, with the plunger lubricated with a small but adequate amount of liquid paraffin. The needle should be of the right bore and not too long. For quantities of 5 ml. blood and over a needle of 20 gauge and about 1 in. (2.5 cm.) long is to be preferred. Needles longer than this, unless they are very stout, tend to be "whippy" and difficult to guide straight. The needles should be sharpened to a fine point, and the edge of the bevel near the point especially should be keenly sharpened. Needles should be examined and, if necessary, resharpened each time they are used. Needles straight from a new supply are usually not satisfactory. In the case of a practitioner who cannot afford time to sharpen his own needles and prepare his own syringes and has not access to a syringe service, the use of evacuated venules, each of which has its own needle, has much to recommend it.

In conclusion, may I add one further general precaution? Veins should be treated gently and with great respect. Slapping the antecubital fossa and massaging the forearm are to be deprecated, since both tend to produce venous contraction in many cases.—I am, etc.,

Epsom.

W. W. KAY.

SIR,—May I supplement your reply to the inquiry regarding the collection of blood ("Any Questions?" January 10, p. 115) by recommending as routine in potentially difficult cases the following points relating to technique?

A sphygmomanometer cuff with the pressure set between the systolic and diastolic blood pressures should replace the tourniquet. The chosen vein should be flicked with the finger to cause dilatation and to counter reflex spasm before the needle is introduced. If the vein does not fill following proper application of the arm band and hand movements it may be distended by stroking the forearm veins towards the antecubital fossa. The needle point should be introduced, bevel up, almost parallel with the vein in a more superficial plane, and slowly advanced by stages in the line of the vein until the dimple which usually appears in the skin overlying the needle point suddenly disappears as the anterior vein wall is pierced.

When it is necessary to withdraw blood from the dorsal veins of the hand it should be remembered that they lie very near to the skin and that it is easy to pass the needle through the posterior as well as the anterior wall of such a vein. The needle point should be advanced well into

the lumen, and, after withdrawing a small quantity of blood into the syringe to confirm that the needle is correctly placed, the blood specimen required should be collected and the constricting arm band should be released before any intravenous injection is given.

Using this technique, I have found that it is necessary to cut down upon veins as a preliminary to blood transfusion in only one flying-squad case out of 30. In these cases the blood pressure is seldom over 80/50, and has been as low as 40/0. A specimen of venous blood is collected as routine prior to any such transfusion.—I am, etc.,

Newcastle-upon-Tyne.

W. HUNTER.

Sister Kenny

SIR,—Professor H. J. Seddon writes (April 12, 1952, p. 802) that Sister Kenny "outlived her welcome in the United States," etc., but the *Daily Mail* (December 1, 1952) states: "It is in America that Sister Kenny is most widely acclaimed and honoured. She was recently voted 'Woman of the Hour' there, and the United States House of Representatives in 1950 passed a Bill granting her the unprecedented privilege of entering and leaving America at will without passport or immigration papers."

In your obituary notice of Sister Kenny (December 6, 1952, p. 1262) no mention is made of Sister Kenny's most important book, published in 1943 by the Bruce Publishing Co., Minneapolis, St. Paul, U.S.A.—*The Kenny Concept of Infantile Paralysis and Its Treatment*, by Dr. John Pohl, M.D., in collaboration with Sister Kenny, with a foreword by Frank R. Ober, M.D., President of the American Orthopaedic Association.

The British Medical Association Library, I am informed, has no printed catalogue of its books available for members; in this way books vital and valuable to the progress of medicine and public health, such as all the books by Sister Kenny, may not become known to members of the Association.—I am, etc.,

Callander, Perthshire.

GERALD G. SANDERS.

*All the books in the B.M.A. Library are listed in a card-index which can be consulted by members. A printed catalogue would quickly become out of date, and to publish supplements at short intervals would be expensive. Lists of books added to the Library are printed from time to time in the *Supplement*.—ED., B.M.J.

Operative Treatment of Hallux Valgus and Rigidus

SIR,—The letter of Mr. J. M. P. Clark (January 17, p. 162) in criticism of my article on the above subject (December 27, 1952, p. 1385) contains some misconceptions which need correction. In that article I stated the well-known and obvious objections to the Mayo, Keller, and Girdlestone operations without "pouring scorn" on them, for I know from much experience that a fair number of patients are satisfied with the results. I maintained, however, that by the operation of arthrodesis, making the metatarsophalangeal joint rigid in the normal resting position of the great toe, the function of the toe in taking the body weight in walking, which is so important for the balance and strength of the foot, is better preserved than by those operations (the Mayo and Keller) which leave weak and poorly controlled movement, or a toe too short to act as a lever (the Girdlestone). It is because, after arthrodesis, the great toe remains as a long and firm lever for propulsion of the foot rather than as a shortened and weakened lever that its function is better preserved than after the other operations. A glance at the wear of the sole of the shoes of patients after these operations will show the difference.

The operation of arthrodesis and the aftercare are not "complicated manoeuvres" to any surgeon used to treating bones and joints. The only small difficulty is in inserting the screw or other means of internal fixation while keeping the functional position of the toe. My registrars and house-surgeons have readily and successfully done this operation in many of my cases. Getting the patient walk-

ing in a plaster casing after two weeks is not claimed as an "advantage" of the operation. Indeed, the plaster casing is recognized as a disadvantage. But it is a small hardship in the treatment of a condition which has usually given trouble for years and has to be borne for no longer than the period of rehabilitation which must follow after the period of arthrodesis. In any case it is the permanent effect of arthrodesis as of other procedures which must be considered and by which the value should be assessed.

Cosmetically the result of arthrodesis is indeed satisfactory, as the great toe is restored to an almost normal appearance—an important matter to the patient. Nor does the position of the toe cause trouble in putting on a shoe. The position of the toe caused by the proximal phalanx at an angle of 30 degrees of dorsiflexion with the metatarsal, the toe is in its normal resting posture, to which both shoe and surgical shoes conform. It is as well, however, for the shoe not to have a toecap so that there is no restriction by hardened leather over the toe, and to have also a metatarsal bar.

Mr. Clark becomes fanciful and unfair when he writes of the operation of arthrodesis producing a "semi-rigid foot"; for, of course, only the metatarsophalangeal joint of the great toe is made rigid and either stiffening of the rest of the foot does not occur during the few weeks of walking in a plaster casing or tends to disappear soon after the plaster is removed, with the more normal use of the foot which the restored strength of the great toe allows.—I am, etc.,

Bournemouth.

N. ROSS SMITH.

SIR,—I had prepared quite a long letter on this subject, but having read the polite one by Mr. J. M. P. Clark (January 17, p. 162) I will content myself by warmly supporting what he says and by adding that in Liverpool any orthopaedic surgeon who, using "Keller's operation," could not get very nearly 100% "quite satisfactory" and well over 58% excellent results would soon be taking down his plate.—I am, etc.,

Liverpool, 1.

BRYAN MCFARLAND.

Measurement of Tissue Components Radiologically

SIR,—The correspondence of Drs. B. C. H. Ward and G. N. Weber in the *Journal* of January 17 (p. 161) brings out some interesting points regarding asymmetrical objects which call for a further amplification of the method as given. Primarily it must be noted that the objections raised by Drs. Ward and Weber, although valid from a purely geometrical consideration of the factors involved, cannot be accepted in this particular method, as other limiting considerations invalidate them from the practical viewpoint.

Under the conditions given as suitable for the method, it will readily be appreciated that the convergence angle of the x-ray tubes is only about 8 degrees. Thus the section parallel to the plane of the x-ray plate through any object will present only a small difference when viewed from tube position I or tube position II, provided the ratio of the axes of asymmetry is not abnormal in relation to this plane (for example, a needle lying in the vertical plane would give such conditions of asymmetry). Any significant difference in the measured diameter of the object in a direction parallel to the tube shift will immediately indicate such an asymmetrical body, when the conditions can be adjusted to suit the asymmetry.

In the method as applied, and as recommended for child study, it is improbable that the major axis of any body will exceed by more than twice the minor axis. For an analysis of this type of body the theoretical considerations can, for this purpose only, assume that the rays from the x-ray tube are parallel. (Although this assumption is justified here, it cannot be justified when the case of the magnification ratio is considered, as assumed by Drs. Ward and Weber.) Thus this gives an equivalent condition to the fixation of the tube in one position for the two exposures,

and a rotation of the object about its centre in the vertical plane containing it and the tube. It is immediately obvious from this consideration that the worst conditions will occur when the longitudinal axis of the object lies in the vertical plane and along the axis of the tube.

Considering an object of size 2 cm. in the major axis and 1 cm. in the minor axis, then if the major axis lies parallel to the plate the shadow lengths will be, under the system adopted by Falkner and Wisdom, 2.18 cm. and 2.32 cm.

The separation of the true centres of the shadow images will be 0.727 cm., and the calculated separation will be 0.797 cm. and 0.657 cm. by measuring the edge separations. Thus a mean value of 0.727 cm. is obtained for the shift.

Assuming initially an approximate distance from x-ray plate to body, the equation for plate-body distance becomes:

$$d = \frac{(K-d') \text{Im}}{s}$$

where d is the distance between x-ray plate and object

d' is the estimated distance between x-ray plate and object

s is the tube shift

Im is the mean image shift

K is the distance between tube and x-ray plate

(NOTE.—As K is large compared with d an approximate value d' may be used with safety in the factor K-d'.)

$$\text{Hence } d = \frac{56 \times 0.727}{8}$$

$$= 5.089 \text{ cm.}$$

Finally the object size in this plane can be calculated as:

$$\begin{aligned} \text{Object size} &= \frac{\text{Mean image size} \times 55}{60} \\ &= \frac{2.25 \times 55}{60} = 2.06 \text{ cm.} \end{aligned}$$

This is in close agreement with the actual object size of 2 cm. in this plane.

The example quoted gives a good indication of the error which may be expected under the adverse conditions chosen; it also illustrates how a study of the two images will give a good approximation to the type of asymmetry present in the body.—I am, etc.,

London, W.C.1.

E. A. MISKIN.

SIR,—Drs. B. C. H. Ward and G. N. Weber in their letter (January 17, p. 161) appear annoyed that we claimed our method was "new." We realize the principle is well known and tried by radiologists, to whom we are most grateful for their guidance and stimulation. It is only new as applied to its use in a growth study.

Various technical objections are raised, which are answered as follows:

1. We do not assume that the outlines of skin, muscle, and bone in a cross-section of a limb are symmetrical, represented by concentric circles, or that their maximum diameters all fall in one plane parallel to the film. First, it is important to measure separately shadow-shifts for each tissue being measured, thus finding separate film-object distances. This is done. Secondly, because the tube-shift distance is small compared with the tube-object distance, measurement of a symmetrical object gives no theoretical error; while the error for an asymmetrical object in the worst position is small.

Our method is intended for the measurement of tissues in such parts of limbs as the upper arm, calf, thigh, etc., in both infant and adult. The effective distance in a plane parallel to the film plane will, in the case of asymmetrical bodies, resolve itself into two planes whose mutual separation will determine the amount of the displacement involved. The distance between these planes in the vertical direction, if the limb is correctly posed (and this can be a source of error, as we pointed out), is always less than 1 cm. This displacement relative to a convergent angle of approximately 8 degrees can be considered insignificant from a practical viewpoint.

The possible errors for normal limbs can never reach a significance which invalidates the method. Other corre-

spondence, which we have had the opportunity of seeing, gives the geometrical considerations which indicate that this assumption is valid. We are not therefore including in our letter any considerations of the geometry of the problem.

We would at this point mention the other possible sources of error, common to any radiological method of measurement.

(a) Focal spot of tube.—Probably not exceeding 0.2 mm.

(b) Density of image on film.—Probably not exceeding 0.2 mm.

(c) Blurring due to movement.—Probably not exceeding 0.2 mm.

These three factors give lower degrees of definition of the image lines. Russel H. Morgan (*Amer. J. Roentgenol.*, 62, 870) points out that various combinations of these errors probably interact and that in practice the error is small.

(d) The measurement of the tube shift.

(e) The measurement of the tube-film distance.

(f) The subjective error of measurement of the measurer.—Say ± 0.2 mm. (A reliability test shows that this has a mean error probably not exceeding ± 0.2 mm.)

(g) The error of measurement of the callipers themselves.—Negligible if checked carefully.

2. Drs. Ward and Weber say that the image shift is "a few millimetres at the most," and "cannot be judged with any great accuracy." Using our film-tube distance and tube-shift, this shift is of the order of 1 cm. and can be measured with photogrammetric callipers to the order of ± 0.2 mm. This gives a possible error of 2% in this measurement.

3. The correspondents are unable to accept the results of a carefully planned experiment with a sectioned human cadaver. The previous notes should explain why in fact the results were so accurate.

4. Drs. Ward and Weber suggest that we should use teleradiography with our 15-mA apparatus at a distance of 6 ft. (1.8 m.) and an exposure of one second. As we pointed out, it is very difficult to keep an infant's limb still that long. The 100-mA machines that they recommend are now unobtainable second-hand, and we have not the necessary resources to obtain a machine capable of supplying 135 mA, which would enable us to cut our exposure time to one-eighth of a second.—We are, etc.,

FRANK FALKNER.

SYLVIA WISDOM.

London, W.C.1.

Butazolidin

SIR,—It is unfortunate that such exaggerated claims have been made for this new drug in the lay Press, and that certain of our medical colleagues have allowed enthusiasm to influence their judgment, particularly as such serious consequences may result from its improper use. It would be a great pity if this valuable drug fell into disrepute through unwise and uncritical employment at the present stage. Data collected by me over the last three years are not yet complete, but certain points have emerged and may briefly be summarized as follows: (1) Butazolidin produces more prolonged relief of pain than aspirin in a proportion (roughly 70%) of cases of rheumatoid arthritis. (2) It produces no greater relief of pain than aspirin in the more common rheumatic disorders such as osteoarthritis and intervertebral disk degeneration. (3) Butazolidin is as effective by mouth as by intramuscular injection. (4) No advantage is gained by increasing the individual dose above 0.4 g. in rheumatoid arthritis, nor in repeating it before the effect of the previous dose has begun to wear off. The duration of the effect varies from one to ten days in different individuals. The dosage should thus be 0.4 g. every one to ten days according to individual requirements, which can readily be determined. If butazolidin is given in this way the maximum benefit will be obtained and toxic effects are unlikely to arise. In my three years' experience I have only had one toxic reaction—a transient erythematous eruption. (5) Butazolidin should not be regarded as a substitute for standard methods of treating rheumatoid arthritis with gold and physiotherapy, but is a useful means of tiding the

patient over the early stages of such treatment. It is also of value in those patients whose sensitivity to gold prevents complete suppression of the rheumatoid process by this means.

Of the value of butazolidin in rheumatic fever, gout, and ankylosing spondylitis I am unable to speak.—I am, etc.,

Walkden, Manchester.

J. STEWART LAWRENCE.

Lung Cancer

SIR,—In their exhaustive paper on lung cancer (December 13, 1952, p. 1271), Dr. R. Doll and Professor A. Bradford Hill do not mention that *rara avis*—the man who 20 or more years ago smoked 2 oz. of tobacco or 50 cigarettes a week, and then stopped smoking. Cancer has a curious tendency to lie latent for years, especially in the case of the industrial cancers. Thus we find cancer due to soot (chimney-sweepers), oil (mule-spinners and shale oil workers), cobalt, and uranium (miners) developing years after men have ceased to work in the offending industry. I suspect that if cancer does follow smoking it will affect the type of individual I have mentioned.—I am, etc.,

Birmingham.

A. P. BERTWISTLE.

Medical Association of South Africa, East London Division

SIR,—We are anxious here in East London to contact any medical visitors to South Africa who may be passing through our port. The Union-Castle mail ships call here every Monday and Friday on their way from and to Britain, so that if we knew in advance of any prospective medical visitor, whether on business or pleasure, we could make contact and arrange for them to visit us. We sincerely hope that once our notable medical visitors know of a welcome awaiting them in East London, and of our keenness to hear their views and news, they will see their way to honour us with a visit and to give us a talk.—I am, etc.,

6. Barnes Court,
St. Michaels Road,
East London, S. Africa.

ELIZABETH M. I. McCABE,
Convener of Clinical Committee.

POINTS FROM LETTERS

The College of General Practitioners

Dr. T. R. THOMSON (Cricklade) writes: Of the societies and institutions which have sprung up in the last 50 years, surely this is the most ridiculous of all. You, Sir, should know as well as most, and more than many, that the *qualifications* of the best type of general practitioner have been, are, and always will be high character, intelligence, independence, and industry. Except for the one word "ability," I can find no interest in these in the *Memorandum and Articles of Association* of the College of General Practitioners. Shall the public be assured that the college boys (after payment of their ten guineas) will have these qualities? The good G.P. will see to it that he does keep up to date. Are the others to be goaded by the college and inflamed by the hope of the Dip.G.P.? A sorry world needs not more politicians and officials, but more poets and saints, not more scientists, but more thinkers and artists.

Early Contraceptive Sheaths

Dr. GEORGE V. BOYLE (Glasgow) writes: I am writing to protest against the inclusion of the article "Early Contraceptive Sheaths" (January 3, p. 40). In my opinion it offends against good taste, and some of the quotations are offensive in many ways as well as being vulgar.

"Et all., etc."

Dr. W. W. ALLISON (Chesterfield) writes: Dr. A. J. Jex-Blake (December 6, p. 1259) is perfectly correct in his condemnation of "etcc.," which was obviously used facetiously. His advocacy, however, of "et all." is not so happy. "Et all." is clearly intended to represent "et alii." To give the term in full would only involve the substitution of two vowels for a consonant and a full stop. I do not think the printer would have reason to complain on the score of brevity or of increased labour. Finally, "et al." though frequently used for "et alius" or "et alii," is not strictly correct in this sense; "et al." really stands for "et alibi," meaning "and elsewhere."

Obituary

T. S. HELE, O.B.E., M.D., F.R.C.P.

We record with regret the death at his Cambridge home of Dr. T. S. Hele, Master of Emmanuel College from 1935 to 1951 and Vice-Chancellor of Cambridge University from 1943 to 1945. He was 71 years of age.

Thomas Shirley Hele was born at Carlisle on October 24, 1881. From Sedburgh School he entered Emmanuel College, Cambridge, as entrance exhibitioner in natural sciences, and took a first in both parts of the Natural Sciences Tripos. He went on to St. Bartholomew's Hospital as Shuter Scholar, and qualified in 1906, graduating M.B., B.Ch. a year later. After holding an appointment as house-physician at Bart's he was awarded a B.M.A. research studentship, and while holding this he worked with Archibald Garrod. Undecided about his future, he tried general practice after working as a house-surgeon at the Bristol Royal Infirmary, and then turned his thoughts towards public health, taking the D.P.H. in 1909. Two years later, a few months after he had proceeded M.D., he was elected a Junior Fellow of Emmanuel College and appointed college lecturer in anatomy and physiology and director of medical students.

For two or three years before the first world war Hele commanded D Company of the Cambridge University O.T.C. During the war he served for five years in the R.A.M.C., mainly in Macedonia, and was appointed O.B.E. for his services. Not long after his return to Cambridge in 1919 he was elected a Senior Fellow at Emmanuel, and two years later he was appointed Tutor of Students in Medicine. In 1921 also he became a university lecturer in biochemistry, a post which he gave up on his election to the Mastership of Emmanuel in 1935. Most of his published work was on the subject of sulphur metabolism. The late Sir Frederick Gowland Hopkins was head of the department of biochemistry in Dr. Hele's time, and for three years during the last war Dr. Hele returned to the bio-chemical department as deputy for Sir Frederick, but he had to give up this work in 1943 when he became Vice-Chancellor. He retired from the Mastership of Emmanuel in 1951. From 1937 to 1942 he was the representative of Cambridge University on the General Medical Council. In 1940 he was elected F.R.C.P.

Dr. Hele's relations with the many Emmanuel medical students were purposely a little casual at first, and to complete strangers he was quite a formidable figure. But as tutor and student got to know each other Dr. Hele's reserve vanished and he showed himself to be the kind and genial man that all his friends remember. He disliked formality, and many an important discussion about a young man's future was conducted while "Timmy" sat on the floor playing with one of his young daughters. This of course was part of his technique, and a very good one it was. For most of his time as Fellow and Master he lived within the college precincts and he came to know the history of every tree, stone, hydrant, and gas-pipe. In particular he gave much time to the interests of the college servants. Some years before the 1939-45 war he introduced for the benefit of the undergraduates at Emmanuel a system of insurance against accident and sickness.

Dr. Hele had very wide experience of university business, and in his time had held nearly every college office save that of dean. He knew better than most the

very heavy load of work put on those responsible for college and university administration, and in his later years he gave a great deal of thought to the problem of how to reconcile the taking of a share in the running of a residential university with remaining an efficient teacher and research worker.

While holding the office of Vice-Chancellor he suffered much physical pain, and the strain of those two years made inroads on his health from which he never recovered. He was twice married. His first wife, the daughter of Mr. Jonathan Hill and sister of Professor A. V. Hill, died in 1941. They had two daughters, one of whom is a member of the medical profession. In 1942 he married Audrey Louise, widow of Mr. F. M. Davis.

Sir LIONEL WHITBY, Vice-Chancellor of Cambridge University, writes: Tim Hele was one whose comfortable figure had become a part of Cambridge. He was affectionately regarded by generations of medical students, being known to them as a lecturer in biochemistry, which he took up on his return to Cambridge after some years in general practice. He became a Fellow and Tutor of his college, then Master, and he was Vice-Chancellor of the University in 1943-5. He was a West Country man from Cornwall with a sunny temperament who did not, however, suffer fools gladly, whether the foolishness was concerned with the elements of chemical pathology or the unwise imaginative adventures of a young undergraduate. His shrewd, forthright, and common-sense judgment on matters of policy or finance or just human nature stood his college and university in good stead, and was greatly appreciated by both. In his last few years he patiently and uncomplainingly endured the discomfort of intractable urticaria.

R. VEITCH CLARK, M.B., Ch.B., D.P.H.

By the death of Dr. R. Veitch Clark in hospital at Galashiels on January 20 at the age of 76 the medical profession has lost yet another of the distinguished veterans of the public health service.

Robert Veitch Clark was born on June 28, 1876, and graduated in medicine at the University of Edinburgh in 1901, having already taken the degrees of M.A. and B.Sc. In 1907 he took the D.P.H. of the University of Oxford. After a short period in hospital appointments, he joined the staff of the University of Leeds and later held a post in the Leeds public health department, which for long has been a training centre from which many medical officers have emerged to undertake responsible appointments in other parts of the country. In 1913 he was appointed medical officer of health for the County Borough of Croydon, and there he laid the foundation of his career as one of the foremost administrators in English public health. After nine years in Croydon he became medical officer of health for Manchester, succeeding Niven, the great sanitarian and statistician, who had occupied the post for 28 years and who had distinguished himself in dealing successfully with the environmental problems of Manchester. Veitch Clark's main task, which he tackled with conspicuous energy, lay in the development of the personal health services. At first these were concerned mainly with infectious diseases, maternity and child welfare, and tuberculosis. The passing of the Local Government Act of 1929, however, increased the duties of the public health departments of local authorities, and in Manchester it resulted in the transfer of the administrative responsibility of some 8,000 institutional beds to the medical officer of health.

Veitch Clark was convinced of the necessity for smoke abatement and was honorary secretary of the Manchester and District Regional Smoke Abatement

Committee, a committee representative of many local authorities. Although it has no statutory powers, this committee has vigorously pursued a policy of public education and investigation in relation to atmospheric pollution. He also took a leading part in the formation in 1928 of the Manchester Committee on Cancer, of which he was chairman and which under his guidance carried out important research into the carcinogenic qualities of oil used in the cotton industry.

Busy though he was in Manchester, Veitch Clark found time to take an active part in national affairs, and his wide knowledge and experience were freely used by central bodies. When the British Medical Association held its Annual Meeting at Manchester in 1929 he served as president of the Section of Public Health. He was president of the Society of Medical Officers of Health in 1934-5, and in 1936 he became president of the Manchester Pathological Society. In 1941 he was appointed an Honorary Physician to the King for a period of three years. He enjoyed excellent health, and on his retirement from his appointment in Manchester in 1942 at the age of 66 he was as active and as virile as ever. The death of Mrs. Veitch Clark was a grievous blow to him, but his strong character and well-founded philosophy helped him in that loss as well as in the increasing loneliness which is the lot of those who survive most of their friends. He rarely missed an opportunity of calling at the health department on his occasional visits to Manchester, to maintain contact with his old colleagues and to keep alive his keen interest in the work of the department where, he so often declared, he had spent twenty happy years. Like so many Scots, he retired to Scotland after a lifetime of service in England. He spent most of the ten years of his retirement at Peebles—well-earned, pleasant, peaceful years—mainly devoting most of his time to the exercise of the art and science of angling, in which he was expert. And so has passed on one whose high sense of vocation, enthusiasm, friendliness, and cheerfulness gave the fullest evidence of a life well lived. In expressing our sorrow we offer our sympathy to his daughter and son.—C. M. B.

A. J. MARTIN, O.B.E., M.R.C.S., D.Phys.Med.

The sudden and entirely unexpected death of Dr. A. J. Martin on January 6 at the early age of 43 has caused the greatest distress to every one of his wide circle of friends.

Alfred John Martin was born on January 1, 1910, at Elstree, and was educated at Rugby School and Emmanuel College, Cambridge, from which he went on to St. Thomas's Hospital to complete his medical training. He qualified in 1937, and after holding the posts of orthopaedic house-surgeon at St. Thomas's and clinical assistant at the Red Cross Clinic for Rheumatism he joined the R.A.M.C. soon after the outbreak of war in 1939. He was three times mentioned in dispatches for gallant and distinguished services in Burma, where he served for most of the war, and in 1945 he was appointed O.B.E. for his work in that theatre of operations. On his release from the Army in October, 1945, with the rank of lieutenant-colonel, he decided to specialize in physical medicine, and he obtained the Diploma of Physical Medicine of the Royal Colleges in 1947. After working as first assistant in the medical rehabilitation unit of the Royal Free Hospital he was eventually appointed to the posts of medical officer in charge of the departments of physi-

cal medicine at the Royal Free Hospital, at Hampstead General Hospital, and at the Queen Victoria Memorial Hospital, Welwyn, the last two appointments being honorary ones.

We are indebted to Dr. G. J. V. CROSBY for the following appreciation: "Tiny" Martin was one of the most lovable, happy, and friendly souls it has ever been my fortune to know. My first memory of him is of his great bulk, clad in bush shirt and bush hat, squeezing into my 180-pounder tent to report as commanding officer of the Indian field ambulance, which became the field ambulance of 33 Corps on the raising of the siege of Imphal. It was the beginning of a very happy association which lasted through the long months and down the long road taken to reach Rangoon. During the whole of that time Martin proved himself to be the most indefatigable worker and one of the best leaders imaginable. His love of the sepoy, his kindness to his patients, and his appreciation of the difficulties encountered by medical colleagues never faltered. It was one of the features of the campaign that the lines of communication became perilously extended and casualty evacuation was at times a near impossibility. It became almost a commonplace to say, "Get hold of Tiny, he'll fix a staging point here or a dressing station there." Somehow or other his field ambulance was the most elastic unit conceivable and it never struck him to say, or even to consider, that a thing could not be done. For his gallantry and devotion he was awarded an extremely well-earned O.B.E. It was not until 1950 that I met him again, and I found him to be the same enthusiast I had known during the war. His one great fault was that he was a "willing horse" and he never gave himself a let-up. Irregular meals and hours and hard work, both in and out of hospital, went a very long way to bring about his sudden coronary failure at the tragically early age of 43. Martin leaves behind him the memory of a happy warrior, a loyal friend, and an ever-helpful colleague. To his wife and young children his loss is bitter, and they must have our deepest condolences. Their sorrow may perhaps be tempered by the knowledge that he was a greatly loved man whose concept of the meaning of service was far wider than normal, and he never hesitated to act accordingly.

We are indebted to Dr. ISAAC JONES for the following appreciation: The very sudden death of Dr. John Martin while having a cup of tea with his colleagues in the out-patient department of the Hampstead General Hospital came as a very severe blow to all who knew him as a man. He was the son of the late Dr. Alfred Martin, who was regarded by all who knew him as one of the finest type of general practitioners, and it is clear by his father's example and teachings that Jack Martin, as soon as he was qualified, entered wholeheartedly into practice and gave of his very best to his patients, whose welfare he considered was his special privilege. At Rugby and Cambridge his genuine character and all-round interest in games won him many friends. He passed on to St. Thomas's, and immediately on qualifying threw himself with the greatest enthusiasm into the study of orthopaedics and physiotherapy. On the outbreak of war he quickly joined up and spent four years in Burma, where his promotion was rapid. On his return from the war he immediately set out to become thoroughly versed in all aspects of physiotherapy, and worked all day and every evening in gaining the required knowledge. His work was soon recognized, and he was appointed as honorary physician in charge of the department of physiotherapy in the Royal Free Hospital group. With his status established he accepted more and more responsibilities, always feeling that he should give his services, no matter where required. There is no doubt that the long hours of work, together with the infections acquired during his long service in Burma, brought about his early demise. At the service held in the very pleasing chapel of the Royal Free, the large attendance of people of all classes gave testimony to Jack Martin's character. He leaves a brave widow and three children.

One of the first women to graduate in arts, science, and medicine at the University of Aberdeen, Dr. A. V. BAXTER THOMSON, died at her home in Aberdeen on December 8, 1952, at the age of 72. Agnes Valentine Baxter was born on May 13, 1880, the daughter of Mr. J. B. Baxter, a Brechin architect, and graduated M.A. in 1902, B.Sc. in 1905, and M.B., Ch.B. in 1907. Her husband, the late Mr. Benjamin Thomson, was rector of Forfar Academy. From 1912 to 1946, when she retired, Dr. Thomson practised in Aberdeen, where she became one of the best known of medical and social workers in that city. The Mother and Baby Home at Richmondhill House, Aberdeen, was founded as a result of her efforts in bringing together the women's organizations in the city for that purpose some ten years ago. At that time Dr. Thomson was chairman of the Aberdeen branch of the Women Citizens' Association, and in 1945 she was elected president of the Scottish Council of Women Citizens' Associations. Other local organizations in which she was keenly interested were the St. Katherine's Community Centre, the Soroptimists, the Aberdeen branch of the Medical Women's Federation (of which she had been chairman), the National Council of Women of Great Britain, and the Aberdeen Old People's Welfare Council. In 1914 she became a medical officer of the Mother and Child Welfare Association, and her work in that capacity was of lasting value to the community. During the last war she served as a medical officer to a first-aid post. Dr. Thomson is survived by her two daughters, both members of the medical profession, Dr. Ann L. Shennan and Dr. Sheila Thomson.

Mr. HENRY THOMAS HICKS, consulting gynaecological surgeon to the Derbyshire Royal Infirmary, died at his home at Derby on December 25, 1952, at the age of 81. Born at Ramsgate on October 26, 1871, the son of Dr. Robert Hicks, a leading general practitioner in that town, he received his medical education at Guy's Hospital, qualifying M.R.C.S., L.R.C.P. in 1896. He was then appointed house-physician at Guy's Hospital and later became resident surgical officer to the Evelina Hospital for Sick Children, where he was surgeon to the out-patients. He took the F.R.C.S. in 1902, and returned to Guy's Hospital as obstetric registrar and tutor. He was also appointed assistant surgeon to the Samaritan Hospital for Women. As a suitable vacancy in his old medical school seemed improbable he accepted the appointment of honorary gynaecological surgeon to the Derbyshire Royal Infirmary in 1908, when the post was created. He went to Derby with considerable experience behind him, and at once established himself as a brilliant operator and a skilful obstetrician. His advice was sought by colleagues over a wide area, and he attended many doctors' wives, but he was not interested in work which he considered was within the province of the general practitioner. He had a sound knowledge of the natural history of disease, not confined to his own specialty, and he was experienced in morbid anatomy and in the histology of tumours. He introduced the technique of section cutting at the Infirmary. The 1914-18 war, on account of personal circumstances and the general disturbance of hospital work, discouraged him greatly. He never quite recovered the same enthusiasm, though he carried on his work in the changed world until 1929, when, because of failing eyesight, he resigned his appointment at the infirmary and retired from practice. For many years Mr. Hicks was an examiner for the Central Midwives Board—work which he enjoyed. When the British Medical Association held its Annual Meeting at Nottingham in 1926 he served as a vice-president of the Section of Obstetrics and Gynaecology. Mr. Hicks always set a high standard of professional ethics, and, though not interested in medico-political work, was a stimulating colleague behind the scenes of any medical society or committee. He published papers on chorionepithelioma, pyelitis of pregnancy, and other subjects connected with his specialty. As a young man he played both cricket and tennis, and in later years he took up golf. He was extremely musical by nature.

In 1904 he married Miss Getz, matron of the Evelina Hospital for Sick Children and the daughter of a German doctor. After Mrs. Hicks died in 1932 he lived a secluded life. There were no children.—H. B.

Mr. WILLIAM JONES RICHARDS, who died at Port Talbot on January 1 at the age of 79, was born on July 25, 1873, and was educated privately and at St. Bartholomew's Hospital. After qualifying in 1897 he spent a few years in the mental health service of the Middlesex County Council, and then turned to surgery, taking the F.R.C.S. in 1906. After clinical assistantships at St. Luke's Hospital and the Royal London Ophthalmic Hospital, he settled at Port Talbot as a surgical consultant on industrial insurance. He entered the R.A.M.C. at the outbreak of war in 1914 and served with a field ambulance at Gallipoli and as a surgical specialist in Palestine with the rank of major. After the war he returned to his practice and built up a reputation for giving a sound and fair opinion. Mr. Richards was a man of many interests, and was always ready to help in local activities, but he would not seek public office of any kind. His loss will be felt in many circles, and perhaps most in the Church he served so well.—D. R.

Dr. J. C. LEE, who was a Canadian by birth but settled in practice in England after serving in the R.A.M.C. in the war of 1914-18, died suddenly at his home at St. Leonards-on-Sea on January 7 at the age of 64. James Carrel Lee was born at Quebec on March 7, 1888, and was educated at Quebec High School and at McGill University, where he graduated M.D., C.M. in 1914. At McGill he was captain of the rugby football team for two years. After holding appointments at the Hospital for Women and the General Hospital at Montreal, he came to England in 1914 and was house-surgeon at the London Homoeopathic Hospital while studying for the diploma of L.M.S.S.A., which he obtained in 1915. In the latter year he married Dr. Ethel W. Gompertz, who was house-physician at the hospital, and he then joined the late Dr. W. C. Pritchard in partnership at Hastings. His wife carried on his share of the practice while he served with the R.A.M.C. in Mesopotamia in 1916 and later in India. Invalided out of the Army, he returned to Hastings and on the death of Dr. Pritchard in 1928 took over the whole of the practice, being joined later by his nephew, Dr. A. H. Grace. In 1931 he was elected chairman of the Hastings Division of the B.M.A. Dr. Lee gave willingly of his time and skill as a member of the honorary staff of the Buchanan Hospital at St. Leonards. He was also surgeon to the Homoeopathic Hospital at Tunbridge Wells. In 1934 he was appointed to the board of management of the Buchanan Hospital and two years later became a member of its finance committee. He was made chairman of the board in 1945 and held the position until the reorganization of hospitals under the National Health Service. In other ways too Dr. Lee served the community in which he lived, for as a J.P. he brought his wisdom and experience to bear on the human problems coming before the juvenile and domestic courts at Hastings. He had suffered from recurring attacks of bronchitis and pleurisy for some time before his death, but his ill-health did not prevent him from responding readily to emergency calls. He will be remembered for his generosity and friendliness and for his companionable nature. He leaves a widow and one son and one daughter.

Mr. FRANK KEITH HAYMAN, who died at his home at Sharnbrook, Bedfordshire, on January 9 at the age of 59, was born on January 28, 1893, and was educated at Clifton College. He graduated M.B., B.S. of the University of London in 1916, obtained the F.R.C.S. in 1920, and in the following year he settled in practice at Great Yarmouth, where he became honorary consulting surgeon to the Great

Yarmouth and Gorleston General Hospital. He was honorary secretary of the East Norfolk Division of the British Medical Association from 1928 to 1930.

Mr. A. WILFRID ADAMS writes: Keith Hayman and I were friends, and close ones, from schooldays at Clifton till in 1916 the war took us to separate fronts. Never then nor since did he let me down. He was notable for his gadgets, and was always making or acquiring or inventing. In sport, he excelled at swimming and diving; in the arts he was a keen exponent of the piano. Always he was a man of deed not word, and what he wanted he usually effected. His independent, enterprising character led him to start practice on the East Coast, and medicine there gained what Bristol has missed—a doctor who sought the precise truth in diagnosis and hated humbug and self-deception. He tended his patients with a kindly human skill. With his self-effacing nature he had slight regard for ceremony and convention, and in him reliability was combined with an intrepid spirit. In lamenting the loss of a dear friend we sympathize deeply with his family; we recall, too, the passing of a name which, through his father's and uncle's practices, added much to the repute of Bristol dentistry at the turn of the century.

Dr. LEONARD LEY writes: Keith Hayman came to Great Yarmouth in 1921 as a partner in an old-established practice, and within five years was appointed assistant surgeon to the Great Yarmouth and Gorleston General Hospital. He reached full surgical status in 1927, and from then until his retirement through ill-health in 1945 he served the hospital loyally and proved a skilful and successful surgeon. He was always cheerful and unassuming, and perhaps his chief characteristic was his equanimity, which in the war years rose superior to several bombing attacks in his neighbourhood—and to one very large bomb which exploded within a few yards of his house. His recreation was to spend holidays in a motor-drawn caravan, which he built himself. The hands of the surgeon could be adapted at will to another skilled craft. After he left Yarmouth he worked in a Ministry of Pensions appointment for some years, until a love of clinical work made him return to general practice. He died "in harness."

The sudden death on January 16 of Dr. D. V. MAXWELL ADAMS, while at the wheel of his car, has removed a figure familiar at many Annual Representative Meetings of the British Medical Association. Daniel Vere Maxwell Adams was born on October 5, 1875, one of a family of 13. He studied medicine at the University of Edinburgh and at the Royal College of Surgeons of Edinburgh, graduating M.B., Ch.B. in 1898. He was the fourth generation of a family of doctors, his great-grandfather, Dr. Alexander Maxwell Adams, of Edinburgh, having attended Mrs. Agnes Maclehose, a friend of Robert Burns and the "Clarinda" of his poems. After holding a house appointment at Glasgow Royal Infirmary, Daniel Maxwell Adams served as a civil surgeon in the South Africa Field Force in the war in South Africa from 1899 to 1901 and later became a plague medical officer under the Punjab Government. During the war of 1914-18 he served in the R.A.M.C. in France and in the Balkans, attaining the rank of major. After the war Dr. Maxwell Adams returned to practise in Lanark, where he enjoyed the confidence and friendship of his patients and where he had a smile and a friendly word for everyone. A member of the British Medical Association for over 50 years, he was chairman of the Lanarkshire Division in 1927-8 and represented his constituency at the Annual Representative Meetings from 1930 to 1949. He had a bad accident while on a cycling holiday in 1950 and was in hospital for some months, but eventually he was able to walk, to dance, and even to cycle again. In 1951 he was appointed a Deputy Lieutenant for the County of Lanark, an honour which he regarded as belonging to the medical profession and to the town as well as to himself. He was also a town councillor for some years and was

president this year of the Lord Cornets Club, which he joined in 1908. A popular visitor at all social functions, he was an entertaining after-dinner speaker. His death has left the people of Lanark with a sense of personal loss. Dr. Maxwell Adams was a widower, and he leaves one son.

Many friends and acquaintances will regret the untimely death in Manchester of Mr. S. BEEDLE, who was well known to the medical profession in the North of England. For nearly 30 years he was manager of the British Medical Bureau in Manchester and for many years clerk to the Manchester Panel and Local Medical Committees. Since 1949 he was in charge of the Medical Practices Advisory Bureau and the Regional Office of the B.M.A. in Manchester. Mr. Beedle, who died on January 7, was 59 years of age. He had few interests outside his work, and his life was one of devoted service to the doctors who formed his clients. Latterly the strain had told on him and he had arranged to relinquish some of his responsibilities. It was hoped that with partial retirement his health would improve, but this was not to be.

Medical Notes in Parliament

Claims for Drug

On January 22 Mr. EDWARD EVANS asked for a statement on the claims made in respect of the drug B.T.Z. ("butazolidin") as a cure for rheumatic ailments, including rheumatoid arthritis.

Miss HORNSBY-SMITH said the use of this substance was still under investigation in this country. Current evidence suggested that in view of the possibility of undesirable toxic side-effects it should not be taken except under medical direction.

Mr. EVANS said it was undesirable that the lay press should spread extravagant claims among the public, leading them to entertain false hopes.

Miss HORNSBY-SMITH agreed that it was most undesirable that hopes should be raised in respect of drugs which were not fully proved.

Atmospheric Pollution

Colonel M. LIPTON on January 22 asked the Minister of Health what representation his department had on the Atmosphere Pollution Research Committee, and whether he had notified the committee that 4,703 persons died in the Greater London area during the week ending December 13, 1952, as compared with 1,852 during the corresponding week of 1951.

Mr. IAIN MACLEOD said his department was not represented on the committee, but he had confirmed that the committee was aware of the figures quoted. The department looked on the matter as a problem of greatest urgency, but the committee was mainly a scientific body concerned with causes, whereas he was more concerned with effects. There was a link between the committee and the Medical Research Council, which he thought a better method.

Identity Cards

Dr. A. D. D. BROUGHTON asked on January 22 what action the Minister of Health proposed to remove the problems that had fallen on dentists, opticians, doctors, and executive councils by reason of the abolition of identity cards bearing national registration numbers now needed as Health Service identification numbers.

Miss HORNSBY-SMITH said a letter would shortly be sent to executive councils amending the procedure for giving and using these numbers, and describing methods for further acquainting the public with their use in the Health Service.

Block Grants for Hospitals

On January 20 Mr. PETER ROBERTS suggested that Mr. Macleod should consider allowing hospitals to run their block grants over a spread of five years, in the same way as universities were financed.

Mr. IAIN MACLEOD answered that the annual amount involved would be for Great Britain some £280m. Apart from other considerations, a sum of this magnitude must be examined each year by the Government and by Parliament.

Old-age Pensioners

On January 22 Dr. A. D. D. BROUGHTON asked whether the Minister of Health, in view of the hardship caused to elderly people, would take steps to remove the charges for drugs, medicines, and dressings in cases where the patient was in receipt of the old-age pension.

Miss HORNSBY-SMITH replied in the negative.

Prescribing at Clinics

Mr. GERALD WILLIAMS on January 22 asked the Minister of Health to arrange for doctors at child-welfare clinics to give prescriptions which could be exchanged for medicine under the National Health Scheme.

Miss HORNSBY-SMITH rejected the suggestion. She said it was for the family doctor to issue any necessary prescriptions.

Capital Expenditure on Hospitals

Mr. W. FIENBURGH asked on January 22 the estimated capital expenditure on hospitals in 1950-1 in England and Wales as compared with the capital expenditure in 1937-8 after allowing for changes in the price level.

Mr. IAIN MACLEOD replied that the expenditure was about £9m. compared with about £17m.

Psychiatrists in Wales.—Eight consultants in psychiatry have been appointed by the Welsh Regional Hospitals Board, three Welsh-speaking. In addition the board employs fourteen, six of them Welsh-speaking, who were in post when the board was established.

Atmospheric Pollution.—In England and Wales 186 local authorities maintain stations for the assessment of atmospheric pollution.

Vital Statistics

Influenza

The influenza at present prevalent in southern England is fairly mild in type. Virus A-prime has been identified. In the week ending January 17 there were 72 deaths attributed to influenza in the 160 great towns of England and Wales. In the previous three weeks there were 51, 29, and 44 deaths respectively. These figures bear out clinical reports that the influenza is not at present severe. Small outbreaks have recently appeared in the North of England.

England and Wales in 1952

The infant mortality rate in England and Wales in 1952 was 27.6 per 1,000 live births (provisional). This is the lowest ever recorded. The rate was 29.7 in 1951, and 52.8 in 1938.

The death rate was 11.3 per 1,000 population, as compared with 12.5 in 1951 and 11.6 in 1950. The stillbirth rate was 22.6 per 1,000 total births, being 0.4 below the rate for 1951.

The birth rate for the year was 15.3 per 1,000 population, as compared with 15.5 in 1951.

Eire Quarterly Returns

Returns for Eire show that the infant mortality rate in the September quarter of 1952 was 36 per 1,000 births registered, the same as for the corresponding quarter of 1951, while the neonatal mortality rate was 20.

The equivalent annual death rate in the quarter was 9.9 per 1,000 population, being 0.4 below the rate for the third quarter of the preceding year.

The tuberculosis death rate was 0.3 for respiratory and 0.1 for other forms, as compared with 0.4 and 0.2 in the third quarter of 1951.

Road Accidents in 1952.

The provisional total of road accidents for 1952 was 208,141. This is 8,352 fewer than in 1951. Included in the total were 4,705 killed, a decrease of 545 on 1951, and 50,371 seriously injured, a decrease of 1,998. Except for the period of petrol restriction, the total is the lowest since 1930, and the number of killed the lowest since records were started in 1926.

Week Ending January 17

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,589, whooping-cough 2,160, diphtheria 12, measles 21,383, acute poliomyelitis 31, dysentery 312, paratyphoid fever 8, and typhoid fever 1.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1943-51 are shown thus -----, the figures for 1952-3 thus ————. Except for the curves showing notifications in 1952-3, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Decreases were recorded in the number of notifications of infectious diseases in England and Wales during the week ending January 10. These included 5,759 for measles, from 30,497 to 24,738; 478 for scarlet fever, from 1,716 to 1,238; 256 for acute pneumonia, from 1,423 to 1,167; 105 for whooping-cough, from 2,165 to 2,060; and 48 for dysentery, from 262 to 214.

The largest declines in the incidence of measles were London 800, from 2,705 to 1,905; Middlesex 705, from 2,507 to 1,802; Kent 656, from 2,053 to 1,397; and Southampton County 514, from 2,190 to 1,676. The largest exception to the trend downwards was a rise of 216 in Hertfordshire, from 484 to 700. The largest falls in scarlet fever were 35 in Yorkshire West Riding, from 157 to 122; 33 in Lancashire, from 230 to 197; and 33 in Kent, from 82 to 49. The fall in the incidence of whooping-cough was contributed mainly by the southern section of the country; the largest falls were 98 in Essex, from 178 to 80, and 60 in Middlesex, from 137 to 77; the largest rise was 69 in Lancashire, from 358 to 427. The number of notifications of diphtheria was 22, and was 3 less than in the preceding week. The chief feature of the returns of diphtheria was a fall from 6 to 3 cases in Lancashire. Almost a quarter of the total cases in the country were notified in Birmingham C.B., where 5 cases were reported.

34 cases of acute poliomyelitis were notified during the week; these were 4 fewer for paralytic and 1 more for non-paralytic than in the preceding week. The largest return was 7 in Middlesex, where 3 cases were notified in each of the adjacent areas of Finchley M.B. and Hendon M.B.

The largest returns of dysentery were Lancashire 59 (Liverpool C.B. 29), Lincolnshire 31 (Grimsby C.B. 31), Yorkshire West Riding 21, and Kent 19 (Penge U.D. 15).

51 deaths were attributed to influenza in the great towns, and 29 of these were registered in Greater London. Influenza virus A has been isolated from patients in the London area.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 10 (No. 1) and corresponding week of 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Regional Board Offers Clinical Research Prizes.—The South-west Metropolitan Regional Hospital Board is offering nine £100 research prizes this year. The object is to encourage minor items of research by members of the board's hospital and clinic staffs who might not feel justified in applying for specific research grants. Three of the prizes are for consultants and senior hospital medical officers, three for senior registrars and registrars, and three for house-officers. The money for the prizes, which are to be annual, will come from the board's allocation of income from the Central Endowment Fund. No Exchequer funds will be used.

Rockefeller Grants.—The Rockefeller Foundation has made a five-year grant of £10,000 to University College, London, for the continued investigation of the selection and teaching of medical students. The study is under the direction of Professor J. Z. Young, professor of anatomy, and he is assisted by Dr. M. L. Johnson. Professor L. S. Penrose is advising on the statistical aspects of the investigation. Other grants for medical work now announced include \$133,940 for psychiatric and psychological work with children in Paris, Vienna, and Florence, \$275,000 for work on viruses both in New York and at field stations in Egypt, India, and Trinidad, and \$23,000 for genetic studies at the Indian Cancer Research Centre, Bombay. Funds have also been provided to allow Dr. W. I. B. Beveridge, professor of animal pathology at Cambridge, to go to America as visiting professor in the department of bacteriology at Ohio State University, and for Dr. Andrew Topping and Dr. Alexander Mair to visit the United States and Canada to observe public health administration and teaching. A grant has been made to Dr. S. W. Stanbury, of the department of medicine, Manchester University, for laboratory equipment.

American Gamma Globulin for Glasgow.—An offer has been made by the American Society in Scotland to present to the Glasgow Public Health Department a limited quantity of gamma globulin similar to that used in recent trials in the United States on the prevention of poliomyelitis. American workers have reported that gamma globulin injected intramuscularly becomes effective seven days after inoculation and the preventive action appears to persist for a period of five weeks. It is as yet unknown whether the American gamma globulin is more potent against poliomyelitis than British gamma globulin. One of the difficulties is to decide the best use for the gamma globulin. The Department at Glasgow is considering the possibility of carrying out small controlled experiments. The short period of immunity, the high cost (estimated at about 30s. a dose), and the fact that poliomyelitis has been relatively less widespread in Great Britain than in America are all arguments against using gamma globulin on a large scale.

Fund for Poliomyelitis Research.—Last month the Infantile Paralysis Fellowship, a lay organization for sufferers from the disease, launched the National Fund for Poliomyelitis Research. The aims of the Fund are to promote and finance research into the causes, cure, prevention, and treatment of poliomyelitis, and research into the rehabilitation of those disabled by the disease. It is stated that the Fund will spend money only at the advice of the medical profession. Among the vice-presidents of the Fund are Lord Horder, Sir Russell Brain, and Sir Cecil Wakeley. The secretary of the Fund is Mr. Duncan Guthrie, 41, Spenser Street, London, S.W. A public appeal for support is to be made at the Mansion House dinner on March 2, and it is hoped to raise £100,000 in the first year.

Local Medical Societies.—Recent meetings have included the following: *Manchester Medical Society.*—On December 22, 1952, Professor W. F. Gaisford read a paper to the

Section of General Practice on "The Treatment of Acute Infections in Childhood." *Liverpool Medical Institution.*—On January 8, after opening papers by Mr. John McFarland and Mr. R. P. Osborne, there was a discussion on the diagnosis and treatment of diseases of the pharynx and larynx, particularly carcinoma of the larynx. On January 15 there was a discussion on "General Practice—Present and Future," opened by Dr. David Johnston and Dr. Thomas Seager. *Chelsea Clinical Society.*—On January 13 Lieutenant-General Sir William MacArthur opened a discussion on "The Small Pocks and the Great Pocks." *North of England Obstetrical and Gynaecological Society.*—The annual general meeting was held on January 23, at which Mr. D. Currie was elected president. Papers on gynaecological and obstetric subjects were read by Dr. T. J. Ryan, Dr. R. M. Corbet, Mr. R. F. Lawrence, and Mr. S. Bender.

Detergents in the River Lea.—The discharge of synthetic detergents into the River Lea, and the consequent foaming of its upper waters, is causing some anxiety to the Metropolitan Water Board, as one of its water intakes is situated not so very far downstream. According to the Board's Water Examination Committee, whose report was adopted at a Board meeting last week, there is no generally applicable test for low concentrations of detergents. It is therefore impossible to tell with any reliability whether the concentration of detergents is increasing or whether it may even be approaching a level at which it might render water unsuitable for supply purposes. The Metropolitan Water Board has drawn the attention of the Ministry of Housing and Local Government to this problem and has suggested research into it.

Supplies of X-ray Film.—Ilford Ltd. have completed two new factories which should lead to a great increase in production of x-ray film in Britain. The first factory is for film-coating, but the second, owned jointly with B.X. Plastics Ltd., is for manufacturing the base from which the film is made. This is a big advance, as until now all x-ray film base has had to be imported, most of it from the United States. Plans for these new factories date from wartime, when enormous quantities of film were needed both for aerial photography and for the medical services.

Reciprocity of Registration with Victoria.—The coming into force of the Medical Act, 1950, at the beginning of this year has had one unexpected consequence. The law in the State of Victoria, Australia, is so framed at present that it now becomes illegal for the Medical Board of Victoria to register qualifications in medicine gained in Great Britain and Ireland. This is because Victorian graduates must produce evidence of experience equivalent to the "pre-registration year" before being admitted to the United Kingdom Register (see *British Medical Journal*, 1952, 2, 774). The Victorian Government—and Victoria is the only State in Australia so to be affected—is now looking into the question of amending its Medical Acts so as to restore reciprocity. Until new legislation is passed, however, the Medical Board of Victoria intends to refuse applications for registration from United Kingdom doctors.

Psychiatry in Wales.—The Welsh Regional Hospital Board has asked the Welsh National School of Medicine to establish a Chair of Psychiatry. Over one-third of the total beds in Wales are for mental patients, and the Board has experienced difficulty in attracting sufficient acceptable candidates for psychiatric posts in the Region. There is particularly a shortage of Welsh-speaking psychiatrists. At present there is no Chair of Psychiatry at either Cardiff or Liverpool, the two medical schools mainly responsible for the training of the Principality's doctors. The Welsh National School of Medicine is sympathetic to the Board's proposal, but at present cannot afford to establish the Chair.

Lady Tata Memorial Trust.—The trustees of the Lady Tata Memorial Fund invite applications for grants, scholar-

ships, or fellowships for research on diseases of the blood, with special reference to leukaemia, in the academic year beginning on October 1. In view of the affinity between leukaemia and other forms of neoplastic disease, candidates with programmes of research on any aspect of malignant disease which may throw incidental light on the related problem of leukaemia will be eligible for consideration. The awards are open to suitably qualified investigators of any nationality, working in any country in which it will be possible to make payments. The normal value of the scholarships is £600 per annum for whole-time research, and for the fellowships £1,000 per annum. Further particulars and forms of application may be obtained from the Secretary of the Scientific Advisory Committee, c/o Medical Research Council, 38, Old Queen Street, Westminster, London, S.W.1. Applications must be submitted before March 31.

Nuffield Dental Fellowships.—The Nuffield Foundation is offering dental fellowships, valued at between £500 and £800 per annum, to graduates in dentistry, medicine, or science. The fellowships for non-dental graduates are to train them for teaching and research on dental health and disease. Those for the dentally qualified are to fit them for an academic career in dentistry. Forms of application and further details may be obtained from the Secretary of the Nuffield Foundation, Nuffield Lodge, Regent's Park, London, N.W.1. The last date for applications is March 1.

"The Gift."—Although doctors are naturally sensitive to the presentation of medical subjects on the stage, and tend to react to the portrayal of technical procedures with irritation or mirth according to their mood, the new play at St. Martin's Theatre, "The Gift," can safely be recommended to them. The play turns on the ability to restore sight by corneal grafting. One may perhaps doubt that there could ever be strong enough reasons to make a surgeon take a living corneal graft from his own wife—a fatal procedure in this instance—but this dramatic deviation from probability does not detract from the obvious sincerity of the piece. It is to be hoped that the play will lead to an increase in the number of eye donors.

Journal Index.—The half-yearly indexes to Volume 2 of the *Journal* and the *Supplement* for 1952 are now being sent to members who receive them regularly and to subscribers. Members who have not previously asked for the indexes can obtain copies, post free, on application to the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Red Warning from Emergency Bed Service.—A red warning was issued on January 27, indicating that the percentage of admissions was less than 75. During the seven days ending January 26 the number of applications made by doctors to the London Emergency Bed Service for admission of patients was 2,191, of whom 73.48% were admitted.

Mr. Philip Wade has been appointed librarian of the Royal Society of Medicine. Mr. Wade joined the staff of the library in 1935, and was appointed assistant librarian in 1949.

COMING EVENTS

Contraceptive Technique.—A lecture-demonstration on contraceptive technique will be given by Marie Stopes, Ph.D., at the Mothers' Clinic, 108, Whitfield Street, London, W.1, on Thursday, February 5, at 2.30 p.m. No fee is charged, but tickets must be obtained in advance.

Salaried Specialists' Annual Meeting.—The annual general meeting of the Association of Whole-time Salaried Specialists will be held at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2, on Friday, February 20, at 4.30 p.m. It will be followed in the evening by the annual dinner of the association at the College. Full particulars may be obtained from the secretary of the association at 45, Lincoln's Inn Fields, London, W.C.2.

SOCIETIES AND LECTURES

Details in this column are necessarily brief. Further information and tickets where required (marked ●) should be obtained from the institution concerned.

Monday, February 2

INSTITUTE OF PSYCHIATRY.—8 p.m., Professor Konrad Lorenz (Germany): Comparative Psychology and Psychiatry.

Tuesday, February 3

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor E. J. King, D.Sc.: Silicosis and Asbestosis.

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. W. R. Bett: Preparation and Writing of Papers for the Medical Journals.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Arris and Gale Lecture by Mr. A. A. G. Lewis: Control of the Excretion of Water by the Human Kidney.

WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Dr. C. Worster-Drought: Neurological demonstration.

Wednesday, February 4

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Blood and Bone-marrow in Dermatology.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, W.C., 4.30 for 5 p.m., Mr. F. R. Kilpatrick: Tuberculosis of the Renal Tract.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Professor J. M. Smellie: Chronic Diarrhoea in Children.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—3.30 p.m., Mr. S. H. Harrison: Reconstructive Surgery of the Hand.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Arris and Gale Lecture by Mr. C. J. Longland: Collateral Arterial Circulation in the Limb.

Thursday, February 5

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor Matthew Stewart: Pulmonary Asbestosis.

FACULTY OF HOMOEOPATHY.—At Royal London Homoeopathic Hospital, 5 p.m., Dr. W. Lees Templeton: Report on Beryllium Proving; Dr. C. O. Kennedy: Research into the Bowel Flora; Dr. L. R. Twentyman: Observations on the Medical Treatment of Cancer.

●INSTITUTE OF CHILD HEALTH.—5 p.m., Mr. T. T. Stamm: Postural Disorders of School Age.

LIVERPOOL MEDICAL INSTITUTION.—At Stanley Hospital, 2.30 p.m., afternoon clinical demonstration.

OXFORD UNIVERSITY.—5 p.m., Dr. G. W. Corner (Washington): The Autobiographical Writings of Benjamin Rush, M.D.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Otolaryngology Lecture by Professor Geoffrey Hadfield: Co-Carcinogenesis.

ROYAL SOCIETY.—4.30 p.m., Professor A. V. Hill, F.R.S.: "Instantaneous" Elasticity of Active Muscle; Professor H. Munro Fox, F.R.S., and Elizabeth A. Phear: Factors Influencing Haemoglobin Synthesis by *Daphnia*.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Dr. P. L. McKinlay: Statistical Concepts in Medicine and Public Health.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—4.15 p.m., demonstration of clinical cases; 5 p.m., Dr. F. T. G. Prunty, Dr. E. G. L. Bywaters, and Dr. G. B. Dowling: Cortisone in the Therapy of Skin Diseases.

●WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At South Kensington Hotel, 7.30 for 7.45 p.m., Professor A. M. Boyd: Management of Thrombo-phlebitis of the Lower Extremities and its Complications.

FRIDAY, FEBRUARY 6

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. S. C. Gold: Contact Allergy.

INSTITUTE OF NEUROLOGY.—5 p.m., Professor E. Bay (Heidelberg): Dynamic Factors in Normal and Pathological Visual Perception.

INSTITUTE OF PSYCHIATRY.—3 p.m., Professor H. C. Rümke (Utrecht): Clinical Significance of Obsessional Phenomena.

ROYAL INSTITUTE OF PHILOSOPHY.—At University Hall, 14, Gordon Square, W.C., 5.15 p.m., Professor J. N. Findlay: Wittgenstein's Philosophical Studies.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Dr. P. H. Dootson: Auscultation of the Heart.

UNIVERSITY COLLEGE.—At Physiology Theatre, 5.30 p.m., Professor F. Bergel: Some Chemical Aspects of Normal Growth.

SATURDAY, FEBRUARY 7

INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—11.30 a.m., discussion. Professor F. Eeman (Belgium): Some Problems Facing the Endoscopist.

MIDLAND TUBERCULOSIS SOCIETY.—At Chest Clinic, 151, Great Charles Street, Birmingham. Dr. J. G. Scadding: Chronic Lung Disease with Diffuse Nodular or Reticular Radiographic Shadows.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Craig.—On January 23, 1953, at the Bristol Maternity Hospital, to Dr. Jean (formerly Simpson), wife of Dr. R. A. Craig, a son.

Goulden.—On January 18, 1953, at the Louise Margaret Hospital, Aldershot, to Margaret (formerly Macrae), wife of Major R. P. Goulden, R.A.M.C., a son—Alastair Michael.

Porritt.—On January 19, 1953, at 31, Queen's Gate, London, S.W., to Kay, wife of Sir Arthur Porritt, K.C.M.G., F.R.C.S., a son.

DEATHS

Adams.—On January 16, 1953, at Lanark, Daniel Vere Maxwell Adams, M.B., Ch.B., aged 78.

Langford.—On January 16, 1953, John Charles Cobden Langford, M.R.C.S., L.R.C.P., of Chiswick, London, W.

Ruston-Harrison.—On January 17, 1953, George Herbert Ruston-Harrison, M.B., Ch.B., of Winscombe, Somerset, aged 82.

Wykes.—On January 17, 1953, William Henry Wykes, M.R.C.S., L.R.C.P., of Barton-on-Sea, Hants, aged 82.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Asthmatic Attacks in Infancy

Q.—Could you tell me the best way of dealing with an acute attack of asthma in an infant? Is an adrenaline injection safe to use in a very young patient in order to stop the attack?

A.—Subcutaneous adrenaline (2 to 3 minims—0.12 to 0.2 ml.) is beneficial and not contraindicated in an acute attack of asthma in an infant. This dose can be repeated, if necessary, two or three times at intervals of about 20 to 30 minutes. Rectal aminophylline (0.1 to 0.2 g. in 20 ml. of water) is often very effective and can be repeated in two to three hours. If adrenaline and aminophylline are not effective, syrup of ipecacuanha by mouth, as an emetic (half to one dram—1.75 to 3.5 ml.), followed by lukewarm water may be considered. Steam inhalation is often helpful. If the attack is severe and prolonged, oxygen therapy in a tent and intravenous glucose 10% (300 ml.) and a sedative such as chloral may be necessary. So often an acute attack in an infant follows after a few days of a mild respiratory infection and in these cases sulphonamides, penicillin, and/or other antibiotic therapy are indicated from the start.

Lacerations of the Ear

Q.—Outline the treatment of a wound of the ear, passing from the junction of the pinna with the side of the head and opening into the external auditory canal.

A.—Sound and clean healing of wounds of this type can be assured only by careful attention to detail. Sepsis can give rise to a good deal of trouble, especially if the cartilage of the pinna becomes infected, but with a careful technique it is unusual for serious trouble of this kind to arise.

With a clean wound, after careful cleansing with ether soap or 1% cetrimide, any ragged edges of cartilage are lightly trimmed. The skin edges should not be excised, but if they are ragged a little trimming may be needed. The skin lining of the auditory meatus should be neatly and carefully repaired, first with fine silk sutures inserted at intervals of about 2 mm. It is important to avoid turning in the edges of the skin, which heals better if it is coated with vertical mattress sutures. Unless there is very extensive damage to the cartilage it is best to avoid inserting any sutures in it; but, should this seem necessary in a large wound, an occasional fine catgut suture may be used. The skin of the pinna should then be carefully sutured in the same way as the lining of the meatus. 0.004 in. (0.1 mm.) suture silk is a suitable material, using three or six "eye-curved" needles for the pinna, and small half-circle cutting needles not more than $\frac{1}{4}$ in. (8 mm.) in diameter for the meatus. When the repair has been completed it is best to keep the meatus splinted with a light pack of "vaseline" gauze or similar material. The external suture line is best dressed with collodion or, if desired, left exposed to the air. Skin sutures should not be left more than five days and can be removed sooner, but the ear should be carefully supported for a week or so with wool and bandages in the case of extensive wounds.

If the wound is contaminated it should be cleansed with still greater care, and in these circumstances it may sometimes be better to sacrifice skin and cartilage edges, especially if there has been much contusion of them. But in any case only a narrow margin of tissue should be excised. No strict rules can be laid down about the method of

repair, but, after insufflation with penicillin-sulphanilamide powder, the edges should be sutured as described above. Only judgment and experience can really help the operator in deciding whether it is justifiable to suture as closely as in a clean wound. Sometimes it is wise to insert only a minimum number of sutures. Parenteral treatment with penicillin may be worth while.

In a neglected wound, the first step is to clear out all infected granulations from the meatus and elsewhere, and to ensure that there are no "sequestra" of cartilage or other foreign bodies in the granulations. Generally speaking it will not be possible to do any effective repair of separated or displaced skin edges, and the primary aim of treatment at this stage should be to clear up all infection. Troublesome perichondritis occurs in some cases, and at this stage it is unlikely that antibiotics will be of any real value. Once the infection has settled, the wound should be allowed to heal soundly before any scar correction is attempted. This will generally mean a wait of at least three months, but often longer. After removal of granulations from the meatus it is most important that it should be carefully and systematically cleansed each day until healing has occurred. The problems of later plastic repair cannot be dealt with in this answer. One last point should be mentioned: if the meatus has been extensively involved it may be wise to make a plug of acrylic resin or dental stent to prevent stricture formation. This can usually be admirably done by any good dental surgeon.

Petit Mal and Marriage

Q.—A patient of 19, who has suffered from petit mal since infancy, has consulted me about the possibility of transmitting her disorder, as she is contemplating marriage. What investigations are indicated and how should she be advised?

A.—It is impossible to give a dogmatic answer to this question. An important point is whether epilepsy of any type has occurred amongst the patient's relations, and careful inquiry should be made about this, as if the disorder is found in more than one member of the family there is a greater chance of transmission to future generations. Another important point is whether there is a history of epilepsy in her fiancé's family. If the patient is suffering from true petit mal she is very likely to have an abnormal electroencephalogram, and, though it would be of interest to have this investigation performed, it probably would not be of great help in deciding on the possibility of transmission of the disease: an electroencephalographic record of the fiancé would, however, be of value, as, if this should show an epileptic record even when clinical fits have not occurred, the possibility of children inheriting the disease would be increased. For further information on this complicated subject reference should be made to an annotation published in the *Journal* (1951, 2, 1330).

C.S.F. Changes in Psychoses and Epilepsy

Q.—Are biochemical changes ever found in the C.S.F. of manic depressives, schizophrenics, or sufferers from idiopathic epilepsy?

A.—Very little is known on this subject. The extent of our ignorance is shown by the fact that in the excellent critical review by Gillies in *Recent Progress in Psychiatry* (1950, London), though biochemistry is covered, no mention is made of work on biochemical changes in the C.S.F. About ten or twelve years ago a worker in Germany produced a flocculation test for the C.S.F. which he said gave almost invariably positive results in schizophrenics. This was not confirmed by other workers. More recently H. H. Fleischacker (*J. ment. Sci.*, 1943, 89, 297) described the use of a modified form of the Takata test, but this work does not appear to have been followed up, and his results do not seem of great importance.

No one to the writer's knowledge has ever suggested that biochemical changes are to be found in the C.S.F. of manic-depressives or idiopathic epileptics. It is, of course, a different matter with symptomatic epileptics.

Altitude and Hypertension

Q.—What effect has high altitude on patients with hypertension? What are regarded as reasonable upper limits of altitude for such patients (a) for permanent domicile, when presumably physiological adaptation may take place, (b) for a month's holiday, and (c) for an aeroplane flight?

A.—Altitudes up to 6,000 ft. (1,830 m.) have little adverse effect on patients with hypertension, and there is no reason why such patients should not take a holiday in the mountains up to this level, provided they are not threatened with heart failure. The adaptations that take place at high altitudes include polycythaemia and a raised cardiac output, and neither of these is beneficial to hypertensive states, so that permanent residence in places of 7,000 or 8,000 ft. (2,134 or 2,438 m.) is not recommended. Most modern airliners are pressurized to the equivalent of the atmospheric pressure at 6,000 ft., and in such artificial conditions the height of the plane does not matter. Patients with serious hypertension should avoid non-pressurized planes because no pilot can guarantee that he will not fly above 6,000 ft., owing to the uncertainty of the weather.

Coke in Open Fires

Q.—Is coke safe for regular use in an open fire in a living-room? I have heard that the fumes are dangerous.

A.—Coke is derived from coal by a process of carbonization in which nearly all of the volatile constituents of the coal are driven off by heating, so it should not be any more dangerous to burn than the parent coal. If coke or coal is burnt in a fire which does not allow complete combustion, carbon monoxide may be produced, and this of course would be dangerous if it escaped into the room. This could happen if the chimney were blocked. In this case, if coal were burnt, the smoke and other fumes, particularly sulphur dioxide, would be so irritating that it is unlikely that anyone would tolerate it, but in the case of coke there is much less smoke and fumes, so that the escape of carbon monoxide into the room might not be noticed and poisoning might conceivably result.

Toxicity of Mercury Vapour

Q.—Some laboratory workers think that mercury can have toxic effects when the vapour is inhaled over a prolonged period in an open laboratory. Is there any justification for this belief?

A.—There is abundant evidence that inhalation of mercury vapour causes chronic mercury poisoning. It is not sufficiently appreciated by those who handle mercury in the laboratory, or in industry, that mercury vaporizes at room temperature, and that the concentration of mercury in the atmosphere increases considerably in winter conditions when natural ventilation is reduced and workrooms are artificially heated. Form 332 issued in March, 1950, by the Factory Department of the Ministry of Labour and National Service deals with industrial mercury poisoning. It states: "Mercury gives off vapour to a certain extent even at ordinary temperatures, but warmth greatly increases this tendency. When the metal, as distinguished from its salts, is used, the danger of poisoning arises chiefly from inhalation of the vapour; and in a minor degree from swallowing or from absorption, in a finely divided state, by the skin." Striking examples of the harmful effects of mercury vapour are cited by Buckell *et al.* (1946). They refer to an incident of fire in a quicksilver mine in Austria in 1804. Mercury vapour escaped into the air and spread over the country-

side; 900 persons in the neighbourhood had mercurial tremor and many cows suffered from salivation, cachexia, and abortion.

NOTES AND COMMENTS

Short-sighted Boxers.—Mr. LIONEL M. GREEN (London, W.1) writes: Having acted as ophthalmic consultant to the British Board of Boxing Control for a good number of years, I feel that the reply given by your correspondent to the query concerning short-sighted boxers ("Any Questions?" January 3, p. 54) is somewhat misleading. The inquiry confined itself to the degree of myopia among schoolboys which might be considered to constitute a bar to boxing, and the answer virtually debars even low degrees from indulgence in this vigorous and healthy sport. Liability to retinal detachment in moderate myopia (up to -4 D.) at this age is probably no greater than in non-myopes, as the vitreous is usually perfectly healthy, and no evidence of early degenerative changes in the region of the ora serrata can usually be found or is expected. A blow suffered during this age-period sufficient to cause detachment would almost certainly be as likely to cause the same type of injury in a non-myope. Only those with the higher degrees of myopia, and particularly towards the latter years of school life and where the myopia has been rapidly progressive, or associated with marked retinal thinning, large temporal myopic crescents, early evidence of vitreous degeneration such as floaters, and slightly subnormal corrected acuity, should be debarred owing to this greater risk of retinal detachment; and indeed in this type of case the poor uncorrected vision present would in itself effectively prohibit participation in the game. The undue prominence of the myopic eye is very largely a fiction based upon the exploded theory that almost all degrees are mainly axial in origin with an increased antero-posterior length. Recent radiological methods of measuring this axial length have shown that up to -6 D. the myopic eye is only 0.5 to 1.5 mm. longer than normal, a degree of additional prominence which surely can be entirely discounted. In my opinion schoolboy myopes up to -3.0 D. certainly, and up to -4.0 D. in most cases, can indulge in the sport without additional risk as compared with their better-sighted playmates. Except in exhibition bouts all boys should wear rubber orbital prominence goggles, a form of protection which has recently been advocated for use among professionals. Within the range mentioned the acuity present without correction is quite sufficient to enjoy the sport and develop a sound technique.

OUR EXPERT writes: I find myself in total disagreement with Mr. L. M. Green. I have seen so many eyes seriously damaged or totally wrecked as a result of blows from boxing that I feel it is superfluous to make a detailed answer to him. Anybody who takes the trouble to consult the literature will find a large list of tragedies not only among professional but among amateur boxers. For example, Jokl, of Johannesburg, has written extensively upon this subject. In my opinion everything that one says about the vulnerability of eyes to boxing injury is enhanced when the boxer in question is a myope—even if the amount of his myopia is only slight.

Correction.—In announcing the award of a knighthood to Dr. F. P. Montgomery (January 10, p. 92) his appointments as senior radiologist to the Royal Victoria Hospital, Belfast, and to the Belfast City Hospital were regrettably omitted.

RESULTS OF THE BLALOCK-TAUSSIG OPERATION IN 200 CASES OF MORBUS CAERULEUS

BY

MAURICE CAMPBELL, D.M., F.R.C.P.

AND

D. DEUCHAR, M.D., M.R.C.P.

(From the Cardiac Department, Guy's Hospital)

In 1949 we reported the results in the first 50 patients with morbus caeruleus who had a Blalock-Taussig operation at Guy's Hospital (Baker *et al.*, 1949). We now report the results in those operated on since and a longer follow-up of the earlier patients.

We have included all our 200 patients who have had an anastomosis performed or attempted up to the end of 1951. Most of these (129) have been operated on by Mr. R. C. Brock, but 57 were operated on by Mr. Holmes Sellors and 14 by Mr. Ian Hill. Most of the patients had Fallot's tetralogy, but we use the wider term morbus caeruleus because of uncertainties of diagnosis: even a successful operation proves only that the blood flow to the lungs was inadequate and has been improved. First, the 200 patients are considered together and later in different groups such as tricuspid atresia, pulmonary atresia, and dextrocardia, to assess the operative risk and the improvement to be expected.

Age and Sex.—Most of the patients were children, and the age distribution is shown in Table I. Nearly half were between 5 and 9 years of age, over half were

etc.). Where the diagnosis seems straightforward and there is no doubt about the presence of adequate pulmonary arteries this seems a reasonable policy. These investigations all involve at least some discomfort to the patient and sometimes a definite risk.

Circulation times were done on most patients at one time, but have now been abandoned, in a centre where cardiac catheterization and angiocardiology are available (Campbell, 1951).

Angiocardiology has been used most often—in just over one-third of the patients in this series; it has proved of great value in difficult cases, but has rarely contributed much useful information in the straightforward ones. Briefly, its chief value in selection for anastomotic operations is in confirming the presence of an overriding aorta and in elucidating the anatomy of the systemic vessels and the presence of pulmonary arteries when this is doubtful. It is less effective than might be expected in deciding in a doubtful case whether the blood flow to the lungs is diminished or not. The change in the density of the lung fields and the speed with which the diiodone passes through the lungs to the left side of the heart are better indications than the time at which the pulmonary trunk first fills (Campbell and Hills, 1950). Like the circulation times, it has no place in post-operative assessment.

Arterial oxygen saturations have rarely been estimated except as a part of cardiac catheterization. Alone, they yield little information apart from confirming, perhaps more precisely than the circulation times, the presence of a right-to-left shunt—although they do not, as the circulation times may, distinguish whether the cyanosis is due to a shunt or to some change in the lungs preventing the normal oxygenation of the venous blood. For this distinction a second arterial sample, taken while the patient breathes oxygen, is necessary. If the patient is frankly cyanotic the arterial oxygen saturation is superfluous. Its use as a means of assessing the severity of the shunt or the degree of improvement we have not felt to be justified; its apparent objectivity gives it a spurious appearance of reliability, for the lability of the cyanosis in these patients is well known. Significant increases in the arterial oxygen saturation are nearly always appreciable clinically as lessened cyanosis.

Cardiac catheterization has been performed on many patients with morbus caeruleus, but not all these have had anastomotic operations. About 30 in this series were so investigated, but as the results are in no way

TABLE I.—Age Distribution of Patients and Operative Deaths

	Age in Years					Total
	0-4	5-9	10-14	15-19	20 and Over	
Total No. of cases	18	90	59	21	12	200
Deaths with operation	3	10	4	1	6	24
Deaths at each age	17%	11%	8%	5%	50%	12%
Very good results among survivors	40%	53%	61%	80%	33%	56%

less than 10, and over four-fifths less than 15 years: the youngest was 3 and the oldest 35 years. Boys slightly predominated, there being 114 to 86 girls.

Disability.—This was graded (Campbell, 1948) as IV in 75, III in 77, II in 44, and I in only 4 of the patients before operation. These last four were mostly older patients, about 20, who were not very disabled but were most anxious to be able to lead a more active life.

Symptoms and Signs.—We are not discussing these further, as we have little to add to our earlier remarks (Baker *et al.*, 1949).

The Role of Special Investigations

All the earlier and many of the later patients have been chosen for operation without any special investigations (angiocardiology, cardiac catheterization,

peculiar to them we have reviewed all who were studied by this technique. We have not used catheterization to study the results of the anastomotic operations. The only change that could be detected is the shunt of arterial blood into one of the pulmonary arteries; by the nature of things it is not possible to assess its volume by catheterization and there are simpler criteria by which its mere presence or absence can be judged.

Fallot's Tetralogy.—In 57 catheterizations on patients with this diagnosis there was only one failure to enter the right ventricle. The pulmonary trunk was intubated in 45 and the aorta as well in 9 of these; in no instance was the aorta entered when the pulmonary trunk was not. A defect of the atrial septum was demonstrated by the passage of the catheter in three patients. The systolic pressure in the right ventricle was within the normal range for the systemic arterial pressure. Whenever they were determined at the same time they showed no significant difference. This contrasts with pure pulmonary stenosis, in which the right ventricular systolic pressure often exceeds the systemic. The pulmonary arterial pressure was generally between 17/6 and 10/3 mm. Hg, and nearly always below the normal value of about 23/8 mm. Hg, measured from the mid-axillary line.

In the patients accepted as having Fallot's tetralogy a right-to-left shunt was always present but varied greatly in size; the arterial oxygen saturation fell within the range 47–92%, but in over half was between 70 and 85%. In keeping with the observations of Deuchar and Knebel (1952), the systemic blood flow at rest has always fallen within the normal range, whereas the pulmonary blood flow has been reduced by an amount dependent on the size of the shunt.

Among the straightforward examples of Fallot's tetralogy there was evidence of a left-to-right shunt into the pulmonary artery in one only, and at operation the surgeon found a small persistent ductus arteriosus. A few patients with a provisional diagnosis of Fallot's tetralogy have been found to have left-to-right shunts into either the right atrium or the right ventricle. The former has been observed only where anomalous pulmonary veins were present and the latter where post-mortem control or further study (angiocardiographic, etc.) nearly always proved the presence of some more complex lesion than Fallot's tetralogy—for example, a single ventricle or pulmonary atresia. The finding of a shunt into the right ventricle is therefore a strong indication for reconsidering a diagnosis of simple Fallot's tetralogy.

Pulmonary Atresia.—We have studied 14 patients believed to be examples of this condition, but were able to intubate the right ventricle in 10 only. Naturally the pulmonary trunk was not entered in any, but the aorta was entered in six: it seems that entry of the aorta with failure to enter the pulmonary trunk may help in distinguishing pulmonary atresia from Fallot's tetralogy. A defect of the atrial septum was demonstrated in 8 of the 14, including those in whom the right ventricle was not entered. The arterial oxygen saturation always fell within the range 60–84%. Basing blood-flow calculations on the assumption that the blood to the lungs has the same oxygen saturation as the systemic arterial, the pulmonary blood flow was less than, equal to, or more than the systemic in about equal numbers of cases, although radioscopes gave a different impression in the last group: again it was the pulmonary blood flow that was changed when it differed from the systemic.

Tricuspid Atresia.—Here cardiac catheterization has little to offer, and the findings, being essentially negative, have

little significance. It can contribute useful information only when by intubating the right ventricle it disproves the suspected diagnosis of tricuspid atresia. In six cases studied the atrial septal defect was demonstrated in three; the arterial oxygen saturation fell within the range 56–79%, and in all except one the pulmonary blood flow was less than the systemic.

Nature of Operation

Most of these patients had end-to-side subclavian-pulmonary anastomosis, as this was regarded as the operation of choice. At first, following the original practice of Blalock and Taussig (1945), the operation was performed on the side opposite to the aortic arch; but after the first 50 Mr. Brock decided on surgical grounds that the left side was the best in all cases (Baker *et al.*, 1949). Provided the anastomosis is a good one, there is no evidence that the side on which it is done makes any difference to the result. Departures from this operative technique were dictated by the anatomical findings at operation.

In about one-twelfth of the cases it was found necessary to divide a pulmonary artery and perform an end-to-end anastomosis. This was mainly in patients with pulmonary atresia in whom the pulmonary artery, if present, was often small and thin-walled. The less good results may therefore be due as much to the original defect as to the end-to-end anastomosis. There is no doubt that it can sometimes produce a very good result, and, strangely enough, the anastomotic murmur resulting from it is indistinguishable from the other.

Pott's modification of the Blalock-Taussig operation was carried out in three patients only. In two the result was very good, but one shows some evidence of the shunt being too large. The third, despite the surgeon's fear that the anastomosis was too large, had no anastomotic murmur and no benefit from the operation, which suggests that the stoma failed to function (Case 1).*

Innominate and Other Arteries.—The innominate artery was used once with an ideal result. The right common carotid artery was also used once; the stoma formed was thought to be rather large, and the patient died of pulmonary oedema. Another patient, in whom the carotid had to be divided to mobilize the subclavian sufficiently, died, apparently from the interference with the cerebral blood supply. After this experience Mr. Brock decided that the use of the carotid or innominate arteries was a gamble that should not be taken (Baker *et al.*, 1949). The internal mammary artery was successfully used for an anastomosis in two cases: one yielded a very good result, though the reduction in cyanosis and haemoglobin was only slight, but the other showed little improvement and had no anastomotic murmur. An attempt to use a large intercostal artery on one occasion failed, and the patient recovered from the operation unchanged.

Method of Follow-up

All these patients were seen by one of us before operation and nearly all by both of us afterwards, generally several times. Often the category in which they should be placed was decided in discussion with others who were working in the clinic. We have tried to see the patients annually near to the anniversary of the operation, but could not always adhere to this strictly. We have therefore grouped the visits between 10 and 21 months as one year, between 22 and 31 months as 2 years, between 32 and 43 months as 3 years, and 44 months or over as 4 years.

Nine patients have gone abroad since their operations, but three had already been followed for 18 to 24 months. We have received recent reports from all except two who were doing well when they left the country 19 and 24 months after operation. Of those in this country none has been lost sight of, but we have accepted reports of several who

*Some cases have been given numbers to save repetition when they are referred to again.

live some way from London, especially when we had seen them previously and have been told that their condition is as good as before.

The period of follow-up of the 165 who left hospital after a completed anastomosis was as follows (the patients who died later have been counted as being followed until the date of death): 4 years, 28 patients; 3 years, 37; 2 years, 42; 1 year, 53; less than 1 year, 5. Some of the patients have now been seen at the five-year follow-up, and none of them has lost ground.

At each visit we have assessed the patient's capacity and progress and have recorded the degree of cyanosis and clubbing, the site of the anastomotic murmur, and the blood pressure. Getting the patients to jump up and down for a short time has proved a simple and useful way of helping to assess the disability and the cyanosis after exercise. Haemoglobin estimations and teloradiographs of the chest have been done as a routine. Electrocardiograms were done often at first, but as it became apparent that there was little if any change, even when the heart became larger, we have been less particular about repeating them. The role of the special investigations has already been discussed. In a few cases all the data outlined have not been obtained or we have had to rely on reports forwarded by their doctors.

Assessment of the Degree of Improvement.—This is not always easy. Some patients before operation could walk only a few yards, whereas others could walk a mile or more, so that the improvement cannot be judged simply by the amount they can do after. At first, with the vivid memory of the severe disability, the result seems miraculous, and for the parents often remains so; later, as the memory of this fades, there is more tendency to compare them with a normal child, and in this way it may seem less dramatic, but the examples given will indicate how great the change is. Even moderate improvement may mean a lot to the patient, but our good results mean much more than this, as such patients can often earn a living and lead a life that is nearly normal instead of being almost completely disabled and a drag on their families. The classification

TABLE II.—Results of the Operation

Group	Results of Operation	No. of Patients
I	Very good	99
II	Good	37
III	Some improvement	17
IV	Good of improved at first, but died later	6
V	No improvement	6
VI	No anastomosis possible	11
VII	Death at or shortly after operation	24

*Two other patients who were originally in this group showed some improvement after a second operation.

of the results is shown in Table II. We have taken particular care not to overestimate the improvement, placing the patient in the lower rather than the higher category whenever there was any doubt.

Results of Operation

Group I. Patients with Very Good Operative Result (99)

We have described a result as very good when the patient can earn his living or attend an ordinary school and can walk three to four miles. He is living an almost normal life except for the more vigorous activities that are not essential. If he had been so disabled that he could not walk 100 yards we have classified the result as very good even if he has not reached this standard but was able to walk at least a mile. The following examples will make the position clearer.

A boy of 3 who could walk only 10 yards was soon running about almost like a normal child. A boy of 7 who could walk 400 yards on a very favourable day was soon at school leading an almost normal life except for football: three years later he was persuaded a friend to run away from school with him, and was found by the police 12 miles away. A young man of 18 who had found it hard to walk across the out-patient hall was able to walk 6 miles and to work at light engineering. A boy aged 12

who could walk only 20 yards had walked 9 miles two years later; and another who could walk only a few hundred yards at a normal pace or half a mile slowly has walked 12 miles. One girl of 12 was carried into the room on her first visit and could walk no more than 20 yards in good weather: after operation she was enormously improved, and the day she was seen had walked round the zoo for three hours with one rest. Another girl, aged 15, had been getting so much worse that even dressing provoked attacks in which she nearly lost consciousness: now, two years after operation, she is working regularly as a machinist and can walk four miles and do everything she wants except dancing; her cyanosis has not improved as much as most (see later) and her haemoglobin has fallen from 135 only to 119% (Case 2).

There were other patients who were much less disabled before operation. For example, one girl of 13 could walk half a mile fairly easily and was not very cyanosed: after operation she was walking five miles, cycling in a hilly district, and doing anything she wanted.

The percentage of very good results increases from the youngest patients to those between 15 and 19, in whom it is 80% of the survivors, but then falls off again in those over 20 (see Table I).

Group II. Patients with Good Results (35)

We have been conservative in including cases in the highest class. When a patient leads a normal quiet life but falls short of this high standard in some particular we have recorded the result as good. For example, a girl of 6 was getting worse before operation and walked only the length of the room; she rarely went outside, and was having frequent cyanotic attacks, in which she was unable to stand. A year after operation she is a different child, almost a normal colour and without attacks, but was not put in the highest class because she was not yet going to an ordinary school or walking more than half a mile.

A boy aged 10, with tricuspid atresia, found it difficult to walk a mile and was still moderately cyanosed, with a haemoglobin of 130%. But his mother called the result a miracle, as he was able to attend an ordinary school and go and return alone, whereas before he had walked only 100 yards (Case 3).

Some cases which would otherwise have been classed as very good have developed another disabling lesion, and therefore have been classed as improved or good. This applies to two patients who have developed tuberculosis of the lungs and to others with neurological lesions from which they have not recovered completely.

Group III. Patients Somewhat Improved (17)

This relatively small group contains all those who were still seriously limited in activity but showed real improvement, which sometimes meant a lot to them. Thus one girl who could walk only 20 yards can now get about the house freely and walk 200 yards outside—a tenfold increase—but we regard this as disappointing, though the change it has made to her inside the house seems to her parents enough to justify the operation.

Group IV. Patients who were Improved but Died Later (6)

All these patients were improved at first, the result being very good in two, good in two, and improved in two, but they died 8 to 37 months after operation. The first two were especially disappointing cases.

The first, a boy aged 3, was very disabled, and the large heart—cardiothoracic ratio (c.t.r.) 62%—made us anxious about the chance of success. He was almost normal 15 months after operation and the heart was no larger. Eighteen months later, in Kenya, he developed weakness of one side and was sent back to England: the condition of his heart was still good, but a diagnosis of cerebral abscess was made, and, though operation for this seemed successful, he died suddenly six hours later (Case 4).

The second, a girl aged 7, was able to walk only 50 yards on a good day and had frequent attacks in which she nearly lost consciousness: afterwards she could walk a mile to school and run 20 yards. Three years after operation she was leading an ordinary life except for no games at school; her heart had not

enlarged unduly (c.t.r. 47 to 53% quickly and 54% three years later). A month later, on holiday, she seemed as well as usual, but woke up one night with symptoms of acute pulmonary oedema and died before a doctor could see her (Case 5).

The third, a young woman aged 20, was classed as a good result but died suddenly in the street 17 months later; the inquest did not reveal the cause of death.

The fourth, a boy aged 4 with tricuspid atresia, was classed as a good result, and there would have been no anxiety had he not been seen after five months and found to have an unusual increase in the size of his heart (c.t.r. 61 to 69%). He died three months later with congestive failure: it is true that it followed bronchitis, but this would probably not have proved fatal had the heart been smaller (Case 6).

The fifth, a boy aged 4, was thought to have Fallot's tetralogy with complications, as the heart was large (c.t.r. 59%). Operation was decided on as he was losing ground and seemed unlikely to live long: he was better for a year, but then lost ground and died in his second paroxysm of ventricular tachycardia 17 months after operation. At necropsy pulmonary stenosis with a single ventricle was seen (Case 7).

The sixth, a man aged 21, was classed as improved only, as he had not been very disabled. A pulmonary abscess had troubled him before his operation, but was thought to be quiescent and healed. A year later, however, he was admitted with recurrent haemoptysis; aspergilli were cultured from the sputum, and in spite of treatment he died a few weeks later. Fallot's tetralogy had been diagnosed, but necropsy showed a pulmonary valvular stenosis with only a small patent foramen ovale and an unusual, small, low ventricular septal defect (Case 8).

These deaths give a rough indication of the mortality that may be expected after an operation that has been successful. Of 159 patients, 6 (3.8%) died during the period of follow-up, but two at least from causes quite unconnected with their original operations—a cerebral and a pulmonary abscess. As the average period of observation was 2.5 years the annual mortality rate from all causes was 1.5%.

Group V. Patients Without Improvement After Operation (6)

There were six patients who were little if at all improved by their operation, and three of them have died since. One was submitted to operation after much doubt, as the diagnosis was uncertain. Only an end-to-end anastomosis was possible, and her colour and capacity were somewhat improved, but she developed signs of congestive failure, which persisted in varying degree over the next two years (Case 9). In a second the surgeon was doubtful if he had been able to achieve a functional anastomosis, and the absence of any benefit and of continuous murmur after the operation supported this. A third had a Pott's operation (Case 1). The fourth seemed better at first but became worse again a few days later, probably from a thrombosis at the site of the anastomosis. She died at home a year later from "meningitis." The fifth, with tricuspid atresia, was better in colour and was able to do more, but this was only at the expense of heart failure, and his liver remained enlarged and pulsating. In spite of a period of treatment in hospital his congestive failure progressed, and he died after ten months (Case 10). The sixth, a girl aged 8, should probably not have been operated on, as she had never walked and had chronic nephritis, but her outlook without seemed hopeless. Her dyspnoea and cyanosis were improved after operation, but a month after leaving hospital she developed gross oedema and died suddenly a few weeks later with an exacerbation of her nephritis. At necropsy severe pulmonary stenosis with a single ventricle was found (Case 11).

There were two others who were at first in this group. However, second operations one or two years later have been followed by some improvement, so they have been included in that group.

Four patients, in all, have had a second operation, and none of them has achieved a good result. This may be bad luck, and often the surgeon has thought that he had not been able to make a good anastomosis, but it hardly encourages one to advise a second attempt when the first has not succeeded.

Group VI. Patients in whom Anastomosis was not Possible (11)

In 11 of the 176 patients who survived the operation no anastomosis was possible. They recovered from the operation unchanged, though one or two later claimed that they were somewhat improved. Two of them had transposition of the main vessels. In retrospect, this mistake should have been easy to avoid: the lung fields may look very dense from a heavy collateral circulation, but the markings are finer and more concentrated round the hilum or in the upper right mediastinum. It is, however, important not to make the opposite mistake of thinking that a collateral circulation indicates an increased blood flow to the lungs, and this has been one of the main medical reasons for angiocardiology.

Taussig (1948), in setting down the criteria for a successful anastomosis, included the presence of a suitable pulmonary artery; lack of this has been the most common cause of failure to complete an anastomosis. In four patients who are discussed in the section on pulmonary atresia no pulmonary artery could be found. In a fifth it was thought wiser to stop the search for the pulmonary artery because of the mass of collateral vessels: in retrospect he was thought to have pulmonary atresia though pulmonary arteries could be seen on the angiogram. In a sixth the pulmonary arteries were too small: the left was so minute that no anastomosis could be made, and at a second operation the right, although apparently adequate on angiocardiology, soon divided into three and proved too small even for an end-to-end anastomosis. In the last three technical difficulties prevented an anastomosis being made, and a further operation has been advised.

Group VII. Patients who Died at or Shortly After Operation (24)

Four of the 24 patients who died were in the groups that are discussed separately. Two (Cases 12 and 13) had a single ventricle and pulmonary stenosis, one with isolated dextrocardia and one with isolated laevocardia (Campbell, Reynolds, and Trounce, 1953). The third (Case 14) had isolated laevocardia, a bilocular heart, and pulmonary atresia, and the lungs were supplied through a persistent ductus (Campbell, Gardner, and Reynolds, 1952); the fourth also had pulmonary atresia with a persistent ductus. A fifth, a woman aged 24, had complete transposition of the great vessels and pulmonary stenosis.

Of the other 19, there were 5 (in addition to the two just referred to) who had pulmonary atresia. Surgical treatment is more dangerous in this subdivision of Fallot's tetralogy. The patient's life is dependent on the collateral arteries that have developed, and the division of some of these produces an extra risk of haemorrhage during operation and of lessening a pulmonary blood supply that is already scanty: in addition, the small and often thin-walled pulmonary artery is poor material for an anastomosis. Even after these difficulties were appreciated and special efforts made to avoid them, three patients with pulmonary atresia have died.

The remaining 14 patients had Fallot's tetralogy: 5 were 19 or older, this being nearly half the patients of that age who were operated on. Our figures show that the operation is more dangerous in the older patients (Table I), though the good results justify some extra risk. Those in whom operation has been advised were often losing ground, for the others are usually reasonably satisfied with the quiet life they can lead.

Even among the nine younger patients (all under 12 years) there was sometimes a special feature to account for the fatal issue: one had a single pulmonary artery and died when it was clamped for the anastomosis; a second had an aorta that arose entirely from the right ventricle; and a third had a large heart and almost a single atrium. A satisfactory feature of this analysis, therefore, is that among those who died there were only six young patients with uncomplicated Fallot's tetralogy.

Patients who leave the operating theatre in fair condition can be expected to do well, for nearly all those who died were already causing anxiety by the end of the operation. Of the 24 patients, 6 died during the operation, generally from cardiac arrest; three of these had Fallot's tetralogy and three had more complicated lesions. Another 13 died within the first 24 hours—two early cases from collapse of the lung after a prolonged operation, one from pulmonary oedema, and most of the others from intrathoracic haemorrhage (especially in pulmonary atresia) or from the effects of cerebral anoxia, usually the result of the low blood pressure and defective cerebral circulation during operation.

Only 4 of the 24 who died left the operating theatre in reasonably good condition with a completed anastomosis. These four died on the second or third day after operation—one from intrathoracic haemorrhage, the second suddenly and without any obvious reason, and the third and fourth after developing thrombosis at the site of the anastomosis. Thus, with one exception, all the patients who have died have done so within 72 hours of operation. This one, soon after a difficult operation, had such a severe haemorrhage of about 6 pints (3.4 litres) that she developed cerebral symptoms: after her death on the eighteenth day widespread pontine haemorrhages and thrombosis of the basilar artery were found. In 5 of the 24 patients who died it had not been possible to complete an anastomosis.

Objective Effects of the Operation

Most of the patients who were improved by the operation show a number of objective changes, which are briefly as follows: Less cyanosis at rest and on exercise, and less clubbing of the fingers and toes; some widening of the systemic pulse pressure; the development of a continuous murmur, similar to that of a persistent ductus arteriosus, arising from the anastomosis; a reduction in the polycythaemia; and an increase in the size of the heart as measured by the cardiothoracic ratio.

All these changes are not found in every case, and any one or more may be absent, except the anastomotic murmur, which is rarely so. They vary in degree in different patients, but, generally speaking, the greater the subjective improvement the greater these changes: it is reasonable to deduce that the greater the changes the larger the shunt through the anastomosis. While this is the picture gained by reviewing the group as a whole, individual patients show many exceptions to it. Each of the changes is discussed separately.

Cyanosis

In many of these patients the cyanosis changes greatly from time to time, and the degree present at any moment is determined by a large number of variables—for example, temperature, emotion, and recent exercise. In addition its assessment depends on the subjective judgment of the observer, so that although we have graded the cyanosis at each visit we have not thought it worth while to attempt any numerical analysis. Our general impression, confirmed by study of the data, is that the lessening of the cyanosis and of the disability are well correlated. When the initial cyanosis is only slight at rest, there is less room for improvement, and so the change is less striking, except perhaps after exercise.

Most patients still show cyanosis even at rest, although it may pass unrecognized by the relatives. About a quarter of the very good results and an eighth of the good results showed no cyanosis at rest, but only two patients showed no cyanosis after exercise. One, a girl of 6 with Fallot's tetralogy, had grade IV cyanosis and severe disability. At three and at four years after a successful operation she could do almost anything, and showed no cyanosis even after exercise. Her haemoglobin had fallen from 150 to 70%; the blood pressure had widened from 105/75 to 120/60; and the cardiothoracic ratio had increased from 52% to 65% at three years and to 67% at four years.

There was a very loud anastomotic murmur, and there is little doubt that this patient has a shunt that is larger than the optimum (Case 15).

There are also a few exceptions to the general rule at the other end of the scale—that is, a good result but yet with deep cyanosis. A boy aged 9 is a good example. Before operation he was severely disabled and cyanosed. Two years after operation he was regularly at an ordinary school and could walk two miles; but his cyanosis was still moderate, and his haemoglobin had fallen only to 125 from 141% (Case 16; see also Case 2).

Clubbing of the Fingers

Before operation the degree of clubbing usually corresponds with the degree of cyanosis. It seems to reflect the anoxaemia present during activity, as when it is more than would be expected for the cyanosis at rest the latter often increases more than usual on exercise. Baker *et al.* (1949) found that after operation the clubbing improved for about six months and then reached a stable level; longer follow-up has disclosed no reason to alter this impression.

The regression of the clubbing has generally been striking, but it is less consistent than the reduction of cyanosis. Only 10 patients had no clubbing after operation; all but one of these showed very good results, and none had more than moderate clubbing originally. In no case has severe clubbing been wholly abolished by a successful operation. It has always looked symmetrical in the two hands before operation, but afterwards the clubbing on the side of the division of the subclavian artery has sometimes been less than on the other side. The difference has been slight except for one patient, in whom it was specially noted at both visits, one and two years after a successful operation. These observations seem to be in keeping with the findings of Lovell (1950) and of Wilson (1952), who was able to demonstrate an increased finger blood flow in patients having clubbing from a variety of causes, and also changes in the clubbing in individual patients associated with corresponding changes in the blood flow.

Changes in Pulse Pressure

After subclavian-pulmonary anastomosis the peripheral pulse in the affected arm inevitably disappears. In every case the collateral circulation has developed well and there has been no trouble in the arm, but even four years after operation the radial pulse has rarely been detected and the blood pressure has never been measured by the sphygmomanometer.

Significant changes in pulse pressure due to the anastomosis must be caused by the blood flowing from the systemic to the pulmonary circuit through this. Generally the change is not great: this is hardly surprising, as even with a persistent ductus the pulse pressure is often not very wide and after subclavian-pulmonary anastomosis the flow is not usually expected to be very large. Satisfactory readings were available for comparison in only 103 of the 158 patients showing improvement (Table III), largely because the diastolic pressure was often difficult to determine before.

The blood pressure in these patients is probably not very different from that of normal children of the same age: the systolic pressures are mostly below 115 and often about

TABLE III.—Increase of Pulse Pressure after Subclavian-pulmonary Anastomosis

Result of operation	No Significant Change	Increase Between 15 and 30 mm.	Increase of 30 mm. or More	Total
Very good	53	11	9	73
Good	14	4	0	18
Somewhat improved	11	0	1*	12
Total	78	15	10	103

* The objective changes—the improved colour and capacity when in hospital—show that the operation had succeeded, but ten years in bed prevented her gaining corresponding improvement.

90-100, and the pulse pressures are rather on the small side. Comparison of the pressure before and after operation is complicated by its variability and by the natural increase that occurs with growth; the former has been allowed for so far as possible by comparing readings taken at different times. From Fleisch's (1927) figures it seems that the pulse pressure increases by about 2-4 mm. Hg a year during most of childhood: in the younger patients, therefore, in four years it may rise about 12 mm. Hg naturally, so that an increase of less than 15 mm. Hg may be without significance. In 18 of the 103 cases there was no change or a small fall in the pulse pressure, and in 60 there was an increase of less than 15 mm.; these changes were not thought to be significant. There were only 25, or about one-quarter of those benefiting from the operation, who showed a larger increase. With one exception (see footnote to Table III) all these showed great improvement. Nine of the 73 showing very good results had an increase of 30 mm. Hg or more, while in the four showing good results with the greatest increase, it did not exceed 25 mm.

There is some correlation between the larger pulse pressures and the larger hearts, but it is not very close. These larger increases must almost certainly be associated with large shunts, and all these patients show at least a moderate increase in the heart size, as well as reduced polycythaemia and lessened cyanosis. Case 15, quoted above, is a good example of this group.

The Anastomotic Murmur

After a successful systemic-pulmonary anastomosis, whether it is end-to-side or end-to-end, a murmur similar to that of a persistent ductus almost invariably appears. If it is not heard it may be that thrombosis or kinking has obstructed the opening.

The main characters of the murmur are fairly constant. It is essentially continuous throughout systole and diastole, with systolic accentuation. Its systolic element is nearly always distinguishable from the systolic murmur usually present beforehand by its lower pitch and its site of maximum loudness. The diastolic element is, however, the essential identifying feature. It is nearly always best heard in the first to third spaces below the medial half of the clavicle on the side of the operation, and is usually widely conducted so as to be audible through to the back.

The loudness of the murmur varies greatly, but it is easily heard in nearly three-quarters. Even when loud it is rarely accompanied by a thrill—a feature noted in only three patients, all with very good results.

Table IV shows that in most cases the murmur correlates with the result. The one case in which a very good result was obtained but no anastomotic murmur was heard seemed greatly improved at first and was thought to have a continuous murmur, but some days after operation the patient lost ground, the murmur could not be heard, and a thrombus at the site of the anastomosis was suspected. He was recorded as only somewhat improved, but he got better over the next year and eventually achieved a very good result. Another unusual feature is the development of a most striking collateral circulation over the chest, such

TABLE IV.—Relation of Anastomotic Murmur to Result of Operation

Anastomotic Murmur	No. of Patients Classified by Result of Operation			
	Very Good	Good	Some Improvement	No Improvement
Loud or good (102)	78	20	4	0
Moderate or faint (28)	15	8	4	1*
None heard (10)	1†	0	7	3

* Patients who died during the follow-up period have been classified according to the result judged before death. 27 cases have not been included in this table either because details about the murmur were not known (22 cases) or because they were obscured by a continuous murmur that had been present before the operation (5 cases).

† Case 9, q.v.
‡ See text.

as one sees in coarctation of the aorta; but it seems impossible that the thrombus should have obstructed his aorta when he has made such steady progress without any major illness, his femoral pulses can be felt normally, and there is no rise of blood pressure in the arms. A systolic murmur that is now heard may be part of the anastomotic murmur or may be due to the collateral circulation.

The seven cases that showed some improvement though no murmur was heard may have had small shunts through the anastomosis, or possibly may show the slight improvement that sometimes follows a thoracotomy even when nothing else is done.

Changes in the Blood Picture

A detailed study of the blood picture in morbus caeruleus before and after operation, including many of the cases reported here, has been published by Brinton (1951). From the experience of this longer series we find no need to amend his conclusions, and therefore do not propose to deal with this matter in detail. He found that in spite of some discrepancies there was, as a rule, good correlation between the clinical assessment after operation and the changes in the blood picture. In the two patients in whom the normal blood picture led to a more favourable view than the clinical assessment, the former has proved right and both have now achieved good results. In the 12 patients in whom the improvement was rated less highly on the blood picture than on clinical assessment the latter has generally been confirmed over the next year or two, and their improvement is certainly due to a successful anastomosis. In about half of these the haemoglobin percentage has fallen to somewhere near normal, but in the others it has still remained high (see Cases 2 and 16).

The haemoglobin has fallen to normal or near to normal in most of our patients who have had a successful operation. The mean fall in those with very good results is from 130 to 102% (Table V), but the range both before and after operation is very wide, and is shown in Fig. 1.

TABLE V.—Reduction of Haemoglobin After Operation

Result of operation:	Mean Haemoglobin Percentages				Death
	Very Good	Good	Some Improvement	No Improvement	
No. of cases	91	28	18	4	24
Before operation	130	129	137	119	148
After "	102	102	122	120	—

FIG. 1.—Frequency distribution of the haemoglobin percentages in all patients before operation and in those with very good results after operation. Before operation the majority were between 120 and 160%. After operation most were between 90 and 120% (100% = 15.6 g. %).

Before operation the majority were between 120 and 160%: after operation most were between 90 and 120%. Only those with very good results are included in Fig. 1, but the mean change is almost exactly the same in those with good results. It is much less in those who showed some improvement—the mean falling from 137 to 122%—and, as might be expected, does not show any change in the smaller number having no improvement. The high mean value in those who died after operation—148%; range 113-186%—reflects the greater average severity of this group.

Among those patients in whom an anastomosis was completed there were 31 without any significant reduction in haemoglobin. This includes 75% of the small number who were not improved, 39% of those who were somewhat improved, and only 18% of the greatly improved. Why some of the good results should fail to show a fall in haemoglobin is uncertain, but as the overriding aorta remains it is remarkable that so many achieve enough reduction in the anoxaemia to bring the haemoglobin down to normal. The haemoglobin remains high in some in whom the anastomosis is not adequate and probably in a larger number in whom the aorta is so dextroposed that there is still a large amount of mixing. Values less than 100% found in a few patients suggest that they were relatively anaemic—that is, had much less haemoglobin than might be expected for their degree of anoxaemia: correction of this after operation may account for some of those who do not show a fall of haemoglobin in keeping with the good result obtained.

Size of Heart

The reduced anoxia that follows from the increased blood flow to the lungs benefits the heart directly, but this is likely to be offset by the extra mechanical work that an effective anastomosis imposes. No reduction of heart size is therefore to be expected from the operation, and, indeed, an increase would be more likely, and was soon recorded (Blalock and Taussig, 1945).

It is almost a principle of cardiology that, other things being equal, the larger the heart the worse the prognosis. Naturally, therefore, the enlargement following these operations has been viewed with apprehension lest it should be progressive and foreshadow cardiac failure. It has, indeed, been used as the main argument against the opera-

FIG. 2.—Size of heart as measured by cardiothoracic ratio before and after operation. The first 20 patients with very good results have been chosen for illustration and have been arranged according to the initial heart size. The unshaded area above each black column shows the increase in size within the first year. The lightly shaded area above this shows the increase during the subsequent three years, but, as will be seen, there was often no further increase; sometimes there was a decrease, shown by the shaded column on the right. Only three of these patients showed a significant increase after the first year.

tion. We have therefore paid particular attention to the heart size, assessing it for simplicity in terms of the cardiothoracic ratio—the maximum transverse diameter of the heart in the teleradiograph as a percentage of the transverse diameter of the inside of the thoracic cage, just above the diaphragm.

The changes in the heart size in the first 20 cases with very good results are shown in Fig. 2. The mean values in the various groups are given in Table VI, where they have been grouped according to the results, and in Table VII,

TABLE VI.—Cardiothoracic Ratio and Result of Operation

	Cardiothoracic Ratios: Mean and Ranges					
	Very Good Results	Good Results	Some Improvement	No Improvement	No Anastomosis	Operative Deaths
Before operation	48.8 39-63	51.0 44-61	50.1 43-57	57.8 51-64	52.5 43-57	50.8 45-61
After operation	52.0 39-67	53.7 44-69	51.9 41-58	52.6 52-67	—	—

TABLE VII.—Average Cardiothoracic Ratio at each Year After Operation (Very Good and Good Results Combined)

No. of Cases	Cardiothoracic Ratio				
	Before Operation	1 Year After	2 Years After	3 Years After	4 Years After
19	48.0	53.4	53.8	53.5	53.5
28	48.5	51.6	51.9	51.8	—
35	49.7	52.7	52.1	—	—
32	50.0	52.7	—	—	—

where they have been grouped according to the time that has elapsed since operation. The mean cardiothoracic ratio before operation is essentially the same in all groups, except that it is a little less in those who have shown very good results and much more in those who gained no benefit, probably because several of these had some more complex defect than Fallot's tetralogy, in which the heart is usually little, if at all, enlarged. After operation the heart size increases rapidly in the first month or so (figures not included in the table), and this increase on the average persists unchanged, at least for the four-year period of our observation. The average increase in the cardiothoracic ratio was 3 points—that is, from 49% to 52% or from 51% to 54%. This picture, gained from the means of the whole series, obscures some of the individual variations. The majority do behave in the manner described, but there are three smaller groups that behave differently: (1) those in whom the heart size shows no change; (2) those in whom it increases at first but subsequently gets less; and (3) those in whom it increases progressively.

In most instances any decrease during the period of observation probably results from a relatively greater increase in the chest than in the heart. Nearly all the patients in whom the heart later became smaller were about the age of puberty, a period when rapid growth of the chest may be expected. Only three of those who showed little if any improvement had any increase in heart size—presumably a reflection of the inadequate size of the shunt. There are, however, many patients who show very good results but no increase in the size of the heart. These patients and the others in whom the increase is only moderate and non-progressive must represent the ideal, where the general benefit to the patient is correctly balanced against the increased load on the heart. A smaller shunt would not give the benefit sought and a larger one might overburden the heart. It is unfortunate that so far we lack the knowledge and the means to tailor the anastomosis so as to achieve this optimum in everyone, but it is encouraging that, despite this, so many do achieve it.

There are also the patients in whom the shunt is too large as judged by the increase in the size of the heart and by

other changes. Symptomatically, these patients do very well unless the shunt is so much too large that congestive failure develops.

Twenty patients are doing well but have shown an increase in heart size that is progressive or at least greater than one would wish. In ten of these, all but one of whom showed very good results, it has shown no tendency to be progressive. In seven of the ten the increase was 7-9 points, but the heart was small, so the cardiothoracic ratio is still between 53 and 55%, and there seems no reason why the very good result should not last. In the other three the increase was only 6-7 points; but the heart was larger before operation, so that the ratio now is between 58 and 60%: in none does it exceed 60%, and it is hoped this will continue, though the long-term prospects of these patients can hardly be as good as in those with smaller hearts.

Of the ten patients in whom the heart has so far enlarged progressively three were not improved (Cases 9 and 10) or died after some initial improvement (Case 6): none of these had Fallot's tetralogy, two having tricuspid atresia and one some more complex lesion. The remaining seven all continue to show very good results, most of them for three years or more. Three had small hearts before operation, so that an increase of about 10 points still leaves them with cardiothoracic ratios between 52% and 55%, and, provided the increase now stops, they should continue to do well. The last four have ratios between 60% and 67%, either because the heart was larger at the start (one case) or because the increase was from 12 to 15 points (three cases) instead of the average of about 3 points. Case 15, the patient with the largest increase, has already been described. These four are the only patients who make us anxious about the possible onset of congestive failure in the near future, though in all other ways they are extremely well. The increase may be reversed, as has happened at least once (Case 18), but we can have no assurance of this.

The outlook is certainly better if the heart is smaller. The proportion of very good results to poor results combined with those in which the patients showed no improvement or died is 3.5:1 where the c.t.r. was 49% or under and 1:1 where it was above this.

We suggested earlier (Baker *et al.*, 1949) that the heart size helped in choosing patients suitable for operation, and that if the c.t.r. was above 52 or 54% less certainty could be felt about a good result. This is borne out by longer experience, but it is clear that there are several (nearly 10%) with a c.t.r. of 55% or above who have shown a very good result, even if it has less chance of lasting. So far these patients do not include an undue proportion of those with hearts getting progressively larger. One of the largest hearts was in this group, but the largest of all (c.t.r. 62%) was in Case 4; this patient was doing very well and showing some decrease in the heart size when he died with a cerebral abscess.

Progress after Operation

We have written so far, except in the discussion on the heart size, as if these changes occurred at once after operation and remained unaltered thereafter. A survey of the 107 patients followed for two years or more shows that this is generally but not always true. The first few months usually see all the main changes established.

The increased capacity is obvious almost immediately after operation, and the only patients not easy to assess early are the very young and those with such poor muscular development that they need some time to show their improvement (see Case 17 below). Apart from these, only eight patients were noted as improving further a year or two after the operation; in some this was probably no more than increased confidence, but in others, as judged by the objective signs, it seemed real organic improvement. These are balanced by six in whom there has been some suggestion of deterioration. In two this was due to the development of pulmonary tuberculosis and in two others

to chronic infections of the upper respiratory tract. There are, gratifyingly, only two in whom slight objective deterioration and a lessening murmur suggest that the anastomosis may be getting smaller. Even if this is so, and it is not certain, they form such a small proportion of the whole that they need not be regarded as early examples of what is likely to befall the majority at a later date.

Post-operative Complications.—Immediate complications have mostly not affected the results. There were three patients with Horner's syndrome on the side of the operation. Five patients had some intracranial thrombosis after operation, but the paresis has made such an excellent recovery that none find it a source of major disability, except one in whom a cerebral thrombosis has left him less intellectually able to do his work. Two patients showed signs of failure soon after the operation: this lasted a few weeks and cleared up spontaneously or with digitalis; but both have done well since.

Bacterial Endocarditis and Cerebral Abscess.—Later complications of the operation have, apart from the cardiac failure and deaths discussed elsewhere, been few. Rather surprisingly, bacterial endocarditis has not been troublesome, though Taussig *et al.* (1951) report 18 cases in their series of 1,000, two-thirds of them occurring soon after operation. Only one of our patients was treated (elsewhere) for subacute bacterial endocarditis, and the diagnosis was not established; subsequently he had a very good result (Case 17). In these patients a cerebral abscess has been found much more often than bacterial endocarditis. This is not the result of the operation but is connected with the right-to-left shunt which remains; it has also been more common than bacterial endocarditis among other patients.

Five patients developed signs of a cerebral abscess, 3, 4, 18, 26, and 34 months after their anastomosis. All except Case 4 (q.v.), who died, have made a good recovery after a further operation, but with some residual symptoms—for example, one has a visual defect of one quadrant and would otherwise be passed as normal except by those who know him well, to whom he seems to have lost something of his exceptional energy and enthusiasm. Two others have slight residual weakness but are able to lead reasonably normal lives. One other was admitted as a suspected case of cerebral abscess, but was thought to have a cortical thrombophlebitis; she recovered with conservative treatment but did not quite regain her previous activity.

Results in Special Groups

So far we have discussed the 200 cases as a whole, but some special groups are worth separate consideration. Two can be distinguished easily—tricuspid atresia and various forms of dextrocardia and isolated laevocardia—and a third, pulmonary atresia, with less certainty. It is not possible to separate the last completely, because the diagnosis can be certain only in fatal cases, and some successful ones may be listed as Fallot's tetralogy.

Tricuspid Atresia

There were seven cases of tricuspid atresia with a non-functioning right ventricle; this diagnosis was made when there was left ventricular preponderance on the electrocardiogram and left ventricular hypertrophy on radiology. All these seven survived the operation; but this must be regarded as good fortune, as it cannot be safer than in Fallot's tetralogy. It seems, however, that it is at least no more dangerous.

Two of the seven died within a year (Cases 6 and 10). The other five have all done well, three of them for two or three years. One has been described (Case 3). Another boy, aged 19, has been regularly at light manual work for two years and can walk four miles with ease, instead of half a mile with difficulty. His heart was very small, so that an increase in the c.t.r. from 39% to 46% still leaves it small.

A third boy, aged 8, was extremely blue, and walking 20 yards left him exhausted. At first it was difficult to say

how much his operation had helped, as he had such poor muscular development that he could not do much. Each year he has improved, so that now, after three years, he can run 50 yards or walk five miles and is regular at school. He has grown 6 in. (15 cm.) and put on 21 lb. (9.5 kg.) in weight (Case 17).

These three compare well with the best results in Fallot's tetralogy and have maintained their improvement for two or three years without much increase in heart size. The other two have done well but the heart has increased rather more in the first year, so longer time is needed to know if they will continue as good.

The difference between the successes and the two deaths may be related to the hearts being larger in the latter, although in one who did well it was nearly as large. The heart size seems the best guide to whether a patient with tricuspid atresia is likely to maintain the improvement after operation: if the c.t.r. is under 54% the good result may last at any rate for several years, but if it is 60% or more it is less certain, though there is not yet enough evidence to decide that operation is not worth doing.

The results of Taussig *et al.* (1951) show a mortality of 26% within six months of the operation. Our results are similar and not as good as in Fallot's tetralogy. The natural prognosis of tricuspid atresia is, however, much worse than that of Fallot's tetralogy. There have been six deaths in the 31 cases of tricuspid atresia among 1,124 cases of congenital heart disease seen in 1947-51. This is a higher mortality than in any other group, except perhaps in pulmonary atresia and transposition of the aorta and pulmonary trunk.

Dextrocardia and Isolated Laevocardia

There were six cases in this group—two with dextrocardia and complete situs inversus, one with isolated dextrocardia, and three with laevocardia but with the abdominal viscera transposed. In cases such as the last four the congenital defects are generally very complex. The mortality in this group was very heavy and half the patients died. These three have been described in the section on deaths after operation (Cases 12, 13, and 14).

Three patients survived, two doing extremely well. One (Case 18) had dextrocardia and situs inversus, probably with Fallot's tetralogy: after operation she could walk three miles instead of a few hundred yards. Her heart increased in size soon after operation, but became smaller during the next two years (c.t.r. 58 to 67% to 63%). Another, who had a continuous murmur that was thought to indicate bronchial artery blood supply to his lungs, probably with complete situs inversus, was able to lead a normal life without much increase in the size of the heart (Case 19). The third, with laevocardia and transposed viscera, was only slightly improved.

Very good results may therefore be obtained but cannot be expected with confidence in dextrocardia and isolated laevocardia. The results of Taussig *et al.* (1951) are better than these, but agree in showing a rather heavy mortality of 17% directly, and another 12% during the ensuing six months.

Pulmonary Atresia

Cases of pulmonary atresia are more difficult. The difference in the surgical treatment of this group and of Fallot's tetralogy is one reason for their separation (Allanby *et al.*, 1950), but the distinction is often difficult, and some cases of atresia are probably left undiagnosed among the cases of Fallot's tetralogy. This will give an unduly pessimistic view of the results of operation.

In a patient with the general picture of Fallot's tetralogy but with a loud and single second sound in the pulmonary area and without a systolic murmur the diagnosis of pulmonary atresia is likely. If the cardiac outline shows a very sharply defined pulmonary bay with an absence of a pulmonary trunk the diagnosis becomes more certain, and is further supported if there are also the special features

that indicate a bronchial artery blood supply to the lungs—isolated nodular shadows in the hila and heavy vascular markings in the right upper quadrant caused by bronchial arteries passing from the arch of the aorta (Campbell and Gardner, 1950). There may be a continuous murmur that is indicative of pulmonary atresia (or sometimes truncus arteriosus) with a collateral blood supply through a persistent ductus or bronchial arteries.

Generally, angiocardiology should be used to confirm the presence of adequate pulmonary arteries beyond the atresia, but in patients with recurrent attacks of unconsciousness we have sometimes thought that thoracotomy is the lesser risk. It should never be dispensed with in this group on other grounds, even though there seem to be pulmonary arteries on radiology.

(a) *With a Continuous Murmur.*—There were nine of these cases (including the two considered in the dextrocardia group). Two died soon after operation (Case 14 and another); in a third no artery adequate for an anastomosis could be found. In the other six the surgeon succeeded in carrying out a subclavian-pulmonary anastomosis, though in three this had to be end-to-end: all these patients were improved. The first, instead of being an invalid who could walk 200 yards, could soon lead a normal life and walk four miles, including many Devonshire hills; her cyanosis was much less and her haemoglobin percentage returned to normal. Her heart, which had been small, increased soon after operation (c.t.r. 43 to 53%) but no further in the next three years, and her improvement is maintained. Case 19, with an equally good result after two years, has been described. The other four have not been followed for so long; all are improved, including two who had end-to-end anastomoses (one very good, two good, and one somewhat improved). All were thought to have patent pulmonary arteries beyond the atresia, one with a persistent ductus and the other three with a bronchial artery blood supply to the lungs.

(b) *Without a Continuous Murmur.*—There were 12 cases: five of these died, two before the special problems of this group had been fully appreciated, and three later, when we were well aware of these. In four more no operation was possible as no artery suitable for an anastomosis was found: two of these were early cases, but the two recent ones, in which the mistake should have been avoided, were accepted as having adequate pulmonary arteries—one after radiology and one even after angiocardiology.

These results are so bad that pulmonary atresia might seem unsuitable for operation, but two of the three good results were outstanding, and it seems unlikely that those without a continuous murmur are worse subjects for operation than those with such a murmur. As an example, one boy was deeply cyanosed and could hardly walk at all; now, two years later, he goes to an ordinary school and is ready to spend his time fighting with the other boys, and hardly shows any change in colour. There is no undue increase in the size of his heart. The clinical diagnosis of pulmonary atresia with a bronchial artery blood supply seems almost certain. In the third the improvement was only moderate.

Comparison of Fallot's Tetralogy with other Groups

Discarding the 32 cases of the special groups described and three cases with transposition (one with the addition of pulmonary stenosis) wrongly put forward for operation, there remain 165 cases in which the diagnosis was simple Fallot's tetralogy. We know that, in fact, two of these had a single ventricle and another an aorta that arose entirely from the right ventricle, but these are points that cannot be diagnosed with certainty on clinical grounds, so we have left them with the group of Fallot's tetralogy. Even so, the results for Fallot's tetralogy are very much better than for the other groups, and the operative mortality is 8% and the expectation of a good result 75%. In the more complicated groups, on the other hand, the mortality so far has been nearly 30%, and the good results only about 35%. Unless this result can be improved with further experience, operation should be advised in these cases only when they seem favourable and only in special centres where every facility for investigation and surgical treatment is available.

Summary and Conclusions

The results of 200 anastomotic operations in patients with morbus caeruleus are described, nearly all of them having been followed for more than a year and several for four years. Most had Fallot's tetralogy, and here the results were excellent. Many were seriously ill, but only 8% died and 75% benefited greatly, so that they can walk a mile or more and lead lives that are almost normal without too much physical activity. In the smaller number of more complex lesions, such as tricuspid atresia, dextrocardia, and pulmonary atresia, the results were much less good. The total mortality was nearly 30%, and only 35% obtained the good results. More experience is needed to decide which of these patients can hope to benefit from operation, but some tentative suggestions are made.

Most patients have an increased capacity and lose much of their cyanosis, clubbing, and polycythaemia. Some cyanosis, at least on exercise, and some clubbing generally remain unless they were very slight. The haemoglobin usually falls from between 120 and 160% to between 90 and 120%. In nearly all the successful cases a continuous murmur can be heard at the site of the anastomosis, and the presence of this soon after the operation is often one of the best indications of success. The pulse pressure may be a little wider as the result of the anastomosis, but not often much wider.

Generally the improvement gained in the first few months after operation is a good guide to the future and is maintained. The annual mortality rate is not much above 1%, and this includes the risks to which these patients are inevitably exposed whether they have an operation or not.

Special attention has been paid to the increase in the size of the heart because this has been thought to be the great drawback to the operation. Generally the increase is not great, and is not progressive after the first few months. The cardiothoracic ratio may increase quickly from 48 to 52% and then remain constant during the period of observation. A few patients in whom the increase is great or even progressive make us anxious lest they may develop congestive heart failure, but except for three with complex lesions in whom this happened within the first six to nine months no others have yet done so.

It is a pleasure to express our thanks to the surgeons who have made this work possible: Mr. R. C. Brock, who has operated on the largest number, Mr. T. Holmes Sellors, and Mr. Ian Hill. Mr. Holmes Sellors has added to our indebtedness by the great trouble he and his surgical staff have taken in keeping us so fully informed about patients operated on in another hospital. We should also like to thank the staff of the cardiac department, who during the last four years have helped with the follow-up at different stages, the doctors who have sent us reports on their patients, and Miss M. Waldron, of the department of illustration, Guy's Hospital, for the charts.

RADIOACTIVE PHOSPHORUS (P^{32}) IN
TREATMENT OF MENORRHAGIA*

BY

H. C. McLAREN, F.R.C.O.G.

J. C. HEATH, B.Sc.

AND

A. QUINTON, M.Sc.

(From the Department of Obstetrics and Gynaecology,
Queen Elizabeth Hospital, Birmingham)

If menorrhagia persists after curettage in the over-40 age group a decision on radical treatment either by induction of the menopause or by surgery may be necessary to avoid anaemia and increasing general debility. Both methods have disadvantages, however; radium or deep x rays practically castrate the patient, so that flushings and premature age-effects such as senile "spotting" of the vagina or introital fissuring may develop (McLaren, 1950). Surgery with ovarian conservation may avoid these sequelae, but it carries a small but definite mortality and morbidity.

The idea of avoiding radical treatment by destroying the endometrium is not new; ten Berge (1936) in Holland, for instance, has described a method of uterine thermocautery which had some success. Our present experiments of irradiating the uterus with beta particles were conducted on the suggestion of Dr. A. G. Glucksmann. As beta particles from a source such as radioactive phosphorus are stopped by the surface layers of tissue it seemed that surface endometrial cautery and uterine haemostasis might be achieved without destroying ovarian function.

The difficulty in constructing an applicator which would pass the human cervix yet allow irradiation of the whole of the cavity of the uterus led us to use a balloon on the lines described by Simon (1949) and by Douglas and his colleagues (1950, 1951). The human uterus, however, is not distended without a high pressure of air or fluid, and this led to difficulty in containing the balloon *in utero*. In the end a simple rod-shaped applicator designed by one of us (J. C. H.) was used, and proved to be easy and safe to handle. Despite the shape of the normal uterine cavity a wide area of endometrium was burned by P^{32} .

The Applicator

In the preliminary experiments three layers of filter paper were wound tightly around an acrylic resin rod 4 cm. long and 1 cm. diameter (Fig. 1). An aqueous solution of sodium phosphate containing the radioactive phosphorus isotope P^{32} was distributed evenly over the filter paper and evaporated. The completely dry filter paper was coated with a solution of acrylic resin.

In later experiments moist filter paper was moulded over the whole surface of a cylindrical "perspex" former with a hemispherical upper end. An aqueous solution of sodium hydrogen phosphate in which the phosphorus is radioactive was allowed to evaporate to produce a dry surface evenly covered with P^{32} . A thin sheath of perspex (0.25 mm. thick) was slipped over the filter paper and a seal made with perspex solution in chloroform at the lower end. This applicator has two advantages: (1) it is easier to assemble, more robust, and less likely to contaminate the patient; and (2)

thinner filter paper may be used, and there is therefore less error due to self-absorption; the absorption in the perspex cover can be allowed for in the calculation. A "winged" applicator was also used which, when in position, formed a letter Y (Cases 10 and 14). The amount of P^{32} used per unit area was the same as for the rod applicator. The two upper short rods were 2.5 cm. long and the single rod 3.5 cm. long; the diameter of all three was 0.8 cm.

Care was taken not to damage the plastic shell containing the P^{32} at insertion into the uterus. For sterilization, 1 in 20 "dettol" was used.

FIG. 1.—The applicator consists of a rod with a covering of P^{32} impregnated blotting-paper ensheathed in perspex.

Animal Experiments

To test the efficacy of the applicator and to prove its ability to contain the P^{32} , tests were made on the vagina of the rabbit. With the animals anaesthetized, P^{32} applicators were inserted into the lower vagina and held in position by vulval sutures of thread. Dummy applicators were used in control animals. With the loaded applicator in position the animals remained healthy, although the vulva became oedematous. Micturition, however, was undisturbed. After the removal of the applicators the vulval oedema rapidly disappeared, although even 14 days later there was a definite cuff of perivaginal thickening at the site of the P^{32} burn (Table I).

Histological Changes after P^{32} Irradiation

The beta-radiation from P^{32} caused a complete necrosis and loss of surface epithelium. Deep to this, the damage to stromal cells was difficult to interpret—that is, it was difficult to say if some of the stromal cells with granular cytoplasm and indistinct nuclei might recover. There was pronounced inflammatory reaction of the deeper tissue due to the surface burn and to those beta particles which penetrated beyond the necrotic surface layers. Leucocytes crowded the stroma, which was oedematous and showed many free erythrocytes. In this partly inflamed, partly damaged area at the periphery of the damaged vagina it was difficult to define exactly the limit of cauterization by P^{32} . Admitting these difficulties, however, it is safe to say that a cuff of vagina was destroyed to a depth of 2 mm. Deeper to that, of course, the tissues were inflamed and oedematous, but not necrotic.

TABLE I.—Effect of P^{32} on the Vagina of a Rabbit: Severe Tissue Damage was Caused to a Depth of About 2 mm.

No.	Details of Applicator				Surface Dose r.e.p.	Depth Dose in Röntgens Equivalent Physical					When Killed	Gross Effects	Histology
	Quantity	Time Hours	Length cm.	Diam. cm.		1 mm.	2 mm.	3 mm.	4 mm.	5 mm.			
1	4.75	120	4	1	190,000	59,000	21,000 10,000	7,000 r.e.p. at 2.8 mm.	2,500	900	Immediately	Vulvar oedema; perivaginal oedema with slough of mucosa	Severe burn, but not complete destruction of tissues down 2 mm.; marked vascularity
2	4.75	120	4	1	190,000	59,000	21,000 10,000	7,000 r.e.p. at 2.8 mm.	2,500	900	After 8 days	Vulvar oedema and marked perivaginal thickening	Slough of lining mucosa and submucosa to a depth of 2 to 3 mm. Deeper to the burn, marked oedema and capillary dilatation
3	4.75	120	4	1	190,000	59,000	21,000 10,000	7,000 r.e.p. at 2.8 mm.	2,500	900	After 14 days	Thickening of perivaginal tissue	Slough separating; lumen packed with inflammatory cells and necrotic tissue; marked submucosal fibrosis and capillary thrombosis, especially in cavernous tissue of clitoris

*Read before the Birmingham and Midland Obstetrical and Gynaecological Society on March 26, 1952.

Clinical Experiments

First of all a dummy applicator was inserted into the uterus of a patient due to have a hysterectomy for menorrhagia. Transcervical sutures of thread were found to hold the applicator safely in the uterus. With this normal (parous) uterus most of the endometrium was found at hysterectomy to be in contact with the applicator. The tissue subjected to histological study served as a control for the irradiated cases.

Four patients—three of whom had uterine fibroids—were then treated with the rod-shaped applicator carrying P^{32} . Total hysterectomy and bilateral salpingo-oophorectomy was carried out within 21 days. After histological studies a further 11 patients were treated with P^{32} , and to judge its curative effect on menorrhagia three months were allowed to pass before hysterectomy.

Prior to insertion of the applicator a bimanual examination of the uterus and appendages was made; curettage of the uterus was also carried out in most cases. On three occasions, however, despite careful bimanual examination and uterine exploration by curette, we failed to diagnose fibroids which were obvious in the uterine muscle on section after hysterectomy. Our failure to make the diagnosis is perhaps excusable because of the intramural position of the fibroids.

After hysterectomy the uterus was opened, photographed, and sectioned to show the depth of burn produced by P^{32} , the degree of endometrial regeneration, and the state of the tubes and ovaries.

Clinical Observation with P^{32} in Utero

As we gained confidence in the technique the patients were allowed up in the ward with the applicator *in utero*. They felt no discomfort or "radium-sickness," although mild flushes of the face affected two patients (out of 15). One patient (Case 6) complained of a pink discharge during the three months between treatment and hysterectomy. She proved to have a mild endometritis with mild endosalpingitis. At operation she had the first "menstrual" loss for three months, and the resulting congestion of the abdominal wall and pelvis made haemostasis difficult. Although the degree of endometrial inflammation was slight, no doubt it added to the physiological congestion of ovarian-pituitary origin. This "menstrual" congestion caused difficulty with haemostasis in another patient (Case 16), although there was no warning uterine bleeding. These two cases are of special interest, since the menstrual congestion of ovarian origin no doubt affected all other patients, whether they menstruated or not.

The need to remove the lower uterus and cervix in another patient led to an unusually difficult dissection of old-standing tough scar between rectum and posterior cervix. A small puncture of rectum followed, but it was easily sutured and caused no trouble during convalescence.

Lastly, our 15-year-old patient, who was bedridden with gross rheumatic heart disease, caused anxiety at hysterectomy.

This girl had been almost exsanguinated with menorrhagia on several occasions; she had repeated transfusions and repeated curettage, and had resisted all efforts to cure her with hormones. After 12 months of bleeding it was thought that hysterectomy might extend the short life

TABLE II.—Control of Menorrhagia by P^{32}

Case	Age	Curettage	1st Menses	2nd Menses	3rd Menses
5	49	Metropathia	Normal	Normal	Normal
6	49	No curettage obtained	Nil	Nil	Began at operation
7	44	Normal proliferative phase	Trace	Normal	Normal
8	15	Metropathia (undiagnosed fibroid)	Loss slightly less	Loss slightly less	Relapse: flooding
9	48	Metropathia (undiagnosed fibroid)	Flooding	Flooding	Emergency hysterectomy
10	43	No curettage	Trace	Nil	Nil
11	36	Patchy metropathia	Nil	"	Normal loss
12	45	Premenstrual (undiagnosed small fibroid)	Heavy	Trace	Normal (4th period flooding)
13	45	Proliferative	Flood	Nil	Normal
14	45	Metropathia	Nil	"	Nil
16	47	No curettage	"	Trace	"

Of 11 patients, 7 were successfully treated; 1 relapsed after 3 months; another was improved for only 2 months; while 2 (with unsuspected fibroids) were failures.

prognosticated by her physician. P^{32} produced only temporary benefit, and hysterectomy with ovarian conservation was undertaken. She collapsed at operation, but a blood transfusion brought a remarkable improvement, and the operation was concluded without difficulty. Convalescence was satisfactory.

Control of Menorrhagia by P^{32}

Of 16 patients treated with P^{32} , 11 were given a three-months trial before hysterectomy. The period of three months was laid down by the Medical Research Council, who advised us in these experiments. It is, of course, not sufficient time to assess the value of P^{32} as a haemostatic agent. Nevertheless, improvement as judged by the onset of amenorrhoea or normal menstruation was achieved in eight of eleven patients; one patient was improved for two periods and then relapsed, while the following two patients with unsuspected fibroids of the myometrium were failures.

Case 9.—A 6-para aged 38. At curettage the uterus measured 3 in. (7.6 cm.) by sound; it was uniformly bulky, but it was not thought to contain a fibroid. Curetting showed metropathia. After P^{32} she had 45 days of amenorrhoea followed by a severe uterine loss over 10 days. She was admitted to a neighbouring hospital as an emergency and after three pints (1.7 litres) of blood

TABLE III.— P^{32} Histology.

Although a superficial endometrial burn was caused by P^{32} , recovery with endometrial regeneration followed. Nevertheless, haemostasis was obtained in 9 out of 12 cases.

hysterectomy was necessary. The anterior wall of the uterus was found to contain a fibromyoma the size of a hen's egg (see also Tables II and III).

Case 12.—A 3-para aged 45. At preliminary curettage the uterus was carefully palpated and fibroids were sought in the uterine cavity with the curette. The uterus was bulky, the cavity $3\frac{1}{2}$ in. (8.9 cm.). A small cervical polyp was removed. The curettings accorded with her menstrual cycle (secretory phase). After P^{32} , menstruation followed at about monthly intervals—namely, heavy loss for seven days, then two normal periods, then a relapse with severe bleeding. At operation a cluster of fibroids some 2 cm. in diameter occupied the upper myometrium.

Two further cases were only partially relieved by treatment with P^{32} :

Case 7.—This patient, aged 44, had three normal periods—that is, an improvement for 103 days—then a recurrence of heavy bleeding. The uterus was bulky, with a myometrium $3\frac{1}{2}$ in. (8.3 cm.) thick but without fibroids. No histological evidence of P^{32} burning persisted.

Case 8.—A girl aged 15 had severe cardiac disease; she had been treated by repeated curettage and blood transfusions. P^{32} led to some improvement for eight weeks, but her third period was heavy. Hysterectomy with ovarian conservation was performed, but there was no uterine abnormality, apart from a hyaline "burn" necrosis of the endometrial stroma.

Effects of P^{32} on the Uterus

Gross Pathology.—Apart from the presence of fibroids or thick myometrium (see Table III), there was little of note to record in the specimens removed at hysterectomy. The ovaries, of course (which would have been severely damaged

by radium), showed obvious signs of activity such as follicles or corpora lutea. In the endometrium the site of burning by P^{32} was obvious—for example, in Case 15, subjected to hysterectomy seven days after P^{32} , the endometrium was burned and congested at the site of irradiation, while as long as three months after irradiation the site of burning was still definable in some specimens.

Histology (Table III).—No specimen was obtained earlier than seven days after irradiation, so that, although the surface dose of beta-irradiation amounted to about 200,000 r.e.p. in both animal and human experiments, we have no human tissue obtained on the conclusion of irradiation. From Cases 15 (seven days after P^{32}) and 702 (18 days after P^{32}) it appeared, however, that the depth of endometrial burn was no more than 1.5 to 2 mm. in the human uterus (Figs. 2 and 3). As in the rabbit's vagina, the surface epithelium and endometrium was necrotic, while the deeper layers were severely damaged and inflamed, with capillary dilatation and clotting, oedema of the stroma, leucocytic infiltration, and so on. As in the rabbit histology, it was difficult to draw an exact outer limit to the depth of cautery achieved by P^{32} . With previous curettage of the uterus, of course, a surface burn and inflammatory reaction affect the deeper part of the endometrium. Nevertheless, the deeper glands and stroma nearest to the myometrium or embedded in the surface muscle appeared to escape irradiation injury, and as recovery proceeded regeneration of endometrium followed. After three months the surface epithelium occasionally showed marked irradiation distur-

FIG. 2.—Case 15. P^{32} caused a surface slough (S), seen separating from tissue which is infiltrated with inflammatory cells.

FIG. 3.—Case 702. Irradiation necrosis of the surface endometrium has not penetrated far enough to destroy deeper glands and stroma.

FIG. 4.—Case 10. After three months. Although some specimens showed apparent recovery from P^{32} , others showed areas of surface epithelium with the irradiation distortion depicted here.

FIG. 5.—Case 11. Three months after 200,000 r.e.p. a type of hyaline or waxy necrosis of stroma developed beneath the lining epithelium (M). In this specimen the "burn membrane" extended down to the upper part of the cervical canal.

tion, while below the surface a waxy or hyaline appearance of the stroma was observed. This we have called a "burn membrane," and it was obvious in four specimens (Figs. 4 and 5). Finally, the ovaries were sectioned in all specimens for evidence of irradiation effects, but, apart from simple follicular cysts, the ovaries were normal.

Intra-epithelial Cancer.—It was an extraordinary coincidence that the first patient to be treated with P^{32} should prove to have what Dr. A. G. Glucksmann calls "near or pre-cancer" of the cervix. The patient was used as a "carrier" of P^{32} , and, of course, surgery was planned when she had recovered from her anaemia. Dr. C. W. Taylor writes: "At the squamo-columnar junction of the cervix there is considerable epidermization of the mucous glands with areas of atypical epithelial proliferation. One section shows apparent pre-cancerous changes with a suggestion of early carcinomatous infiltration, but serial sections taken from the block show, in fact, no more than an indirect cut of a 'cleft' with atypical proliferation of the basal epithelium. The lesion found, therefore, is no more than a tiny fragment of pre-cancer without true carcinomatous infiltration."

The area of cervix in question was well outside the range of beta particles emanating from the applicator, so that the pre-cancerous changes were coincidental.

Discussion

P^{32} produced a surface burn of the endometrium some 2 mm. in depth without ovarian damage. The resulting slough with inflammatory reaction and vascular thrombosis was healed in about 90 days with endometrial regeneration. A recurrence of menorrhagia, however, did not follow in all cases, and, although only 11 out of 16 cases were subjected to a three-months trial, we can report a cure in seven and an improvement in two. Menstruation usually reappeared, suggesting that no more than temporary haemostasis can be expected of the method. Nevertheless, even temporary haemostasis, if it could be guaranteed, would be valuable—for example, in younger women who declined radical treatment or who wished to have children. Not only would the patient be freed from serious haemorrhage, but menstruation when re-established might be normal. The same possibility of normal menstruation after P^{32} exists in the older age group studied in this series, although, of course, the achievement of the amenorrhoea of the menopause without ovarian destruction is the aim of treatment.

The carcinogenic action of x rays or repeated small doses of gamma rays on the skin raises the possibility of endometrial cancer as a sequela of beta-irradiation of the uterus. If, however, the endometrium heals after a surface burn, as happened in most of our cases, and, secondly, if menstruation and shedding of the endometrium follow, it seems unlikely that cancer will develop. Nevertheless, cells which have been irradiated by sublethal doses of beta rays must undergo proliferation, and it is not known if these cells have a tendency to become carcinomatous. The problem must therefore be held *sub judice*, and certainly all patients treated with P^{32} (without hysterectomy) will require a prolonged follow-up so that in time we may have the answer to the question of the risk of carcinogenesis.

The possibility of foetal abnormality is another theoretical objection to the irradiation of the uterus without castration, in that the ovum, by embedding itself in damaged tissue, might in some way grow abnormally. By the time the endometrium has been shed at menstruation, however, and by the time it has recovered sufficiently to develop premenstrual endometrium, it seems a very remote possibility that a healthy ovum would suffer any damage as it developed *in utero*. The ovaries, of course, are not subjected to beta-irradiation, and there is therefore no question of fertilization of a damaged ovum.

Finally, with the idea of achieving a deeper endometrial burn we are now experimenting with cerium¹⁴⁴. Beta particles from this have a maximum energy of 3.1 meV., and in theory the radiation should burn endometrium to a

depth of 5 to 7 mm. If this calculated depth is in fact achieved we may obtain better clinical results. A further improvement may also follow the development of an applicator which will irradiate all of the endometrium.

APPENDIX A

Calculation of Dose in Equivalent Röntgens at Various Depths

Absorption experiments in tissue-like materials (alkathene wax) show that the beta rays from the P^{32} emerging from the applicator had a half-value layer of 0.075 cm. and an absorption coefficient of 9.23 cm.⁻¹ in tissue. The blackening of photographic film was used to confirm the even distribution of the P^{32} along the applicator and also the calculated dose rates.

Let l = length of filter paper in cm.
 $2a$ = diameter of filter paper in cm.
 t = thickness of perspex sheath in cm.
 q_0 = strength of P^{32} in mc. when applicator inserted.
 q = " " " " " " removed.
 Decrease in strength = $(q_0 - q)$ mc.
 Number of beta particles emitted during treatment =
 $(q_0 - q) 6.57 \times 10^{13} = N$.

Consider the number of particles crossing the boundary of an elementary cylinder diameter $2r$.

Half the particles emitted will be ejected outwards from the filter paper, and allowing for the absorption of the rays:

$$\text{No. of particles crossing the boundary} = \frac{N e^{-9.23(r-a)}}{2}$$

$$\text{No. of particles absorbed in the elementary volume } 2\pi r l dr =$$

$$= \frac{N}{2} \times 9.23 \times e^{-9.23(r-a)} \times dr.$$

$$\text{No. of particles absorbed per unit volume} = \frac{N \times 9.23 \times e^{-9.23(r-a)}}{4\pi r l}$$

Assuming that the beta particles have an average energy 1.12×10^{-6} erg.

$$\text{Energy absorbed} = \frac{N \times 9.23 \times e^{-9.23(r-a)}}{4\pi r l} \times 1.12 \times 10^{-6} \text{ erg. g.}$$

$$\text{Depth dose} = \frac{N \times 9.23 \times e^{-9.23(r-a)} \times 1.12 \times 10^{-6} \text{ r.e.p.}}{4\pi r l \times 85}$$

If we put $r = a + t$,

$$\text{Surface dose } S = \frac{N \times 9.23 \times e^{-9.23.t} \times 1.12 \times 10^{-6} \text{ r.e.p.}}{4\pi r l \times 85}$$

$$= \frac{(q_0 - q) 6.57 \times 10^{13} \times e^{-9.23.t} \times 1.12 \times 10^{-6}}{4\pi (a+t) l \times 85}$$

$$\text{Surface dose } S = \frac{(q_0 - q) e^{-9.23.t} \times 6.36 \times 10^5}{(a+t) l} \dots (1)$$

$$\text{Tissue dose} = S \times \frac{(e^{-9.23(r-a)})}{(e^{-9.23.t})} \times \frac{a+t}{r} \dots (2)$$

$$= S e^{-9.23(r-a)} \times \frac{a+t}{r} \text{ r.e.p.}$$

For the standard applicator $l = 4$ cm., $a = 0.475$ cm., $t = 0.025$ cm. The value of $q_0 - q$ varies, but is approximately 1 mc. If we substitute these values,

$$S = \frac{e^{-9.23 \times 0.025} \times 6.36 \times 10^5}{2} = 252,000 \text{ r.e.p.}$$

$$\text{Percentage depth dose} = 100 \times e^{-9.23(r-0.5)} \times \frac{0.5}{r} = 50 e^{-9.23(r-0.5)}$$

$$\text{If } d = \text{depth in cm. \% D.D.} = \frac{50}{0.5+d} e^{-9.23.d}$$

Table Showing How Dose Varies With Depth

Depth in mm.:	Surface	1	2	3	4	5
% D.D.	100	37	11.3	3.9	1.39	0.5
Tissue dose in rep	252,000	80,600	28,500	9,800	3,500	1,260

The minimal lethal dose of radiation on endometrium is not known, but if 10,000 r.e.p. is accepted as a lethal dose then the "cautery" effect of 5 mc. of P^{32} in the uterus for five days is about 3 mm.

Summary

A method is described for producing uterine haemostasis by P^{32} without damaging the ovaries.

A surface burn by P^{32} is quickly healed and regeneration of endometrium follows.

Preliminary animal experiments were followed by a clinical trial on 16 patients, 11 of whom were allowed three months between irradiation and hysterectomy. Seven cases were cured, two were somewhat improved, and two, with unsuspected fibroids, were failures.

We wish to thank Dr. A. G. Glucksmann, of the Strangeways Laboratories, Cambridge, who initiated and took part in this study, and Dr. C. W. Taylor, Director of Pathology at the Birmingham and Midland Hospital for Women, who advised us on the histology. We are also grateful to our colleagues Miss M. Neville and Mr. L. M. Park, Selly Oak Hospital, who operated on one of the patients and sent us the clinical notes and pathological material to complete this report. Finally, we wish to thank Miss M. E. Attwood and Mr. D. H. S. Boyd for technical assistance.

VARIATION IN TECHNIQUE OF INTRACUTANEOUS B.C.G. VACCINATION

BY

CARROLL E. PALMER, M.D.

Organization, Copenhagen

The technique for giving an intracutaneous injection is ordinarily set forth very clearly: 0.1 ml. of fluid is to be injected as superficially as possible into the skin. Yet when even such a simple procedure becomes a commonplace in the everyday work of a great number of persons, as is the case in the large public health programmes of to-day, individually insignificant errors and deviations from the prescribed technique may, when taken collectively, amount to considerable variations, and thereby create problems of unexpected magnitude. The full impact of this situation—and its possible consequences—was probably not really felt until intracutaneous injections of B.C.G. vaccine were being given to literally millions of persons in the international mass vaccination campaigns. The present paper gives the results of several studies designed to provide preliminary information on the immediate measurable results of B.C.G. vaccination in schoolchildren when the technique of intracutaneous injection of vaccine was deliberately varied within the limits likely to occur under ordinary field conditions.

There are two principal ways in which an intracutaneous injection may deviate from the recommended technique. First, more or less than the specified volume of 0.1 ml. may be given; and, secondly, the fluid may not be injected superficially into the skin. Theoretically, these two kinds of deviation ought not to be correlated: variation in volume should be independent of variation in depth.

So long as B.C.G. vaccination remained mostly in the hands of a few interested people, the technique of injection was probably more of an art than a science. Each worker undoubtedly developed his own method of gauging the volume and depth of his injections. With the start of mass vaccination, however, hundreds of new workers had to be instructed in the technique, which could no longer be left to the whim of each worker; some uniformity and standardization was essential. In mass vaccination campaigns it would be difficult, or even impossible, to enforce a standard procedure for measuring the volume from the graduated marking on the syringe, because most syringes—even new syringes—soon begin to leak badly. Experience had already shown, however, that the size of the wheal—the white, rounded elevation of the skin caused by the injection—corresponded at least roughly with the volume of fluid injected; and this method was adopted for gauging the dose. There seems, however, to be little agreement on the size of the wheal representing the standard (0.1 ml.) dose of vaccine.

The first edition of *B.C.G. Vaccination against Tuberculosis* (Holm, 1948), issued by the International Tuberculosis Campaign, contained the following instructions for making intracutaneous B.C.G. vaccination: "By the intracutaneous vaccination, 1/10 c.cm. of the vaccine is injected as superficially as possible into the skin. . . . If the injection is given correctly, a wheal will appear, in which the follicles of the hair are easily visible. The wheal must have a diameter of about 10 mm." Two years later, in the *Second Annual Report of the International Tuberculosis Campaign* (1949–50) the instructions for vaccination were revised to read: "(a) The injection should be made as superficially as possible, and very slowly. (b) The dose should be as accurate as possible—0.1 c.cm. If judged by the size of the wheal, the diameter of the wheal must be 8 mm." An account of the B.C.G. vaccination programme in Finland (Savonen, 1949) did not specify the volume of vaccine or depth of injection, but simply stated that "so much vaccine is used that the anaemic wheal appearing on the skin has a diameter of 10–12 mm."

The British Ministry of Health (1950) issued the following instructions for B.C.G. vaccination programmes: "0.1 c.cm. (ml.) of the vaccine is then injected *strictly* intradermally without loss due to leakage from the needle track. A satisfactory vaccination should produce a white wheal 5 mm. in diameter." A brochure from the Bureau of Tuberculosis Control (1952), Commonwealth of Pennsylvania and the Henry Phipps Institute in the United States, does not mention the size of the wheal but merely states: ". . . 0.1 c.cm. is injected intracutaneously as superficially as possible into the skin."

A volume of 0.1 ml. is almost always specified, yet the wheal expected to result from this volume varies in diameter from 5 to 12 mm. There must therefore be considerable variation in interpreting what is meant by a very superficial injection, for about the only way the size of the wheal could differ and still represent a constant volume of vaccine would be by variation in the depth of injection.

Thus one may be justified in thinking that intracutaneous injections of B.C.G. vaccine, and of tuberculin as well, must have varied widely in mass campaigns.

Many vaccinators began working in the campaigns after only the most cursory instruction and little

practice in giving injections. Often lacking critical supervision, they naturally developed their own habits for estimating the size of the wheal and the depth of the injections. A consistent error of only a few millimetres in estimating the size of the wheal from a deep intracutaneous technique could, as we shall show, result in their giving much more than the recommended dose. Moreover, large doses could easily pass unnoticed, because a leaking syringe makes it difficult for anyone to estimate the volume injected. On the other hand, it can be assumed that no vaccinator (even with a badly leaking syringe) would refill her syringe before completing at least one vaccination, so the maximum volume injected is not likely to have exceeded 0.6 or 0.7 ml.

Independently of technique, the volume of vaccine given has probably also been influenced by the attitude of the vaccinator (and the supervisor) towards the work: a strong conviction that a larger dose assures greater protection, coupled with an equally strong belief in the harmlessness of B.C.G., is known to have accounted for many conscientious vaccinators routinely and deliberately giving each person "a good vaccination." On the other hand, some vaccinators, fearing complications from too much vaccine, especially in younger children, have undoubtedly overestimated the size of the wheal and given only a fraction of 0.1 ml. Precise information on this subject is unobtainable; but from what is known of variations between vaccinators, both in their technical performance and in their attitude to the work, it is reasonable to conclude that the average volume of vaccine routinely given by some vaccinators has been at least four or five times that given by others. Furthermore, taking into account the range of variation for each individual vaccinator, it is quite possible that some vaccinated persons received eight or ten times as much vaccine as others.

Material

The data in this paper are derived from an extensive series of field studies on B.C.G. vaccine and vaccination, carried out during the past three years by the Tuberculosis Research Office of the World Health Organization, Copenhagen, in co-operation with the Danish Statens Seruminstitut and the International Tuberculosis Campaign. In general, the work was done among Danish schoolchildren, in groups large enough to provide reliable results. Each study was carefully planned and supervised to ensure that the observations were, so far as possible, objective and free of personal bias. Children were selected for vaccination on the basis

of their reactions to a Mantoux test with 10 units of purified protein derivative (P.P.D.*); those in whom the indurated area was less than 6 mm. in diameter were vaccinated. Post-vaccination tests were made with the same dose and batch of tuberculin, and all observations were made according to a standard procedure by the same team of highly trained field personnel.

FIG. 2.—Mean diameter of wheals according to (a) volume of B.C.G. vaccine injected very superficially, and (b) depth of injection of 0.1 ml. of B.C.G. vaccine.

Results

Wheal Size with Variation in Volume and Depth of Injection

Before investigating the relation between the size of wheal and the volume and depth of vaccine injected the personnel chosen for this work had to be specially trained. Varying the volume presented no problem: with carefully selected non-leaking syringes, different volumes could be measured quite accurately by reading from the graduations on the barrel of the syringe. But after having become skilled in giving injections very superficially for other studies the vaccinators needed practice in order to become proficient in varying the depth of their injections. For this purpose members of the office staff volunteered as subjects on whom one of the vaccinators practised with saline until she could inject, at will, into different layers of the skin and could classify her injections according to depth.

Two studies were then made in groups of Danish schoolchildren totalling nearly 1,400. In the first study only volume, not depth, was varied: each child was given 0.05, 0.1, 0.2, or 0.3 ml. of vaccine, always injected very superficially. In the second study depth was varied but volume kept constant: 0.1 ml. was given at one of four different skin levels, graded as superficial, intermediate, and deep intracutaneous, and just below the subcutaneous tissue. A regular sequence was followed in both studies: the different volumes

FIG. 3.—Frequency distributions of diameter of wheals according to depth of injection of 0.1 ml. of B.C.G. vaccine.

or depths were given in rotation as children came in line for vaccination. In this work, the vaccinator herself measured the diameter of the wheal immediately after each injection; the measurements therefore may not be entirely free of bias. The vaccinator also classified each injection according to its actual rather than intended depth, since she did not always strike the depth aimed for. Her classification of depth was used for analysing the material. (Wheals produced by subcutaneous injections are not included in the results, because often no wheal appeared, and when it did it was very small with indistinct margins, and it rapidly disappeared.)

The histograms in Fig. 1 show that the usual amount of 0.1 ml. of vaccine, given superficially, very often produced a wheal 8 mm. in diameter; and almost all of the wheals which were not 8 mm. in diameter measured either 7 or 9 mm. Larger and smaller volumes caused a corresponding change in the size of wheals, associated with slightly greater variations in the distribution around the central value. The average size had a linear relation to the logarithm of the volume injected, as shown by the line in Fig. 2. Doubling or halving the dose made a difference of about 1.5 mm. in the average size of the wheals; a sixfold increase (from 0.05 to 0.3 ml.) made a difference of about 4 mm.

The mean size of the wheals resulting from injection of 0.1 ml. at different depths is also shown in Fig. 2, and the corresponding histograms in Fig. 3. The size of the wheal clearly decreased with increasing depth of injection: the difference in average size between wheals produced by superficial and by deep intracutaneous injection was 3.1 mm., a difference as great as that produced by a fourfold difference in volume of vaccine given superficially.

Analysis of the influence of age and sex on the size of the wheal showed that older children had slightly larger wheals than younger ones, but the difference was too small to be important. These studies were carried out in healthy, well-nourished white children. We believe, from what field workers from different parts of the world have told us, that skin qualities may differ appreciably in different races and perhaps also with different nutritional conditions. These factors may influence the size of the wheal, although we have no definite data on this subject.

Unfortunately we have no information about the variation in size of wheal for volumes other than 0.1 ml. given by intermediate and deep intracutaneous injection. But if we assume that the size of wheal and volume of vaccine injected have the same linear relation (and slope) for the deeper as for the superficial injections, then small differences in size of wheal may represent very large differences in volume. For example, it appears that a wheal of 5 mm. may be produced by hardly more than one-quarter of the usual (0.1 ml.) dose given very superficially, whereas a wheal of 6 mm.—only 1 mm. larger—could result from a dose nearly twice the regular dose if injected deeply into

the cutaneous tissue. If, in addition, the vaccinator underestimates the size of the wheal, the dose may be three or four times the recommended 0.1 ml.

Effect of Variations in Volume of Vaccine on Post-vaccination Response

Many workers favour the intracutaneous method of giving B.C.G. vaccine primarily because they assume that with it the amount of vaccine injected can be measured. But, as we have already explained, in practice the amount given is probably far from constant. It is important to know whether, and how much, the observable consequences of vaccination are affected by failure to give a constant dose of B.C.G. Information on post-vaccination allergy and size of local lesions is available from the studies in which volume and depth were deliberately varied. One restriction on this work was that the total amount of B.C.G. given to any child could not exceed the Danish standard dose (0.075 mg. of organisms), so dilutions of a regular batch of vaccine were prepared and used in various volumes.

*RT XIX-XX-XXI from Statens Seruminstitut, Copenhagen.

The results (Table I) are from the study designed to determine the effect of varying the volume alone and both volume and strength of vaccine simultaneously. Altogether 951 children were vaccinated. They were divided into eight subgroups, each receiving one of the various volume-dose combinations. The horizontal rows in Table I show the average size of the tuberculin reactions (left) and local lesions (right) for the groups given different volumes (0.05 to 0.3 ml.) of the same dilution of vaccine (1/2 to 1/12 standard strength). The vertical columns furnish similar data for groups given different dilutions but the same volume. From the diagonal rows one can compare the results when different volumes and dilutions were combined so that the groups got the same total milligram dose of B.C.G. organisms.

The figures in the left-hand section of the table may surprise many B.C.G. workers: over quite a broad range neither volume nor strength of vaccine had much, if any, effect on the average size of the tuberculin reactions either 10½ weeks or one year after vaccination. For example, 0.05 ml. of 1/4 strength vaccine (0.0094 mg. B.C.G.) gave reactions whose diameter averaged 16.9 mm. at 10½ weeks, compared with 17.6 mm. from 0.2 ml. of the same dilution (0.0375 mg. B.C.G.): a fourfold difference in volume (and in milligram dose of B.C.G.) made a difference of less than 1 mm. in the size of the tuberculin reactions.

By contrast, the figures on the right of Table I show that varying the volume or varying the strength of vaccine has a slight but consistent effect on the average size of the local lesions at 10½ weeks, and of the resulting scars at one year. An increase in dose (either by increasing the volume or the strength of the vaccine) is associated with larger lesions. This observation is confirmed by an earlier study (Edwards and Gelting, 1950), in which 0.1-ml. volumes of standard strength and of four-times standard strength vaccines were compared. The average size of post-vaccination tuberculin reactions differed by only 1 mm., but with the stronger vaccine the local lesions were on average 2.3 mm. larger.

An additional point, perhaps of more theoretical than practical interest, is shown by the diagonal rows in Table I. Apparently increasing the quantity of diluent for a constant dose of B.C.G. is associated with a very slight tendency for the post-vaccination tuberculin reactions to decrease in size. This may reflect a true relation between dose and volume, or it may depend on some systematic error associated with the injection of different volumes. (Vaccine may tend to ooze from the larger wheals resulting from the superficial injection of large volumes; or possibly the vaccinator tended to inject a little more than she should when giving small volumes and a little less when giving large ones.)

Effect of Variations in Depth of Injection on Post-vaccination Response

Studies of the effect of varying the depth at which vaccine was injected gave striking results, shown in Tables II and III. In the first study 188 children were alternately given a superficial and a deep injection of 0.1 ml. of vaccine; and each injection was classified by the vaccinator as superficial, intermediate, or deep intracutaneous, or subcutaneous. The same procedure was followed in the second study, on about 500 children; but here both standard strength and 1/100 standard strength vaccine were used. As the children came in line to the vaccinator, the first was given a superficial, the second an intermediate, and the third a deep intracutaneous injection. When this sequence had been completed three times the next child was given an injection just below the skin into the subcutaneous tissues. Thus, 1 out of every 10 injections was subcutaneous (given only to boys). The same rotation system was followed for both strengths of vaccine.

It is evident from both studies that the average sizes of the tuberculin reactions were not appreciably affected by the depth at which standard strength vaccine had been injected. For the 1/100 strength vaccine, however, the dia-

	Subcutaneous	11.7	0.8	3.8

* Scar surrounded by zone of discoloration, irregular and often retracted, adherent to underlying tissues.

more superficial injections gave a higher level of allergy: the most superficial gave an average at 10½ weeks of 14.6 mm., compared with 12.9 mm. for the subcutaneous, while at one year the averages were 14.0 and 11.7 mm. respectively.

The average size of local lesions 10½ weeks after vaccination showed a systematic and pronounced difference with the depth of injection. In both studies the lesions averaged about 8 mm. for the superficial technique and increased with depth of injection to become twice as large (15–16 mm.) for subcutaneous injections. Of even more practical importance, the frequency of local subcutaneous abscesses also increased with deeper injection technique.* Superficial injection of standard strength vaccine led to an abscess in less than 1% of cases, but the frequency of abscesses increased substantially with increasing depth, and nearly one-third of the children given vaccine subcutaneously developed a local abscess. (The subcutaneous injections, it may be recalled, were given not deeply into the subcutaneous tissues, but just under the skin.)

A further interesting point is brought out by Table III. With the 1/100 strength vaccine the depth of injection had much less, though probably still some, effect on the size of the local lesions, and there were no local abscesses. It is also noteworthy that the measured size of superficial scars at one year for the standard vaccines in both studies (Tables II and III) increased only slightly with increasing depth of injection. There was, however, a pronounced difference in the scars after deep injection: they were commonly surrounded by a zone of discoloration; they were irregular in shape, and often retracted and adherent to the underlying tissues.

Fig. 4 gives histograms of the local lesions at 10½ weeks and resulting scars at one year for the four different depths of injection for the two studies combined; the frequency of local abscesses and abnormal scars is shown by the darker shading. With increasing depth the whole distribution moved towards the right on the scale and local abscesses became more frequent with increase in the proportion of lesions over 14 mm. in diameter. None of the smaller lesions were associated with an abscess; but an abscess was associated with 30% of the lesions over 14 mm. in diameter, and with more than half of the lesions over 20 mm. in diameter.

Discussion

The widespread adoption of the intracutaneous method of giving B.C.G. vaccine in mass campaigns has been explained in several ways: (a) it is regarded as more exact than other methods because a measured amount of vaccine can be injected; (b) the technique is believed to be fairly easy to learn and to apply rapidly in mass vaccinations; and (c) results, in terms of post-vaccination tuberculin sensitivity, are thought to be better than with other methods.

Practical problems have, however, arisen. At least one problem can be inferred from the inconsistencies, almost amounting to contradictions, in the instructions for making intracutaneous injections. Nearly all of these instructions

*The term "abscess" is used to denote a collection of fluid beneath the corium, as opposed to the normal ulceration in the corium, which, when covered, is covered by epidermis and crust only.

specify that 0.1 ml. of vaccine should be injected very superficially. But the size of the resulting wheal is usually also specified, testifying to the fact that the volume of vaccine is not expected to be measured by the graduations on the barrel of the syringe. The reason for this cannot be doubted: the syringes often leak so badly that some other way had to be found to gauge the volume injected. Even if syringes did not leak it would be questionable whether the graduated markings could be used for vaccinations done at the speed expected in mass campaigns. In practice, therefore, volume is commonly gauged by the size of the wheal, and this is usually estimated rather than measured. Some vaccinators are told to try to make wheals 5 mm. in diameter, and others wheals 10–12 mm. in diameter, but at the same time all are told to inject 0.1 ml. very superficially.

Quantitative data from the studies described in this paper show that the diameter of the wheal is directly related to the volume as well as to the depth of the injection; the largest wheals are produced by the largest volumes given most superficially; the smallest wheals by the smallest volumes given most deeply. A wheal 8 mm. in diameter, for example, was usually found to represent 0.1 ml. of vaccine injected superficially, but a wheal of this size could probably represent 0.4 ml. or more given in the deeper layers of the skin. On the other hand, only one-quarter of the recommended dose, given very superficially, can give rise to a wheal 5 mm. in diameter. The results indicate that there must be enormous differences in the volume of B.C.G. given in mass campaigns—the differences between vaccinators alone amounting to four or five times, and probably still greater variations in the amount given to individual persons.

This investigation has shown that tuberculin allergy, measured by the size of tuberculin reactions at different intervals after vaccination, is practically unaffected by variations of technique within the likely range in mass campaigns. The size of the local responses at the vaccination site, on the other hand, depends to a large extent on the depth of injection and to a less extent on the volume of vaccine injected. A given volume injected subcutaneously produces lesions twice as large as those resulting from the same

FIG. 4.—Frequency distributions of diameter of local vaccination lesions, and frequency of local abscesses and abnormal scars, according to depth of injection of 0.1 ml. of B.C.G. vaccine.

volume injected superficially. Moreover, abscesses at the site of the local lesion are rare after superficial injections, but increase progressively in frequency with increasing depth of injection; and in this investigation nearly one-third of the children had associated subcutaneous abscesses when the vaccine was injected just below the skin into the subcutaneous tissues.

These findings bear directly on the question whether laymen should be employed as vaccinators for mass B.C.G. campaigns in countries with few professional personnel. So far as post-vaccination allergy is concerned, variations in the technique of giving intradermal injections apparently make so little difference that lay vaccinators could probably be employed with impunity. If, however, the success of a campaign depends on keeping to a minimum the frequency of large vaccination lesions and of complications, then all vaccinators must be intensively trained to inject the vaccine into the most superficial layers of the skin.

What bearing do these findings have on the search for more fundamental knowledge on the problem of tuberculosis immunization? We cannot answer this question, yet it may be permissible to speculate on certain possibilities. To regard a large, ugly vaccination lesion as a promise of strong and long-lasting immunity is, if not an obvious inference, at least a tempting idea to the vaccinator, and a consoling idea to the person vaccinated. But our findings provide little support for such an inference. Certainly a weak vaccine (such as the 1/100 dilution of standard strength used here) gave rise to extremely small lesions and rather weak allergy; but when standard strength vaccine was injected at different depths in the skin very considerable differences in the size of the lesions were not associated with differences in allergy. The inconstant correlation between the local reaction and the allergic response to B.C.G. does not justify the belief that both can be used as a true guide to immunity. A strong or a weak local reaction—a good or fair “take”—may reflect properties associated with immunization we do not know; yet from these studies it seems to depend to such an extent on the way the vaccinator did her work that size of the local lesion may well reflect factors that have nothing whatever to do with immunity.

Summary

An intracutaneous injection of B.C.G. vaccine may deviate from the recommended technique in two principal ways: more or less than 0.1 ml. may be given, and the vaccine may not be injected superficially into the skin. This paper reports the results of several studies, altogether comprising about 1,400 schoolchildren, in which volume and depth of injection of B.C.G. vaccine were deliberately varied within the limits likely to occur in ordinary mass vaccination campaigns, and the effect of such variations on the resulting post-vaccination tuberculin allergy and the local reactions at the site of vaccination.

Because of the fact that most syringes leak, the volume of vaccine injected is commonly gauged by estimating the size of the wheal formed on the skin rather than by reading from the graduated markings on the barrel of the syringe. In a study of about 950 children when different volumes of B.C.G. vaccine were injected very superficially into the skin, 0.1 ml. of vaccine produced wheals averaging 8 mm. in diameter. Doubling or halving the volume caused a difference averaging 1.5 mm.; a sixfold increase (from 0.05 to 0.3 ml.) caused a 4 mm. increase in the diameter. In a second study of over 400 children, depth of injection was varied but volume was kept constant: deep intracutaneous injection of 0.1 ml. gave wheals averaging 3.1 mm. smaller than the same volume injected superficially—a decrease as great as that from a fourfold reduction in volume given superficially.

Tuberculin allergy in schoolchildren, measured by the tuberculin reaction at intervals after vaccination, was practically unaffected by variations in intracutaneous technique likely to occur in the field. Volumes of 0.05–0.3 ml. of vaccine injected at depths ranging from very superficial in the skin to subcutaneous all gave about the same mean level of post-vaccination allergy.

A given volume of vaccine injected just beneath the skin into the subcutaneous tissue produced local lesions twice as large as those from the same volume injected superficially. The frequency of local subcutaneous abscesses increased with increasing depth of injection.

These studies show that the size of the reaction at the site of vaccination is influenced by the depth of injection of vaccine, but the level of B.C.G.-induced tuberculin allergy is not. If, therefore, post-vaccination allergy is to be taken as an index of immunity, the local vaccination reaction does not necessarily measure the same thing.

MEASUREMENT OF LEAKAGE OF TUBERCULIN SYRINGES

BY

JOHANNES GULD, M.D.

AND

CHRISTIAN RUD, M.D.

(From the Tuberculosis Research Office, World Health Organization, Copenhagen)

Many of the syringes used for intracutaneous injections tend to leak between plunger and barrel, often to such an extent that reading from the graduated scale may be grossly misleading. In practice the quantity of liquid actually injected is therefore usually estimated by measuring the size of the wheal produced at the site of injection. For scientific work, however, where accurately measured dosage is required, unsatisfactory syringes must be detected and eliminated before use.

A simple and easily constructed apparatus for accurate and quantitative measurement of leakage in syringes is

FIG. 1.—Diagram of apparatus for measuring leakage in syringes. a=lever with adjustable weight; b=joint for vertical rotation of lever; c and d=rubber disks; e=tuberculin syringe.

illustrated in Fig. 1. The syringe, when filled with distilled water, is placed vertically in the apparatus. The tip, with no needle attached, is pressed against the soft smooth rubber disk (c) and the lever with a certain weight (a) is brought down upon the plunger. This lever, while holding the syringe steady, subjects the plunger and consequently the contents of the syringe to a constant pressure. As the tip is embedded in the rubber disk, the contents can escape only by leaking out between plunger and barrel, and the rate of decrease of the contents thus becomes a measure of the rate of leakage. The pressure is correct only if the lever is nearly horizontal, so when testing short or partly filled syringes the distance between rubber disk and lever must be correspondingly reduced by placing the rubber disk on a box of appropriate height.

If the diameter of the plunger is about 4.5 mm. (as in most all-glass tuberculin syringes) an external pressure of about 1 kg. is used, corresponding to a pressure inside the syringe of 5 to 6 kg. per cm.² or approximately 70 lb. per sq. in. (This pressure corresponds roughly to what was found in the following experiment. Several experienced testers were asked to exert pressure, by hand, on a tight air-filled syringe, corresponding to the estimated pressure used for an ordinary Mantoux test. By this procedure the air volume was reduced to between one-fifth and one-eighth, corresponding to an internal pressure of five to eight atmospheres.)

If the diameter of the plunger exceeds 4.5 mm. (as in most Record syringes) the external pressure must be correspondingly increased in order to keep the internal pressure per cm.² constant.

Experiments

A series of experiments designed to provide data on the leakage rate of syringes—as measured by the apparatus—have been carried out. Twelve new all-glass 1-ml. tuberculin syringes of the type used for field studies by the Tuberculosis Research Office were filled with distilled water to a certain level and subjected to constant pressure in the apparatus.

Each syringe was tested for leakage at five different levels of filling—namely, filled to the 1, 0.8, 0.6, 0.4, and 0.2-ml. marks. Starting from each of these levels, the decrease in the contents of the syringe was measured by reading the scale every minute for a period of five minutes. All tests were repeated once, and then the syringes were boiled in distilled water for 30 minutes and tested again at two different levels of filling—1 ml. and 0.4 ml. When the tests were repeated the person reading the scale had no knowledge of previous results. The results were plotted on a graph, the time during which the fluid in the syringe was kept under pressure being indicated on the horizontal scale and the contents of the syringe during the testing period on the vertical scale. The slope of each curve thus gives the leakage rate, illustrated in Fig. 2 for four of the twelve syringes tested.

The leakage rate varied to a surprising extent from syringe to syringe, ranging from 0.06 to more than 0.4 ml. in five minutes. In some instances the leakage rate showed great variations from level to level in the

same syringe. There was good agreement between the results of the first and the second series of tests; and boiling in distilled water for 30 minutes did not appear to alter the leakage rate.

Practical Application

Syringes to be used for research by our field teams are now pre-tested for a period of six minutes (not five) with an internal pressure of 5–6 kg. per cm.² (70 lb. per sq. in.). As leakage may be different in different parts of the syringe, each syringe is tested for two different degrees of filling—namely, completely and two-fifths filled. The results are expressed in units of 0.01 ml. per six minutes (0.1 ml. per hour). When a syringe is said to have a leakage of 15, for example, it means that the leakage in six minutes (average of the two trials) amounts to 0.15 ml.

From such information it is also possible to estimate the percentage of fluid lost in injecting 0.1 ml. If it is assumed that the injection is made in five seconds, and that the internal pressure in the syringe is 5–8 atmospheres, a leakage rate of 10 corresponds with a loss of 2% or less of the 0.1-ml. dose. A leakage rate of 20 corresponds with a 3–4% loss, and a rate of 30 with a loss of 5–6%.

Fig. 3 summarizes the results of testing 387 new syringes of the particular brand we have found to be most satisfactory. The rate of leakage is plotted on the horizontal scale, percentage of syringes on the vertical scale, and each point on the line indicates the percentage of the total number of syringes which have a leakage rate below a specified value.

It may be seen from the figure that while the leakage rate ranged from 4 to 70 the syringes were not equally distributed over this range. About half of the total sample had

FIG. 2.—Results of experiments with four tuberculin syringes (A, B, C, and D). Each curve shows decrease in contents under pressure by time.

rates of between 4 and 15, while the other half were scattered between 15 and 70. Of incidental interest is the fact that if the arithmetic value of the leakage rate is replaced by its logarithm, the distribution is very nearly normal. It may also be seen from the figure that the maximum leakage may be lowered from 70 to 25 by rejecting 15% of the syringes. To have a maximum leakage of 20 means rejecting 25% of the syringes, and a maximum leakage of 15

FIG. 3.—The cumulative distribution of the leakage in 387 new syringes. Leakage is measured in units of 0.01 ml. per six minutes under a pressure of approximately 5 kg. per cm.², and these units are marked on the horizontal scale of the figure. The vertical scale gives percentages of the 387 syringes tested, and each point on the curve indicates the percentage of the total sample which have a leakage rate below the specified value.

means rejecting half of the syringes. Information from a curve of this kind is thus a good guide when a compromise is sought between economy and low maximum leakage.

It should be understood, of course, that the particular curve shown here applies to a rather expensive brand of syringes selected as one of the best from a number of different products available in large quantities. As an example of the results obtained with other brands, we found leakage rates ranging from 19 to 144 with one sample of 24 new Record syringes of the type selected for a mass programme as having comparatively low leakage. Half of this sample of syringes had rates above 52.

New syringes with a leakage rate below 20 are seldom found to show any apparent leakage when first used in the field. Only the sides of the plunger become moist, evaporation evidently keeping pace with minimal leakage. After 1,000 to 1,500 injections, however, syringes usually begin to leak, one or two drops for every 10 to 20 injections. Both the syringe and the tester's hand then begin to get wet, and further increase in leakage (or leakage from between the needle and the tip of the syringe) can no longer be detected. Thus it is not difficult in the field to know when a syringe is leaking, but it is difficult to estimate how much fluid is lost.

In the Tuberculosis Research Office we have adopted the plan of testing all new syringes before they are sent to the field, rejecting those with leakage rates above 20. The moment a syringe begins to leak steadily in the field we ask that it be returned for retesting in the apparatus (to control gross error in the tester's judgment). Leakage rates between 20 and 30 are usually found; if above 20 they are rejected for further field use.

The cost of such strict criteria may seem prohibitive even for research work, but the cost of leakage cannot be disregarded. For example, the leakage rates for a sample of 55 syringes, discarded because of leakage in a mass B.C.G. campaign where "some" leakage was tolerated, was found to vary from 20 to 540, with half of the sample we tested having a rate above 90. A rate of 90 probably corresponds to a loss of 15 or perhaps 20% of the amount of fluid actu-

ally injected—a net loss of 15 ml. of tuberculin or vaccine for 1,000 injections, at a cost which cannot be considered negligible when compared with the cost of a new syringe. Workers from some of the mass campaigns maintain that occasionally they have used 1-ml. syringes yielding only one or two vaccinations for each refilling—a very costly procedure indeed, in terms of both time and money.

Summary

A home-made apparatus is described for measuring leakage between the plunger and barrel of tuberculin syringes. Even with the brand of syringe which we have found the most satisfactory, about one out of every four new syringes leaks to a greater extent than is compatible with accurate work. After being used for 1,000 to 1,500 intradermal injections, many syringes begin to show obvious signs of leakage, and, when retested, fail to meet the criteria we have adopted for acceptability. Unless new syringes are first tested before use and a plan for periodic retesting is followed, it is unreasonable to expect field workers to be able to measure accurately the amount of fluid given in intradermal injections or to avoid wasting rather large amounts of tuberculin and vaccine.

A NEW DIPHTHERIA PROPHYLACTIC (N.A.F.T.)

BY

D. C. LAHIRI, M.B., D.T.M.&H., Dip.Bact.
(From the Haffkine Institute, Bombay, India)

It has been known for some time that culture filtrates of toxigenic *Corynebacterium diphtheriae* may vary greatly in their antigenicity per Lf when tested in guinea-pigs and in horses (Barr and Glenn, 1949). Hartley (1935) suspected an undetermined factor in the original culture medium as a possible reason for these variations, but failed to isolate any substance having an adjuvant effect on a poorly antigenic sample of toxoid.

Experiments

During the past few years we have experienced the same phenomenon of marked variation of antigenicity of different samples of crude toxoid per Lf injected, particularly in respect of the hyperimmunization of horses. This was particularly clear-cut when the results from three types of culture medium were examined. The three media were: (a) veal-infusion-proteose-peptone, (b) pig-stomach autolysate, and (c) casein hydrolysate. The toxoid derived from the veal-infusion-proteose-peptone gave by far the best antitoxin responses. This observation was confirmed by carefully controlled experiments in guinea-pigs. Since the responses to the veal-infusion-proteose-peptone medium toxoid were so much better our attention was directed to a possible non-toxoid component of the crude toxoid possessing adjuvant properties. That the veal-infusion-proteose-peptone toxoid did contain such an adjuvant substance was revealed by the results from the following experiment.

The toxoid contents from each of the three culture media toxoids were removed by the addition of the optimal amounts of highly purified horse antitoxin. The T.A.F. floccules were centrifuged and the supernatants separated. Then a fixed amount of freeze-dried toxoid purified by the method of Levine *et al.* (1949) was added

to equal volumes of each of the three supernatants, using physiological saline as the control. Potency tests in guinea-pigs, tested four weeks after one dose of 1 Lf, showed that the veal-infusion-proteose-peptone toxoid supernatant greatly increased the antigenicity of the added toxoid, the casein hydrolysate supernatant decreased it, and the pig-stomach hydrolysate had no apparent effect compared with the controls.

Subsequent research in the veal-infusion-proteose-peptone crude toxoids showed that the adjuvant factor—previously described as the synergic factor (Lahiri, 1951)—was diffusible through "cellophane" (grade 600), then could be adsorbed on to activated charcoal and be eluted with N/50 sodium hydroxide. The method now adopted is to dialyse the crude toxoid, adsorb the adjuvant factor on to activated charcoal, and elute with diluted sodium hydroxide. The eluate is then neutralized and evaporated to dryness. Technical details of the method have already been described (Lahiri, 1952), and further details will be published later. The following experiment illustrates the adjuvant effect of the material obtained.

Freeze-dried purified toxoid was dissolved in (a) detoxified crude toxoid, (b) the parent broth, (c) the neutralized charcoal eluate, (d) the residual fluid of the diffusate

TABLE I.—Survival of Guinea-pigs Challenged with 20 C.L.D.* of Test Toxin, Administered Four Weeks After Immunization with 1 Lf of the Purified Diphtheria Toxoid, Dissolved in Different Fractions of Crude Veal-infusion-proteose-peptone Toxoid: Control in Saline

Fraction into which the Purified Toxoid was Dissolved	Survival Rates in Three Animal Assays

after treatment with charcoal, and (e) saline—the control. The immunity-response results, using guinea-pigs, are recorded in Table I.

Subsequent experiments, using the same culture medium, failed to reveal the presence of the adjuvant factor in tetanus culture filtrates, and, conversely, the diphtheria toxoid adjuvant factor failed to augment the antigenicity of purified tetanus toxoid. This is illustrated by the following experiments: purified tetanus toxoid was dissolved in (a) a solution of the partially purified diphtheria toxoid adjuvant factor, (b) analogous material derived from tetanus toxoid diffusate, and (c) physiological saline. The results are recorded in Tables I and II.

Field Trials

These results were so promising, as judged by laboratory tests, that a series of field trials were carried out, employing 433 young children and 80 adults. Each of our groups of children (aged 1–8 years) were immunized with a different prophylactic: (1) with our purified diphtheria toxoid augmented with the charcoal eluate adjuvant factor Batch No. 1; (2) with a duplicated preparation, Batch No. 2; (3) with an A.P.T. of British manufacture; and (4) with A.P.T. made in the Haffkine Institute. The children were Schick-tested before their single dose of diphtheria prophylactic and post-Schick-tested four to eight weeks after inoculation; careful note was also made of the number and severity of the reactions encountered. The results obtained are summarized in Table III, and show (a) that the new prophylactic, termed N.A.F.T. (natural adjuvant factor toxoid) is as good an antigen as the A.P.T. of British manufacture or as that made in our Institute; and (b) that N.A.F.T. is much less prone to cause reactions than the two kinds of A.P.T.

In our experiments with 80 adults (aged 25–50), none of whom had previously received anti-diphtheria prophylactic, each of the subjects was bled before inoculation and again four weeks after inoculation. They were subdivided into six groups, each group receiving a different form of prophylactic. The results are analysed in Tables IV, V, and VI. The value of this experiment, however, was seriously diminished by the quite unexpected finding that nearly

every adult tested gave evidence of having been in contact with toxigenic *C. diphtheriae*, as 90% possessed very significant amounts of antitoxin before receiving the toxoid. Even so, as a consequence of this experiment, it will be seen that purified toxoid augmented with our N.A.F. gave the best antitoxin response. It is realized that the antigenicity of a diphtheria prophylactic cannot reliably be assessed by its performance as a secondary stimulus. A factor of considerable importance, arising from this experiment using adults, is the almost complete absence of reactions in subjects receiving N.A.F. in the prophylactic used, and this confirmed our observations made in children. It must be recorded, however, that the crude veal-infusion-proteose-peptone diphtheria toxoid itself proved quite unsuited for human prophylaxis owing to the severity of the reactions produced. This is remarkable in view of the observation that the N.A.F. is derived from this very material.

Summary

As a consequence of an examination of the antigenicity of toxoids derived from three different types of culture media, it was found that those derived from our veal-infusion-proteose-peptone medium were outstandingly greater than the other two per Lf.

Research into the reason for the valuable difference showed that the adjuvant factor is diffusible through cellophane, and can be adsorbed on to activated charcoal and eluted by dilute sodium hydroxide. The addition of

this neutralized partially purified natural adjuvant factor—N.A.F.—to purified formol-toxoid greatly augmented its antigenicity when tested in guinea-pigs.

This factor did not augment the antigenicity of purified tetanus toxoid, and, conversely, an analogous preparation derived from crude tetanus toxoid made in the same medium failed to augment the antigenicity of purified diphtheria toxoid.

Field trials made in children showed that purified toxoid augmented with this natural adjuvant increased its antigenicity to a level at least equal to British-manufactured and our own make of A.P.T. Furthermore, the reactions encountered were nil, compared with a high incidence from control materials.

A detailed trial in adults revealed the unexpected fact that diphtheria is endemic in the region of Bombay, since 90% of the subjects tested possessed highly significant amounts of circulating antitoxin before inoculation. This fact considerably diminished the value of the experiment from the point of view of assessing the comparative antigenicity of the prophylactics under test, although the highest titres were obtained from those subjects receiving toxoid together with the purified natural adjuvant factor. A valuable observation, however, was the almost complete absence of reaction in those subjects receiving N.A.F. with the prophylactic, whereas without it the incidence was high.

This new prophylactic is a perfectly clear solution that can be sterilized by filtration and freeze-dried without damage to its antigenicity.

I wish to express my grateful thanks to Dr. L. B. Holt, of the Wright-Fleming Institute of Microbiology, for help in the arrangement of this paper.

THE PANCREATIC SIDE-EFFECTS OF MORPHINE

BY

H. WAPSHAW, M.D., F.R.C.Sed., F.R.F.P.S.
 Assistant Surgeon, Western Infirmary, Glasgow

Prior to the publication of Lagerlöf's studies (1945, 1947), information regarding the influence of morphine on the pancreas was very fragmentary. In 1907 Bickel and Pincussohn observed in two dogs with pancreatic fistulae that it first decreased and later increased the output of the external secretion. Cohnheim and Modrakowski (1911), using dogs each with a duodenal and an ileal fistula, found that morphine depressed the natural response to food. Babkin (1928) also noted a diminution in the duodenal content after its administration to animals. A more remote effect, which has been reported in rabbits, is an increase in the diastatic index of the urine (Sato, 1940).

The first recorded studies in humans are by Lagerlöf. Primarily interested in the fat-splitting enzymes in the blood, particularly those elaborated by the pancreas, he conceived that morphine might serve as a safe means of deranging the function of the gland. He compared the effect produced by the intravenous administration of purified secretin on the content of digestive ferments in the blood and duodenum with the effect of secretin given along with morphine. For the recovery of the duodenal juice he made use of the gastro-duodenal tube, thus minimizing the amount of gastric juice entering the duodenum. Secretin alone produced an abundant flow of pancreatic juice of high bicarbonate content unassociated with any appreciable change in the lipase levels in the blood. When it was given along with morphine there resulted a reduction in the volume of the duodenal fluid and a concomitant lowering of the secretory rates of amylase, trypsin, and, to a less extent, the bicarbonate of the pancreatic secretion: the amount of bilirubin in the duodenal contents was also diminished. These changes were maximal approximately 30 minutes after morphine. Soon afterwards there appeared in the blood a lipase that had not previously been present. Lagerlöf interpreted these findings as being due to overaction of the sphincter of Oddi interfering with the delivery to the duodenum of the bile and pancreatic secretion, and leading to absorption of a portion of the latter into the blood stream. He could not, however, exclude altogether the possibility that morphine depresses the function of the pancreas. The procedure just outlined has come to be known as the morphine-secretin test, the focus of attention having shifted to the response on the part of the serum-enzymes (see below). Lagerlöf has also made the arresting suggestion that the nausea and abdominal discomfort, sometimes amounting to pain, which not infrequently follow the administration of morphine, may be symptomatic of a drug-induced pancreatitis.

This paper is principally concerned with the serum-enzyme effects of morphine on healthy humans. Some were investigated in the fasting state, others were given a substantial meal before morphine, and in a third group an attempt was made to exalt the so-called vagus response of the pancreas to food by giving a parasympathetic stimulant before the morphine. Carbachol (carbachol B.P.) was chosen, since it has been shown to exert a vagus-like action on the pancreatic secretion (Wapshaw, 1952).

Biochemical Studies

Methods.—In most of the experiments both the amylase and lipase estimations were carried out with the same sample of venous blood. For the former the Somogyi iodometric test was employed, for which the normal range of values is 70–200 units per ml. of serum, although for each individual the value varies very little. The lipase activity was determined by the Cherry and Crandall (1932) test. By this method it is unusual for normal values to exceed 1.5 ml. N/20 sodium hydroxide per ml. of serum. A rise in the serum amylase of 50% over the premedication reading was regarded as significant. It was more difficult to decide what constituted a positive lipase response; but in view of results in the literature and after considerable experience an increase of at least 100% over the premedication control reading was taken as a positive result.

Effects of Carbachol.—This was a control study. Twenty-eight normal volunteers were investigated. These were divided into two equal groups. The first group fasted during the experimental period. The second received a meal consisting of soup, a meat dish with potatoes and vegetable, and a milk pudding 45 minutes before the injection of carbachol. Each subject received 0.5 mg. of carbachol intramuscularly, which is twice the upper therapeutic dose. Only lipase estimations were carried out in this series. (a) *Fasting Group*: Three out of 14 subjects showed a slight but apparently significant increase in the lipase concentration two to five hours after carbachol. The most pronounced increase was a rise from 0.7 ml. to 1.7 ml. N/20 NaOH per ml. serum. (b) *Fed Group*: Only 1 of the 14 subjects had altered readings. The control reading in this case was 0.6 ml., and four hours after carbachol the reading was 1.2 ml.

Effects of Morphine Hydrochloride.—The 84 individuals investigated were divided into three groups, each comprising 28 subjects; all received a subcutaneous injection of ½ gr. (16 mg.) of morphine hydrochloride. The first group fasted throughout the experimental period. The second group had a meal (see above) 60 minutes before the administration of morphine. The third group received a similar meal and 45 minutes later an intramuscular injection of 0.5 mg. of carbachol; after a further 15 minutes the morphine was injected. Thus it was arranged that the morphine was given at a time when the pancreas was likely to be in a state of active secretion. (a) *Fasting Group*: An increase in the amylase and lipase levels was observed in 5 of the 28 subjects (18%). The highest rise for amylase was three times the premedication reading in that subject and the highest for lipase 20 times (see Table I). (b) *Fed Group*: Raised levels were noted in 9 of the 28 investigated (32%). The highest rise for amylase was 9.1 times the premedication reading, and the highest for lipase 14.7 times (see Table II). (c) *Food plus Carbachol*: Raised levels were observed in 19 subjects (68%). The maximum responses were observed in the same case (No. 15, Table III) and amounted to 22 times and 17 times the premedication values for amylase and lipase respectively. In several the changes were marked within the first hour, but maximum augmentation more usually occurred two to four hours after the morphine injection. A comparison of the two sets of readings indicated that the lipase concentration was more readily affected than the amylase concentration.

Bodily Reactions

Carbachol.—The somatic effects varied from case to case. Some subjects were apparently unaffected. Others complained of flushing of the face and neck, diaphoresis, salivation, a desire to void urine or go to stool, and one suffered from fairly severe precordial distress.

Morphine Hydrochloride.—One-fifth of all the subjects complained of nausea and about half of those affected vomited. The detailed incidence of sickness in the three groups was as follows: fasting, 21%; fed, 18%; fed and received carbachol, 25%. In some the feeling of sickness, often with giddiness, came on soon after the injection of morphine; in others it did not come on for one to two hours. It passed off after about two hours.

There was no correlation between the occurrence of sickness and the enzyme findings in the blood.

Pain developed in the epigastrium in three subjects. One belonged to the fasting group and the other two to the group which received food and carbachol. One of the latter was in great distress when examined, not only with pain that radiated in the lumbo-dorsal region but also with vomiting and retching. None of the three, however, showed signs of intra-abdominal irritation, and all the unpleasant effects had passed off within a few hours.

The serum enzymes were slightly raised in two of the three affected with pain. The one with the severe pain was No. 4 in Table III, and the other No. 2 in Table I.

Discussion

It is generally accepted that the amylase concentration in the blood remains constant irrespective of the state of nutrition or the relative abundance of carbohydrate in the diet (Carlson and Luckhardt, 1908; Cohen, 1925; Somogyi, 1934). Opinions differ, however, whether or not the blood

is normally endowed with the capacity to split the glyceryl esters of the more complex fatty acids, and there is no agreement on what effects the ingestion of fat may have on this property. Crandall (1935) and Lagerlöf (1945) hold that the olive-oil-splitting esterase or lipase is normally confined to the pancreatic secretion and that it finds its way into the general circulation only when the gland becomes the seat of disease. Others believe that its presence in the blood is consistent with sound health (Comfort and Osterberg, 1940; Johnson and Bockus, 1940; Wapshaw, 1948).

There is evidence that certain parasympathetic-mimetic drugs modify the digestive activity of the blood. Thus, the beta-methyl derivative of acetylcholine (methacholine B.P., "mecholy") was administered intramuscularly to dogs by Antopol, Schiffrin, and Tuchman (1934), and by Friedman and Thompson (1936), and observed to cause a rise in the amylase titre, which attained maximal levels within a few hours. Friedman and Thompson tied off the pancreatic ducts in dogs and found that the subsequent response on the part of the serum amylase to methacholine diminished *pari passu* with the degree of acinar atrophy which resulted from that procedure. In similar experiments Popper, Olson, and Necheles (1943) were likewise able to correlate their serum-lipase findings with the amount of parenchymatous loss. Indeed, the latter authors went so far as to suggest that the serum-enzyme response to methacholine, especially when administered together with secretin, might serve as a means of detecting pancreatic insufficiency.

Myhre, Nesbitt, and Hurly (1949) performed the methacholine-secretin test on a group of 24 healthy subjects. Only 70% of them yielded positive responses in the blood, which is obviously too low a normal register for a test that is intended to discover faulty function. The impression gained from the present investigation was that carbachol would also be unsuitable for this purpose.

As regards the effects of morphine, the serum-enzyme levels were raised in 33 of the 84 subjects examined—that is, 39%. Taking each group separately, positive responses occurred in 18% of the fasting group, in 32% of those furnished with a meal, and in 68% of those who received carbachol in addition to food. Peak levels were reached between the second and the fourth hours, and by the tenth hour the readings approached normal. Some very remarkable findings were recorded; in fact, judging from previous experience (Wapshaw, 1948) the increments in certain instances were of such a high level as to justify a biochemical diagnosis of acute pancreatitis; but the lack of supporting clinical evidence allayed any misgivings on that score. Lagerlöf expressed the view that although a certain parallelism exists between the lipase and amylase responses the former is the more pronounced. The present findings agree with this.

The increased incidence of positive findings in the third group of the morphinized series—that is to say, those on whom presumably the most testing conditions were imposed—corresponds with that reported by others. Thus, Myhre *et al.* (1949) found that morphine and secretin modified the amylase levels in 70% of 30 normal subjects. It would appear that Burke, Plummer, and Bradford (1950) subjected the pancreas to a still greater stress by giving concurrently morphine, methacholine, and secretin, since, according to their results, 79% of the 68 individuals so treated exhibited raised enzyme readings. In the present series the disparity between the results in the three groups of subjects, all of whom had morphine, leads to the view that the mobilization of the serum enzymes is conditioned by (1) the potent action of the drug on the sphincter of Oddi and the surrounding duodenal musculature, and (2) the functional state of the pancreas at the time when the morphine takes effect. The proportionately higher readings in the carbachol group was also regarded as evidence that this drug enhances the natural secretory response to food. Whether or not carbachol, itself a powerful excitant of visceral muscle, reinforces the action of morphine on unstriated muscle, thereby increasing the compression of the *pars intestinalis* of the pancreatic ducts, is a matter for further study. The findings with carbachol alone suggest that it does not seriously hamper the flow of the pancreatic secretion, which it stimulates, though, judging from the data, methacholine may conceivably have such a dual effect.

The nausea that so often affects those under the influence of morphine has been ascribed variously to one or several of the following actions—excitation of the vomiting centre in the medulla (Goodman and Gilman, 1941), pyloric spasm (Schroeder, 1933), a more general effect on the motility of the intestinal tract (Plant and Miller, 1926; Carlson, 1933; etc.), and biliary side-effects (Lueth, 1931; McGowan, Butsch, and Walters, 1936). Clinical support for Lagerlöf's assumption that the nausea may be of pancreatic origin is lacking. None of the subjects in the investigations of Myhre *et al.* showed symptoms which were referable to the pancreas. Burke *et al.* cited one instance of epigastric pain following morphine, but it is noted that this particular subject had previously undergone cholecystectomy and the pain could well have been due to a rise in the intrabiliary pressure. The overall incidence of nausea in the present series was 21% and did not bear any obvious relation to the functional state of the pancreas at the time when the morphine was given. There were three instances of associated epigastric pain—one in the fasting group, and the other two in the carbachol group; in two the enzyme levels showed a rise, but only of slight degree. All three were completely free of pain and nausea within a few hours, and enjoyed their evening meal.

It would be premature to conclude that these findings have any direct bearing on the aetiology of acute pancreatitis. They do infer, however, that morphine may cause the pancreas a considerable degree of embarrassment, although these short-term experiments indicate that the disturbance was largely functional.

Summary

The influence of morphine on the pancreas was investigated in 84 normal subjects. The observations included a study of (1) the ensuing changes in the amylase and lipase levels in the blood, and (2) the somatic effects of the drug.

The serum-enzyme concentrations were significantly raised in 39% of the series. These changes appear to be due mainly to a state of secretion-retention within the pancreas, for which the excitant action of morphine on the sphincter of Oddi and contiguous muscularis, with consequent absorption of the ferments into the general circulation, is responsible. The present findings suggest that this effect is conditioned also by the functional state of the pancreas.

Carbachol alone does not materially affect the enzyme concentration of the blood, though it would appear to intensify the effect of morphine in this respect.

The incidence of nausea among the morphinized group was 21%. Three instances of transient epigastric pain are recorded. It is questionable if these bodily reactions, though attributable to morphine, have a pancreatic basis.

The rapidity with which exchange of information on influenza has taken place since the first signs of the present epidemic has made it possible to determine with certainty that the virus concerned in 1953 is the A-prime virus. This, in turn, has made possible the immediate use of vaccines prepared from it and the carrying-out of large-scale vaccination, whose results may prove of great value in the prevention of the disease. Thus, in Holland, workers and employees in large works and factories have been vaccinated. In the United States, Canada, and Great Britain mass vaccination has been carried out, mainly in barracks and hospitals, ideal places for the transmission of the infection. World Health Organization experts now hope that when they meet in Geneva in 1954 they will be able to announce that they have mastered this disease, thanks to the work carried out by the network of W.H.O. laboratories established throughout the world, and thanks also to the fact that for the first time it has been possible to use in good time a vaccine prepared in advance.

GASTRO-ENTERITIS IN GENERAL
PRACTICE

A STUDY OF 90 UNSELECTED CASES

BY

W. J. SMITHER, M.D., D.P.H.

The *British Medical Journal* (1951) notes a real as well as an apparent increase in the amount of gastro-intestinal infection. There has also been a steady annual increase in the number of cases of food-poisoning notified. The *Monthly Bulletin of the Ministry of Health* (1951) states, "That better reporting accounts for the whole of the increase is unlikely, and it appears that food-poisoning is still increasing."

It is often said that earlier bacteriological investigation would reveal an increased proportion of specific infections. The Chief Medical Officer to the Ministry of Health says in his report for the year ending March 31, 1950: "The fact that no causal agent could be found in a large number of sporadic cases [of food-poisoning] was because many of these cases were not reported until it was too late for investigation." In the United States Felsen (1945) concluded, *inter alia*, that "when the unclassified infectious diarrhoeas are studied the majority appear to be bacillary dysentery. . . . The reported incidence of bacillary dysentery far exceeds that of any other specific infectious diarrhoea."

That statement holds true for this country, where the picture of bacillary dysentery is acknowledged to be very different from that seen abroad. The number of corrected notifications rose to the record figure of 17,223 in 1950. Of these, 14,085 were investigated bacteriologically, and 96% of this number were due to *Shigella sonnei*. When these figures are compared with the total number of "incidents" of food-poisoning for the same period—that is, 3,979—it would appear that *Sh. sonnei* is the commonest cause of acute diarrhoea. Particularly would this be expected in general practice, where the mild type of diarrhoea is so commonly seen.

For the year ending March 31, 1950, when there were 2,431 incidents of food-poisoning, the Chief Medical Officer reported that "there was evidence that at least 11,000 persons were affected." Even if we allow that the increase in the number of incidents in 1950 was entirely a real increase and in no way due to the new method of reporting, the proportionate number of estimated as opposed to reported persons affected should not rise above the total reported cases of dysentery. Thus the general practitioner should still expect to find that Sonne dysentery is the commonest cause of diarrhoea.

It was decided to test the truth of these assumptions and the value of the statements that early bacteriological investigation would reveal more specific causal agents. A study of unselected cases of acute diarrhoea, with or without vomiting, was felt to be of value.

The Investigation

The method chosen was to investigate bacteriologically by means of rectal swabs every case of acute diarrhoea, with or without vomiting, seeking treatment. From June to November, 1951, inclusive, 74 cases occurred in a general practice in an industrial area near London. A

second group of 16 cases were investigated from mid-December, 1951, to mid-February, 1952, with a slightly different technique. The number considered to be at risk—that is, likely to seek advice—was approximately 7,000. No attempt at selection was made and all acute cases were investigated. Cases of chronic or recurrent diarrhoea were excluded. Rectal swabs were sent to the local laboratory without a provisional diagnosis, and the bacteriological diagnosis quoted is the one arrived at by this laboratory.

Because of criticism of rectal swab efficiency in general practice, the technique was changed for the second group of 16 cases. In these the rectal swab was used to inoculate immediately a bottle of selenite medium, and both swab and inoculum were sent to the laboratory.

The results obtained are shown in the Tables. Following the terminology of the Ministry of Health, a "family outbreak" means two or more related cases in the same family, and a "sporadic case" means a case which had no ascertainable relation to another case. Each family outbreak and sporadic case has been treated as one unit and described as an "incident." The Ministry of Health defines an "outbreak" as the occurrence of two or more related cases in persons of different families. No relationship was observed between any of the sporadic cases reported, so the term outbreak is not used.

Table I shows the incidence by the presumed cause. In the largest group no pathogenic organisms were isolated. All the second series of cases came into this group, making

TABLE I

Presumed Cause	Sporadic Cases	Family Outbreaks	Total Incidents	Total Cases
No pathogens	68	1	69	71
<i>Sh. sonnei</i>	3	4	7	14
<i>Pr. vulgaris</i>	1	1	2	3
<i>Salm. typhi-murium</i>	1	—	1	1
Food-poisoning (toxin type)	1	—	1	1
	74	6	80	90

a total of 69 incidents. *Sh. sonnei* was the most frequently isolated specific causal agent—7 incidents comprising 14 cases. *Proteus vulgaris* was the next most frequent—two incidents comprising three cases. *Salmonella typhi-murium* was isolated in only one case.

One family outbreak occurred in the group from which no pathogenic organisms were isolated. There was one family outbreak in the proteus group. This contrasts with the comparatively large number of four family outbreaks of Sonne infection.

Only one case required admission to hospital. This patient was a young woman with high fever whose failure to respond to treatment led to her admission on the third day of the illness. The hospital diagnosis was food-poisoning (toxin type). She recovered in eight days. All the other cases responded rapidly to treatment and yielded negative swabs on the second attempt, except the case from which *Salm. typhi-murium* was isolated. This gave a positive rectal swab one week later. One case, subsequently diagnosed as acute appendicitis, presented as acute diarrhoea.

Table II shows the incidence by age and presumed causal agent. The youngest patient was 4 months and the oldest 74 years. No pathogenic organisms were isolated in the majority of incidents at all ages, but the smallest number of these negative swabs occurred in the group under 1 year. Most cases of Sonne dysentery occurred in the 5–14 years group. Half as many occurred in the 1–4 group, and there was one case in each of the groups of under 1 year and over 14 years. There was one case of proteus infection in the under-1-year group, and a family outbreak comprising

TABLE II

Presumed Cause	Age in Years			
	Under 1	1 to 4	5 to 14	Over 14
No pathogens	6	23	16	26

	8	29	24	29

two cases in the 1–4 years group. The individual case of salmonella infection and that of food-poisoning (toxin type) occurred in adults.

Table III shows the incidence by weekly intervals. Those incidents in which no pathogenic organisms were isolated were fairly evenly distributed throughout the whole period. Incidents of Sonne dysentery were evenly spaced until the beginning of November, after which no further cases occurred. This is not in keeping with the comment of the

British Medical Journal (1951) that "in this country dysentery, as opposed to food-poisoning, is now almost a winter disease." The incidents of proteus infection occurred together in mid-September, and those of salmonella infection and of food-poisoning (toxin type) in early July.

Discussion

It may be said that there is no justification for regarding those mild cases of gastro-enteritis in which no pathogenic organisms were isolated from rectal swabs as food-poisoning. However, the clinical course, the rapid response to treatment, and the absence of parenteral infection lend support to such a clinical diagnosis. The Chief Medical Officer (1951), noting the increased incidence of food-poisoning, gives three main reasons for that increase. The first is the retention overnight and reheating of meat dishes cooked the previous day for reasons of economy. The second is the great increase in communal feeding in schools, mines, and factory canteens, where such cooking practices are common. The third cause is the lack of personal hygiene. These conditions are so widespread in this area, where domestic refrigerators are rare and food is commonly kept in the

larder or kitchen, that a history of any of the predisposing factors is of little value. Histories are unreliable in isolated cases of food-poisoning.

Only one case, that infected with *Salm. typhi-murium*, gave an unequivocal history. This patient was a woman of 43 who was quite sure that her symptoms followed the eating of a boiled duck egg. The *Lancet* (1951) casts doubt on the role of duck eggs in salmonella infections. It is difficult, however, to get bacteriological proof in the case of a boiled duck egg. There is rarely any of the egg left, and these eggs are not common articles of diet eaten as such in this area. Large numbers are used in cookery, particularly in catering establishments, where they fetch a high price. It seems interesting that in this series the only person who volunteered information concerning the ingestion of suspected food was the sole case of salmonella infection.

The cases of Sonne dysentery reported here were so mild and their response to treatment so rapid that, but for the interest engendered by this study, they might never have been investigated and reported. There were more family outbreaks of this infection than of any other. The group of cases in which specific organisms were isolated was dominated by Sonne infections—14 cases out of a total of 18. This suggests that infection with *Sh. sonnei* is even more common than the numbers of reported cases would indicate.

The presence in this series of one isolated case and one family outbreak of gastro-enteritis in which *Pr. vulgaris* was isolated may or may not be of significance. However, it seems fair to comment that this organism was found more often than *Salm. typhi-murium*, believed by many to be the commonest cause of food-poisoning. The one case of the latter infection noted was so mild that it might easily have passed unnoticed.

There were six infants under 1 year with diarrhoea from whom no pathogenic organisms were isolated. Since no special bacteriological techniques were employed, there is no means of determining whether these were due to a specific strain of *Bact. coli*. No parenteral infection was noted. The numbers compare with two sporadic cases of specific infection under the age of 1 year. In one of these *Sh. sonnei* was isolated and in the other *Pr. vulgaris*.

It is submitted that any of the cases from which no pathogenic organisms were isolated could be due to the heat-resistant enterotoxin produced by certain strains of staphylococci. These organisms may be extinct in the food, and even more probably extinct in the rectal swab, and yet cause symptoms. The ubiquitous distribution of such organisms, and the ideal conditions for toxin production in the common cooking practices mentioned previously, support this view. The one case in which food-poisoning (toxin type) was the final diagnosis presented clinically as a severe gastro-enteritis with marked vomiting and high fever. There was some abdominal tenderness but no other physical sign. The patient was mentally alert throughout to a degree unusual in such a pyrexia. Her failure to respond to home treatment led to early admission to hospital. No pathogens were isolated from the rectal swab, and bacterial investigation in hospital was quite negative. The final diagnosis was therefore a clinical one. This would seem to be an isolated case of unusually severe enterotoxic food-poisoning due to individual hypersusceptibility.

Any of the cases from which no pathogenic organisms were isolated could have been due to a great variety of causes. So far as was possible, many of these causes were eliminated clinically. Most of these other conditions are comparatively rare. One case subsequently diagnosed as appendicitis presented as acute diarrhoea, and one case of adenomatosis of the colon was picked up. Neither of these has been included.

It is realized that more argument than evidence has been adduced to support the belief that most of the cases in which no pathogenic organisms were isolated were due to staphylo-

coccal food-poisoning; what evidence we found is negative rather than positive. Nevertheless it would seem that staphylococcal food-poisoning is the commonest cause of the frequent mild cases of diarrhoea, with or without vomiting, met with in general practice.

Summary

Ninety unselected cases of acute gastro-enteritis, occurring over a period of nine months in an urban practice, were investigated. In by far the greatest number of these no pathogenic organisms were found. The commonest specific organism isolated was *Sh. sonnei*. *Pr. vulgaris* was the next most common. Only one case of infection with *Salmonella typhi-murium* was found. One case was subsequently diagnosed in hospital as food-poisoning (toxin type).

Arguments are advanced for the belief that staphylococcal food-poisoning is the commonest cause of mild cases of gastro-enteritis.

Medical Memoranda

Intra-partum Uterine Rupture

Mr. Hodgkinson's article in the *British Medical Journal* of February 9, 1952 (p. 308), on this subject prompts me to record my experiences at the Government Hospital, Gatooma, with similar cases during the past two years. This hospital contains some 250 beds for Africans and about 150 to 200 deliveries take place in it every year. Caesarean section is often carried out, since contracted pelvis, and especially pelvis with contracted outlets, are common. I have averaged about 25 such operations a year during the past five years. Uterine rupture has not occurred in any case in which caesarean section has been carried out, although nearly all these operations have been of the "classical" variety. I attribute this immunity to following the advice of Mr. Victor Bonney to use a layer of non-absorbable sutures in the uterine wall. Our present practice is to use a deep layer of catgut and a superficial layer of nylon. No irritation seems to be set up by the latter, and in a case on which I operated for the second time recently it was extremely difficult to trace the previous scar in the uterus. The following four cases of uterine rupture have been met with.

CASE REPORTS

Case 1.—An African woman aged about 35 was admitted to hospital on January 14, 1950. She had had five previous pregnancies; the first three were normal full-term deliveries of live children, the fourth was a full-term delivery of a stillborn child, and the fifth a four-months abortion. She stated that labour began late in the evening of January 13, and she did not think that the membranes were ruptured. On examination she was shocked and collapsed, and had just come about 40 miles by ambulance over rough roads. No foetal parts could be distinguished through the tense abdomen, and the foetal heart was not heard. Per vaginam there was a foul-smelling discharge, and a shoulder was presenting. The cervix was fully dilated. In spite of all the usual restorative measures the woman died two hours after admission without recovering sufficiently to warrant

active treatment. At necropsy it was found that the uterus had ruptured into the left broad ligament, and that the child was still *in utero*. The patient had lost only about a pint (570 ml.) of blood. Death was obviously due to shock and toxæmia.

Case 2.—This patient, an African woman aged about 25, was admitted to hospital on February 1, 1950. She had had two previous pregnancies, both of which terminated normally in live children. The present labour began the evening before admission. The uterus was tonically contracted, no foetal parts were felt through the abdomen, and the foetal heart could not be heard. Vaginal examination revealed that the cervix was three-quarters dilated and a head could be felt high up at the pelvic brim. There was a large caput and the cervix was hanging loosely below it. The patient was profoundly collapsed and pains had ceased some hours before admission. After the usual shock treatment a laparotomy was performed. A full-term dead foetus was found loose in the abdomen. The uterus had ruptured through its left side behind the broad ligament and the peritoneum contained about 3 pints (1.7 litres) of blood and clots. Subtotal hysterectomy was performed. Convalescence was stormy, but the patient eventually made a complete recovery.

Case 3.—An African woman of about 30 was admitted on May 22, 1951. She had had five previous full-term pregnancies, all of which terminated in easy and normal labours. On examination the child was lying in the L.O.A. position and seemed very large. The maternal pulse rate was 80 and the foetal 96. The foetal head was fixed at the pelvic brim, and a large caput reached nearly to the vulva. A catheter drew off 2 pints (1.1 litres) of very blood-stained urine. It was decided that caesarean section was indicated, and a laparotomy was performed in order to do this. To our surprise the uterus was extensively ruptured through the anterior part of the lower segment. The child was still *in situ*. It was removed by enlarging the uterine hole, and a subtotal hysterectomy was carried out in view of the extensive laceration of the lower segment. The child was dead, but the mother made a good recovery after a stormy convalescence.

Case 4.—This woman, who appeared to be about 40 years old, was admitted on September 30, 1951. She had had ten previous full-term pregnancies with easy labours. She was very collapsed. The foetal parts could be felt with difficulty and the head was palpated in the right iliac fossa. Vaginal examination revealed severe bleeding, and the case was thought to be one of placenta praevia. On laparotomy the peritoneal cavity was found to contain about 2 pints (1.1 litres) of blood and clots.

The child was free amongst the intestinal coils, and the uterus was found to have a large rent through its posterior lower segment. The child was removed, dead, and a subtotal hysterectomy was performed. Apart from some trouble with atony of the bladder—a common difficulty in post-partum African cases—the woman made an un interrupted recovery.

COMMENT

In none of these cases had a caesarean section been performed previously, nor had there been any interference in the present labour so far as is known. All the cases occurred in multiparae, and it is suggested that the cause of the obstructed labour in each case was progressive enlargement of children with each pregnancy. It is felt that a lesson to be learnt is that a good previous obstetrical history should not be allowed to warp one's judgment into expecting that all will necessarily be well with subsequent labours even with a child in a good obstetric position.

My thanks are due to Dr. R. M. Morris, the Secretary for Health, for permission to publish this article.

"Lethane" Poisoning: Report of a Fatal Case

Insecticides containing "lethane" are in common use for the treatment of pediculosis. Harrison (1947) reported a fatal case of poisoning due to this type of preparation, which he believed to be the first recorded example of its kind. A further non-fatal case was recorded by Guy (1951).

CASE REPORT

A male child aged 1 year and 11 months had recently been treated for milary tuberculosis for about a year. While in his own home he drank a small quantity (the exact amount being unknown) of a liquid insecticide, believing it to be lemonade. He rapidly became unconscious, and was admitted to hospital in this condition.

On examination the child was deeply comatose. The limbs were flaccid; the colour was good, and the breathing regular. There was a smell of paraffin in the breath. The pupils were equal, were dilated, and did not react to light. There were no other clinical abnormalities. Gastric lavage was carried out and nikethamide given, both intramuscularly and intravenously. Later the breathing became stertorous and cyanosis was noted. Generalized clonic convulsions then developed, and these were controlled only by sodium phenobarbitone and lumbar puncture. Respiratory failure then set in, with prolonged periods of apnoea, and the child died two and a quarter hours after admission.

Necropsy showed milary tuberculosis of lungs, liver, spleen, and kidneys, the milary lesions being in varying stages of development and healing. The stomach was moderately dilated, but was otherwise normal. The lungs showed hypostatic congestion. There was no abnormality of the central nervous system. Analysis of the gastric contents showed the presence of a thiocyanate.

COMMENT

The composition of the preparation, as stated on the label, was as follows: lethane 384 special, 49%; oil of petrolol alb., 49%; and oil of citronel., 2%. "Lethane 384 special" has the following composition: β -butoxy- β -thiocyanodiethyl ether, 12.5%; β -thiocyanoethyl laurate, 37.5%; and refined paraffin, 50%.

The clinical features of the present case were those of rapid coma, convulsions, and respiratory depression and failure. These findings are in agreement with those of Cameron *et al.* (1939), who investigated the toxic effects of several thiocyanates on rats, rabbits, and guinea-pigs. They concluded that β -butoxy- β -thiocyanodiethyl ether was highly toxic to these animals, and that death was due to respiratory failure, probably of medullary origin. Harrison, in his report of a fatal case of lethane poisoning, suggested that death was due to respiratory failure.

Guy (1951) reported the case of a child of 20 months who took 1 to 2 dr. (3.5 to 7 ml.) of a lethane hair-oil. Some of this was apparently inhaled, as a bronchopneumonia developed. The child remained ill for about two weeks and showed slight neck rigidity, drowsiness, and irritability. There was no evidence of hepatic or renal dysfunction. It is possible that the bronchopneumonia may have been due, in part at any rate, to the paraffin base. The neurological features probably represented a toxic effect from the thiocyanates; on the other hand it is possible that these findings could have been complications of the pneumonia *per se*.

Absorption of the poison seems to be rapid, and there appears to be no effective antidote. Glaister (1945) suggested a trial of methylene blue (50 ml. of 1% solution intravenously) or sodium thiosulphate (10–50 ml. of 20% solution intravenously). Apart from these measures, treatment must be symptomatic, and should include early and energetic gastric lavage.

The present case is reported in order to re-emphasize the dangerous nature of these preparations, which, as Harrison has pointed out, can be readily bought at any chemist's shop

and which are not labelled "poison." As the contained thiocyanates have a toxic action similar to that of hydrocyanic acid, it is suggested that the future sale of such preparations should be brought within the scope of the poisons regulations.

Our thanks are due to Dr. A. M. Tripathy for the necropsy report; to Mr. H. K. Lawton for the analysis of the gastric contents; and to Dr. R. W. M. Strain for permission to publish the details of this case.

Death After Intravenous Iron

More or less severe reactions to the intravenous injection of saccharated iron oxide have occurred on several occasions during the last few years, but none of those previously reported have ended fatally. Nissim (1947) suggested gradually increasing dosage, and Nissim and Robson (1949) reported that "several patients received repeated doses of as much as 300 mg. of iron by intravenous injection without the slightest toxic reaction." In mice they said that "death is presumably due to multiple capillary embolism in internal organs." Davidson and Girdwood (1948) reported a case treated by repeated intravenous injections of saccharated iron oxide, in which sickness and rigors occurred with the last three injections of 100 mg. Severe reactions also occurred in several other cases. Slack and Wilkinson (1949) used 25 mg. on the first day, increasing to 50 mg. on the second, 100 mg. on the third, and 200 mg. subsequently. One of 60 patients developed a mild reaction at the 200-mg. level. In 60 other cases more than 800 mg. had been given intravenously. Mitchell (1949), Sinclair and Duthie (1949), and Govan and Scott (1949) have also described reactions, while Ramsey (1950) gave initial doses of 300 to 900 mg. of "ferrivenin" in 11 cases, in all but one of which there were severe reactions (weakness, sweating, sickness, and collapse for a few hours). Mooney (1950) reported one case treated with an initial dose of 100 mg., which three hours later developed a temperature of 103° F. (39.4° C.) with intense headache, shivering, and copious vomiting lasting some six hours. The manufacturers suggest the use of graded doses.

Below we record a case in which an initial intravenous dose of 100 mg. led to severe reactions and death.

CASE REPORT

A man aged 69 was admitted to hospital for treatment of anaemia. His blood count was haemoglobin, 61% (9 g. %); red cells, 3,890,000; C.I., 0.79; white cells, 6,500. Red cells showed marked anisocytosis, moderate poikilocytosis, anisochromia, and polychromasia. A few target cells were seen. Reticulocytes were less than 1%.

A slow injection of 5 ml. (100 mg.) of saccharated iron oxide ("ferrivenin") was given intravenously, and three minutes later the patient became hot and flushed. After a further two minutes he became cold and drowsy. Ten minutes after the completion of the injection he became dyspnoeic and cyanosed, and then collapsed. He was pulseless, and no apex beat could be felt or heard. Gasping respirations continued. Intracardiac injections of nikethamide and adrenaline, as well as intravenous injections of nikethamide and lobeline, were given. Artificial respiration and oxygen were given from the time of the collapse. Weak heart beats were noted shortly after the intracardiac injections, but the patient died 30 minutes after the original injection.

At necropsy 18 hours later the only evidence of disease was in the coronary arteries, both of which were calcified, and the right artery was completely occluded. There was no evidence of multiple emboli.

The LD 50 of the batch of ferrivenin when originally tested was approximately 300 mg. of iron per kg. of body weight in mice, and a recent toxicity test on the same batch showed no significant departure from this original figure.

COMMENT

Trivial and severe reactions to the use of intravenous ferrivenin have previously been reported. This case in which sudden death followed the first injection emphasizes the necessity for care: the initial dose should not exceed 25 mg. and the possibility of severe reactions even in patients who have had repeated injections should be kept constantly in mind.

We are indebted to Dr. R. A. Hickling for permission to publish details of this case.

Long-delayed Rupture of Spleen: Report of Two Cases

Delayed bleeding occurs in about 15% of all splenic injuries, the latent period varying between a few hours and many days. According to Zabinski and Harkins (1943) this latent period is less than seven days in 50% of the cases and less than 14 days in a further 25%. They could find only eight reported cases in which the delay was longer than 19 days, one of these being as long as two years. The following cases are of interest mainly on account of their long latent period—22 and 26 days respectively.

CASE REPORTS

Case 1.—A soldier aged 22 was admitted to a military hospital in 1942 with gunshot wounds of his feet and hands, sustained when he was blown up by a landmine. He had apparently no other injuries. These wounds healed, and on the 22nd day after injury he reported to the commanding officer's office for discharge from hospital. Here he collapsed with sudden severe abdominal pain and considerable shock. After resuscitation a laparotomy was performed and a ruptured spleen removed.

Case 2.—A married woman aged 29 was brought to hospital in November, 1950, having collapsed in the street with sudden severe upper abdominal pain, radiating to the tip of the left shoulder. She gave a history of a fall from a chair 26 days before, when she had "bruised" her left side. After this injury she had been confined to bed for five days with severe pain in her left side and shoulder. She had then returned to her work as a school teacher, which included "keep-fit exercises." She had experienced a dull ache in her side but no severe pain until her sudden collapse. On examination she was shocked and very pale. There was great tenderness in the upper abdomen, with rigidity in the left hypochondrium and loin. At operation, after resuscitation, the peritoneal cavity contained a fair amount of liquid blood. Examination of the spleen showed a small tear on the costal surface with a large amount of surrounding clot. Splenectomy was performed, and the patient made an uneventful recovery.

COMMENT

Numerous theories have been advanced to account for the latent period. The formation and later rupture of a subcapsular haematoma probably account for some cases, and McIndoe (1932) points out that the severity of the tear as found at operation may be much greater than the original injury suggests, and that it is possible that the haematoma ruptures with almost explosive violence, causing the very sudden collapse of the patient.

The theory of the perisplenic haematoma as advanced by McIndoe and later by Delannoy (1939) seems to fit in with the symptoms in many cases and with the findings at operation of large amounts of clotted blood in the region of the spleen. Other theories are: intrasplenic bleeding controlled by pressure of the haematoma on the pulp; temporary haemostasis due to shock; tamponade by omentum, colon, stomach, etc. McIndoe places these injuries in three categories: (1) minor capsular rupture or parenchymal injury; (2) subcapsular haematoma; and (3) capsular haemorrhage with perisplenic haematoma. Of these, Nos. 2 and 3 are the most important.

Delannoy associated these pathological lesions with the symptomatology, and suggested two clinical types. (1) Splenic rupture with delayed haemorrhage. This corresponds with McIndoe's subcapsular haematoma and usually with a symptom-free latent period. (2) Rupture with retarded symptoms, corresponding with the perisplenic haematoma. Here the latent period may be marked by pain of varying severity occurring in the left hypochondrium and shoulder or sometimes by generalized abdominal discomfort.

Examination at this stage will reveal persistent tenderness and rigidity in the left upper quadrant, and x-ray films may show a paralysed diaphragm on this side. Other symptoms are pallor, weakness, dizziness, and fainting attacks, though these latter are probably more common with a slow continuous leak than with true delayed rupture. A number of such cases have been recorded, and one reported by Coyle, Kleiman, and Smith (1950) presented with gradual abdominal distension and anaemia.

The cases reported here fit well into these clinical categories. Case 1 had no symptoms referable to the abdomen between the time of his injury and his collapse 22 days later. Case 2 experienced intermittent pain in the left hypochondrium, and at operation a large clot was found around the splenic region, with liquid blood in the rest of the peritoneal cavity.

The pain in these cases is usually sudden and severe, and most commonly felt in the splenic region. Zabinski and Harkins reported the frequency of associated fractures of the ribs—a fact previously recognized by McIndoe, who stressed the importance of keeping under observation for at least 14 days any patient with an injury to the left side, particularly if complicated by fractured ribs. It must, however, be remembered that delayed rupture of the spleen can occur after quite a trivial and sometimes forgotten injury, and it is probable that many, if not all, the cases reported as "spontaneous rupture of a normal spleen" fall into this category.

My thanks are due to Mr. Stanley O. Aylett for his helpful advice and for permission to publish these cases, which were treated under his care.

Reviews

• CANCER IN GENERAL PRACTICE

Cancer in General Practice. By Ronald W. Raven, O.B.E., F.R.C.S., and P. E. Thompson Hancock, F.R.C.P. (Pp. 265; 71 figures. £1 10s.) London: Butterworth and Co. 1952.

The authors of this book give a condensed but systematic account of malignant disease in the various organs of the body. The word "cancer" in the title is used colloquially and includes such diseases as the leukaemias and lymphadenoma as well as the sarcomata, which are given a modern and no doubt highly scientific nomenclature. The early and when generally accepted, the pre-cancerous stages of tumours are clearly and concisely described, with the common modes of spread. The authors emphasize early diagnosis, and give a brief account of the treatments available and their results.

Mr. Raven's vigorous ideas on the education of the public about cancer are well known. It is natural that he should also be interested in the education of the general practitioner. In so far as the descriptions prove the value of good history-taking and thorough examination in order to make an accurate diagnosis, the general practitioner will be stimulated and encouraged to be on his mettle. It is rather the result of treatment which is so discouraging. To take, for example, one of the commonest cancers of the human body, he learns that 5 out of 10 patients with stage 1 carcinoma of the breast die within five years in spite of all forms of treatment. He wonders how many of the survivors will be subjected to more and more treatment at ever lessening intervals. There is much to be said for one radical operation or one radical course of radiotherapy which either cures or kills, but the mutilation of mind as well as of body which results from repeated operations or therapy is one of the most distressing sights in general practice to-day. The general practitioner will learn much from this book, but the knowledge may make him sick at heart.

C. W. WALKER.

ARTHRODESIS

Architectural Principles in Arthrodesis. By H. A. Brittain, O.B.E., M.A., M.Ch., F.R.C.S. With foreword by Sir Harry Platt, M.D., M.S., F.R.C.S. Second edition. (Pp. 208; 257 illustrations. £2 2s.) Edinburgh and London: E. and S. Livingstone. 1952.

It is eleven years since Mr. H. A. Brittain published his monograph on arthrodesis, and the outstanding feature of it was his operation for fusion of the hip. Since then what everyone now calls Brittain's arthrodesis has been practised by surgeons the world over with results far superior to those obtained by any other method, especially in tuberculous disease. This is the test of a good operation—that it succeeds in the hands of many surgeons of reasonable competence and does not depend on some legerdmain of the originator. Brittain's distinction is therefore derived from his conception of ischio-femoral arthrodesis, and when he talks about architectural principles in arthrodesis he knows what he is about and is not merely a clever craftsman. Thus there is every justification for a second edition of this valuable monograph, and he now speaks with a certainty and authority that would have been premature in 1941. Some of his other operations are coming along well, too. The posterior arthrodesis of the shoulder is in the same class as his operation on the hip, and his encouraging experience of it has been powerfully reinforced by Professor Mercer's. The V-arthrodesis for osteoarthritis of the hip is still, I think, rather personal to Mr. Brittain, but we may all come round to it in time as we have done to ischio-femoral arthrodesis for tuberculosis.

Although our ultimate aim must always be to restore the function of a damaged joint, it must be confessed that even in favourable circumstances arthroplasty is still an unpredictable procedure. Too often conditions are against us, and then a painless ankylosis is often the best that we can offer a patient crippled by a painful or unstable joint. Brittain, more than any other surgeon in this country, has set himself the task of devising methods of arthrodesis that really work, and his success has been such that no orthopaedic surgeon can afford not to read his *Architectural Principles*.
H. J. SEDDON.

ELECTROLYTES AND THE HEART

Gli Elettroliti nella Funzione Contrattile del Miocardio e nella Genesi dell'Elettrocardiogramma. By F. Lenzi and A. Caniggia. Monografie Cardiologiche I. Preface by Professor L. Condorelli. (Pp. 355. No price.) Siena: La Poligrafica.

This book on the electrolytes in the contractile function of the heart muscle and in the causation of the cardiogram is an account of extensive experimental work done on the hearts of tortoises. The authors have investigated the effect of various ions, taking them in the groups of the Mendeleff table. They point out how the important ionic reactions which occur round the muscle cell depend mainly upon the movements of the sodium and potassium ions. The cardiogram indicates what they call the cationic gradient between the high concentrations of potassium inside the cell and the low concentrations outside, and also the difference between the various concentrations of sodium inside and outside the cell. They explain how, by altering the levels on either side of the membrane, the activation process can be changed—that is, an increase of sodium in the blood will accelerate it, but slow down repolarization. In the same way, with increase of potassium outside the cell, activation is slowed but recovery is promoted. This process will cause a prolongation of the QRS and a shortening of the ST intervals. For the clinician these are perhaps the most important points of interest, but the authors have also investigated very fully the effects of lithium and calcium, rubidium, and caesium. These little-known elements play no appreciable part as yet in clinical medicine, but possibly calcium may be important, for QRS is prolonged by an increase in the calcium, strontium, and barium group. They have also considered some of the heavy metals as well, including mercury. The records of the cardiograms are clear and easy to follow.

No doubt this work is more of interest to the physiologist or the pharmacologist at present, but these matters will probably take their place in clinical medicine in due course. The book is comprehensive; over 1,000 references are given; there is no index, but the table of contents is a good guide. The clinician may not find time to read the book very closely, but it contains many interesting facts worth studying.

TERENCE EAST.

RESPONSE TO AIR BOMBARDMENT

Angst und Schreck. By Professor Friedrich Panse. (Pp. 189. M. 12.60.) Stuttgart: Georg Thieme. 1952.

Although extensive clinical observations on air-raid casualties were made during the second world war, we have, perhaps mercifully, been spared a voluminous post-war literature on war psychiatry. Here, exceptionally, is a substantial brochure on anxiety, fear, terror, panic, etc., based on a study of 95 patients who experienced severe air bombardment, mostly in Western Germany. The subjective reactions of 20 of these are recorded in some detail. And on the strength of these data, together with his own clinical observations, Professor Panse gives a detailed classification of the various types of anxiety reaction observed, including, for example, the vegetative components of anxiety discharge, interference with the field of consciousness and with emotional expression, influence

of suggestion, disturbance of time sense, the development respectively of sensitization and of immunity, "conditioned" reactions, and the like.

As the book is written throughout from a neuro-psychiatric point of view, and as the psychological categories used are borrowed almost exclusively from a general psychology in which unconscious factors have no place, it is not surprising that the author's findings do not add to what was current psychiatric knowledge in Britain at the end of the Blitz. Nevertheless, the excerpts from case histories are interesting, the clinical observations apposite, and the bibliography, with the exception indicated above, adequate. On the whole, therefore, the brochure constitutes a useful descriptive introduction to the subject, suitable for students of general psychiatry. It would have been still more useful had the author provided an index.

EDWARD GLOVER.

CONQUEST OF FEAR

The Conquest of Fear. By Harley Williams. (Pp. 240. 16s.) London: Jonathan Cape. 1952.

Dr. Harley Williams continues to delight and instruct us with his biographical studies of famous men and women. Members of his own profession form the majority of his subjects, but his facile and erudite pen probes at times into the lives of statesmen like Woodrow Wilson and Roosevelt and of captains of industry like Carnegie and the first Lord Leverhulme. He has the gift of describing the personality and character of the individual he presents in a few expressive sentences. This appears effortless, but one has only to read on to find that it is based on careful and prolonged study of the life and times of the subject of his essay.

In the present volume Dr. Williams treats of the lives of thirteen men who have helped in "The Conquest of Fear"—that is, humanity's fear of illness. He begins with Edward Jenner. Often as his life and work have been recounted—especially recently in W. R. Le Fanu's admirable *Bibliography of Edward Jenner*—we can enjoy this sympathetic study of the man who first scientifically explored the possibility of preventing a disease due to a virus. In telling of the romance of tropical disease investigation the author chooses Father Damien, Patrick Manson, Ronald Ross, David Bruce, Gorgas, Noguchi, and Adrian Stokes. Then come two scientists, Crookes and von Röntgen. Two medical peers, Lord Moynihan and Lord Dawson, follow. The influence and strength of these two men lay chiefly in the success of the one at the operating table and of the other at the bedside. They were both medical statesmen, as is clearly brought out in this book. Finally, the author concludes with a study of Franklin Roosevelt, to illustrate how a patient can triumph over the handicap of a crippling disease and rise to the highest office in his country.

In recording certain of these illustrious lives, Dr. Williams performs a most useful service to posterity. For when the present generation, who knew many of these men and women, has passed on, these studies will retain a freshness and value which only the work of a contemporary could achieve.

ARTHUR S. MACNALT.

LEUCOTOMY STUDIES

Psychosurgical Problems. Edited by Fred A. Mettler, M.D., Ph.D. By the Columbia Greystone Associates Second Group. (Pp. 357. £2 2s.) London: Routledge and Kegan Paul. 1952.

Workers in the field of leucotomy have been awaiting with interest this further report from the Columbia Greystone workers. Criticism of their first well-controlled investigation was directed mainly at the rather routine character of the testing procedures, and this time there can be no doubt that imagination and initiative have played an important part in the selection of the tests. It is depressing, therefore, that, in the words of the editor, "careful planning, high motiva-

tion, ample funds, sincere co-operation, a real problem and an energetic attack cannot produce positive data." It is not, however, likely that "the correct data are of a negative character," and it is of great interest to examine the causes for the comparative failure of this investigation.

The main difficulty with co-operative research projects, as with any large-scale organization, is that the planning is essentially that acceptable to the majority of the group. Thus in this instance the two main faults—which are gross enough to impair the whole project—bear the imprint of group intelligence at its most mediocre. First, the emphasis on "statistical methodology" has involved a demand for a uniformity of case material which, admirable as an ideal, has in the event led to the selection of a very small number (23) of the least suitable patients—deteriorated schizophrenics. (The exclusion of those with a positive family history means only that the diagnosis is less well substantiated.) Secondly, the need for radical changes in procedure revealed by the results of the first project has caused unnecessary and fatal alterations to the operative techniques. The admirably balanced and interrelated topectomies have been replaced mainly by two series of: (1) cerebral venous ligation, and (2) orbital "ice pick" leucotomy. Both these techniques are essentially inexact, uncontrollable, and unlikely to be effective in the treatment of the present material. The first survey of these workers showed that topectomy was justifiable and almost certainly effective in some cases. It should have been followed by an improved investigation on better case material. The ample funds would then have provided a rich return.

The title of the book is as pretentious as the literary style: it is not an analysis of psychosurgical problems interesting to the clinical psychiatrist or neurosurgeon, but a collection of observational papers of value primarily to specialized research workers. To those interested in the development of tests of frontal-lobe function the relevant chapters will provide both information and stimulation.

ALICK ELITHORN.

MEDICAL DICTIONARY

Blakiston's Illustrated Pocket Medical Dictionary. Edited by Normand L. Hoerr, M.D., and Arthur Osol, Ph.D. (Pp. 1,005; 60 illustrations on 24 plates. £1; thumb-indexed £1 3s.) New York and Toronto: The Blakiston Company. London: H. K. Lewis and Co. 1952.

This is a new book, produced under the supervision of the editors of the larger *Blakiston's New Gould Medical Dictionary*. It is not an abridgment of this, but was prepared by the same method as the *Oxford English Dictionary*. Over 100 contributors searched all new textbooks and about 50 medical journals for words in action. The words chosen were defined by specialists. The result is an authoritative work defining over 33,000 words. One-fifth of the book is an appendix containing much miscellaneous information on such topics as anatomy, blood constituents, diets, the elements, hormones, prescription writing, and weights and measures. The plates include illustrations of parts of the body, types of suture, bandages, fractures, and operative positions.

The book is meant for all concerned with medicine other than doctors, especially nurses, dentists, pharmacists, and laboratory workers. It is also considered suitable for laymen, including lawyers and physical education teachers. Many of the words are part of the doctor's vocabulary, and a doctor rarely needs a medical dictionary; when he does, it is a large standard dictionary, which is also desirable for all who have to write many medical terms, especially medical laboratory technicians and medical typists.

The dictionary includes many ordinary words that needlessly increase its bulk—for example, *gasometer*, *sigh*, *cough*, *yawn*, *bedpan*, *steam*, *giant*, *cosmetic*. People who do not know what these words mean may reasonably be expected to look them up in an ordinary dictionary. A *dwarf* is defined as "a diminutive human being"; apt enough, but if a definition is really necessary Walt Disney has lived in vain.

SURGERY OF THE HEART

On another page Drs. M. Campbell and D. Deuchar discuss the results of treating 200 patients suffering from congenital heart disease by means of anastomotic operations as described by Blalock and Taussig in 1945. They use the term *morbus caeruleus*, for, except in patients who die, an exact anatomical diagnosis may be impossible. Probably over four-fifths had Fallot's tetralogy, and the best results were obtained in these. In this condition there is stenosis of the outflow tract of the right ventricle, sometimes of the pulmonary valve, more often below it in the infundibulum; the interventricular septum is patent, the opening lying in the upper part; the aorta is dextroposed, so that it receives blood from the right ventricle as well as from the left; and the right ventricle is enlarged. As a result of the pulmonary stenosis, not enough blood reaches the lungs. The aim of the operation is to increase the pulmonary blood flow by making an anastomosis between a systemic artery and one of the pulmonary arteries.

The patients treated were mostly children, rather more boys than girls; three-quarters of them were between 5 and 14 years old. The principal symptoms are cyanosis and breathlessness on exertion, resulting in a disability that may be severe, so that the child may not be able to walk more than a few yards. Three-quarters of the patients were severely disabled in this way.

The diagnosis was ordinarily made by clinical examination combined with electrocardiography, radiology, and blood counts. Sometimes special investigations were used; they all subject the patient to discomfort and some risk. Angiocardiography may confirm dextroposition when the diagnosis is in doubt by showing early filling of the aorta, and it may help in deciding on operation by demonstrating the presence of pulmonary arteries and the anatomy of systemic branches. Levels of arterial oxygen saturation may be determined on blood obtained by puncturing the femoral or brachial artery, before and after breathing oxygen, but the information obtained does little more than confirm the clinical finding of

cyanosis. A catheter may be passed through a superficial arm vein into the various chambers of the heart, and it can usually be made to enter the pulmonary artery. The position of the catheter can be seen with fluoroscopy; sometimes the presence of a patent septum or a pulmonary stenosis can be deduced; blood samples can be withdrawn for estimations of oxygen saturation; and the most valuable information to be obtained is from the pressure readings in the various chambers and vessels. In patients with Fallot's tetralogy there is always evidence of a shunt from the right to the left side of the heart.

The operation performed on Campbell and Deuchar's patients was, when possible, end-to-side anastomosis of the left subclavian artery to the left pulmonary artery. Occasionally it was necessary to do an end-to-end anastomosis, but this is less beneficial because the systemic blood then reaches only one lung. Nearly all the patients have been followed up for over one year, some of them for five years. Good or very good results were seen in 136 (68%); 17 were improved; 6 were improved but later died, 2 from causes probably unrelated; 17 have not changed; and 24 (12%) died from the operation. Many of the patients now lead normal or practically normal lives, earning their living or attending ordinary school. In 11 patients it was found that anastomosis could not be done, usually because there was no suitable pulmonary artery. Of the 24 patients who died from the operation, 13 had a lesion other than an uncomplicated Fallot's tetralogy, and 5 of the remainder were aged 19 or older. Nearly all those who died caused anxiety during the operation, and all except one died within 72 hours of its completion. The figures may be compared with those of Belcher and Sellors,¹ who reported 70 cases with 8 operative deaths, and very obvious benefit in 42, and with the large series of Taussig's²—1,000 cases with a 16% mortality and good results in 78%.

After an anastomosis is established a murmur can be heard resembling that in patent ductus arteriosus; it is continuous, with systolic accentuation, best heard below the inner half of the clavicle but widely conducted. A thrill is unusual. Clubbing of the fingers regresses, but seldom disappears. Cyanosis becomes less; but it is nearly always still present after exercise, and usually just visible at rest. The pulse pressure is sometimes increased. The raised haemoglobin falls, approaching normal; there is a wide range of readings both before and after operation, the average final value in the patients with good results being 102%. The presence of an anastomosis increases the work that the heart must do; it therefore enlarges. In most cases the heart enlarges fairly rapidly in the

¹ *Lancet*, 1950, 2, 887.

² Taussig, H. B., et al., *Trans. Ass. Amer. Phys.*, 1951, 64, 67.

first month or so; the size then remains stationary. On the whole patients with large hearts before operation do not do so well; and too large an anastomosis is suspected in patients whose hearts continue to enlarge after the initial increase: the onset of congestive failure is then a serious possibility. Symptoms improve immediately after operation, and the main changes are usually established within a few months. Subsequent deterioration, or evidence that the anastomosis is becoming smaller, have been very rare. All patients have lost their radial pulse on the side of operation, and no blood pressure can be registered in this arm, but there have been no more serious effects of devascularization. Horner's syndrome and minor cerebral thromboses have been the only post-operative complications, both uncommon. No patient has developed bacterial endocarditis, another complication that was expected, but five have had cerebral abscesses—a common event in the untreated disease.

Campbell and Deuchar do not report any results of direct operations for pulmonary stenosis—division of a stenosed valve by a valvulotome or resection of an infundibular stenosis. These operations are now accepted as useful in treating isolated pulmonary stenosis, but they can also be applied to many cases of Fallot's tetralogy, the commoner condition. They have the attraction of reducing the abnormalities to three instead of increasing them to five, as does an anastomosis, but these direct operations are still in the experimental stage. The gratifying results of the anastomotic operation, as reported by Campbell and Deuchar in the longest series yet published in this country, confirm the reputation of this procedure.

MODERN YAWS CONTROL

The First International Symposium on Yaws Control was held in March, 1952, at Bangkok under the auspices of the World Health Organization with the assistance of the United Nations International Children's Emergency Fund and the Government of Thailand. Over 30 papers were presented, and collected summaries of these papers and the related discussions have been made available in duplicated form by the W.H.O. This symposium marks the coming of age of yaws and the passing of its control from the enthusiastic amateur to the professional slayer of dragons. With this evolution the technique of control has changed from one of individual fancy to one based on scientific principles, though there are still some aspects of yaws that remain to be carefully studied.

Great changes have come about since the discovery of penicillin, and especially since the development of

long-acting penicillin preparations such as procaine penicillin in aluminium monostearate (P.A.M.). In the past anti-yaws campaigns by mass treatment have often been made ineffective by the failure of the patients to attend long enough to receive adequate treatment, though in some areas the incidence of yaws has been greatly reduced after several years of free, rather haphazard bismuth injections. The optimal dose of P.A.M. that will render non-infectious the largest number of patients with infectious yaws lesions is not yet known for certain, but it is probably not more than 2.4 million units in one or two injections.

The modern effective anti-yaws campaign is no beginner's exercise. It must be initiated by a census and survey of the whole population, and six to twelve months after the campaign there must be another survey to assess the results. This may sound academic to the "practical" man, but there have unfortunately been recent anti-yaws campaigns whose effectiveness no one has been able to assess, and only good results, properly confirmed, can justify the expenditure of effort and money. In modern anti-yaws campaigns much, if not all, the work of surveying, diagnosis, and treatment is being done by selected local lay people after a short period of practical training. General supervision is by a doctor trained in public health and familiar with the problems of yaws control.

An important problem is to decide who is to receive treatment. An effective campaign is a public health measure and is not concerned only with the treatment of patients with yaws, though for practical reasons a certain amount of this may be necessary. There is no doubt that in an anti-yaws campaign previously uninfected contacts of patients with infectious lesions should be treated, perhaps with a smaller dose. But more important numerically and from other points of view are those patients who, having had an attack of early, secondary, or infectious yaws, have no clinical manifestation of yaws at the time they are examined. If untreated, many are certain to relapse during the following year or so and thus infect the uninfected and cured members of the population. At present there is no infallible way of detecting these latent secondary cases, which potentially, at least, cease to be a danger only when they develop late or tertiary destructive lesions or undergo spontaneous cure with serological reversal. The most practical way of reducing this menace is to treat all persons who give a history of having had yaws during the previous five years.

Two other important aspects of yaws control, originally found by Harding,¹ were emphasized at the Bangkok conference. One is that mass treatment

alone is not adequate to control a disease so closely related to the social and hygienic conditions of the population. Mass treatment must be associated with the construction of simple treatment centres, sited so that they are readily available to the population they serve. And from these centres itinerant medical auxiliaries, who are selected and suitably trained local people, must make frequent visits to the villages or homes in the area to seek and treat any infectious relapses or new cases which may have originated locally or come in from an outside area.

Harding's anti-yaws campaign followed his anti-trypanosomiasis campaign, since he found his team had to remain in the field to treat the few cases of the latter disease that are certain to follow any mass-treatment campaign. When his anti-yaws campaign was completed he started campaigns against other diseases that were important to the community, that could be diagnosed by the staff of the rural centres, and for which effective chemotherapeutic agents that could be administered by the staff were available. He was thus putting into practice what was probably the most important principle discussed at the conference—namely, that an anti-yaws campaign is not an end in itself but must pave the way to a gradually improved rural health service. Each step as it is taken is consolidated, and no further commitment is entered into unless the financial resources to carry it out successfully are assured. The effectiveness of modern yaws therapy is such that the most undeveloped people can appreciate it. And it is on this appreciation, as Harding emphasized, that the further improvement in rural health must be made. Towards this improvement the teaching of healthy living that should come from the rural treatment centres must be regarded as of utmost importance.

HORMONES AND ENZYMES

Almost twenty years ago Sir Frederick Gowland Hopkins remarked¹: "Only the end-results of the profound influence which minute amounts of substances with adjusted structure exert upon living cells or tissues can be observed in the intact bodies of man or animals"; and biochemistry "must learn to describe in objective chemical terms precisely how and where such molecules as those of hormones and vitamins intrude into the chemical events of metabolism." Perhaps in another twenty years our knowledge of how hormones influence metabolic processes will be sufficiently advanced to find useful applications in medicine. But at present experimental study of the influence of hormones on enzymes has given few clear-cut results. Moreover, our knowledge of enzymic changes in pathological states is limited to some isolated examples, such as the increase of urinary diastase in acute pancreatitis

and the rise in plasma acid-phosphatase in carcinoma of the prostate. It would be of particular interest to know whether metabolic diseases with an endocrine basis are associated with changes in tissue enzymes.

Workers engaged on the study of enzymes in relation to hormones are seeking to put their own house in order, as shown by the collection of papers entitled "The Influence of Hormones on Enzymes."² This publication indicates that encouraging progress has been made in some limited fields, despite the difficulty in devising experiments which can yield unequivocal results.

Steroid hormones have been studied particularly. As reported by W. H. Fishman and S. L. Cohen, quantitative changes of the enzyme β -glucuronidase may occur, on the one hand, in association with mammary cancer, and, on the other, under the influence of steroid hormones, particularly oestrogens. But, since the function of this enzyme is debatable, the theoretical implications of the findings are obscure. This is also true of the discovery that in certain tissues cortisone can enhance the oxidation of the "unnatural" D-amino-acids. Cortisone can also enhance the oxidation of proline, an amino-acid in which collagen is particularly rich. In reporting this effect, W. W. Umbreit points out that there are indications of "some vague relationship between collagen and the action of cortisone," but also remarks: "We do not at this stage know whether the basis of the action of cortisone lies in the failure . . . of a particular enzyme system, or of a group of enzyme systems or, in fact, whether its basis is enzymatic at all."

Umbreit studied tissues incubated after removal from animals to which cortisone had previously been administered. Effects of hormones *in vitro*—that is, added to the incubation medium—are more amenable to analysis, although less easy to demonstrate. Such effects, when cautiously interpreted, may help to clarify our knowledge of physiological processes, as notably illustrated by the hormonal effects which S. J. Folley and collaborators^{3,4} have demonstrated with isolated mammary gland tissue. But much evidence will be needed to support the suggestion of G. S. Gordan and his colleagues² that the decreased cerebral respiration in certain pathological states, such as hypopituitarism and adult eunuchism, may be related to effects exerted on brain tissue *in vitro* by certain steroids such as desoxycorticosterone and androgens.

Carbohydrate metabolism is known to be under complex hormonal control, and the mechanisms are being unravelled in a number of laboratories, notably that of C. F. Cori. Thus it appears from the work of E. W. Sutherland² that the glycogenolytic action of adrenaline, and also that of the hyperglycaemic factor of the pancreas, is associated with an increase in the effective concentration of the enzyme phosphorylase within liver

cells. Insulin has been shown by W. C. Stadie and other workers to facilitate the entry of glucose into muscle tissue such as a preparation of the isolated diaphragm. Whether or not M. E. Krahl is correct in suggesting that it is the enzyme hexokinase that is influenced by insulin, it is clear that the increased glucose "utilization" which insulin produces in intact animals can be attributed, at least in part, to a direct action of insulin on tissue cells. It is not clear, however, if an action of insulin on a single metabolic process—a process by which glucose is metabolized—could account for such diverse effects of insulin as inhibition of amino-acid oxidation² and stimulation of lipogenesis³ in liver tissue.

Studies such as these may eventually throw light on the metabolic derangements occurring in diabetes. Pituitary and adrenal hormones can scarcely be left out of account, particularly since diabetes can be induced in certain test animals by administration of growth hormone, A.C.T.H., or 11-oxy-corticosteroids. Here again the isolated diaphragm has proved a useful tool. Its glucose uptake can be reduced, or the enhancing action of insulin prevented, by pretreating the animal with growth hormone, provided that there is no deficiency of adrenal cortical hormones. But, in view of recent findings by Krahl² and Ottaway⁶ that growth hormone may have an insulin-like action under different experimental conditions, no simple theory can be advanced at present.

As to how thyroxine works, H. A. Lardy has suggested² that an enhancement in metabolic rate, as found with tissues removed from thyroxine-treated animals, may be achieved at the expense of a lowering of the efficiency of "oxidative phosphorylation"—the process by which energy derived from tissue oxidations is stored in the form of phosphate compounds such as adenosine triphosphate. Recent findings by Askonas⁷ are in agreement with the view that the latter process may actually be impaired by thyroxine. But Lardy has yet to produce evidence in support of his recent suggestion⁸ that certain other hormones act by a similar mechanism.

The clinical investigator will pardonably be bewildered rather than enlightened by present-day literature on the influence of hormones on enzymes. In view of the vigour with which this field is being studied, we may hope soon to see unifying concepts with a sound experimental basis.

INTRADERMAL INJECTIONS

In many reports the phrase "0.1 ml. intradermally" is used to describe the quantity and technique of injecting a test or therapeutic material, and in general both author and reader believe that an accurate description of the facts has been recorded. We publish this week two papers from the Tuberculosis Research Office of the World Health Organization which show that quite a wide range of quantities and depths of injection is probably covered by this description. Drs. J. Guld and C. Rud (p. 368) describe their technique for estimating leakage in new syringes, and even among those of the make they regard as most satisfactory 25% of syringes leak

to an extent which calls for their rejection; with other makes of syringes tested this percentage is even higher. Boiling did not affect the leakage rate, but after the syringes had been used for 1,000–1,500 injections the tendency to leak increased. Leakage is of greater importance in intradermal than in subcutaneous or intravascular injections because of the much greater pressure required to press down the plunger. The ordinary subcutaneous injection requires negligible pressure, but Guld and Rud estimate that a pressure 5–8 times that of the atmosphere is normally required for intradermal injection. It must be the experience of all who have made many intradermal injections that when the needle is too deep practically no pressure is required on the plunger.

This possibility of leakage has long been recognized, and experienced workers have tended to adopt the practice of checking the quantity injected by the diameter of the wheal raised by the injection. Drs. Carroll Palmer and Phyllis Edwards (p. 363) report that the diameter recommended in various publications varies from 5 mm. to 12 mm. From their own experiments they find that a very superficial injection of 0.1 ml. from a satisfactory syringe gives a wheal 8 mm. in diameter. But they also show that wheal diameter is an unsatisfactory index of volume, for with very superficial injections a six-fold increase of quantity increased the mean diameter of the wheal only from 6.3 mm. to 10.5 mm. Further, variation in size of wheal is related to the depth of injection, the most superficial injections giving the largest wheals for a given volume injected, while subcutaneous injections give no clearly defined wheal. From their experiments it is clear that a technique described as 0.1 ml. intradermally may even under closely regulated conditions with properly tested syringes lead to quite surprising differences: the range of variations with indifferent syringes in the hands of workers not using the greatest care must be very wide indeed.

In an attempt to find out how these variations might affect the results of B.C.G. vaccinations, Palmer and Edwards then carried out experiments in which the depth of injection and the strength of vaccine were deliberately varied. The mean diameter of Mantoux reactions ten and a half weeks and one year after vaccination showed no great variation with the depth of injection. The diameter of the area of induration round vaccination lesions at ten and a half weeks increased with the depth of injection, though there was little difference in the size of the scars at one year. The proportion of children with local abscess at ten and a half weeks increased with the depth of injection, and there was a tendency for abnormal scarring also to be associated with the deeper injections. The experiments show that a superficial injection is just as effective as a deep one in bringing about Mantoux conversion, but carries a very much lower rate of undesirable complications.

These papers are concerned particularly with the field use of B.C.G. on a large scale, but the lessons to be drawn from the experiments on syringe leakage and variation of wheal size with depth of injection are equally applicable to the injection of test materials,

notably tuberculin. The intradermal tuberculin test (Mantoux) has become the standard in this country largely because the quantity of material and the exact site of injection are supposed to be accurately known. In view of the variations shown by these papers it may be that the apparently less standardized methods based on a scratch in contact with old tuberculin (Von Pirquet test) or tuberculin jelly covered with adhesive plaster (patch test) are no more variable in results. If this is so, the main advantage of the Mantoux technique would be the greater opportunity it offers for intentional variation in the strength of the solution injected, and for detecting the less sensitive individuals by a final intradermal injection of 100 tuberculin units.

IMMUNIZATION AGAINST BACTERIAL TOXINS

Three distinct methods are known whereby a sample of diphtheria toxoid may have its potency as an antigen increased: by the removal of substances which depress the antitoxin response,^{1,2} by the admixture of a vaccine with the toxoid,^{3,4} and by the adsorption of the antigen on to an insoluble carrier, such as hydrated aluminium hydroxide or phosphate^{5,6} (A.P.T. comes into this category). Elsewhere in this issue Dr. D. C. Lahiri claims that crude diphtheria toxoid prepared in a veal-infusion-proteose-peptone medium contains a substance which not only enhances the antigenicity of purified toxoid—without precipitate formation—but reduces or abolishes the incidence of allergic responses when the mixture is inoculated into human subjects. The substance, termed natural adjuvant factor (N.A.F.), appears to be absent in toxoids derived from pig-stomach or casein hydrolysate media. If Lahiri's claim is confirmed—and it certainly needs confirmation—this will be the first demonstration of the enhancement of the antigenicity of purified diphtheria toxoid by the addition of a soluble substance which does not precipitate the antigen. The method used by Lahiri for preparing his N.A.F. almost certainly excludes the possibility that it is a protein or polysaccharide. His claim that it abolishes the allergic reaction needs confirmation by some direct and certain method, such as the simultaneous inoculation of subjects known to be allergic with purified toxoid and with the same toxoid in which has been dissolved Lahiri's N.A.F.

Recently it has been reported that one form of purified diphtheria toxoid administered in a simple solution is as potent as A.P.T. when tested in guinea-pigs by the two-dose method of assay.⁷ This is indeed remarkable, and it would be interesting to know the antigenicity of a prophylactic made with this purified toxoid adsorbed on to aluminium phosphate gel, and correspondingly whether Lahiri's N.A.F. would increase the potency of

alum-precipitated toxoid (A.P.T.) and purified toxoid, aluminium phosphate-precipitated (P.T.A.P.).

These recent observations, and other quantitative studies in diphtheria prophylaxis, show that the antitoxin response in animals (and humans) can be increased by two very different procedures. The first is to disperse the injected toxoid over a very large area of relatively inert mineral carrier; this greatly increases the efficiency of response per unit of toxoid injected.⁸ The second is to modify, by the addition of another reagent, the activity, or perhaps the susceptibility, of the antitoxin-producing cells to the injected toxoid in simple solution. The road seems still open to great advances in active immunization against bacterial toxins.

COMMONWEALTH CO-OPERATION

When Mr. Menzies opened the Proceedings of the British Commonwealth Scientific Conference in Canberra a year ago he referred to one of the perpetual dilemmas of science—"every time a scientist solves a problem he creates at least one more"—and he chose as an example the extension of human life which medical science has helped to bring about. This is creating, in Mr. Menzies's words, "one of the greatest social problems in history." The conference report,¹ which has just been published, contains a recommendation of its medical committee on the most important aspect of this problem—world food supplies and population trends. It stands to reason that the possibilities of agricultural development should be clearly known when efforts are made to eradicate a killing disease from an under-developed and perhaps over-populated territory. With this in mind the committee recommended that Governments concerned should take joint action with the Food and Agriculture and World Health Organizations to secure examination "of the relation between population, world food supplies, agricultural systems, and the results of medical research." If gloomy prophecies about the inadequacy of food supplies are to remain unfulfilled, co-operation between medical and agricultural research will have to be not only close but also prompt, and it is to be hoped that all Commonwealth Governments will act vigorously on this recommendation.

The medical committee, which was under the chairmanship of Dr. F. H. K. Green, of the Medical Research Council, considered a number of other subjects which seemed particularly suited for collaboration within the Commonwealth, among them environmental physiology and geographical anthropometry. The committee recorded its appreciation of the work of the laboratories of the Public Health Laboratory Service in the United Kingdom, some of which already serve as reference laboratories for the identification of a number of pathogenic organisms on a Commonwealth or international basis. These arrangements might well be copied elsewhere. The committee also called particular attention to the great value of the work of

develop because of the spread of the pulmonary infection to the pleura. Pulmonary suppuration and also consolidation in relation to bronchiectasis may be associated with a similar spread of infection. In many cases of this kind there is no great difficulty in recognizing the cause. There may be definite evidence of the pulmonary disease—for instance, the expectoration of purulent sputum. The specimen of pleural fluid may contain numerous polymorphonuclear leucocytes or may, indeed, be frankly purulent, and the infecting organisms—for example, pneumococci, streptococci, or a mixture of pyogenic organisms—may be recovered from it. However, with the early use of chemotherapy in pneumonia many of these effusions remain sterile, and it is with these that difficulties arise. Thus, a young person who develops pleuritic pain, fever, and, because of the pain, shallow breathing may be thought, reasonably enough, to have pneumonia. After treatment with penicillin and a sulphonamide he is found to have a clear sterile effusion, and the question arises whether this results from an abortive pneumonia or whether it is tuberculous.

I think two features may help: if the initial fever responded promptly to the chemotherapy and if the effusion remains small in amount and is absorbed quickly, usually within two to three weeks, then a pneumonic cause is likely. Tuberculous effusions tend to be associated with a longer febrile course, not responsive to penicillin, and with slow absorption of the fluid. When there is real doubt it is best in young people to regard the effusion as being tuberculous and treat the patient accordingly. Sometimes this course will be supported later by the growth of tubercle bacilli from the fluid, but even when this does not occur, if the features of the illness suggest tuberculosis, the long course of treatment outlined later is in the best interests of the patient.

Effusions with Pulmonary Tuberculosis

Tuberculous pleural effusions, although commonest in young people, do occur at all ages. Besides the sort already mentioned, which is not usually associated with detectable pulmonary disease, patients with established pulmonary tuberculosis may develop effusions. These effusions also occur at any age, but are relatively commoner in the middle-aged and elderly. It is usually possible from the history, or from clinical or radiological evidence of pulmonary tuberculosis, to establish the cause of this type of effusion.

Effusions with New Growths

While the causes of pleural effusion referred to above all occur in the middle-aged and elderly as well as in young people, it is wise to suspect the presence of a bronchial carcinoma when a man aged 40 or more develops fluid in his pleural cavity. The effusion may be caused by extension of the growth to the pleura or the presence of secondary deposits there; or by involvement of the mediastinum and the production of venous or lymphatic obstruction; or by inflammation of the pleura in relation to infected atelectatic lung beyond a blocked bronchus. The third of these causes may produce an illness with a febrile onset and most of the features described as occurring in post-pneumonic effusions. Effusions produced in the other ways are usually not associated with fever, and, while the onset may be painful, it is quite often insidious and not productive of pleural pain.

In most cases the diagnosis is not difficult. There may be features of the illness, such as loss of weight, the development of cough or the increase of an already existing smoker's cough, the expectoration of blood, or the discovery of secondary deposits outside the chest, which suggest the diagnosis. When the sample of fluid is taken it may be found to be uniformly blood-stained, or malignant cells may be found on examination of specially prepared specimens from it. All such patients must have postero-anterior and lateral chest radiographs taken, and in some cases these may confirm the presence of the neo-

plasm by demonstrating massive shadows in the lung or mediastinum; others may demonstrate segmental or lobar atelectasis, suggesting bronchial occlusion. It may be possible in some cases to obtain final confirmation of the diagnosis by bronchoscopy.

Difficulty in diagnosis arises in the following circumstances, which although not common are not altogether rare. A middle-aged or elderly man complains of some breathlessness of recent onset. He is otherwise well and has had no increase in his usual slight cough. He is found to have an effusion in his chest, and a specimen is taken which is not blood-stained. The chest radiographs do not show anything suggesting pulmonary or mediastinal new growth. This may still be true after aspiration of the liquid and its replacement with air, although this sometimes reveals the presence of a neoplasm which had been obscured in the radiograph by the opacity caused by the fluid. Careful examination of the patient for new growths elsewhere which may be responsible for metastases to the pleura may be negative, and bronchoscopy may show a normal bronchial tree. Although the onset is not characteristic, some effusions of this type may be tuberculous, and this is eventually shown in some by the growth of tubercle bacilli on culture.

So far as the immediate situation is concerned, it is usually best to treat the patient in the way described below for the treatment of tuberculous effusions. Most of those which are in fact tuberculous will subside over a few weeks. On the other hand, those due to neoplasms will increase, requiring repeated aspiration and frequently becoming blood-stained. They are usually caused by secondary pleural deposits from a bronchial carcinoma which may remain inconspicuous for some time. Although the wait of a few weeks will usually make the diagnosis clear, in some patients in whom this does not occur, or in whom it is necessary to come to a more exact diagnosis as early as possible, the remaining diagnostic procedure is thoracoscopy and pleural biopsy after replacing the effusion with air.

In women carcinoma of the breast is an important cause of pleural effusion. The effusion may sometimes be the only evidence of intrathoracic metastasis, and sometimes it occurs a long time—occasionally a few years—after apparently successful treatment of the primary growth. A rare cause in women, which is worth mentioning because of the possibility of curing it, is the condition known as Meigs's syndrome. In these cases persistent clear pleural effusion and usually ascites also are associated with benign fibroma of the ovary, disappearing after removal of the neoplasm.

Other Causes of Effusion

It sometimes happens that in pulmonary infarction pleural effusion is the most striking feature of the illness. The fluid is often but not always blood-stained. In most cases, by bearing in mind the circumstances in which pulmonary embolism and infarction occur, it will be possible to make the diagnosis. Occasionally, real difficulty arises in middle-aged and elderly men in whom blood-stained pleural effusion, especially if associated with haemoptysis, must suggest the presence of a bronchial carcinoma. However, effusions associated with infarction do not persist, increase, and recur after aspiration as malignant effusions do, and the condition usually resolves after a few weeks.

An effusion frequently develops in the pleural cavity in relation to a subphrenic abscess. This is usually small, being detectable in the posterior costophrenic angle of chest radiographs, and is often helpful in diagnosing subdiaphragmatic disease. When a subphrenic abscess is present the diaphragm on the affected side is high in position, and from clinical examination it may be thought that a basal pleural effusion is present. In most cases there will be a previous history of abdominal disease which will lead to further investigation, including radiographs to show the position of the diaphragm. Occasionally, a larger pleural effusion may be present, but, if the recent history of the patient is carefully considered, there is rarely much difficulty in perceiving that the cause is in the abdomen.

Treatment

The treatment of many pleural effusions is part of the treatment of the causative condition. Thus effusions occurring with established pulmonary tuberculosis and those complicating bronchial carcinoma often affect the course of treatment adopted for the primary disease and frequently do not require separate consideration. Here I shall refer briefly to the treatment of three varieties of pleural effusion.

Malignant and Post-pneumonic Effusions

Some patients in whom an accumulating effusion is the main manifestation of a bronchial carcinoma may be kept comfortable by repeated aspiration, sometimes for several months. This also applies to women with large effusions caused by metastasis from breast cancer. In both cases additional methods of treatment must be considered, such as, for example, the use of testosterone in metastatic breast carcinoma. These procedures will usually need to be controlled by experts, but the mechanical distress of a large effusion can often be well dealt with in the patient's home.

In patients who are confidently diagnosed as having post-pneumonic effusions no special treatment is needed if the fluid is sterile and quickly disappears. Larger sterile effusions may be aspirated and usually do not re-form. If organisms are found in the fluid the treatment should be conducted with special care. If the fluid is still clear and the patient is febrile and ill it is probably best for him to be treated in hospital. If this is not possible at once the fluid should be aspirated and at the end of aspiration one million units of penicillin should be left in the pleural cavity. This should be done each day, combined with the administration of parenteral penicillin in large doses—that is, two million units each day. If the organism recovered from the fluid is not sensitive to penicillin, then some other suitable antibiotic should be given systemically, and, because of the special dangers of this sort of infection, the patient should certainly be treated in hospital. In any case, if the patient does not promptly become well and his fluid sterile in a day or two the further treatment is best carried out in hospital. If the fluid is or becomes purulent treatment in hospital is imperative.

Tuberculous Effusions

The management of patients with tuberculous effusions is a long process. Moreover, those effusions which occur in young adults in the absence of demonstrable pulmonary tuberculosis are common, and general practitioners are often concerned in their treatment. It may therefore be helpful to describe the main principles of treatment. Those patients who are ill or who have a large effusion are best treated in hospital. However, there are many whose illness is relatively slight and in whom the effusion remains small, and some of these, if their home conditions are good, may be treated there quite satisfactorily. It should be pointed out that these patients have active tuberculosis and should be notified as such so that a search may be made for the person who is the source of the infection, and so that the general practitioner may co-operate with the chest physician in the treatment of the patient.

Rest in Bed.—This is the first essential of treatment, and many patients are most comfortable if they are propped up with pillows. The period of rest in bed is in practice best related to the patient's temperature. This usually settles to normal levels in three weeks, but is sometimes raised for six weeks or even longer. It is a good working rule to keep the patient in bed for three to six weeks after the fever has settled; the more severely ill he has been, the longer the period of extra rest. He may then begin to get out of bed, provided the fluid is diminishing in amount and he feels well, as he probably will.

Management of the Fluid.—In patients with small effusions the management of the fluid usually presents no difficulty. After the diagnostic aspiration it should be left alone, and nearly always is absorbed almost completely in

a few weeks. Patients with larger effusions should be treated in hospital, if possible, and in some of them it will be necessary to carry out further aspiration. The cardinal indication for this is dyspnoea. The usual practice is to aspirate without air replacement, and because large aspirations produce pulmonary oedema not more than 20 to 30 oz. (570 to 850 ml.) are removed at a time. When it is necessary to remove more the aspirations are repeated daily. Aspiration is also carried out when the fluid persists an unduly long time and for persistent fever.

Chemotherapy.—Although these methods are adequate for the treatment of most tuberculous effusions, it should be mentioned that some physicians consider it wise to use streptomycin and *p*-aminosalicylic acid (P.A.S.) in addition. It is, of course, too early to assess the benefit of chemotherapy in a condition in which the immediate results are in any case good. However, the argument is that effusions develop soon after the primary tuberculous infection, when there is an active pulmonary or glandular lesion and perhaps widespread dissemination of tubercle bacilli. In these circumstances they think it reasonable to use antibacterial treatment. Certainly in very ill patients and in those with prolonged fever the administration of these drugs seems to be a valuable addition to treatment.

Further Management of the Patient.—When the patient begins to get up his activity should be gradually increased until after about two to three months he is up almost all day. Walking exercise may then be begun and increased gradually until he is walking two to three miles by the end of a further month. In most patients it will have taken about six months to reach this point in their treatment. The majority will then be able to return to work, but should do no more than half-time for the first two to three months. The period of increasing activity is undoubtedly best undertaken at a sanatorium. When this is not possible, with care it can often be managed quite successfully at home.

Radiography.—Radiographs of the patient's chest should be taken throughout the period of treatment, and the frequency with which this is done will depend on the course of the illness. If there is no anxiety, weekly films for the first four to six weeks and monthly ones afterwards should suffice. Radiographs will usually show the steady diminution of the amount of effusion, and will also reveal complications, such as the presence of pulmonary tuberculosis and increase or recrudescence of the effusion.

Aftercare.—Although the immediate prognosis is good so far as restoration to health and disappearance of the effusion are concerned, about 25% of these patients are found to have pulmonary tuberculosis within five years. In addition to the long period of treatment it is therefore necessary to continue the period of observation for at least five years. A satisfactory scheme is to see the patient and have a chest radiograph every three months for three years, and then every six months to the end of five years.

Because of the age at which this illness so often occurs many of the patients will ask whether it is wise for them to marry and have children. In general, provided the patient understands that he or she is passing through a particularly dangerous period, there can be no objection to marriage. So far as child-bearing is concerned, it is impossible to be dogmatic. There is no evidence that pregnancy alters the outlook for patients with established pulmonary tuberculosis and none that patients who have had pleural effusions are more likely to develop pulmonary tuberculosis if they become pregnant. Nevertheless, I think it not unwise to suggest a delay of two years, or longer for very young women, in order to avoid the period in which pulmonary lesions are most likely to appear. It may be added that a patient who has been treated on these lines and who is being kept under regular observation is not likely to be a source of tuberculous infection.

Next Refresher Course Article.—"Miscarriage," by Mr. John Beattie.

attitude to illness and accident—these alone are the healing factors that unify the often bizarre and complex pathology of the allergic neurosis from which this child and her family had suffered.

Another child arrived at this family school with a description of how cold air would precipitate a severe attack of asthma. This same child, sleeping in an unheated bedroom, endured the severe frost of 1947 and played daily with uproarious enjoyment in the snow, and was never in better health.

The above are examples only of a consistent pattern of progress observed by me in the group of allergic children that have passed through this community. Without drugs, without nursing, without doctoring for their allergy, their problems have largely ceased to exist so long as there has been no introduction from without, or from within, of stress, anxiety, or insecurity. Bronchial asthma and associated sinus infections vanish; and other even more violent allergic explosive phenomena cannot be produced, as formerly, by the offending antigenic proteins.

As an example of this, one boy was on arrival unable to eat even cakes made with eggs, and on this account was having a special diet. Incontrovertible medical testimony arrived with him that he became ill, "swelling up," if he ate eggs in any form; yet with no drugs, no nursing, no fads, and no doctoring this same boy was eating boiled eggs with relish and no ill effects within three days of arrival, and remained well and free from this trouble thereafter.

No useful purpose would be served by quoting further examples, especially as every observer with wide knowledge of such types of illness can match these illustrative cases with many others in which, though the circumstances are different, the pattern of experience is identical. Objective reading of the advertising material dealing with the treatment of allergy forces a realization that, though activated by a sincere desire to heal, much therapy in this and allied fields is at present widely divorced from reality.

An Explanation Suggested

I have already outlined a theory by which some of these apparent contradictions can be explained. To use again the sense of smell as a schematic example, it is as if there persists a "morbid echo" of what was in the past evolutionary history of man an important defence reflex. In its original physiologically efficient state such a reflex would, in an appropriate physical emergency, readjust the vascular supply to the nasal mucosa, thus alerting the olfactory apparatus. To-day the obsolete paths seem to be used to relieve the pressure of morbid nervous tension. One of the most striking clinical findings in children of the type I have described above has been the cessation, without treatment, of constant nasal discharges, the clearing of the sinuses, often draining for the first time in months, and a return to normal of the upper respiratory tract, once the children have settled down in the relatively stress-free atmosphere of this family school. To those better versed in comparative physiology the idea will be less novel than it must appear to the clinician. Man is full of structures relating him to his more distant ancestors of which the significance is still obscure. Under the tension caused by unfavourable conditions a frequent, and useless, reflex discharge to the olfactory mucous membranes might be expected to cause engorgement and ultimate structural hypertrophy, with a resulting interference with the normal drainage of the paranasal sinuses and their consequent enhanced vulnerability to infection.

The phenomenon of morbid tension, so familiar to all workers in the psychiatric field, yet still obscure in its nature, seems to have its own clear relation to an earlier physiological defence mechanism. The sudden increase in the dynamic potential of the brain to ensure a maximum efficiency in the complicated reflex responses to danger was surely a universal attribute of survivors under the laws of natural selection. Pavlov (1941) has described qualities of brain type in dogs where "high mobility" in the cerebral cortex was not matched by adequate powers of "inhibi-

tion." At human level we describe as "worry" the constant morbid reaction to psychological equivalents of danger. People who worry often have brains that, except for this relative weakness of "inhibition," seem most efficient, and are frequently highly successful social types. Under conditions of stress over a prolonged period they quickly produce the high degree of morbid tension so apparent in their manner and their typically violent reflex responses on clinical examination. It is suggested that during such times vestigial autonomic and other reflex defence patterns not now in normal use can become reactivated along anatomical lines appropriate to the genetic inheritance of the susceptible individual.

It is, I think, probable that, as in the case of the upper respiratory tract, analogous "morbid echoes" of obsolete defence mechanisms may also prove to be a factor in other stress-conditioned diseases—for instance, certain of those affecting the heart, the stomach, the colon, the lungs, and the skin, to name but a few. To take the last two named: at amphibian level the skin is closely integrated through the autonomic system with the lungs and the pharyngeal exchange area as organs of blood-oxygen exchange. Watch any amphibian partly immersed in water, partly still in the air. It is apparent that in such an animal danger may call for a vasomotor response of maximal degree in the skin and lung, with the object of obtaining optimum oxygen exchange with which to face the emergency. The theory of a long-lost but once vital defence reflex helps us to understand why, at human level, there should be the close liaison between organs of such widely differing origins and with such diverse functions. Every experienced physician has seen the asthmatic person exchange this neurosis for a neurodermatitis, and later again change the neurodermatitis for an attack of rhinitis or asthma. Such a hypothesis would give us a possible physiological explanation of a number of debilitating and frustrating illnesses of obscure origin. For example, it might even help to sort out from the acute coryzas the many "stress-colds" that must confuse the issue in contemporary research on this subject.

The Adult Patient

As I have constantly seen, in the security of the family school described a child can be relieved of all these symptoms; but what of the adult, often burdened by irreversible structural changes in the affected organs; how can he get similar relief?

Here we must face the problem that at present no such effective relief is possible as that available to the child, whose environment is so easily modified and whose morbid habit of life is not yet so deeply ingrained. Benefit in neurotic illness seems to follow the most diverse measures, including an immense range of medicines and treatments. The explanation here presented might, however, reveal why so many are benefited through the powerful suggestion of security induced by the heterodox disciplines of many cults of healing, often based on contradictory foundations.

The adult patient will, I believe, be greatly helped by a better understanding of why he is ill. Too frequently the nervous patient is discouraged and depressed by an acute sense of personal failure. Should the theory we have considered be true, it would relieve the patient of much of the burden of social disapproval that, however well concealed, is a constant reality for the sufferer from neurotic illness. In the wider field of therapeutics a true appreciation of the underlying physiology may lead ultimately to more successful treatment.

It is not possible to discuss here the successful surgical treatment of certain types of nervous illness. The reduction of tension by lobotomy would again seem to depend upon the apparently paradoxical yet fundamental anatomical linking of the phylogenetically modern prefrontal areas with the very old thalamic and autonomic mechanisms.

At an earlier stage of evolution the fundamental reflex patterns would be excited mainly by danger, climate, sexual

Reports of Societies

HYPNOTISM

On January 8 a largely attended conference of the B.M.A.'s Psychological Medicine Group, with Dr. H. B. CRAIGIE in the chair, discussed the profession's attitude to hypnotism. The Group Committee had drawn up a statement on hypnotism, as follows:

(a) Hypnotism may be defined as follows: the use of suggestion with the intention of bringing about an altered state of consciousness involving a surrender by the patient of his normal powers of control.

(b) The hypnotic state should be induced only for therapeutic purposes. Its value as a therapeutic agent is, however, extremely limited, since its results are indefinite, and, although it may apparently induce relief of certain symptoms, this relief does not appear to be permanent. It tends to increase the subject's degree of suggestibility, and for this reason its use has been largely given up by the medical profession. When, however, it is used the hypnotic state should be induced only by a registered medical practitioner or under his direction and in his presence.

The words in italics were subsequently deleted at the suggestion of the Central Ethical Committee, and the statement so amended has been approved by the Council and reported to the Representative Body.

A Method of Approach to the Unconscious

Dr. E. A. BENNET, who opened the discussion, said that it was surprising to learn that the Group Committee's statement on hypnotism in 1952 was to all intents and purposes identical with the pronouncement made in 1892 by a special investigating committee of the British Medical Association and even with a report made to the medical section of the French Royal Academy of Sciences as far back as 1831 on the subject of animal magnetism. Was it to be concluded that no more was known on the subject than 60 or even 120 years ago? Surely not. Hypnosis was a method of reaching the unconscious, and the unconscious—whatever connotation be given to the term—was a main interest in psychotherapy. The unconscious contained the energy they sought to release for therapeutic purposes. There were other roads to the unconscious—for example, free association or active imagination, and hypnotism was by no means the best method.

Dr. Bennet criticized the definition which stated that hypnotism involved a surrender by the subject of his normal powers of control. The patient came for treatment because he felt he had already surrendered, and wished to regain, his powers of control. The balance between the conscious and the unconscious had been disturbed and the aim was to restore this. A patient was not treated by hypnotism; rather hypnosis permitted something to be done, just as an anaesthetist facilitates a surgical operation. Hypnosis required rapport, collaboration, between patient and doctor. This was not the same thing as transference. Before employing hypnosis the therapist should know his patient well and explain the procedure fully. Under special circumstances it could be employed with benefit in the removal of certain symptoms, of which amnesia, psychogenic loss of muscular power, impotence, and vaginismus were examples, but such treatment must be followed by abbreviated analysis. Many patients, thus treated, got well and remained well, and they did not develop a dependence upon the therapist.

There were certain real dangers in applying hypnosis. For example, the potentially psychotic patient, under hypnosis, might be seriously harmed by the release of more energy from the unconscious than he (or the therapist) could control. A further danger—and this might happen with non-psychotic patients—was that the restriction of consciousness

For patients who are faced with a long stay in hospital or prolonged convalescence following a serious illness, the Preparatory Training Bureau run by the British Council for Rehabilitation will assist towards a return to normal work. In some cases patients may be unable to go back to their previous employment, or illness may have interrupted a university or technical training course, but whatever the situation the Bureau assesses each case on its individual merits and needs, taking into consideration such factors as personal preference and educational background. The main medium for instruction is correspondence, although it is sometimes possible to arrange direct tuition from a visiting instructor. Subjects taught range over a wide variety of subjects from agriculture to criminal psychology. The Bureau works in close co-operation with medical officers, welfare workers, and especially with local education authorities, who have powers to reimburse tuition fees, although wherever possible students are encouraged to contribute towards the cost of their training. Further details may be obtained from the Registrar, Preparatory Training Bureau, Tavistock House (South), Tavistock Square, W.C.1.

which occurs in hypnosis might give an outlet to tendencies at variance with the patient's conscious moral standards. Hypnotism should be practised only by those whose training and experience enabled them to make a psychiatric diagnosis and whose judgment in selecting suitable patients for this treatment was sound.

Lack of a General Theory

Professor ALEXANDER KENNEDY said that he spoke neither as an expert nor as an enthusiast, but simply as a psychiatrist who felt that some knowledge of the subject should be part of the background of every psychiatrist. Mr. Somerville Hastings's Bill was not by any means the first legislation on the subject. There had been laws and decrees concerning hypnotism in many countries during the nineteenth century.

There had been many attempts to explain the phenomena of hypnosis, and hypnotism seemed often to attract explanations in terms of current theory. Just as it was magnetism in Mesmer's time, so at the present time extra-sensory perception was being invoked. One view which was of great interest was that pointed out by Charcot and later by William Brown—hypnotism had a great deal in common with hysteria. It was known that in certain conditions of the nervous system in which hysteria was a common complication the patients exhibited a state at times which was not unlike hypnosis. To the popular view hypnotism was an example of the power of one person over another, or of mind over matter. To the layman the whole thing was so striking that it was impossible for anyone to feel neutral towards it. Historically, hypnosis was the first abreactive technique.

As to the medical attitude towards hypnotism, if medical men were to take the responsibility of doing what lay hypnotists were doing they must acquire competence at it, or if they thought it a wrong thing they must give sound reasons for their view. It had been suggested in some quarters that the therapeutic use of hypnosis should be regarded as a special branch of medicine. He himself did not hold that view. Hypnotism could not rank as a specialty and could never be a very high-grade occupation. If people were going to use hypnotism in the course of psychiatric treatment they should use it against the general background of psychiatry, and it was in psychiatry itself that they should be specialists.

Lay Hypnotists

Dr. J. R. REES said that it would be interesting to learn Dr. Kennedy's objections to lay hypnotists. He understood the objection to be not only to stage performances but to the little clinics afterwards which might be formed around the lay hypnotist.

Professor KENNEDY replied that he thought it would be wise to suppress such demonstrations, but largely on the grounds of good taste. It was possibly more of a public matter than specifically a psychiatric one. There were, however, dangers arising from what might be called the side activities of the mesmerists, and these might be greater than those arising from their public performances. One of the difficulties was that the public was apt to say, "These people can do it; can you?" If doctors combined to suppress something which apparently they could not make use of themselves they looked rather feeble in the eyes of the public. Braid, Elliotson, and Esdaile had been persecuted by their colleagues because they investigated hypnosis.

Discussion

In the subsequent discussion Dr. M. N. PAI gave a short talk on suggestibility, especially that form prevalent during social upheavals, such as war. Dr. W. G. MASFIELD, replying to questions about the Committee's definition, observed that the statement that hypnotism should be used

only by a medical practitioner was another way of saying that its *raison d'être* was therapeutic. Whereupon one or two speakers expressed concern lest legislation brought in to stop lay hypnotism might have an unfortunate effect on activities such as spiritual healing.

Dr. CULVER BARKER said that hypnotism was helpful in selected cases, but he would hesitate very much before sending a patient to a hypnotist unless the latter had a very good background of psychiatric experience. Dr. DORIS ODLUM hoped that the point would be fully emphasized that they were speaking of hypnosis in the interests of the patient. Danger arose when such a method as this came into the hands of those who used it apart from this dominating consideration.

Professor FERGUSON RODGER said that what the Committee had framed was something like a legal definition so that hypnotism could be recognized when it was seen; it was not done with the intention of describing the therapeutic means used by a particular practitioner. A number of psychiatrists who at one time used hypnotism now used it no longer or only very rarely, because they did not like the "feel" of it. There were very few occasions, he thought, when they needed to use it; they could nearly always use some other method. Dr. SYBIL TREMELLEN mentioned that hypnotism was used extensively in dental clinics in America.

MINISTER AT MENTAL HEALTH CONFERENCE

The annual conference of the National Association for Mental Health was held in London on February 5 and 6 under the chairmanship of Professor C. FRASER BROCKINGTON, Professor of Social and Preventive Medicine, University of Manchester. The conference took the form of a symposium on the practical applications of research and experiment in the mental health field, and one session was devoted to mental deficiency and another to research into the causes of mental illness. Delegates were present from W.H.O. and Unesco, and from health services in the United States, Australia, Canada, France, Denmark, Holland, Switzerland, Egypt, and Argentina.

A Dual Social Problem

The Conference was opened by the Minister of Health, Mr. IAIN MACLEOD, who said that in coping with mental illness and deficiency great shortages were encountered on many sides. In the mental-deficiency field alone there was a waiting-list of some 8,000, and with mentally defective children this constituted a dual social problem, for not only was it better for the child himself that he should have the trained care which could be given to him in hospital, but it could make all the difference to the mother and the family if what was potentially a disruptive element was removed from the home environment. He regarded this as the biggest problem which faced him as Minister of Health.

It was true that they were all to some extent prisoners within the difficulties with which the country was faced, but it was a great tragedy that in the more carefree days of the Health Service, before a ceiling was imposed by the late Sir Stafford Cripps, more money had not been devoted to the mental health field. Surely the first thing they should do was to seek to instil into the people of this country a different and more wholesome attitude towards mental illness. In the future they must associate the problem of mental health more closely with the problem of the general health. When the time arrived the claims of mental health should have first call on the capital resources available in the hospital field, and side by side with the provision of buildings must go the training of more nursing staff. He

assured the delegates that he would look forward to receiving the conclusions of the conference and would give them every consideration.

Professor L. S. PENROSE, Galton Professor of Eugenics, University College, London, then addressed the conference on recent research in mental deficiency. Thirty or forty years ago the hereditary factor was thought to be the only one worth investigating. But now environmental causes, such as maternal infection during pregnancy, had come to the fore, and both aspects must be continually remembered and balanced against each other. In discussing the possibility of a decline in intelligence of the whole population, Professor Penrose said there was no evidence of this, but there was a related problem to consider—namely, the increase in the number of low-grade defectives. Dr. L. T. HILLIARD, physician-superintendent, Fountain Hospital, described some modern institutional developments. He pleaded for a quicker turnover of patients to reduce the waiting-list, and if a certain amount of risk were taken it was surprising what could be done.

Other discussions at the conference were on the subject of child care and on the influence of recent advances in the prevention and treatment of mental illness.

HOSPITAL OUT-PATIENT DEPARTMENTS

On January 27 the Sections of Medicine and General Practice of the Royal Society of Medicine held a discussion on "The Function of the Hospital Out-patient Department."

Sir JAMES SPENCE, introducing the subject, said that it all depended on whether you looked at the question as a patient, who might be a *habitué* or a new-comer; as a general practitioner, who might be either genuinely requiring a consultation or just decanting patients from an over-busy surgery; or as a consultant, a hospital administrator, or busy surgeon; or as a student, a hospital administrator, or busy surgeon. Each had a different point of view, and the "time-and-motion" experts also had their point of view. Then there were different kinds of departments, some arranged primarily for true consultation, others trying to combine this with clinical displays to students, others arranged for technical examinations or treatments by specialists. Behind all this lay the casualty departments with their daily load of work. The picture therefore required clear analysis.

The true consultation department reached its highest level when practitioner and consultant were friends, or when the consultant dealt with the patients as if they were friends. The purpose of consultation was to give appropriate explanation and advice both to patients and to practitioners. The manner in which this was done was in itself a valuable method of teaching students. This concept of true consultation had been rather lost sight of in teaching hospitals, where it was made difficult, if not impossible, by the presence of nurses or students in the room. By simple arrangements they could be kept in the background. He preferred to have only two students in his room, and no nurse. Then it became true out-patient teaching. The other method of clinical displays in out-patient departments to a large number of students was something different. While legitimate for its own purposes, it was not out-patient teaching. When offered the choice of consultation with or without students present, 90% of patients accepted the presence of students if there were no more than one or two. The introduction of a patient to a consultant whom he had never seen before required thought. For this he used a voluntary social history writer. Apart from this a letter from a doctor was required; a telephone conversation was better still; but best of all was to have the general practitioner accompany the patient. A study of the history and origin of out-patient departments revealed the cause of their weaknesses. Most of them had evolved out of underground casualty departments in buildings designed primarily for in-patients.

A General Practitioner's View

Dr. R. J. F. H. PINSENT, speaking as a general practitioner who had referred his patients widely to both general and special hospitals, said that the general practitioner must look to the out-patient department for services which he himself could not give his patients, either because their problems were beyond his skill or because some special investigation was required. He had come to regard the hospitals around him as fulfilling the purpose of an extension of himself. Hospital care was but one phase in the course of an illness, and it might be very short in relation to the duration of the disease or the lifetime of the patient. In one year he had seen in his practice 2,176 patients (first attendances), and of these he referred 413 (19%) to hospital for opinion or advice. The greatest demand was made on the casualty department, to which 19% of the patients who went to hospital were referred; this was a reflection of the general practitioner's lack of facilities rather than his lack of skill.

After referring briefly to an example of delay in dealing with a patient, Dr. Pinsent went on to discuss the form of a consultant's report. It need not be long, but it should be clear and answer all the questions if possible. It would help if hospitals used a standard size of notepaper which would fit unfolded into the N.H.S. record envelope. He urged that the general practitioner should be encouraged to go to hospital as a clinical visitor, with or without the care of patients. On the other side, for some time he had been privileged to have visitors from the hospital world (registrars) come to share an evening surgery with him. This gave them an opportunity of seeing illness as it presented itself in the home and in the surgery, and he had learned much and had been stimulated by the contact.

Appointments

Brigadier G. P. HARDY-ROBERTS spoke from the point of view of a lay administrator. General practitioners could help in the smooth running of an out-patient department if, when making appointments for their patients, they would indicate more clearly the kind of specialist required, and if they would refrain from asking for an urgent appointment except in cases of real need. No appointments system could work satisfactorily unless consultants and their assistants began their sessions punctually, but it was important that out-patients should understand that good treatment was incompatible with a "conveyor-belt" system. Unnecessary delays should be avoided, but patients themselves were not always blameless. There were frequent instances of unpunctuality on their part, and of failure to attend clinics, especially after their initial visit.

Discussion

Dr. W. A. BOURNE said that during the last 13 months he had seen at hospital 2,634 out-patients, but he had been able to make a diagnosis which really satisfied him in only 60%. He was impressed by the number of elderly people making vague complaints who came to the out-patient department. Apparently they used the hospital as a social centre, and therefore he decided to arrange that they should go to the hospital without necessarily having to see a medical man at all. Two or three out-patients' clubs had been formed, and these had proved beneficial as well as exceedingly popular.

Dr. L. W. BATTEN spoke of his failure to induce hospitals to play the good consultant. Sometimes he had to write not to an individual but to a department, and it was then that trouble arose. Apart from the notorious delay in getting an answer, his persuasive letters often evoked merely a list of findings as if the patient were a box of tricks, not a person. Often the patient sent only for an opinion was presented with a bottle of medicine and invited to come again—in fact taken over by the hospital.

In private practice he tried always to accompany his patients to consultations. He would most gladly do the same in hospital if, first, he was made to feel he would be welcome; secondly, he could hope the consultation would be reasonably punctual; and, thirdly, if he did not fear it would be semi-public—as Sir James Spence had said, not a real consultation at all.

Dr. ALEXANDER BROWN said that the out-patient department was being run for different purposes, including the training of registrars to become consultants and of students to become doctors. It was time that people got down to the planning of the out-patient departments so that the important cases which came from the general practitioner for the opinion of a particular consultant could really have a consultation. In his own district (Cambridgeshire) the general practitioner had free access to the pathological and radiological facilities, and if this were arranged generally out-patient attendances would be appreciably cut down.

Nova et Vetera

Sir FREDERICK TREVES

Sir Frederick Treves, the centenary of whose birth falls on February 15, was born at Dorchester and educated at Merchant Taylors School. He qualified from the London Hospital in 1874, and by the 'nineties had become the best-known and most successful surgeon in London. In another coronation year—1902—his name was on every tongue as the surgeon who operated on King Edward VII. Since June 13 the King had been suffering from abdominal pain but was anxious not to postpone the coronation, despite the advice of Sir Francis Laking and Sir Thomas Barlow, who recognized that the appendix was involved. After further consultation with Treves and Lord Lister they persuaded the King to submit to an operation, which was carried out by Treves at 12.30 in the afternoon of June 24, two days before the date fixed for the coronation. Treves found a deep-seated abscess round the appendix, necessitating two large drainage tubes in the abscess cavity. Convalescence was uninterrupted, and the postponed coronation took place on August 9. It is said that Treves did not go to bed for seven nights after the operation.

By a strange chance Treves's Cavendish Lecture "On Some Phases of Inflammation of the Appendix" was delivered on June 20 and published in this *Journal* on June 28. He was one of the first surgeons to devote special attention to diseases of the appendix, and opened a discussion on the surgical treatment of "typhlitis" at the B.M.A. annual meeting at Leeds in 1889. In a subsequent paper contributed to *Albutt's System of Medicine* (1897) he used the term "perityphlitis," regarding the term "appendicitis" as uncouth.

Treves was a man of many interests and travelled extensively, recording his impressions and experiences in a number of books. His last work was *The Elephant Man and Other Reminiscences* (1923). The story of John Merrick "the elephant man" was first told by Treves in this *Journal* (1886, 2, 1188; 1890, 1, 916). The man had been victimized by showmen for some time. He suffered from congenital hypertrophy of certain bones, with pachydermatocele and papilloma of the skin, and his countenance was so hideous that he wore a mask. His death in 1890 followed continued growth of the skull, which became so heavy that it fell backward while he was asleep and dislocated his neck.

Treves retired in 1908, and in that year became one of the founders of the British Red Cross Society. At the beginning of the first world war he offered his services and became president of the headquarters medical board at the War Office. He died in Lausanne on December 3, 1923.

Preparations and Appliances

EXTRADURAL SPACE INDICATOR

Professor R. R. MACINTOSH, Nuffield Department of Anaesthetics, University of Oxford, writes: Extradural analgesia would be more popular if the anaesthetist knew for certain when the point of his needle had passed the ligamentum flavum (L.F.) and reached the extradural space. Any device to indicate this must work decisively, for the advancing needle might otherwise penetrate the dura (D). Mr. R. Salt, technician to the Nuffield Department of Anaesthetics, has designed a spring-loaded stylet for this purpose, and in practice it has proved robust and effective. The distal end of the stylet is blunt, and the proximal end is housed in a small metal case (S.H.) containing a spring.

FIG. 1.—A spring-loaded stylet for extradural analgesia.

FIG. 2.—Section of the stylet.

An 18-gauge needle is inserted until the point lies in the ligamentum flavum. The stylet is inserted through the needle, but the distal blunt end is held up by the tough ligament, compressing the spring and keeping the proximal end $\frac{1}{2}$ in. (8.5 mm.) out of the casing. The needle is held by its two flanges (W) and advanced slowly. As soon as the bevel is clear of the ligamentum flavum the stylet is propelled forward by the spring. That the point of the needle has reached the extradural space is shown by the sudden disappearance of the proximal end of the stylet into the casing.

The needle is manufactured by Vann Bros., Ltd., of 63, Weymouth Street, London, W.1.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Assistance for Doctors in Flood Areas

SIR,—Through the appropriate divisions of the Association and local medical committees information has been sought about the forms of assistance needed by the doctors in the areas affected by the recent disastrous floods. It is known that numbers of our colleagues have sustained grievous losses. There are some whose houses and cars are under water. Others may suffer through the evacuation of large numbers of patients who may not be able to return to their former homes. One of our divisions is raising a local emergency fund, but I am sure that our members in all parts of the country will welcome an opportunity of assisting. Indeed, we have friends farther afield who are anxious to help, as is shown by a most kind offer received from the Canadian Medical Association.

We have in the Association a small fund known as the Sir Charles Hastings Fund, the object of which is to give prompt assistance to doctors who, through misfortune of one kind or another, find themselves in temporary difficulties. The fund is administered by three trustees—the Chairmen of Council, the Chairman of the Representative Body, and the Secretary of the Association—who are in a position to deal expeditiously with all cases of need brought to their notice. I invite readers of the *Journal* to send contributions necessary relief in the present emergency. Will contributors please make their cheques or postal orders payable to the Sir Charles Hastings Fund, and send them to the Secretary of the Fund at B.M.A. House, Tavistock Square, London, W.C.1, marking the envelope "Flood Relief."—I am, etc.,

E. A. GREGG,
Chairman of Council.

Smoking and Lung Cancer

SIR,—In view of the present interest in the relationship of smoking to lung cancer there is undoubtedly a large body of opinion, both professional and lay, which accepts, as though it had been proved, that smoking is the main cause of the recorded increase in lung cancer; and no doubt there is considerable distress in the community on this account. In the present state of our knowledge, is this anxiety really justified?

What do we really know? What do we not know? It is agreed that (1) the Registrar-General's recorded figures of deaths from lung cancer have been mounting with startling rapidity since the early 'twenties of this century, and are still rising; (2) the national habit of cigarette-smoking has increased in corresponding measure—indeed, there is an intriguing correlation between the increase in cigarette-smoking and the recorded increase in deaths from lung cancer; (3) there is an immeasurably greater ability to diagnose this condition to-day, as compared with the first decade of this century. There is probably as close a correlation between the increase in lung cancer as there is between the increase in cigarette-smoking and the increase in lung cancer; and (4) it has yet to be shown that there is a carcinogenic agent in tobacco smoke, and, even if there be such an agent, it will be necessary to show that it is capable of inducing cancer in the bronchial epithelium.

In judging the relative importance of (2) and (3) we must admit that we do not know how much of the rise in the death rate can be explained by our greater ability to recognize the disease. At the same time, we cannot assume that,

because there is a correlation between the increase in smoking and the increase in lung cancer, there is necessarily a connexion between the two. It is easy to call to mind other close statistical correlations. What catches the popular fancy is the way the rise in the habit of cigarette-smoking goes hand in hand with the rise in lung cancer mortality. But in the long history of our profession's attempts to elucidate the causes of cancer it has found many correlations of a comparable nature which have in the end proved false. In the early days of the present century it was taught, and it was in the students' textbooks, that breast cancer might be related to the bone and metal supports of the corsets of the Edwardian days; but in the intervening 45 years the incidence of mammary cancer has not fallen. It is as high to-day as it was then. The high frequency of liver cancer in the East was long considered to be associated with liver parasites—a belief now rapidly dying out. There have been other such false assumptions. If the reported increase in lung cancer is due to tobacco smoke, how does it come about that there is no increase in the incidence of cancer in other parts of the respiratory tract, such as mouth, tongue, and pharynx, which suffer a greater exposure to the smoke and for a longer time? In point of fact, there is some slight decrease in these sites.

With regard to the statistical approach of Dr. Richard Doll and Professor A. Bradford Hill (December 13, 1952, p. 1271), I feel unhappy about results obtained from analysis of male figures when it would appear that over 95% of their men smoked, and when there are no controls who have not smoked. They record that out of 108 cases of lung cancer in women 40 had never smoked. This is a formidable proportion. We do not know how many of their 68 women who had smoked, and who died of lung cancer, would have developed lung cancer had they not smoked. With regard to their men, the same difficulty arises: how many would have developed lung cancer had they not smoked. Why not as many as the women? This aspect is not given its proper weight by these authors. Their whole emphasis is on smoking.

It is clear, and this is sometimes, perhaps, better than being statistically clear, that lung cancer takes a certain toll of women whether they smoke or not. The same must be true of men. From what we know of cancer in other sites it is not unreasonable to suppose that the incidence will be higher, perhaps much higher, than in women. It may, indeed, be this natural incidence, not the smoking, which is, at least in part, responsible for the higher male figures. The only satisfactory solution of the problem would be the study of a large group of smokers in comparison with an equally large group of non-smokers.

In the early 'thirties it was the fashion to ascribe lung cancer to the tarring of the roads and to the exhaust fumes of motor vehicles, but the failure to demonstrate any higher incidence in those specially exposed to such hazards resulted in the abandonment of the hypothesis. Then the traces of arsenic in British tobaccos received the blame, but that belief, too, has been discredited. The industrial pollution of the air we breathe has been considered as a factor, in spite of the fact that, while lung cancer figures are rising, the aerial pollution is definitely decreasing. When doctors disagree it is bad for the patient.

It may be that a proportion of lung cancers in man are induced by tobacco smoke: at the moment we do not know, but let us be sure of our evidence before we scare our public. As a profession we have that responsibility.—I am, etc.,

Leeds.

R. D. PASSEY.

Damages Against Casualty Officer

SIR,—We have read with dismay your account (January 17, p. 166) of the action and judgment in the case of *Payne v. St. Helier Group Hospital Management Committee and Another*. The opinion of the learned judge cannot fail to cause disquiet among medical practitioners, who are as jealous of the traditions and good repute of British justice

as they are of their own inheritance. From your account of the case it appears that the findings of the casualty officer were borne out by the evidence of the general practitioner, for he and his locum remained satisfied with the patient's progress for a fortnight after the injury. This seems to have been completely ignored by the judge in his summing up. Furthermore, why should Mr. Justice Donovan reject in its entirety the evidence of Professor Ian Aird? Professor Aird's teaching and writings are a guide to surgeons all over the world. His opinion in this case supported the defendant in every particular. Most of us would rest content with such support.

Even more disquieting is the judge's reference to the casualty officer failing to observe signs which "must have been present." There are no "musts" in medicine, especially where such fickle things as physical signs are concerned. Moreover, the casualty officer is held to be negligent, not for what he failed to do, but for what he failed to observe. This surely introduces a new precedent into the law regarding negligence and malpractice. Mr. Justice Donovan further remarks that the patient in this case should have been seen by a consultant. It seems that to satisfy the courts an ordinary medical qualification is of negligible value. Hospital management committees had better begin staffing their casualty departments with consultant surgeons.

May we conclude by expressing sympathy with the defendant and the vehement hope that an appeal will be made against the judgment? If this decision is allowed to stand, it will be impossible to practise medicine without constant fear of litigation. "Who then shall be saved?"—We are, etc.,

lows certain abdominal operations. If early clearance of the blocked bronchus does not occur some infection and inflammation of the collapsed segment probably nearly always results and the patient develops a segmental aspiration pneumonia of the type described in these papers. (This point is, indeed, mentioned in the earlier paper.) If, then, the conclusion of the second paper—that segmental aspiration pneumonia may occasionally result in an established bronchiectasis—is correct we should expect to find that post-operative segmental collapse may also, sometimes, lead to bronchiectasis. It would be interesting to know if this is the case. Do physicians or surgeons seeing large numbers of cases of bronchiectasis feel that in some of their cases the beginning of the disease can be traced to an abdominal operation? Does the frequency of a history of a previous abdominal operation in any large series of cases of established bronchiectasis suggest that the former is sometimes an indirect cause of the latter?

These papers should emphasize, once again, the importance of the prevention, early diagnosis, and effective treatment of post-operative segmental collapse. Unlike the more dramatic, but much rarer, massive pulmonary or lobar collapse, the symptoms of this condition may be slight and clinical signs scanty, so that it may be easily overlooked if not expected. The papers also stress again that correct treatment is essentially the mechanical drainage of the blocked bronchus with antibiotics playing only a secondary role. This is certainly true of the post-operative condition. Brock's classical paper¹ on "Post-operative Chest Complications" gives a very good account of the treatment of post-operative pulmonary collapse. His method is essentially postural coughing adapted for the surgical patient. If carefully carried out at an early stage the blocked bronchus can nearly always be cleared. The development of an aspiration pneumonia with the remote possibility of bronchiectasis may thus be prevented. Bronchoscopy or tracheo-bronchial suction is rarely necessary or desirable.—I am, etc.,

Omagh, Co. Tyrone.

SIR,—The Council of the Medical Defence Union, like yourself, has been made aware of the disappointment with which many practitioners have read the judgment in the case of *Payne v. St. Helier Group Hospital Management Committee and Another* reported in your medico-legal columns (January 17, p. 166). A similar reaction was experienced by individual members of the Council when they learned the substance and framework of that judgment. Steps were immediately taken to instruct the solicitors who act for the Union to examine jointly with leading and junior counsel the question of entering an appeal forthwith. Two conferences were held with learned counsel, who eventually advised that there was a total absence of any promising ground whereon to base an appeal, and that, indeed, an appeal if entered would not carry any hope of success. In these circumstances the Council had no alternative but to follow the advice of its chosen legal experts, much though they regretted their inability to seek a reversal of the unfavourable judgment.

The profession can rest assured that the probable repercussions of each case sponsored by the Union and heard in court are carefully considered in the light of any additional available legal procedure that can be undertaken to protect directly the interests of a member and indirectly those of his colleagues.—I am, etc.,

London, W.C.1.

ROBERT FORBES,
Secretary,
The Medical Defence Union.

Segmental Aspiration Pneumonia and Bronchiectasis

SIR,—The papers by Dr. K. D. Forgan Morle and Squadron Leader Philip W. Robertson in the *British Medical Journal* of October 27, 1951 (p. 994), and January 17 (p. 130) should be of interest to all those concerned with the care of patients after surgery. It has long been recognized that broncho-pulmonary segmental collapse not uncommonly fol-

One observation made by the authors possibly provides a useful clue to the nature of the infective element either as primary or secondary invaders. "The bronchial secretions have been found to be so thick and tenacious as to block the suction tube" (during bronchoscopy). In our

experience (Allison *et al.*)¹ this appearance of bronchial aspirations is rather characteristic of muco-pus due to the presence of *Haemophilus influenzae*, so much so that we are usually able to forecast the culture result by the appearance of the bronchial secretion. We are not alone in regarding *H. influenzae* as an important agent in bronchiectasis. Elkeles² first drew attention to the prevalence of this organism in bronchiectasis. This was confirmed in a large number of cases by Mulder³ and again later in a smaller series by Benstead.⁴ Admittedly these reports deal with fully established cases of bronchiectasis, but for precisely this reason it is of importance to determine whether *H. influenzae*, or any other organism, is predominantly present in what is so plausibly described by Drs. Morle and Robertson as the early stage. Hegglin and Grumbach⁵ described lung conditions in Swiss Servicemen similar to those seen by Drs. Morle and Robertson. Pure cultures of *H. influenzae* were a constant finding in this Swiss series. It is of some interest in this context to recall that it was suggested as long ago as 1911 by Chedini and Breccia⁶ that metabolic products of *H. influenzae* lessen to a marked degree the tone of unstriated muscle. If confirmed this would go some way towards explaining at least part of the mechanism played by the infective element in the pathogenesis of bronchiectasis.

Morle and Robertson's therapeutic suggestions must be accepted as an important part of rehabilitation, or, probably, even of prophylaxis, but a rational therapy must take all pathogenic factors into consideration. When the infective component has been more fully elucidated and appropriate antibacterial drugs will most likely come to be considered as essential as the removal of the bronchial obstruction in every single case of incipient bronchiectasis.—I am, etc.,

K. ZINNEBANN.

School Dental Service

SIR,—With reference to your annotation (January 10, p. 87), the future of the school dental service should not lightly be linked with the treatment of verminous heads. Its future development is important, and merits similar consideration to that devoted to the future of child medical care.

Like medical services, dental services for children are duplicated in the National Health Service and the local authority health service. As in medical practice, arguments are being put forward which, if carried to their logical conclusion, would result in the extinction of the family dentist. The Chief Medical Officer of the Ministry of Education (*Report for 1950-1 of the Chief Medical Officer, Ministry of Education*; H.M.S.O.) argues against "a transfer of a substantial part of the school population from the school dental service to the general dental service for treatment. . . ." He favours an expanded school service, using dental auxiliaries to fill and extract teeth.

In considering the relative effectiveness of treatment by the school service and the general dental service, one must remember the state of mind created towards having teeth filled. Many children who have been given fillings by the school service grow up to lose their teeth. In trying to find the reason for this undesirable result, one discovers other flaws in the school dental service besides that of shortage of dentists. The report recognizes a difference between the two services, saying that the "private dentist" deals with "those individuals who are sufficiently enlightened to seek his services. . . ." This explanation, however, misses an essential point. Many of those who seek the private dentist's aid are not enlightened, they are merely in pain. It is with this class of patient that the private dentist can compete with the school dental officer in winning new patients for fillings. It would be invidious for a general dental practitioner to claim more

success than a colleague in the school service, but one must record that many of to-day's extraction patients were yesterday's school service filling patients. One must conclude, having questioned hundreds of such patients, their parents, school dental officers, and school teachers, that the school service is relatively inefficient in putting over the idea of fillings.

The future role of the family dentist in winning patients for the filling of teeth must not be underestimated: plans for expansion of the school dental service which ignore the general dental practitioner should be resisted in the national interest. The refusal of the British Dental Association's offer of help for the school service is a tragic mistake. The Minister of Education's arguments are unsound. She should think again, not merely for short-term advantage, but in the long-term interests of the health of the schoolchild.—I am, etc.,

Birmingham.

C. N. JEFFRIES.

SIR,—The opposition to Brigadier R. A. Broderick's proposal (January 3, p. 43) to experiment with the training of dental nurses, contained in the letters of Dr. E. Davies-Thomas and Mr. C. N. Jeffries (January 17, pp. 162-3) must arise from a mistaken idea of the proposed function of these nurses. The proposal is to train dental nurses to do some of the more simple procedures in children's dentistry under the direction of dentists in school clinics. Much of this work is now neglected, owing to the difficulty in obtaining dentists to do it. A similar scheme has been working in New Zealand for about 30 years.

The British Dental Association has raised several objections to this scheme. First, it has been suggested that these nurses will "dilute" the dental profession. Doctors have the assistance of the nursing profession in the treatment of their patients. State-registered nurses have a three-year training which equips them to treat patients by difficult and potentially dangerous procedures. No one would suggest that they dilute the medical profession, or that their use is in any way harmful to the patient's or the doctor's interests. It is hard to see why dental nurses should be considered a menace. The second objection raised is the lack of trained teachers for the dental nurses. At the outset of the scheme, when the numbers to be trained would be small, this difficulty could be overcome. After that time sister tutors could be trained in teaching duties as is done in the nursing profession. Thirdly, the British Dental Association is concerned that the practising life of dental nurses would be short, owing to domestic wastage. This objection surely applies to any training for women who do not take vows of celibacy before starting their careers.

As an alternative to this scheme the British Dental Association suggests that more dentists be trained for this work. At the present time this is impracticable, but in any case it is uneconomical to employ a person with five years' training when the work can be equally well done by personnel whose training has been limited to more simple tasks. The practising dentist would benefit from this scheme in that it would increase the demand for comprehensive treatment in the adult. If children have the opportunity to receive regular treatment and education in dental hygiene at school, they are encouraged to try to keep their mouths sound and clean throughout their lives. This early training is possibly better done by an enthusiastic dental nurse than a dentist, conscious in many cases that the work he is doing does not match his capabilities.—I am, etc.,

Medical Care of the Schoolchild

SIR,—The picture which you draw in an annotation (January 10, p. 87) is so different from that known to myself that I wonder what is your conception of this service. I would be interested to know what provision you would make in your proposals, to mention only a few

claim only slight experience, is a procedure which removes the obstruction at one operation and thus provides adequate drainage for an obstructed and infected urinary tract.—I am, etc.,

Glasgow.

JAMES H. LEVACK.

Intestinal Microflora

SIR,—My letter (December 6, 1952, p. 1257) regarding kwashiorkor was necessarily brief and to the point, so much so that it was too subtle for some and misread by others. I wanted to put forward the idea of the role of intestinal microflora as a dynamic part of the nutrition of the human body and that it was not only the biosynthesis of the B group of vitamins, but also other metabolic activities, that took place in the gut.

Laboratory studies of bacterial metabolism show that growth factors are the main or side products, and aerobic organisms can be used in submerged culture processes to produce many organic substances by fermentation. Commercial work on streptomycin has shown that when its manufacture is stepped up large amounts of vitamin B₁₂ are produced in the substrate. Clinically it has been shown that aureomycin will produce vitamin-B deficiencies by the killing of the intestinal microflora; and in the treatment of some of the vitamin-B lesions with large doses of multiple vitamin-B concentrate the lesions may not all disappear, but some will be further activated or unmasked (vitamin-B shift). It is not only the B group of vitamins that share in the biosynthesis in the gut, but other factors may enter into the picture for the true origin and maintenance of a suitable intestinal microflora. It was because of this that I pointed out that, in the absence of a suitable diet *ab initio*, the failure to take in meat and meat products meant the failure of a suitable type of intestinal microflora to flourish in the first place. The ingestion of large amounts of vegetable protein in a gut not properly conditioned would eventually work out right, but could work better under more suitable circumstances—i.e., a more receptive intestinal microflora.

It is suggested that many conditions relating to nutritional pathology may be explained on the basis of an aberration of the intestinal microflora, so that the various types of pernicious anaemia could be explained on this basis. The differential absorption of iron, with complete failure of absorption in some people, may also be explained on this basis, and so on.—I am, etc.,

Watford.

CHARLES ROTMAN.

In Remembrance of Mr. Philip Mitchiner

SIR,—In view of Mr. Philip Mitchiner's known dislike of funeral flowers, and his great interest in the Royal Medical Benevolent Fund, it was suggested that donations to this charity would have pleased him. The Committee of the Fund would like it to be known that the sum of £163 was contributed, and many letters expressing affection and respect were received. The Committee desires to thank all his friends who joined in this remembrance of a well-loved and honoured man.—I am, etc.,

London, S.W.15.

E. C. PENNEFATHER,
Secretary, Royal Medical
Benevolent Fund.

POINTS FROM LETTERS

The Catheter and the Prostate

Mr. WALTER McC. SCOTT (London, W.2) writes: Having read the correspondence on this subject (January 24, p. 216), I would like to suggest that perhaps the best view is to fit the treatment and operation to the patient rather than the patient to them; and that "the art" lies in selecting the right one for each.

Collection of Blood

Dr. P. M. VICARY (Littlestone, Kent) writes: May I add yet one more point in the correspondence on collection of blood? Before inflating the already applied cuff of the sphygmomanometer, ask the patient to put the arm down as near the floor as possible. Inflate the cuff after a minute in this position and then elevate the arm to the position for venepuncture. One word of warning: Hold on to your sphygmomanometer.

Obituary

G. D. HALE CARPENTER, M.B.E., D.M.

Professor G. D. Hale Carpenter, professor emeritus of zoology (entomology) in the University of Oxford, died at the Radcliffe Infirmary on January 30 at the age of 70 after a long illness.

Geoffrey Douglas Hale Carpenter was born on October 26, 1882, and came of a distinguished academic family; both his father and his grandfather were doctors of science and Fellows of the Royal Society. He had the rare privilege of being born in Eton College, where his father was an assistant master and his mother the daughter of another. He was educated at the Dragon School (Lynam's), Bradfield College, and St. Catherine's, Oxford, graduating B.A., with a second-class in his final examination, in 1904, and then passing with a University Entrance Scholarship to St. George's Hospital. He qualified M.R.C.S., L.R.C.P. in 1908, taking the degrees of B.M., B.Ch. in the same year, and he proceeded to the D.M. five years later. After qualification he held the appointments of house-surgeon and house-physician at St. George's Hospital.

From his earliest preparatory-school days Hale Carpenter displayed a keen interest in natural history, and he came to know the plants, birds, snails, and insects of the Oxford district exceedingly well. The ground was thus well prepared for his future activities, and when as a young student he attended his first lecture on insect-borne diseases the effect was profound. He decided forthwith that that was the field for him, and in 1910 he entered the Colonial Medical Service.

At the close of the nineteenth century sleeping sickness, which had hitherto been confined to the west coast of Africa, appeared in Uganda and spread with such terrible rapidity around the shores of the great lake, Victoria Nyanza, and among the dense population of the islands in the lake that over 200,000 natives died within a few years. To study the disease the Royal Society appointed a commission, which came to the conclusion that the control of sleeping sickness demanded a greater knowledge of the bionomics of the tsetse fly, *Glossina palpalis*, and Hale Carpenter was engaged for the work, taking up his residence in the Sesse Islands, in the north-west part of the lake, in February, 1911. The results of his investigations appeared in the *Reports of the Sleeping Sickness Commission of the Royal Society* (1912, 1913, and 1919), and were presented in another form as a dissertation for his degree of doctor of medicine at Oxford.

The war of 1914-18 caused him to be withdrawn from tsetse research, and he served as a captain with the Uganda Medical Service, being constantly moved about from post to post waiting for the casualties that never came. As he said in the preface to his book, *A Naturalist in East Africa* (1925), which dealt with the war years, "Many long periods of what would otherwise have been 'excessive boredom' were relieved by the pursuits of a naturalist, and, indeed, it was only the interest of these pursuits that made life possible." So it was he studied and collected insects of all kinds, paying special attention to the phenomena of mimicry, polymorphism, and matters of evolutionary interest and keeping up a correspondence about his work with the late Sir Edward Poulton, of Oxford. For his services

in the war he was appointed M.B.E. in 1918. After the war he was specialist officer for the control of sleeping sickness in Uganda until he retired from the Colonial Medical Service in 1930, but he undertook a special investigation into tsetse fly in Ngamiland at the request of the Secretary of State for the Colonies in 1930-1.

On returning to England, Hale Carpenter built a house on Cumnor Hill, within easy cycling distance of the Oxford University Museum, which housed in the Hope Department of Entomology so many of his African specimens. For a year or two he visited the department daily, studying and identifying his collections and assisting Sir Edward Poulton, whose disciple he had been for so long. When Sir Edward retired in 1933 Hale Carpenter succeeded him as Hope professor, occupying the chair until 1948, when he retired on reaching the conage limit. The title of emeritus professor was then conferred upon him. During the period he was professor he continued his studies on mimicry, geographical distribution, and evolution, and he did all he could to make his department more useful, finally appealing to the University for a new building and for a greatly increased staff.

During the last war Hale Carpenter lectured on tropical medicine and camouflage to the troops in training near Oxford, and he prepared special booklets for the African campaigns, besides serving as head warden of the air-raid precautions service for the Cumnor district. He was keenly interested in the Linnean, Zoological, and Royal Societies, and was a frequent attendee and speaker at their meetings in London, serving as vice-president of the Linnean in 1935-6 and as president of the Royal Entomological Society in 1945-6. His monumental study of *Euploea*, a genus of butterflies ranging widely across the Pacific, was completed shortly before his death, and is to appear in the *Transactions of the Zoological Society of London*. His other writings included *A Naturalist on Lake Victoria* (1920) and *Mimicry* (1933), as well as numerous technical publications.

Hale Carpenter was a tall, good-looking man, with white hair, easy of address, and with a keen sense of humour. His recreations included boating on the Cher-humour. His recreations included boating on the Cher-humour. He took a prominent part in the well and gardening. He took a prominent part in the church life of Cumnor. The funeral service was held in the chapel of Jesus College, Oxford, where he was a Fellow from 1933 to 1948. He married in 1919 Amy Frances Thomas-Peter, of Treviles, Cornwall, who survives him. There were no children.—B. M. H.

JOSIAH OLDFIELD, D.C.L., M.R.C.S.

Dr. Josiah Oldfield, who died on February 2 at the age of 89, was a reformer of the old school, vigorous in the advocacy of the many causes he had at heart.

Josiah Oldfield was born at Shrewsbury on February 28, 1863. From Newport (Salop) Grammar School he went on to Oxford, where he gained second-class honours in theology and civil law. After being called to the Bar by Lincoln's Inn, he practised for a time on the Oxford circuit. He then decided to study medicine at St. Bartholomew's Hospital Medical School, qualifying in 1897. He never lost his interest in the law, however, and in 1901 Oxford awarded him a doctorate in civil law for his thesis on capital punishment. In the same year he founded the Society for the Abolition of Capital Punishment, and also went out to India to see for himself how the people of India lived and what substance there was in their grievances.

While a student at Oxford Oldfield came to the conclusion that meat-eating was unnecessary, and after qualifying as a doctor he became warden and senior physician to the Lady Margaret Fruitarian Hospital, Sittingbourne. His views as a medical man undoubtedly added weight to those of other advocates of dietary reform, G. B. Shaw included. During the first world war Oldfield held a commission as a Territorial in the R.A.M.C. and commanded a field ambulance. He was mentioned in dispatches and awarded the Territorial Decoration. After the war he returned to his hospital and private practice, describing himself in a book of reference as a consultant in diseases of digestion and resulting neuroses. He wrote numerous books, mainly on dietetics, for the instruction of the lay public, and he also addressed meetings up and down the country. He died after a short illness; increasing age did not prevent him from continuing the work he considered so important. He leaves a daughter, Dr. Josie M. Oldfield.

The death at a comparatively early age of Dr. HARRIET E. ACHESON, formerly professor of obstetrics and gynaecology at the Lady Hardinge Medical College, New Delhi, at Glenavy, County Antrim, on January 21, will be a matter of regret to the many who knew her in India. Harriet Elizabeth Acheson was born in Ulster, the daughter of the late John Acheson, of Portadown, and studied medicine at the Royal Free Hospital School of Medicine for Women, qualifying M.R.C.S., L.R.C.P. in 1924. She graduated M.B., B.S. at the University of London in the following year and proceeded M.D. in 1931. Dr. Acheson went to India in 1926 to join the Women's Medical Service there, and served in several of the smaller hospitals. Her professional ability and her kindly disposition stood her in good stead, and her last appointment of a general nature was at the Aitchison Hospital, Lahore, one of the biggest hospitals staffed by the Women's Medical Service. In 1938 she was appointed professor of obstetrics and gynaecology at the Lady Hardinge Medical College. She hesitated before accepting that onerous position because, although she wished to specialize, she did not really care to give up the freedom which being in sole charge allowed. However, specialization won the day, and Dr. Acheson was very successful in the College. Many students, house-surgeons, and assistants owe her much for her careful and patient teaching and for her personal interest in their welfare. She remained at the College until the partition of India in 1947, and her retirement then was much regretted. For her services she was appointed O.B.E. in 1948. Dr. Acheson had an artistic side which she developed in the latter years of her service in India and after retirement. Sketching in water colours was not a mere hobby but a matter of self-expression which gave her great satisfaction.—R. Y.

Dr. A. S. WHITEHEAD, consultant radiologist to hospitals in the Liverpool and District Eastern Hospital Group, died at his home on February 2, at the early age of 36. Alan Stuart Whitehead was born on October 11, 1916, and was educated at King George V School, Southport, and at the University of Liverpool, where he graduated M.B., Ch.B. in 1941, being awarded the clinical exhibition in medicine. He had proceeded M.D. only last year. After graduation, Dr. Whitehead acted as house-surgeon and house-physician at the Emergency Hospital, Southport, and then entered the R.A.M.C. Owing to ill-health he was obliged to relinquish his commission in 1944. He then spent a short time in general practice until in 1947-8 he took the postgraduate course in radiology at the University of Liverpool, obtaining the degree of M.Rad. as well as the diploma of D.M.R.D. of the Royal Colleges in 1949. He served as registrar in the Royal Liverpool United Hospitals in 1948-9.

and later became senior registrar at Broadgreen Hospital and Mill Road Maternity Hospital. In 1951 he was appointed assistant radiologist to the Liverpool and District Eastern Hospital Group, and finally, in October, 1952, consultant radiologist to Mill Road Maternity Hospital, Newsham General Hospital, and Bootle General Hospital. He leaves a widow and two children.

We are indebted to Dr. P. H. WHITAKER for the following appreciation: Whitehead was an exceptionally able student who did very well in his final examination, as was shown by the award of the clinical exhibition in medicine. During the war he acquitted himself well, and later, when he took up radiology, he was one of the outstanding students of his year, proving that radiology was, in fact, the specialty for which he was most suited. His rapid promotion to consultant status was further evidence of his considerable ability, particularly as during that time he had published papers on congenital toxoplasmosis, radiological double contour effect, and placentography. At the recent annual meeting of the British Institute of Radiology he took part in the discussion on placentography. His advice was continually sought by his colleagues on all matters pertaining to radiology, and they thought very highly of his opinion, which was most willingly given. Since his work was of such a specialized nature we invited him to help us with the postgraduate course in radiology. He gave freely of his time to the teaching of the students, and we could always rely on him to help with additional work. He will be greatly missed by all his colleagues in hospital and by the students. It is tragic that so young a life should be cut short at the commencement of what must have been a very promising career.

Medical Notes in Parliament

WELFARE OF FLOOD VICTIMS

The disaster which storm and flood inflicted on the east and south-east coasts on January 31 has been a major pre-occupation of Ministers and Members since the Prime Minister first promised the House on February 2 that everything in human power would be done to repair the sea defences and alleviate distress. The progress on health and welfare provisions is recorded in the following statements.

On February 3 the Home Secretary, as chairman of the committee of Ministers set up to control operations, stated that some 30,000 people were believed to have left their homes, of whom some 6,000 were in rest centres. Except in a few cases such essential services as gas, electricity, water, and fuel were working, and food supplies were adequate.

The next day he had to say that the breaches in the sea defences were so extensive that it would not be possible to complete the repair work before the next high tides on February 14. Although everything possible would be done, the country must be prepared for the possibility of further flooding in some areas. To prevent further loss of life, and to minimize the risk of disease, residents who had had to leave their homes should satisfy themselves by local inquiries that it would be safe for them to return before they did so.

Requisitioning

Discussion was inflamed by controversy over a proposal to requisition 20 houses in Erith.

Mr. H. MACMILLAN, Minister of Housing and Local Government, made a statement on welfare in which he sought to settle the dispute over requisitioning. He pointed out that the responsibility for welfare and first-aid relief rested with the county and county borough councils, under the general direction of the Ministry of Health. The Minister had no hesitation in permitting those authorities to requisition such property as they felt most convenient to perform their task.

After first aid came the stage of convalescence and rehabilitation. The Minister of Health and he were already considering the dispersal of those in the rest centres. If for this purpose he felt it necessary to authorize the requisitioning of empty houses he would do so, but in that case the authority concerned would be the housing authority—county boroughs and district councils—who were responsible for long-term housing as distinct from the short-term welfare problem.

Health Good

Sir DAVID MAXWELL FYFE had more to say about dispersal from rest centres on February 5. As rehousing became possible furniture would be required, and arrangements had been made to store in a Government depot at Royston any gifts of furniture made by the public. He assured the House, on the authority of the Minister of Health, that the state of public health in the flooded areas gave them no cause for anxiety, although it was being closely watched.

Mr. N. W. DODDS returned to the question of requisitioning, and said that the Kent county medical officer of health was pressing the Ministry of Housing and Local Government to grant the request of the Erith Borough Council to requisition houses. The HOME SECRETARY replied that it was a health matter and the Minister of Health would do what he considered necessary. He had been in touch with the county medical officer, who had advised him that he was satisfied that for the time being arrangements were adequate, and he would not press the local authority on health grounds to clear the rest centres. The clearance of rest centres, the Home Secretary added, must be considered with the greatest urgency.

Mr. T. C. PANNELL referred to experience in the blitz that after 48 hours people wanted to get home again, and that public morale fell if they could not. The idea in Erith that the rest centres should be kept open for a fortnight or three weeks, with 70 people sleeping in a room, was not the sort of situation that the local people envisaged. He pressed again that the county medical officer's request should be considered on welfare grounds. To this the HOME SECRETARY replied that there were less than 3,000 people in rest centres. But he agreed that that, while reassuring, was no reason for stopping the urgent consideration he had promised.

Lodging Allowance

The first decision on billeting was announced by Mr. MACMILLAN on February 6. It was that the Government had decided as an immediate short-term measure to pay a lodging allowance, without applying any form of means test, to householders affording shelter to victims of the flood.

Specialists on Tribunals

Mr. J. T. PRICE asked the Minister of National Insurance on February 2 if in cases of industrial dermatitis referred to medical appeal tribunals adjudicators were in all cases qualified dermatologists. Mr. R. H. TURTON, the Parliamentary Secretary, said they were not, and he could not accept the suggestion that tribunals should always include specialists in the particular condition from which an appellant might be suffering. In a case of dermatitis the evidence before the tribunal always included a report by a dermatologist. There was general satisfaction with the decisions of the tribunals, which consisted of physicians of great eminence. To adopt the suggestion of Mr. Price would involve great delay.

Female Mortality in Scotland

Mr. HECTOR HUGHES on February 3 asked the Secretary of State for Scotland if he was aware that in Scotland the death rate for young women was higher than the death rate for young men; that Scotland was the only country in Europe where this was so; if he would state the reason for this disparity; and what he would do to reduce the high mortality among young women.

Commander W. W. GALBRAITH said he was aware that for the 15 to 35 age group in Scotland, contrary to the usual experience elsewhere in Europe, the female death rate was higher than the male death rate in the years 1948-50. This was due to an excess of female deaths from respiratory tuberculosis. With the greatly reduced tuberculosis mortality in 1951, the latest year for which detailed figures were available, the female death rate fell below the male rate.

Mr. H. HUGHES and Major W. J. ANSTRUTHER-GRAY questioned the Under-Secretary about the disparity between the tuberculosis death rate among women in this age group in England and Scotland.

Commander GALBRAITH informed them that the death rate from respiratory tuberculosis among women between 15 and 35 years of age in Scotland had fallen from 149 per 100,000 in 1948 to 56 in 1951. The corresponding rates for England and Wales were 68 and 28. The precise reasons for the continuing disparity between the two countries were not known, but he saw no reason why the measures taken in recent years to combat the disease should not result in this disparity being further reduced in the near future.

Tuberculosis and Housing

Mrs. JEAN MANN asked for information about the living accommodation density in England and Scotland, and Commander W. W. GALBRAITH stated that according to the 1% sample tables of the 1951 census the number of persons per room in Scotland was 1.04 (compared with 1.27 in 1931) and in England and Wales 0.73 (compared with 0.83 in 1931). Mrs. MANN asked if this was related to the disparity in the tuberculosis rate, and Commander GALBRAITH agreed that it might be.

Flour for Bread

Major G. LLOYD-GEORGE, Minister of Food, rejected a request by Dr. BARNET STROSS on February 4 that the addition of chalk to flour used for bread should be discontinued.

Vaccination of Troops

Mr. N. BIRCH, Parliamentary Secretary to the Ministry of Defence, assured Mr. C. R. HOBSON on February 4 that of British soldiers, sailors, and airmen to refuse the right of vaccination had been maintained in respect of troops in Korea serving under United Nations command.

Dogs and Disease

Sir WILLIAM DARLING asked on February 5 whether domestic dogs were known to be carriers of disease. Miss PAT HORNSBY-SMITH told him that the Minister of Health was advised there was little evidence that domestic dogs were commonly responsible for any human disease in this country.

Vital Statistics

Poliomyelitis and the Weather

Drs. W. H. Bradley and A. E. Richmond have explored the hypotheses that meteorological conditions govern the rise and fall of the incidence of poliomyelitis, that fluctuations in weather affect the trend of the incidence during an outbreak, and that the total weather conditions affect the size of the epidemic. The criteria used for the meteorological conditions were dry-bulb temperature and vapour pressure. Since the incidence begins to rise in early June it seems that a certain minimum temperature and humidity are necessary for the spread of infection, but "beyond this it has not been possible to correlate the incidence with any specific meteorological factor." The beginning of the seasonal fall does not appear to be related to temperature and humidity. Variations in temperature and humidity during an outbreak do not seem to have any effect on

¹ Monthly Bull. Minist. Hlth (Lond.), January, 1953.

the course of the epidemic. There is a very slight suggestion that the years with below-average temperature and humidity are associated with the lowest incidence of poliomyelitis.

Decennial Supplement, 1931

Statistics of births, deaths, marriages, and population in the period 1921-30 are given in Part III of the *Decennial Supplement* for 1931 just issued by the Registrar-General for England and Wales. Since the events recorded happened more than 20 years ago, the Registrar-General has understandably omitted the customary commentary on them: the volume is issued "to complete the historical record and for the more efficient study of long-term demographic events in England and Wales."

Influenza

In the week ending January 31 there were 313 deaths from influenza in the great towns of England and Wales, compared with 132 in the preceding week. In London and the south-eastern region there were 219 deaths, while in Greater London as a whole there were 170. Elsewhere, only in East Anglia has there been any considerable relative increase in deaths—from 3 to 25. Other regions of England and Wales continue to remain free from any widespread outbreak of the disease. The number of deaths in the great towns since the first week of the year is 568, as compared with 157 in the corresponding period of 1952 and 4,959 in 1951.

In the past week it is on the older members of the population that the illness has fallen most heavily. Of the total deaths, 283 have been in those aged 55 and over, 133 being in those over 74. Most cases are due to the "Scandinavian" strain of virus A-prime, though there have been reports of the presence of virus B in certain areas.

Week Ending January 31

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,850, whooping-cough 2,799, diphtheria 24, measles 26,460, acute poliomyelitis 29, dysentery 435, paratyphoid fever 7, and typhoid fever 1.

Infectious Diseases

Infectious diseases were more prevalent in England and Wales during the week ending January 24. The rises in the number of notifications included 632 for whooping-cough, from 2,160 to 2,792; 499 for measles, from 21,383 to 21,882; 243 for scarlet fever, from 1,589 to 1,832; 145 for acute pneumonia, from 1,204 to 1,349; and 107 for dysentery, from 312 to 419.

The largest rises in the number of notifications of measles were Derbyshire 255, from 464 to 719; Southampton County 201, from 1,767 to 1,968; Surrey 134, from 551 to 685; and the largest falls were London 356, from 1,777 to 1,421; Essex 349, from 1,810 to 1,461; and Yorkshire West Riding 338, from 1,520 to 1,182. Small increases in the incidence of whooping-cough were recorded throughout the country; the largest were Lancashire 133, from 483 to 616, and London 44, from 99 to 143. The only rise of any size in the number of notifications of scarlet fever was 38 in London, from 65 to 103. 19 cases of diphtheria were notified, 7 more than in the preceding week. The chief feature of the returns of diphtheria was a rise from 2 to 6 in Warwickshire, where all the cases were notified in Birmingham C.B.

During the week 38 cases of acute poliomyelitis were notified; these were 10 fewer for paralytic and 3 more for non-paralytic than in the preceding week. The largest returns were 3 in Surrey and in Yorkshire West Riding.

The chief centres of infection for dysentery were Essex 86 (East Ham C.B. 79), Lancashire 69 (Liverpool C.B. 18, Preston R.D. 13), Lincolnshire 44 (Grimsby C.B. 44), London 33 (St. Pancras 14), Kent 33 (Penge U.D. 9), Yorkshire East Riding 28 (Kingston-upon-Hull C.B. 27), and Yorkshire West Riding 25 (Barnsley C.B. 8).

132 deaths were attributed to influenza in the great towns, 60 more than in the preceding week; 94 of these deaths were registered in London and the South.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1943-51 are shown thus -----, the figures for 1952-3 thus ———. Except for the curves showing notifications in 1952-3, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 24 (No. 3) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

Hospital Endowments (Scotland) Bill.—A Bill providing for the establishment of a Scottish Hospital Endowments Research Trust was introduced in the House of Lords last week. The Trust is to "receive and administer part of the endowments of former voluntary hospitals on trust for the purpose of assisting the conduct of medical research." The Trust will also have power to accept new gifts or legacies. The arguments in favour of this move are given in a memorandum by the Hospital Endowments Commission which was published last July as a White Paper (Cmd. 8615). From this it appears that the annual income of the Trust will be about £120,000.

Beit Centenary.—Alfred Beit, financier and philanthropist, was born at Hamburg on February 15, 1853. As a young man he went to Kimberley, where he set up on his own as a diamond merchant. He had success and became the intimate friend of Cecil Rhodes and Starr Jameson. By the time of his death in 1906 Beit had amassed a fortune. Although much of this was left to members of his family, his public benefactions amounted to £2,000,000. King Edward's Hospital Fund and Guy's Hospital were each left £20,000. A scheme for an institute of medical sciences, for which Beit had bequeathed £50,000, was abandoned, but in December, 1909, his brother Otto increased the amount to £215,000 and founded the Alfred Beit memorial fund for medical research. The first list of awards, made in March, 1910, included the names of Thomas Lewis, F. W. Edridge-Green, Sidney Russ, and Edward Mellanby.

How Children Develop.—An ambitious study of the physical and mental development of normal children, from birth until the end of adolescence, is being carried out by the Child Study Research, a joint organization of the Institutes of Child Health and Education of London University. After a pilot study of 23 infants the main project began in the summer of 1951. Now there are about 100 infants being regularly examined in their homes as well as at the Child Study Centre (Coram's Garden, Brunswick Square, London, W.C.1). It is hoped gradually to increase the number to a total of 250. Each time a mother visits the centre she reports on her child's progress, her own training methods, and the first appearance of signs of temperament and personality in her offspring. Her report is checked by tests and observations on the child, who also has a full physical examination including anthropometric measurements, a radiograph of the wrist, etc. Later on these records and observations will be correlated with school progress.

Walkie-Talkie Ambulances.—The Health Department of Kingston-upon-Hull has equipped some of its ambulances with radio-telephones. The ambulances are deployed at various points in the City away from their station, so that local calls can be dealt with more promptly. The points selected for deployment are not necessarily the same on each occasion. Account is taken of peak traffic periods or other circumstances which may warrant special coverage. It is also found that some parts of the city are particularly favourable for radio transmission and reception. The scheme is working well and has eliminated delays caused by traffic congestion.

A.C.T.H. Factory.—Armour Laboratories, whose American laboratories played such a prominent part in the development of A.C.T.H., are to build a laboratory in this country for the production of their long-acting brand of A.C.T.H. "acthar gel." On February 6 the Mayor of Eastbourne laid the foundation of the new laboratory at Hampton Park, Eastbourne. Large-scale production of the hormone is expected to start early next year.

Westminster Abbey Appeal.—The Dean and Chapter of Westminster are appealing for a million pounds to restore the Abbey. Many famous men of medicine and science are commemorated there, and it is felt that doctors will wish to support the appeal generously. Contributions should be sent to the Dean of Westminster, c/o Barclay's Bank Ltd., Abbey House, London, S.W.1.

B.M.J.s for Korea.—Korean doctors have expressed a keen desire to read about modern British medicine, and would be grateful to receive used copies of the *B.M.J.* or the Association's special quarterly journals. Readers who have finished with their journals, and would like them to go to Korea, should send them to Chungchong Namdo Medical Association, c/o Dr. L. N. Yhap, U.N.K.R.A., Pusan, Korea, B.A.P.O. 3. After circulation in Korea the journals will be placed in the library of the Union Medical College, which comprises the Seoul Medical, the Seoul Women's Medical, and the Ewha Medical Colleges.

Nursing on Television.—A television documentary programme entitled "Under Her Skilled Hand" was transmitted on February 4. The story, by Dr. Cormac Swan, assistant editor of *Family Doctor*, told of the preliminary interview of a prospective nurse, her classroom training, introduction to ward work in a general hospital, and her final emergence as a fully qualified nurse. The authentic scenes and dialogue and the excellent acting must have had a good effect on anyone considering taking up nursing as a profession.

The Horder Club was formed about six years ago to honour Lord Horder and his work in connexion with the rheumatic diseases. It is composed of a group representing many of the facets of the study of rheumatic diseases. The Club met on January 29 and discussed a film shown by Dr. Campbell Golding on radiography in rheumatoid arthritis.

Dr. E. C. Ellis and Mr. Hugh Owen Jones have received letters of commendation from the Minister of Fuel and Power, Mr. Geoffrey Lloyd, for their part in the successful treatment of 20 miners burnt in an explosion at Bedwas Colliery, Monmouthshire, last October. After expressing admiration for their work, Mr. Lloyd goes on to say that "the saving of the lives of so many casualties from such extensive burning injuries is quite unprecedented in the mining world."

Dr. Cyril Darlington, F.R.S., director of the John Innes Horticultural Institution, has been appointed Sherardian Professor of Botany at Oxford.

Dr. W. G. Penfield, O.M., professor of neurosurgery at McGill University, will receive the honorary degree of doctor of civil law at the Rhodes centenary celebrations at Oxford next July. Dr. Penfield was himself a Rhodes Scholar.

Dr. P. D. White, the well-known Boston cardiologist, has gained a Lasker award for "distinguished achievement in the field of cardiovascular diseases." He was given a golden statuette of the Winged Victory of Samothrace and \$1,000.

Dr. William Pickles is leaving England on February 26 for South Africa, where he will give a series of lectures at the invitation of Dr. T. B. Davie, Principal and Vice-Chancellor of the University of Capetown.

Emergency Bed Service: Applications and Admissions.—During the seven days ending February 9 the number of applications made by doctors to the London Emergency Bed Service for admission of patients was 1,992, of whom 79.58% were admitted. A yellow warning indicating that the percentage of admissions fell below 80 was issued on February 10.

COMING EVENTS

Medical Librarianship.—The First International Congress on Medical Librarianship is to be held in London in July under the presidency of Sir Cecil Wakeley. There will be symposia on the education and training of medical librarians, the organization of new medical libraries, and international co-operation. A full programme of visits to medical libraries and institutions has also been arranged. Further information may be obtained from the honorary secretaries of the Congress, London School of Hygiene, Keppel Street, London, W.C.1.

British Association of Sport and Medicine.—The first annual general meeting of the British Association of Sport and Medicine will be held in the Meyerstein Theatre of the Westminster Hospital Medical School, London, S.W.1, at 5 p.m. on Friday, February 27. Sir Adolphe Abrahams will speak on the policy of the association, and all registered medical practitioners who are interested in the medical aspects of sport will be welcome. Further information may be obtained from the Hon. Secretary, c/o The British Olympic Association, 95, Mount Street, London, W.1.

Postgraduate Symposium on Dermatology.—The next of the monthly symposia for general practitioners arranged by the Cambridge University Medical School is to be held at Addenbrooke's Hospital, Cambridge, on Saturday, February 28, the subject for discussion being dermatology. The symposium is open, without fee, to medical practitioners whose names are on the National Health Service list, and those wishing to attend are asked to notify the Secretary, Cambridge University Medical School, The Naval Hut, Downing College, Cambridge, not later than February 21.

NEW ISSUES

Journal of Clinical Pathology.—The next issue (Vol. 6, No. 1) will be available in a week's time. The contents include:

- A THROMBIN GENERATION TEST. R. G. Macfarlane and Rosemary Biggs.
- A SIMPLE METHOD OF STUDYING THE GENERATION OF THROMBIN IN RECALCIFIED PLASMA. W. R. Pitney and J. V. Dacie.
- THE MEASUREMENT OF PROTHROMBIN IN PLASMA. Rosemary Biggs and A. S. Douglas.
- THE THROMBOPLASTIN GENERATION TEST. Rosemary Biggs and A. S. Douglas.
- PSEUDO-HAEMOPHILIA: AN ACQUIRED HAEMORRHAGIC DIATHESIS DUE TO A CIRCULATING ANTICOAGULANT. C. Houglic.
- A MODIFICATION FOR ROUTINE LABORATORY USE OF STEFANINI'S METHOD OF ESTIMATING FACTOR V ACTIVITY IN HUMAN OXALATED PLASMA. Peter Wolf.
- THE ESTIMATION OF HEPARIN IN BLOOD. M. Bassiouni.
- TRANSFUSIONS OF SUSPENSIONS OF BLOOD PLATELETS IN THROMBOCYTOPENIA AND THROMBOPATHIA. S. van Grevel, M. M. P. Paulsen, H. L. J. M. Bartels, and R. Vonk.
- LABORATORY TESTS FOR IMPICIENT THROMBOSIS. G. I. C. Ingram, Rosemary Biggs, and P. Amlidge.
- A THIRD EXAMPLE OF THE BLOOD GROUP ANTIBODY ANTI-K. Hal Crawford.
- VITAMIN B₁₂ CONCENTRATIONS OF SERUM AND URINE IN THE FIRST 72 HOURS AFTER INTRAMUSCULAR INJECTIONS OF THE VITAMIN. D. L. Mollin and G. I. M. Ross.
- ANTIBODY FORMATION IN MYELOMATOSIS. J. Marks.
- THE MIDDLEBROOK-DUBOS HAEMAGGLUTINATION TEST AND ITS HAEMOLYTIC MODIFICATION IN THE DIAGNOSIS OF TUBERCULOSIS. J. C. Sherris.
- AN INVESTIGATION INTO THE DETERMINATION OF CORTICOSTEROIDS IN URINE. S. L. Tompsett.
- A STUDY OF BARBITURATE INTOXICATION BY AN ULTRA-VIOLET SPECTROPHOTOMETRIC TECHNIQUE. J. T. Wright and R. G. S. Johns.
- LUNG BIOPSY IN MITRAL STENOSIS. J. B. Ericknap.
- TECHNICAL METHODS:
 - A SIMPLE METHOD FOR THE DETECTION OF L.E. CELLS. R. H. Marten and E. K. Blackburn.
 - AN ELECTRICAL COLONY COUNTER. W. D. Linsell.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

Details in this column are necessarily brief. Further information and tickets where required (marked ●) should be obtained from the institution concerned.

Monday, February 16

UNIVERSITY COLLEGE.—At Physiology Theatre, 5.30 p.m., Dr. T. S. Work: Biosynthesis of Proteins.

Tuesday, February 17

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. J. C. White: Human Haemoglobins and Derived Pigments.

CAERNARVONSHIRE AND ANGLESEY PEDIATRIC CLUB.—At Clinic, Sackville Road, Bangor, 4.30 p.m., Mr. A. Sutcliffe Kerr: Neurosurgery in Childhood.

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. W. J. O'Donovan: Hysteria Cutis.

MIDDLESEX COUNTY MEDICAL SOCIETY.—At North Middlesex Hospital, 3 p.m., clinical meeting.

●SOCIETY FOR THE STUDY OF ADDICTION.—At Meyerstein Lecture Theatre, Westminster Hospital Medical School, 5 p.m., Fifth Kelyack Memorial Lecture by Professor E. M. Jellinek: International Aspects of Alcoholism.

WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Dr. D. Gordon: Neuro-radiological demonstration.

Wednesday, February 18

EUGENICS SOCIETY.—At 26, Portland Place, W., 5 p.m., Galton Lecture by Professor T. H. Marshall, M.A.: Social Selection in the Welfare State.

HARVEIAN SOCIETY OF LONDON.—At St. Mary's Hospital, Paddington, W., 5.30 p.m., clinical meeting.

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Diseases.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, W.C., 4.30 for 5 p.m., Mr. D. I. Williams: Spina Bifida and Incontinence.

MIDLAND MEDICAL SOCIETY.—At Queen Elizabeth Hospital, Birmingham, 8.15 p.m., clinical meeting.

OXFORD UNIVERSITY.—At Radcliffe Infirmary, 5 p.m., Litchfield Lecture by Professor Dugald Baird: Some Epidemiological Aspects of Obstetrics.

SCHOOL OF PHARMACY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Charter Lecture by Sir Henry Dale, O.M., F.R.S.: Future of Pharmacy and Pharmacology.

Thursday, February 19

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., Professor R. McWhirter: Radiotherapeutic Technique in Breast Carcinoma.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Sir Alan Drury, F.R.S.: Uses and Applications of Human Blood Plasma Fractions.

EDINBURGH CLINICAL CLUB.—At B.M.A. Scottish House, 8 p.m., Dr. W. F. T. Haultain: Some Problems in the Conduct of Abnormal Midwifery in General Practice.

GLASGOW UNIVERSITY MEDICO-SURGICAL SOCIETY.—At Glasgow University Union, 7.30 p.m., Dr. A. Sessor: Experimental Salt Depletion.

●INSTITUTE OF CHILD HEALTH.—5 p.m., Dr. D. V. Hubble: The Thin Child.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Dr. J. Berkson: Oxygen, the Premature Baby and Retrolental Fibroplasia; Mr. A. S. Kerr: Unilateral Proptosis.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At 11, Chandos Street, W., 8.30 p.m., Mr. S. M. Cohen: Place of Sympathectomy Procedures.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor J. E. Richardson: Early Renal Symptoms of Parathyroid Tumour.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., Dr. M. A. C. Dowling: Malaria Eradication Experiment in Mauritius.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor J. Crighton Bramwell: Normal Heart.

UNIVERSITY COLLEGE.—At Physiology Theatre, 4.45 p.m., public lecture by Professor V. B. Wigglesworth, F.R.S.: Chemical Aspects of Insect Physiology.

Friday, February 20

BIRKENHEAD MEDICAL SOCIETY.—At Borough General Hospital, 8.30 p.m., Dr. S. G. James: Some Aspects of Mental Disorder and Crime.

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members: 6.30 p.m., Mr. A. Nemet, M.I.E.E., F.Inst.P., and Mr. W. B. Cox, B.Sc.: Contrast Problem in High Kilovoltage Radiography.

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 4 p.m., Radiotherapy Section meeting. Professor B. W. Windeyer: Radiotherapist's Impressions of a Visit to Canada.

●INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. R. T. Brain: Common Skin Diseases in Children.

KENT AND CANTERBURY HOSPITAL.—8 p.m., clinical meeting.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—5.30 p.m., Dr. D. P. Cuthbertson: Problems of Quality and Quantity of Protein.

NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Liverpool Medical Institution, 5 p.m., discussion: Tuberculosis and Pregnancy.

ROYAL INSTITUTE OF PHILOSOPHY.—At University Hall, 14, Gordon Square, W.C., 5.15 p.m., The Reverend Vincent Turner: Theologians and Logicians.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Mr. W. N. Morley: National Health Service.

UNIVERSITY COLLEGE.—At Physiology Theatre, 5.30 p.m., Dr. T. S. Work: Biosynthesis of Proteins.

Saturday, February 21

BIOCHEMICAL SOCIETY.—At London School of Hygiene and Tropical Medicine, 11 a.m., Symposium: Biological Transformation of Starch and Cellulose.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Alexander.—On February 6, 1953, at Ellersburn, Nunburnholme Avenue, North Ferryby, East Yorks, to June Alexander, M.B., Ch.B. (formerly Tyson), wife of Gordon Alexander, M.B., B.S., D.Path., a son.

Davies.—On January 11, 1953, at the Royal Infirmary, Cardiff, to Marie, wife of Dr. D. M. Davies, a son—John Stuart.

MARRIAGES

Cooling—Bentley.—On December 27, 1952, at St. Peter's Church, Shaldon, Devon, Edwin Nicholas George Cooling, B.Sc., Colonial Forest Service, Northern Rhodesia, to Rosalind Mary Bentley, M.B., Ch.B., of Shaldon, Devon.

DEATHS

Bean.—On January 25, 1953, at Worthing, Sussex, Algernon Carter Bean, M.R.C.S., L.R.C.P., Surgeon Captain, R.N., retired.

Wood.—On January 29, 1953, in a nursing-home, Brighton, Walter Robert Wood, M.R.C.S., L.R.C.P., L.D.S., of Trechills, Hassocks, Sussex, aged 80.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Morphine in Acute Ventricular Failure

Q.—How long does morphine take to act when given for acute left ventricular failure from coronary occlusion? Is there any danger in giving it intravenously?

A.—Subcutaneous morphine begins to act within 5 to 10 minutes in acute left ventricular failure. Intravenous morphine acts at once and is certainly preferable if given extremely slowly and in a relatively small dose, certainly not exceeding $\frac{1}{4}$ gr. (16 mg.). The chief danger of intravenous morphine is depression of the respiratory centre, but this can be avoided if due care is taken.

Aminophylline acts more quickly than subcutaneous morphine, and is a drug of great value in acute left ventricular failure from any cause. The usual dose is 0.24 g. intravenously, but this dose may be doubled if necessary. It is an effective venous-pressure-lowering agent, and may also have some direct stimulating effect on the heart itself.

Lipotropic Factors in Atherosclerosis

Q.—Of what use are lecithin and other choline-containing substances in the treatment of coronary artery disease and atheroma?

A.—There is good evidence that the lipotropic factors, such as choline, have no influence whatever in protecting animals from experimental atherosclerosis, or in diminishing established atherosclerosis; nor has any well-controlled study proved that such lipotropic agents benefit human atherosclerosis. At the present time it is clear that treatment with such agents is not justified.

Goitre Prophylaxis in Backward Communities

Q.—What is the best way of preventing endemic goitre in a primitive community where the introduction of iodized salt is impracticable? I have seen a reference to work by Marine, who is said to have prevented endemic goitre in schoolchildren in Ohio by the twice-yearly administration of 2 g. sodium iodide. Is this method successful, and could it be applied to a primitive community? Such a method would certainly have administrative advantages.

A.—The work referred to was by Drs. David Marine and O. P. Kimball in 1917-19; the best account is in the *Journal of the American Medical Association* (1921, 77, 1068). Girls aged 5 to 12 years were given 2 g. of sodium iodide, divided into 10 daily doses of 0.2 g., each spring and autumn. Of 2,190 girls so treated for 30 months, only five developed goitre; whereas of 2,305 untreated girls, 495 developed goitre. Marine and Kimball later considered this dose unnecessary high. In goitre areas, 0.1 mg. of iodine (=0.13 mg. of potassium iodide) is probably an adequate daily prophylactic dose. These results speak for themselves, but the method has never, so far as is known, been repeated, as shortly afterwards the use of iodized salt was introduced and has proved equally effective and more convenient in most countries of Europe and North and South America. This latter method is now universally recognized as the method of choice, but if it is impracticable for the population in question, that of Marine and Kimball, possibly using half the dosage, would almost certainly be effective. Other measures that might be considered include adding iodine to the water supplies, administration of iodized sweets or tablets, and importation of sea-food—for

example, dried sea-fish. Attempts have also been made to increase the iodine content of vegetable foods by the application of iodine-rich fertilizers.

Risk of Explosion or Toxic Effects during Repeated Ether Abreaction

Q.—I use open ether for abreaction treatment. (1) Are there any risks of explosion in the presence of a closed anthracite stove? If so, what precautions should be observed? (2) Are there any dangers to patients (or psychiatrist) from administering ether in this way several times a week for several months?

A.—(1) There is certainly a risk of explosion in these circumstances. The likelihood, however, of explosions occurring with ether and air, as distinct from ether and oxygen, seems to be small. The risk of fire, however, is a very grave one, since the anthracite stove is at floor level where the ether vapour is certain to collect.

(2) Many patients in the past have had open ether several times a week for a period of weeks or months without apparent damage. However, the possibility cannot be ruled out that in certain individuals such repeated administrations might in time produce degenerative changes in various organs, notably the liver and kidneys.

A.C.T.H. in Status Asthmaticus

Q.—What is the place of A.C.T.H. and cortisone in the prevention and treatment of status asthmaticus?

A.—A.C.T.H. and cortisone undoubtedly have a place in the treatment of status asthmaticus. Although in a small proportion of cases they are ineffective, the large majority are markedly benefited, often dramatically so. One must remember the recognized contraindications, and that A.C.T.H. and cortisone have a temporary suppressive action only. The attacks will recur after the A.C.T.H. or cortisone is stopped, perhaps within a few days, although just occasionally not for a few months. It is just as well to keep patients so relieved under observation for a few weeks, for the writer has found severe asthma recurring within that time. It has also been recorded that two cases relieved by A.C.T.H. died of status asthmaticus 20 and 29 days later (*Acta allerg.*, 1952, 5, 75).

If there is a dominant infective factor in a case of status asthmaticus, antibiotics should be used. At the present time it may be that we should reserve A.C.T.H. and cortisone for those cases of status asthmaticus in which adrenaline and intravenous aminophylline have failed. The prevention of status asthmaticus is best done by specific diagnosis and therapy and not with A.C.T.H. or cortisone.

Troublesome Cough in a Child

Q.—Can you please tell me how to stop the unproductive cough which usually follows even a slight cold in a child of 5? The child does not cough much during the day, and her general health is unimpaired, but she is awake several times every night, and from about 5 a.m. onwards. There are no prolonged bouts of coughing—I am certain there is no question of pertussis—but the child and her mother are losing hours of sleep every day. The tonsils are not enlarged and the adenoids were removed last year.

A.—A satisfying answer to this question cannot be given as it presents a really difficult problem.

Some children develop a high fever and a severe cough with every cold and some a cough which persists for weeks after the cold, and in either case it is difficult to treat satisfactorily. The statement that the cough is unproductive does not mean very much in childhood, because sputum or discharge from the posterior pharynx is in any case swallowed. The posterior wall of the pharynx should always be examined, and a post-nasal muco-purulent discharge may then be seen or the pharyngeal wall may be noted to be reddened and granular. In that case nasal

drops—1% ephedrine in normal or half-normal saline—may be helpful if the child allows them to be given. They should be given three times a day for not more than a month, with the child lying on her back, with her head bent back over the edge of her bed, so that the drops pass down the nose and do not simply trickle out again.

Chloramphenicol may be extremely effective in cutting short a cough of the nature described, but it is not desirable to use it for a comparatively minor disorder in view of the possibility of toxic effects. These are of course very rare, but of such gravity that this drug should not be used lightly, especially for conditions which may frequently recur. The writer has had no experience of the use of topical chloramphenicol.

Oral Vaccines

Q.—Where can I find an authoritative opinion on the value of oral vaccines?

A.—On p. 74 of the Second Book of *Any Questions?* The book is obtainable for 7s. 6d. (postage 6d.) from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Relationship between Clinical and Biochemical Findings in Diabetes

Q.—How close is the relationship between the presence and severity of diabetic symptoms and the level of the blood-sugar curve? During a glucose-tolerance test one of my patients had a fasting level of 260 mg., rising to 337 mg. per 100 ml., yet he has almost complete freedom from symptoms. Is this common, and what is the explanation?

A.—It is difficult to assess the severity of diabetes from the sole consideration of the blood-sugar curve, although it is safe to say that if the curve shows only a slight degree of carbohydrate intolerance the diabetes is mild and symptoms slight or absent. When there is a high fasting level, as in the case in question, a steep rise, and slow return it is impossible, without knowledge of the clinical condition, the presence or absence of ketosis, etc., to say with any degree of certainty whether the diabetes is severe or not or whether symptoms are likely to be severe. One of the reasons for this lack of relationship between symptomatology and glucose tolerance is the duration of the disease. If the patient is young and the onset of diabetes relatively rapid, there will almost certainly be such symptoms as loss of weight. But if the patient is middle-aged or old, and especially if the patient is an obese woman with the relatively mild type of diabetes, symptoms are often absent, even when the blood sugar is considerably raised. It seems possible that in these cases the patient has become gradually acclimatized to a higher level of blood sugar and is able to tolerate it without marked loss of fluids—the factor responsible for many of the classical symptoms of diabetes. Pruritus vulvae is a marked exception and is frequently the only symptom present in such cases.

Essential Hyperidrosis

Q.—A healthy young engineer finds that excessive sweating of his hands corrodes the delicate metal parts with which he works. Can you suggest a remedy? Wearing gloves, by impairing the sensitivity of his hands, would be a disadvantage.

A.—It may be that treatment of the metal parts with protective or rust-proof oils should be considered here.

The treatment of what may be called an essential hyperidrosis of the hands is difficult. Local measures, including fractional doses of x rays and astringents, such as 10% solution of sodium hexametaphosphate or aluminium salts, are of limited value. Atropine or sedatives internally are similarly seldom helpful and are not desirable in an other-

wise healthy subject. The channel through which the physiological dysfunction acts is nervous, and theoretically ganglion-blocking agents, such as hexamethonium bromide or tartrate, should prove useful. Often, however, the effective dosage is near the toxic dosage and may be dangerous, but this measure should receive a trial. If the position is serious the question of surgical cervical sympathectomy might be considered. A preliminary nerve block would indicate its value.

Arthrogryposis Multiplex Congenita

Q.—What is known about the aetiology, course, and treatment of arthrogryposis multiplex congenita?

A.—This disease—also known as amyoplasia congenita—is rare. It is certainly a congenital abnormality, but whether it is hereditary or due to some interference during pregnancy is unknown—the latter is more likely.

The primary condition is now known to be an absence or marked hypoplasia of muscles, particularly in the forearms and below the knees. The skin changes and the stiffness of the joints are thought to be secondary to this. The main effect of the lack of muscle development is the formation of deformities such as club foot, club hand, flexion of knees or elbows, and dislocations of the hip. The treatment is largely confined to the correction of these deformities, and it always proves difficult, long continued, and finally often incomplete. However, as time goes on, the child learns to become more active, and there is a general improvement in function. Treatment, therefore, may be said to be that of the deformities existing in any particular patient, along fairly orthodox lines. The extent of the disease is very variable from child to child.

NOTES AND COMMENTS

Night Starts.—A DOCTOR writes: With reference to your expert's reply to this question ("Any Questions?" December 13, 1952, p. 1319) I have considerable personal acquaintance with "night starts." I get them in my legs as a result of organic mischief, an old paralysis of both legs from transverse myelitis. These jerks have steadily diminished during the last 22 years. I seldom have a night quite free. They do not worry me much. Either by change of position or other simple means I can get to sleep. But sometimes I may have a poor night with them, and even get jerks in my arms. The exciting cause is a late night, often with too much food and some alcohol and a smoky atmosphere. Whether that is indigestion or a temporary plethora I am not sure. As one of my friends of rather more than my age (71) gets similar troublesome nights on rare occasions, I wondered whether you might have added to your answer that the evening habits of food and drink may need revision.

OUR EXPERT writes: The observations of your correspondent are interesting; and so little is known about this subject that the possible effect of evening habits in food and drink is well worth bearing in mind. Flexor spasms are well known in disease of the spinal cord—e.g., from disseminated sclerosis—though their causation is unknown. It is possible that what your correspondent has to put up with after a transverse myelitis is an abortive form of the flexor spasm.

THE HEALING SUN-GOD

In Egypt, five thousand years ago, the Eye of Horus symbolised the Sun, recognised in the most ancient of days as the source of life and health. The Children of the Sun penetrated to the furthest parts of the earth, and left behind them evidence of sun-worship that remains to this day in Stonehenge and the ancient ruins of Mexico. Strangest of all, the Eye of Horus persists in every modern physician's prescription, as the "R" with the crossed tail.

Prescribing today is no longer associated with the rites of sun-worship, for modern science has made available potent drugs which have no need of magical adjuvant.

IMPERIAL CHEMICAL (PHARMACEUTICALS) LTD.

A subsidiary company of Imperial Chemical Industries Limited

WILMSLOW, MANCHESTER

is no doubt that undue emphasis has been laid upon this aspect. The study of lung volumes alone in various lung diseases can be particularly misleading if the observers assume that changes in the lung volumes are closely correlated with total lung function or the severity of a particular disease.

The terminology employed in the study of lung volumes has been so diverse that unnecessary confusion has arisen. Christie (1932) made excellent suggestions to standardize the nomenclature, and his terminology has been almost universally accepted. Recently, however, a further standardization has been put forward by a large group of interested workers (Pappenheimer *et al.*, 1950), and their suggestions are a further advance (see Diagram). The primary subdivisions of lung volume are

Subdivisions of the lung volume (after Pappenheimer *et al.*, 1950). All gas volumes corrected to body temperature, pressure, and saturated with water vapour (B.T.P.S.).

shown on the right, and apply to all levels of respiratory effort and contain no overlapping volumes. On the left are the terms used when the patient is studied at rest. It will be noted that the expression "air" to denote a volume is carefully avoided. All gas volumes should be corrected and stated at body temperature, pressure, and saturated with water vapour (B.T.P.S.), as the vital phenomena occur within the chest and not within the spirometer.

The vital capacity is, by Hutchinson's (1846) original definition, the volume of gas that can be expelled by a maximal expiration following a maximal inspiration. It can be measured by expiring into any gas-volume-measuring apparatus that affords no appreciable resistance and is of sufficient accuracy. In the closed circuits usually employed, when a tracing is obtained, high percentages of oxygen are used. Accurate volumetric tracings while breathing air or any other mixtures of gases can be obtained by the box-bag technique (Donald and Christie, 1949). In a series of observations on four normal subjects by this method I could find no significant change in vital capacity when breathing oxygen, air, 12% oxygen and nitrogen, or 5% carbon dioxide in air. When determining the vital capacity several trials are carried out. If successive measurements show a large increase, owing to better understanding and effort, then the procedure should be continued until nearly constant values are obtained. According to definition, the maximal value observed is recorded as the vital capacity.

If a respiratory tracing is taken over a period the two components of the vital capacity, the inspiratory capacity (O.T. complementary air) and the expiratory reserve volume (O.T. reserve air) can also be determined. This subdivision affords some difficulty even in normal subjects. There is a tendency to alter and vary the "respiratory level" (which can be precisely described by the volume of air in the chest at the end of quiet expiration) during such breathing gymnastics. Further, subjects with respiratory disability are even

more prone to such alterations. The temporary increase of oxygen uptake resulting from a deep inspiration (Armitage and Arnott, 1949) also makes the analysis of the record more difficult.

The vital capacity alone is not of great value in assessing respiratory disability. A patient with greatly reduced vital capacities may have remarkably good ventilatory function, and vice versa. The two subdivisions of vital capacity have also been overinterpreted.

It was thought that the determination of the residual volume (that volume of gas remaining in the lungs after a maximal expiration) by various indirect methods would give far more meaning to lung-volume measurements, particularly as this would allow the total lung capacity to be studied. Thus the residual volume and the total capacity would give the minimal and maximal lung volumes. The residual volume could be considered not only absolutely but also as a percentage of the total lung volume. Christie (1932) has reviewed 47 methods of determining the residual volume.

Open-circuit Method.—The so-called "open-circuit" of Darling *et al.* (1940) is used extensively in America. When a subject breathes oxygen the total amount of nitrogen in the expired gas will be a simple function of the volume of gas in the lungs and the change in the lung nitrogen concentration. The expired gas is collected in a large spirometer (Tissot) for seven minutes. The patient is then switched out of the oxygen circuit and told to exhale maximally, an alveolar sample being taken with an evacuated gas-sampling tube. There are many valid criticisms of this method: poor washing-out of under-ventilated areas of lung, no tracing is available, and direct alveolar samples (end of maximal expiration) are unreliable in many lung diseases.

Closed-circuit Method.—This method of determining the residual volumes, which is used extensively in this country and Europe, employs a closed circuit and a physiologically inactive gas. Its principle is that the degree of dilution of a known quantity of inert gas is a simple function of the combined volumes of the lungs and the spirometer circuit. In 1800 Humphry Davy used hydrogen for this purpose. Van Slyke and Binger (1923) measured the residual volume by first determining the functional residual capacity during quiet normal breathing. Christie (1932) improved this technique and used the nitrogen present in the lungs at the time of turning the patient into the circuit as his indicator gas. Herrald and McMichael (1939) introduced the important modification of running oxygen into the circuit so as to keep the spirometer tracing level. This procedure ensured a constant spirometric and circuit volume despite oxygen uptake. They also employed a katharometer, which, by measuring the changing thermal conductivity of the gas, indicated the completion of mixing in the circuit and lungs. McMichael (1939), by reintroducing hydrogen as the indicator gas, with its high thermal conductivity, was able to use the katharometer not only to determine the rate and completion of mixing, but also the final concentration of hydrogen. Meneely and Kaltreider (1941) introduced the use of helium as the indicator gas. It has all the advantages of hydrogen without the risk of explosion, and it has been almost universally adopted for this purpose. These workers also pointed out that the rate of mixing of helium in the lungs, while measuring the residual air, was greatly retarded in emphysema.

The present methods of determining lung volumes are undoubtedly satisfactory, and the results obtained are certainly not far from the actual volumes being measured. Lung-volume studies of the same patients by the open- and closed-circuit methods have shown a remarkable agreement despite the faults of the simpler method (Gilson and Hugh-Jones, 1949). Many excellent studies of the lung volumes in various types of pulmonary disease are available. The stage has now been reached where it is more important to consider the value and meaning of lung-volume determinations than to attempt to improve their accuracy. It is also important that the values and ranges of variation of the lung volumes in normal persons at various ages should be more carefully determined.

The upper "normal" limit of the residual volume of the lungs, when expressed as a percentage of the total capacity, is usually considered to be from 20 to 30%, increasing slightly with age. However, in recent years more and more instances have been reported of healthy persons, particularly those over 50 years of age without any history of lung

disease or dyspnoea, with a residual volume of well over 40% of their total lung capacity (Greifstein *et al.*, 1952). This is in no way surprising to anyone who has attempted to measure biological phenomena, but it has not deterred an appreciable number of workers from assessing the degree of severity of such diseases as pulmonary emphysema by this figure alone.

Pulmonary Emphysema

The old clinical observations that the lungs cannot empty adequately and that the respiratory level is much raised in this disease are in general confirmed. Stating this in terms of lung volumes, the residual volume and functional residual capacity are increased. However, the relationship of this increase to the degree of disability is very variable indeed. Baldwin *et al.* (1949b), in their extensive study of emphysema, divided the patients into four different groups, the severity of the disease being judged by the degree of arterial blood desaturation at rest and with exercise, by the presence or absence of carbon dioxide retention, and, finally, by the development of right heart failure. Although they found that most of these patients had a pronounced increase of total capacity was in the region of 50 in all groups, despite the fact that these groups represented from moderate to very severe emphysema. Further, some of the most disabled patients had almost normal residual-volume/total-capacity ratios, and some patients in the earliest group, who did not even show arterial blood desaturation on brisk exercise, had some of the highest residual volumes. It has been my own experience and that of many other workers that, although the residual volume is usually greatly raised in emphysema, the relation of this rise to respiratory function, as judged by exercise tolerance and other tests, is most variable and unreliable.

Baldwin *et al.* also found, as many others have reported since, that there was very poor correlation between the vital capacity and ventilatory capacity (as measured by voluntary hyperventilation). Further, although the total capacity is increased in some cases of emphysema, this is by no means invariable, and most patients with this disease have a total capacity within the normal range. It follows, speaking generally, that if the total capacity, which is the combined residual volume and vital capacity, is not greatly altered in this disease then the size of the residual volume cannot be expected to correlate any better with function than the vital capacity.

Pulmonary Fibrosis

In diseases in which there is generalized pulmonary fibrosis the interpretation of lung volume data becomes even more difficult. Pulmonary fibrosis can occur without any significant degree of emphysema. In most of these patients all the various subdivisions of the total capacity and the residual volume are abnormally small.

However, if the vital capacity is reduced but the residual volume is still normal then the latter will represent an abnormally large percentage of total capacity. In the absence of knowledge of how pulmonary fibrosis may affect the filling and emptying of the lungs it is difficult, if not impossible, to assess the degree of emphysema in such patients on this evidence alone. The diagnosis of emphysema in pulmonary fibrosis is of great importance, as it is most desirable to be able to assess in what ways pulmonary fibrosis causes respiratory disability, apart from concomitant secondary emphysema. Increase of the absolute residual volume over the normal range is usually thought to be good evidence of emphysema, but the assessment of emphysema in the presence of lung fibrosis is exceedingly difficult.

If the disease process is unilateral or different in each lung—that is, collapse or fibrosis with contralateral lung distension—the lung-volume measurements, as obtained by external spirometry, are impossible to interpret. Even if

the lung volumes of the separate lungs are obtained by bronchial catheterization, one cannot be certain whether the changes demonstrated are due to actual emphysema or fibrosis or to mechanical events in the chest such as mediastinal shift and collapse. Again, it should be emphasized that it is unwise to regard the various subdivisions of lung volume as a permanent expression of morphological or pathological changes. There can be great changes in the respiratory level (as measured by the functional residual capacity) and the residual volume in the same patient in relatively short periods of time. Exacerbations of bronchospasm and bronchitis will cause considerable but reversible increase of the functional residual capacity and residual volume.

Finally, it can be stated that, although the lung volumes are useful data and represent one of the first attempts to measure disturbances of lung function, they are of very limited value alone, and in our present state of knowledge they can be grossly overinterpreted.

Ventilatory Capacity (Maximum Breathing Capacity)

The lung-volume measurements are entirely spatial and have no relation to time. Thus the vital capacity is a measure of the maximum filling and emptying of lungs, but provides no information whatsoever concerning the speed and efficiency of this filling and emptying during increased ventilation. The ventilatory capacity depends more upon this speed and efficiency than upon the absolute size of the range of movements. The voluntary maximum breathing capacity first introduced by Hermannsen (1933) is of great value in the assessment of ventilatory function. The maximum breathing capacity (M.B.C.) is defined as the maximum volume of air that can be breathed in unit time. It is usually measured for 15 seconds and then converted to litres a minute. It should be emphasized that the ventilatory volumes obtained by maximum voluntary hyperventilation, although a most useful measure of the efficiency of the bellows action of the lungs, far exceed those obtained during the heaviest possible exercise or by maximum respiratory stimulation by increased tensions of carbon dioxide. If the true ventilatory capacity were defined as the maximum volume that can be ventilated in unit time without undue discomfort, then it is usually about half the maximum breathing capacity. The maintenance of a high ventilatory capacity requires good neuromuscular co-ordination (which is rarely affected), even and adequate application of negative pressure to the lung surfaces, a normally patent tracheo-bronchial tree, normal elasticity and rebound of the lung tissue, and movable components of the chest wall. It is manifest that a large number of important factors are being assessed simultaneously. The prediction formulae of the maximum breathing capacity employ the age and body size (Baldwin *et al.*, 1948) or age alone (Wright *et al.*, 1949). There is a large reduction of maximum breathing capacity as the age increases.

There are two commonly used methods of determining the maximum breathing capacity. In the first and more informative method an ordinary Benedict type spirometer is employed. It is important that the resistance is kept to a minimum, and wide non-corrugated tubing should be employed: 1½-in. (3.8-cm.) tubing is adequate; the use of very wide tubing introduces new errors. The inertia and natural frequency of the system will cause inaccuracies, but if the bell is reasonably light it has been shown (D'Silva and Mendel, 1950) that reliable results can be obtained up to respiratory frequencies of 110 a minute. Other workers measure the maximum breathing capacity with non-return valves each side of the mouthpiece and collect the expired air in a Douglas bag or a Tissot spirometer. It is important that the valves used should have a reasonably low resistance even at very high rates of air flow. This method is particularly useful when dealing with a "mixed" population of tuberculous and non-tuberculous patients. Only the mouthpiece and valves need be cleaned and sterilized, as there is no rebreathing.

In this test the subject is usually told to breathe as deeply and as rapidly as possible. These instructions are self-contradictory, but many authors state that the compromise reached by the patient is his best ventilatory state. There is as yet no proof

of this, and there is in fact good evidence (Bernstein *et al.*, 1952) that unless a respiratory rate of 70 a minute or over is reached low values will be obtained. Emphasis on speed and dictating the rhythm imparts a sense of urgency and need for maximum effort. The personality and power of exhortation of the observer is important, and this factor is another cause of the varying figures obtained in different laboratories. It would be more satisfactory if a standard apparatus and technique could be agreed upon by all workers in the field, but at present this does not seem to be possible. There may be some risk in pulmonary tuberculosis and other chronic infections, such as bronchiectasis, that this highly unnatural and relatively violent respiration will cause aspiration of actively infected material into healthy lung tissue. Although several workers have mentioned this hazard, only to dismiss it, common sense would suggest that the procedure is not without danger. In such instances I have satisfied myself with asking the patient to take a few rapid and forced respirations, using a high-velocity tracing. The ventilatory rate for each breath is measured in litres a minute, and the highest recorded is noted. The comparison of such results with the maximum breathing capacity measured by the usual method in less ill patients has been most satisfactory.

Gaubatz (1938), Tiffeneau and Pinelli (1948), Gaensler (1951), and Kennedy and Stock (1952) have measured the volume of gas expired in standard time during a single forced expiration after filling the lungs. Gaensler employs a spirometer with an automatic timing device so that the volume expired in a fixed time can be measured without a tracing. This is a great advantage in routine clinical work. He has shown an excellent correlation between this "timed capacity" ($\frac{1}{4}$ second) and the maximum breathing capacity.

How is the maximum breathing capacity affected in pulmonary emphysema? It is in this disease, in which the ventilatory capacity is most impaired, that the test is most valuable. It is much more simple than those used to determine the residual volume, and assesses the disability which is the main cause of the patient's dyspnoea and discomfort. One important disadvantage of this method should be mentioned. Bronchospasm, including bronchiolar obstruction due to oedema or secretion, will greatly reduce the maximum breathing capacity, and thus its value as a measure of true emphysema and permanent lung damage is greatly reduced in just those cases in which emphysema threatens and needs to be assessed.

A study of the ventilatory capacity before and after the inhalation of such "antispasmodics" as adrenaline can be carried out in order to assess the separate effect of bronchospasm. However, this is only a crude method, as such a procedure never raises the figure to that obtained if and when the bronchospasm remits naturally.

In patients with generalized pulmonary fibrosis and without emphysema, as judged clinically, radiologically, and by normal or reduced residual volumes, the ventilatory capacity is not greatly impaired. The mean of the maximum breathing capacity in a series of 39 such patients was 78% of the mean of a large group of normal subjects (Baldwin *et al.*, 1949a). Yet the vital capacity of many of these patients was greatly diminished. The decrease of the range of the lung bellows seemed to be compensated by increased efficiency and speed of movement. However, despite their relatively unimpaired ventilatory capacity, many of these patients were dyspnoeic on moderate exertion.

Ventilatory Capacity and Dyspnoea

Cournand and Richards (1941), in order to study the relationships between ventilatory demands and ventilatory capacity, employed a standard step-test of thirty 20-cm. steps in one minute and measured the minute-ventilation during this time and for five consecutive minutes afterwards during recovery. This gave the minute-ventilation during a standard exercise and also allowed the study of the various ventilatory volumes associated with various degrees of dyspnoea. They studied a large group of patients suffering from pulmonary tuberculosis with varying degrees of disease, fibrosis, and collapse. After the step-test 68 patients experienced dyspnoea. During the last minute of dyspnoea the mean minute-ventilatory volume, when expressed as a percentage of the

patient's maximum breathing capacity, was 37%. In the minute following relief from dyspnoea the mean ventilation was 29% of the maximum breathing capacity. They emphasized that there was considerable variation in different individuals.

In a later study of patients with generalized pulmonary fibrosis (Baldwin *et al.*, 1949a) a remarkably similar relationship was found. They also reported that the mean minute-ventilation of those with moderate dyspnoea was 49% of the maximum breathing capacity, and with very severe dyspnoea 69%. It was clearly shown that the cause of the dyspnoea in these patients with pulmonary fibrosis was partly the loss of ventilatory capacity and partly the abnormally large volumes ventilated on exercise.

When patients with severe emphysema and very limited ventilatory capacity, as measured by the maximum breathing capacity, were studied many signalled that they were relieved of dyspnoea when the minute-volume fell to 50-60% of the maximum breathing capacity (Baldwin *et al.*, 1949). It has been suggested that the emphysematous patient is grateful for small mercies and regards what, to him, is only moderate ventilatory discomfort as tolerable and not constituting shortness of breath. In any case there is no doubt that these relationships are no longer valid in patients with extremely impaired ventilatory capacities.

Cournand and Richards (1941) termed the unused percentage of the maximum breathing capacity the "breathing reserve" and related this figure to the various degrees of dyspnoea. This term can be criticized, as a large amount of this so-called reserve can never be used. Even a normal subject ventilating 50-60% of his maximum breathing capacity after very violent exertion is uncomfortably dyspnoeic. It cannot be overemphasized that the maximum breathing capacity is only an arbitrary measure of the bellows action of the lungs and does not represent the maximum volume that can be ventilated by that person in response to natural physiological stimuli.

Other workers state the ventilation in any given state as a fraction of the maximum breathing capacity, and call this the "dyspnoea index" (Wright, 1944). It is simpler to state the actual ventilation under any given condition as a percentage of the maximum breathing capacity. This is self-explanatory and avoids the false inference of infallibility associated with the word "index." The term "dyspnoeic index" has been employed (Hugh-Jones and Lambert, 1952) to describe the percentage of the maximum breathing capacity ventilated during a step-test when standard work is performed. The height or the number of steps in unit time are adjusted to standardize the work done with different body weights. The standardization of the amount of work done is of value when studying the ventilatory responses in patients whose weights vary greatly or in the study of ventilatory behaviour in different groups of patients. However, it is undesirable to convert this well-established method of measuring ventilatory discomfort in various degrees of activity into a rigid "index of dyspnoea." The careful elimination of the effect of body weight in assessing dyspnoea in real people with different body weights is also unfortunate. These variable body weights will cause varying ventilation and resultant dyspnoea during any standard activity (walking, stair-climbing, etc.).

It is still not known why a person should be extremely uncomfortable when his physiological demands—for example, exercise—cause him to ventilate about half of the air he can shift at rest, and without distress, by voluntary hyperventilation. There is great need for a more precise study of the ventilatory mechanisms during exercise causing dyspnoea in normal subjects and in those with various lung diseases. The level at which these patients breathe, the range and speed of their respiration, and the movement of the diaphragm and ribs during shortness of breath would not only be of fundamental interest but would bring important knowledge that could be applied to the various collapse and surgical procedures causing reduction of the ventilatory capacity.

Ventilatory Volumes

These can easily be determined by collecting the expired air during various activities. A Douglas bag can be carried by the observer if the patient is walking or going upstairs, and the volume of gas expired during a fixed period be measured by passing the gas collected through a flowmeter or into a Tissot spirometer. Walking on a treadmill or a simple step-test will allow the expired gases to be collected and measured with greater ease, and a gas-meter type of recorder can be used. The disadvantage of the step-test is that the patient is usually not in a stable state, nor can the data be easily related to everyday activities. Many workers take the opportunity of carrying out arterial blood studies during these exercise tests.

Remarkably different ventilatory volumes are obtained in different patients. Many will ventilate only 10 litres a minute while walking at moderate speed, whereas patients are encountered who ventilate as much as 50 litres a minute. The demands on the ventilatory capacity will obviously be very different in two such patients, and, although they may have the same ventilatory capacity, the latter patient will obviously become dyspnoeic with a far less degree of exertion.

Passing from these empirical determinations of ventilatory volumes, let us briefly consider some of the factors that influence the amount of ventilation in various diseases.

In the normal subject about one-quarter to one-third of the inspired air does not pass beyond the passages lined by mucosa (the so-called anatomical dead space) where no significant gas exchange with blood takes place. In many lung diseases this "dead space effect" is greatly increased by the ventilation of unperfused lung tissue, and thus an abnormally large proportion of inspired air takes no part in the removal of carbon dioxide and the oxygenation of blood. This will render larger ventilatory volumes necessary for a fixed task, and this added demand can be ill afforded in the face of reduced ventilatory capacity. In certain lung diseases the changes in the elasticity and physical properties of the lung tissue in certain areas of lung may result in overventilation of the more healthy areas, and this overventilation is also wasteful and will have the same effect as increased dead space.

Secondly, there is the influence of changes in the partial pressure of carbon dioxide in the alveoli and body fluids, which are compensated and perpetuated by similar changes in body base. If the partial pressure of carbon dioxide is lowered by intermittent but repeated hyperventilation on exercise the respiratory centre will become more sensitive to a fixed amount of carbon dioxide produced on exercise, as the resulting increase in H-ion concentration will be greater than normal owing to the decreased buffering effect. These increased ventilatory volumes are necessary to remove a standard amount of carbon dioxide, as the alveolar gas is now relatively poorer in carbon dioxide content. In a number of cases of pulmonary fibrosis, pathological infiltration of lung, and heart failure, the carbon dioxide in the alveoli and blood is much reduced and there is little doubt that this factor is partly responsible for the hyperventilation encountered in these diseases.

If, as in severe emphysema, there is a lag of carbon dioxide excretion on each occasion when the patient exercises, owing to ventilatory disability, there will be a tendency for the partial pressure of carbon dioxide to rise, and if this is increasingly buffered then carbon dioxide retention (compensated gaseous acidosis) occurs. It must be emphasized that the gradient of this gas across the alveolar membrane between blood and alveolar air is unaltered, the partial pressure of carbon dioxide being raised throughout the lungs and body. In such cases the respiratory stimulation by a fixed amount of carbon dioxide is diminished, as the increased buffering will cause less increase in H-ion concentration. It can be shown that there is significantly less ventilation on exercise in this group of emphysematous patients as compared with those without high blood and

alveolar carbon dioxide tensions. It has also been suggested that the respiratory centre becomes less sensitive to carbon dioxide and H-ion changes in these cases.

Thirdly, the added anoxic stimulus to respiration is important in certain diseases. Although it is generally known and taught that anoxaemia at rest causes a definite but not very pronounced increase of ventilation, it is less often appreciated that anoxaemia associated with exercise causes a most dramatic increase of ventilation. The increased ventilation caused by anoxaemia at rest washes out carbon dioxide and also reduces the H-ion concentration in the body. Thus two of the normal stimuli to respiration are reduced and the effect of anoxic stimulation is mainly counteracted. If, however, the patient is exercising, and the body carbon dioxide and H-ion concentrations are maintained or increased despite the increased ventilation, then the anoxaemic stimulus becomes more fully apparent (Gray, 1950). This mechanism is particularly important in diseases in which oxygen transfer is inadequate but the ventilatory capacity is but little impaired, as such patients are capable of marked temporary activity, causing abrupt anoxaemia. Good examples of this are certain types of pulmonary infiltration causing difficulty in oxygen transfer across the alveolar membrane (Austrian *et al.*, 1951; Donald *et al.*, 1952). Such patients become anoxaemic and dyspnoeic despite a relatively unimpaired ventilatory capacity. Their dyspnoea is due to the enormous ventilatory volumes that occur with exercise.

Another instructive example is seen in patients with large intracardiac shunts and pulmonary stenosis. On exercising these patients are unable to increase the pulmonary blood flow and oxygen uptake to any appreciable extent, and extreme anoxaemia ensues. Despite their relatively normal lungs and ventilatory capacity they become extremely dyspnoeic owing to their enormous ventilatory volumes—that is, 50-60 litres a minute walking slowly. The low carbon dioxide tension in the body will also contribute to this extreme hyperpnoea.

It is often stated that the Hering-Brauer reflex, causing inspiratory inhibition with a certain degree of lung distension, is increased in activity in many pulmonary diseases, particularly in pulmonary fibrosis. If overactive this reflex causes more frequent and shallow respiration. It is not yet proved that overactivity of this reflex can cause increased total ventilation. There is good evidence that the inhibition of inspiration occurs earlier than normally in the pulmonary congestion of cardiac origin, causing more frequent and shallow respirations, although it is still doubtful whether this is the cause of increased ventilation (Christie, 1932). With regard to the Hering-Brauer reflex being increased by pathological processes or fibrosis in lung disease, this is still only a hypothesis, and no good definitive evidence has yet been forwarded to substantiate it.

Intrapulmonary Gas-mixing

Efficient gas exchange is to a large extent dependent upon the efficient distribution of inspired air to all alveolar spaces. Overventilation of one part of the lung cannot compensate for poor oxygenation in underventilated lung. The haemoglobin is saturated to all intents and purposes by adequate ventilation, and further ventilation will add but little oxygen to the blood perfusing that area. If the tidal air that passes the relatively rigid anatomical dead space is almost equally distributed to all alveoli, as we have good reason to believe is the case in the healthy lung, then it is certain that normal lung will be a remarkably efficient mixer of inhaled gases. Further, if the rate of mixing of inhaled gases is studied, then this will be a useful measure of the efficiency of gas distribution in the lungs. A number of factors that will influence the speed at which an inhaled foreign gas will be mixed throughout the lung spaces can be predicted on first principles—for example, the tidal volume, the size of the rigid anatomical dead space, the functional residual volume, and the rate of respiration (Darling *et al.*, 1944; Birath, 1944).

Cournand *et al.* (1941) measured the alveolar nitrogen after seven minutes' quiet oxygen breathing during the determination

of the residual volume. They showed that this was abnormally high in emphysema and attributed this to the inefficient ventilation of many alveoli and air spaces.

Birath (1944) compared the actual mixing curves obtained by serial sampling while breathing a hydrogen mixture with theoretical curves calculated with all the known variables, and assuming mixing to be perfect. Any retardation of mixing, no matter what the cause, was expressed as being due to a certain-sized rigid space between the mouth and properly ventilated lung. If this figure was greater than the accepted size of the normal anatomical dead space, then the excess figure expressed the mixing deficiencies of the lung. This method is unsatisfactory, as the anatomical dead space cannot be accurately measured or foretold even in normal subjects. Other workers (Boothby *et al.*, 1948; Carlson *et al.*, 1948; Fowler and Comroe, 1948) have carried out continuous recordings of the nitrogen washed out and alveolar nitrogen concentration (end of tidal air samples), while breathing oxygen, by means of the Lilly-Hervey nitrogen meter.

As previously mentioned, Meneely and Kaltreider (1941) showed that the rate of helium mixing in emphysema during lung-volume determinations is much reduced. Bates and Christie (1950) studied this phenomenon with greater thoroughness. They determined and corrected the effect of delayed mixing in the circuit and katharometer lag as well as allowing for the known variables already mentioned. No attempt was made to correct for the anatomical dead-space effect. Gross impairment in mixing was demonstrated in a group of emphysematous subjects. They also showed that there was considerable impairment of mixing, even in normal subjects, with increasing age. One asthmatic subject was studied while in severe bronchospasm and on two occasions during his recovery. The mixing efficiency rose remarkably as his bronchospasm abated. It is apparent that, like lung-volume and ventilatory studies, this test is also at the mercy of bronchospasm and bronchial obstruction, and is therefore not a reliable index of permanent lung damage.

All these methods show that the mixing capacity and inspired gas distribution in various lung diseases are impaired and abnormal. However, this disturbance is only assessed as if the lungs were dry unperfused organs. Such an assessment gives no information concerning the relationship of the alveolar underventilation, which is being indirectly demonstrated, to the blood flowing through the lungs. Fowler and Bateman (1950), who have contributed greatly to the study of mixing deficiencies, now feel that the study of the gases encountered in the lungs while breathing air and the correlation of such studies with arterial blood-gas tensions will yield far more valuable data on the real effects of alveolar underventilation. Although hydrogen and helium are excellent gases to demonstrate mixing deficiencies they are light and highly diffusible gases which behave very differently from the gases present in the lungs during ordinary air-breathing. Rauwerda (1946) has produced a valuable monograph on the subject of intrapulmonary gas-mixing.

Respiratory Velocities

The physician of the last century who asked a patient with respiratory disease to whistle or blow a candle out was crudely assessing the maximum respiratory velocities. Sensitive and accurate instruments have been evolved to record instantaneous air-flow velocity (Silverman, 1945). The rate of flow is stated in litres a minute, as the actual velocity recorded is a function of the cross-section of the apparatus where the air flow is being measured. The velocity of flow in the air passages and finer bronchioles, under different conditions and in various diseases, is yet to be determined. Although many workers have obtained records in a number of normal and abnormal subjects under different conditions, little of real significance has emerged from its use. However, this approach is relatively new and may yet yield important findings. It is possible that a simple whistle-like instrument to measure the maximum expiratory velocity will become a standard clinical tool.

Breathing Exercises

Most of us are inclined to believe that breathing exercises are a convenient placebo, and an indirect form of psychotherapy in respiratory conditions where little else can be offered. I would make an exception of post-operative

breathing exercises, where the principle of encouraging an early return to full function, in what is usually normal lung, is sound. It must be remembered that these physiotherapy sessions are expensive in personnel, time, and money. It is my belief, although I have no proof, that breathing exercises have no effect whatsoever on emphysema and bronchospasm. Recent studies have shown that physiotherapists and singing teachers have no more control over their diaphragmatic movement than those whom they instruct (Wade, 1951). It is high time that more precise studies of the effect of these procedures on respiratory function were carried out to determine in what type of case, if any, physiotherapy is of value.

Summary

Summarizing this rapid and imperfect survey of spirometric methods relating to the efficiency of ventilation, I would like to repeat that in the past too much emphasis has been laid on the static aspects of the lung volumes. It is more important to determine the ventilatory capacity of the lungs by such simple tests as those described and then to determine what ventilatory demands will be encountered in conditions that simulate normal activities as closely as possible. The factors that increase these ventilatory demands in various diseases have not been adequately studied. Finally, I would state that if I could have only one figure in a case of emphysema, although I should like many more, I would ask for the maximum breathing capacity.

THE PULMONARY CIRCULATION

Let us next consider the haemodynamics of the pulmonary circulation, particularly the flow and pressure relationships. The important aspects of the relationships of alveolar circulation to ventilation will be considered separately. It has long been a matter of debate whether the pressure and volume variations in the pulmonary circulation are the passive result of conditions imposed upon it by respiration and the systemic circulation or whether there is active vasomotricity of pulmonary vessels. Except for transient differences, the blood flow through the lungs is equal to that through the whole systemic circulation. However, despite this, the pressures in the lesser circulation are of a far lower order than those in the systemic circulation. The short, distensible, and capacious pulmonary arteries, arterioles, and pre-capillaries, and the enormous network of large pulmonary capillaries surrounded by air, allow the whole cardiac output to flow through the pulmonary vascular bed with a pressure head of only one-sixth of that in the systemic circulation.

The introduction of the technique of cardiac catheterization has made it possible to study the pulmonary circulation in both normal and abnormal subjects without any great disturbance of physiological status. Many normal subjects have now been investigated under near basal conditions, and the upper limit of normal pulmonary artery systolic pressure is believed to be 30 mm., of mean pressure 15 mm., and of diastolic pressure 10 mm. Hg. These pressures are measured from the level of the right atrium, and are the mean of the values throughout a full respiratory cycle.

Riley *et al.* (1948) studied the effect of exercise on the pulmonary artery pressures in three normal subjects. Resting studies were carried out with the subjects lying supine and exercise studies while riding a bicycle ergometer in the upright position. It was shown that, even though the oxygen consumption increased sixfold and the cardiac output more than doubled, the pulmonary artery pressure did not alter significantly. The resistance of the pulmonary vascular bed to this increased flow was greatly diminished on exercise, being only a third of the resistance at rest. As a result of this, the work of the right ventricle against pressure was only doubled; whereas that of the left ventricle was trebled. Hickam and Cargill (1947) obtained similar results, although their subjects did not increase their oxygen uptake and cardiac output to the extent of Riley's subjects. Both these groups of workers pointed out that the decrease of pulmonary resistance could not be explained by the passive

dilatation of the vascular bed, but that there must be independent and active widening of the vessels, or the opening up of new channels. Dexter *et al.* (1951) have shown that if normal subjects are exercised in the supine position so that the oxygen consumption exceeds 400 ml. per m.² of body surface, per minute, then a slight but significant rise of the pulmonary artery pressure occurs. They found that under these conditions the pulmonary resistance showed little alteration during exercise. These different findings may have been due to errors of pressure-recording in the erect position or as yet undemonstrated differences in intrapleural pressures while exercising in the supine and erect positions.

This demonstration that the pulmonary vascular bed is a low-resistance low-pressure system both at rest and with exercise is important. Not only is it advantageous from a purely mechanical aspect, but these properties of the lung vessels will allow considerable restriction of the vascular bed by resection or disease without marked pulmonary hypertension or right ventricular embarrassment.

Motley *et al.* (1947) have convincingly demonstrated that a rise in the pulmonary artery pressure is rapidly induced in normal subjects by breathing 10% oxygen for a short period of time (ten minutes). The average rise in mean pulmonary artery pressure in five subjects was from 13 to 22 mm. Hg. This increased pressure could not be attributed to increase in flow, as the cardiac output was but little altered. More recent experiments (Cournand, 1950) show that there is, in fact, some increase of cardiac output under these conditions, but that this increase is of such an order that it could have little effect on the pulmonary artery pressure. The work of Dexter *et al.* makes it necessary to review the accuracy of this statement, but it would seem to be still valid. Drinker (1945) has demonstrated that anoxia can cause altered capillary permeability, oedema, stasis, and per-haps increased resistance. However, the almost immediate reversibility of the rise in pulmonary artery pressure due to anoxia makes this hypothesis unlikely. There is no good evidence of left ventricular failure with back pressure. Wade, Cumming, and I (1951, unpublished observations) have measured the pulmonary "capillary" pressure, a crude transpulmonary measurement of pulmonary venous pressure obtained by occluding a branch of the pulmonary artery with the tip of the cardiac catheter, in several subjects with normal cardio-respiratory systems, while breathing air and 10% oxygen, and no significant change in this pressure was recorded. The only feasible explanation of the rise in pulmonary artery pressure when breathing low tensions of oxygen is that there is active constriction of pulmonary vessels.

Liljestrand and von Euler (1946) demonstrated that moderate anoxia caused pulmonary hypertension in intact cats. They produced good evidence that this rise in pressure was due to the direct action of low oxygen tension upon the tone of the arterioles or pre-capillaries. They did not believe that it was due to nervous influences, increased flow, or increased back pressure. It was suggested that this local anoxic action would result in an exquisite control of alveolar ventilation and normal oxygen tensions were present.

Pulmonary Circulation in Lung Disease

As the only reliable method of studying the haemodynamics of the pulmonary circulation in lung disease is by cardiac catheterization, the present knowledge (Riley *et al.*, 1948) is scanty. In one of the earliest studies (Riley *et al.*, 1948) a very heterogeneous collection of lung diseases was investigated. The diagnosis included pulmonary fibrosis, bronchiectasis, emphysema, and silicosis with tuberculosis. Most of these patients were unable to exercise vigorously. Even in these severe, chronic, and disabling respiratory diseases the pulmonary artery pressures were normal or but little raised while at rest, and showed only a moderate rise above normal when the patients exercised. Those who suffered the greatest rise of mean pulmonary artery pressure—that is, 13 to 42, 23 to 42 mm. Hg.—on exercise also showed a significant degree of arterial blood desaturation. However, even those

who did not develop arterial hypoxaemia showed some abnormal rise of pressure, and it seemed that the pulmonary vascular bed was no longer capable of accommodating increased flow without some rise in pressure.

Pulmonary Emphysema

The piecing together of the natural history of pulmonary hypertension and right ventricular hypertrophy and failure in this disease requires ventilatory and arterial blood studies, and cardiac catheterization of a large number of patients over long periods. I am particularly grateful to Drs. Harvey, Ferrer, Richards, and Cournand (1951) for allowing me to use, before publication, some of the results in the largest series yet studied, of which I have some personal knowledge.

The first group studied consisted of mild to moderate cases of emphysema as judged clinically and radiologically. Their residual volumes were increased and the ventilatory capacity greatly impaired. There was no significant degree of arterial blood oxygen desaturation (90% or above) and the standard step-test did not cause any fall in arterial oxygen saturation below this level. None of these patients showed any rise of pulmonary artery pressure or circulatory abnormality while at rest. A few who were exercised showed a moderate increase in pulmonary artery pressure. Such a finding in the absence of arterial hypoxaemia would suggest that the pulmonary vascular bed was unable to accommodate the increased flow with exercise without a rise in pressure. This would further suggest that the pulmonary bed is damaged and restricted in this disease.

In the second group studied the emphysema was more severe, as judged clinically and radiologically and by the increase of residual volume and impairment of ventilatory capacity. All these patients showed considerable arterial blood desaturation on exercise and most of them had carbon dioxide retention (high arterial pCO₂). As in the previous group, none had a history suggesting right heart failure. Only moderate pulmonary hypertension was found, the mean pulmonary artery pressure at rest being about 25 mm. Hg. There was no alteration of the size of the heart or of the pulmonary arteries. Electrocardiographic studies, using the criteria of Goldberger (1944), Wilson *et al.* (1947), and Myers *et al.* (1948), showed no evidence of right ventricular hypertrophy. The cardiac output, total blood volume, and haematocrit reading were slightly raised. There are no reports of the effect of exercise in this type of patient, although a few that I have catheterized have shown a considerable rise of pulmonary artery pressure.

Lastly, there is the group of emphysematous patients in congestive heart failure (cor pulmonale). Almost without exception the failure had been precipitated by an acute anoxic episode such as severe bronchitis or pneumonia. All these patients had severe pulmonary hypertension (around 50 mm. Hg. mean pressure) and extreme arterial blood oxygen desaturation (50 to 60% saturation). Polycythaemia was pronounced and the total blood volume was increased. These patients had large right ventricles and the electrocardiogram showed marked right ventricular hypertrophy. These electrocardiographic findings are a measure of muscle mass, and one must conclude that hypertrophy of muscle mass, and one must conclude that hypertrophy had been present for some time. In most of these cases the cardiac output was high or high normal. The few patients who had low cardiac outputs in this state did not recover.

When these patients responded to treatment such as oxygen therapy, antibiotics, aerosol inhalations, and "anti-spasmodics" to improve ventilatory function, and mersalyl, digitalis, and bleeding to relieve the circulatory embarrassment, and were again studied, a surprising series of findings emerged. The pulmonary artery pressure dropped to very moderate and, in some cases, near normal figures. The respiratory function, as judged by arterial percentage haemoglobin saturation, lung volumes, and ventilatory capacity, was also greatly improved. In fact, after recovery from heart failure these cases were almost indistinguishable from the previous group, who had very mild pulmonary hyper-

tension and no evidence of right heart hypertrophy or insufficiency. A number of patients who had had right-sided heart failure, and had recovered, showed similar findings. The blood volume was significantly raised, and there was of course evidence of right ventricular hypertrophy. This marked fall in pulmonary artery pressure on recovery is probably due to relief of the anoxic vasoconstriction, decrease in the blood volume and viscosity, and the reduction of cardiac output. Thus the old concept that right-sided heart failure in these patients is mainly due to irreversible structural damage to pulmonary vessels can no longer be supported. Prompt and active therapeutic measures are life-saving and cause a dramatic reversal of many of the most adverse factors.

Although many cases of severe emphysema are under medical supervision over long periods, it is most unusual for one of these patients to develop a large heart with right ventricular hypertrophy and, finally, failure while under observation. In fact, practically all patients with cor pulmonale due to emphysema are seen for the first time when they are, or have recently been, in heart failure and already have right ventricular hypertrophy. Further, when these patients are studied after recovery a number show a smaller degree of pulmonary distension and a better ventilatory capacity than severely emphysematous patients without cardiac involvement.

I would like to offer a tentative explanation of these facts. If a patient with emphysema suffers from severe ventilatory disability, then this of itself may protect the right ventricle by greatly limiting activity and any resultant pulmonary hypertension due to increased blood flow and, perhaps, severe anoxia. Thus right ventricular hypertrophy and dilatation, which in some ways is the "beginning of the end," does not develop. However, those patients with less ventilatory impairment are not so limited in their activities and are able, without intolerable ventilatory discomfort (dyspnoea), to carry out regularly enough exercise to cause pronounced pulmonary hypertension. Thus right ventricular hypertrophy may develop and any sudden further stress due to infection or added anoxia may cause failure.

Although ventilatory studies help to measure dyspnoea, the most important symptom and disability so far as the patient is concerned, the circulatory aspects of this disease must also be studied, especially when prognosis is being considered. Clinical examination, electrocardiography, and screening make this assessment relatively easy in most cases, without cardiac catheterization, which should be reserved for those who are studying the disease, as well as the patient. Even in cases with moderately good ventilatory function, if there is right ventricular hypertrophy then there is constant danger of heart failure that may be precipitated by one of the almost inevitable respiratory infections that are a feature of this disease. At present there is no general agreement as to whether patients with emphysema should restrict their activities or not. It would be of great use to know whether elaborate and unremitting therapy to improve alveolar ventilation, in an attempt to avoid anoxaemia and pulmonary hypertension, is really worth while. Further work is needed to clarify such problems so that the clinician is better equipped to advise the patient with emphysema.

Pulmonary Fibrosis

Up to the present pulmonary circulatory studies have been carried out in very few cases of generalized pulmonary fibrosis. Any attempt to assess the disability and prognosis in occupational lung fibrosis must include a thorough study of the effect of the disease upon the pulmonary circulation and the right heart. Electrocardiographic studies are not enough, and the development of pulmonary hypertension, and its relation to exercise, must be determined. In view of the fact that the ventilatory capacity is often not greatly restricted, the safety of encouraging men with pulmonary fibrosis to increase their activity, and even carry out hard physical tasks, should be more carefully considered.

[Part II, with a list of references, will appear in our next issue.]

SYMPATHETIC NERVES AND ECLAMPSIA

BY

G. W. THEOBALD, M.D., F.R.C.Sed., F.R.C.O.G.
M.R.C.P.

(From St. Luke's Maternity Hospital, Bradford)

It is the rule, rather than the exception, for a woman who suffers from eclampsia at the end of her first pregnancy to have normal subsequent confinements. The earlier the onset of hypertension and proteinuria during pregnancy the more likely is the patient to suffer the same sequence of events in succeeding pregnancies. The onset of this so-called toxæmic state at or about the 30th week of pregnancy is often associated with an unduly small foetus, which does not appear to grow, and which is prone to die *in utero*, with or without evidence of ante-partum haemorrhage.

These facts are illustrated by the following two case histories; several others could be cited.

Case I.—The patient was aged 36 in 1949. *First pregnancy*, 1941: eclampsia at 32nd week; stillborn premature infant. *Second pregnancy*, 1944: eclampsia at 32nd week; S.B. premature infant. *Third pregnancy*: last menstrual period (L.M.P.) March 4, 1949; expected date of delivery (E.D.D.) November 12. On May 26 the blood urea was 20 mg. per 100 ml.; urea concentration, 4.4%; intravenous pyelogram, normal. No abnormal cells discovered in urine. July 5: booked; B.P., 130/80 mm. Hg; urine, N.A.D.; weight 11 st. 6 lb. (72.6 kg.). September 1: 26 weeks pregnant; urine, N.A.D.; B.P., 140/90. From September 1 to October 10 the B.P. varied between 140/90 and 170/120; no proteinuria. October 11: B.P., 180/130; proteinuria; oedema; weight, 13 st. 3 lb. (83.9 kg.). October 19: 32 weeks pregnant; alb.,* 11 parts; oedema; emesis. Caesarean section: male infant, 4 lb. 3 oz. (1.9 kg.), died from pulmonary atelectasis. November 25: B.P., 140/70; urine, N.A.D.; very well.

This patient, influenced largely by her doctor and her husband, refused to have her iliac vessels denervated and asked instead to be sterilized.

Case II.—This patient, aged 25, had Raynaud's disease. Bilateral cervical sympathectomy had been successfully carried out in 1950.

First pregnancy, 1949 (in Sunderland): 30th week. B.P., 166/110; alb., 2-8 parts; oedema of ankles. April 3: spontaneous delivery; stillborn (S.B.) foetus, 3 lb. 2 oz. (1.4 kg.). *Second pregnancy*, March, 1950: an abortion. *Third pregnancy*, 1951: L.M.P., February 27; E.D.D., December 6. May 29: 12-14 weeks pregnant; B.P., 100/64; urine, no protein; weight, 8 st. (50.8 kg.); Hb, 65%. From May 29 to August 17 the B.P. varied between 110/66 and 120/80. August 25: admitted with B.P. of 150/100; no proteinuria. B.P. then varied between 140/90 and 156/90; no symptoms. September 17: sudden appearance of 6 parts of albumin in urine; oedema; B.P. rose to 170/120; weight, 8 st. 5 lb. (53 kg.). September 29: spontaneous breech delivery; S.B. macerated foetus, 2 lb. 6 oz. (1.1 kg.). October 7: B.P., 104/76; trace of albumin in urine. October 9: B.P., 150/110; trace of albumin in urine; recurrence of symptoms of Raynaud's disease.

Such cases are not common, but they demonstrate that women without detectable stigmata of the cardiovascular-renal system may develop recurrent hypertension, proteinuria, oedema, and other symptoms at about the 30th week of pregnancy in spite of the most careful antenatal care.

*Alb.=proteinuria expressed in parts recorded in Esbach's albuminometer.

Apart from the preparations women may get from the food office, each who attends the antenatal clinic receives:

Tabellae ferri sulphatis compositae (N.F.), 1 tablet thrice daily. Each tablet contains exsiccated ferrous sulphate, 3 gr. (195 mg.), copper sulphate, 1/25 gr. (2.4 mg.), and manganese sulphate, 1/25 gr. (2.4 mg.).

Tabellae calcii cum vitamino D (N.F.), 1 tablet thrice daily. Each tablet contains calcium sodium lactate, 7½ gr. (488 mg.), calcium phosphate 2½ gr. (163 mg.), and calciferol 1/4,800 gr. (0.014 mg.), which is equivalent to 500 international units of vitamin D.

Those in the antenatal ward are given:

Tabellae ferri sulphatis compositae (N.F.), 2 t.d.s.

Tabellae calcii cum vitamino D (N.F.), 1 t.d.s.

Vitamin B₁, 3 mg. t.d.s.

Vitamin C, 25 mg. t.d.s.

Capsules containing 4,500 units of vitamin A and 450 units of vitamin D, 1 t.d.s.

Case II was also given stilboestrol, 5 mg. t.d.s., working up to 30 mg. daily from the time that she booked. She was seen by me almost every week, and put on only 5 lb. (2.3 kg.) in weight.

A number of gynaecologists have attributed eclampsia and pre-eclampsia to abnormalities in the haemodynamic balance (Baker, 1925, 1948; Page, 1939; Bouwduik and Bastiaanse and Mastboom, 1950). Bartels (1928) and Wettley (1938) reported that the vascular system was hypoplastic in a high proportion of fatal cases of eclampsia. Kellogg (1945), Newell and Smithwick (1947), and Peet and Isberg (1949) have recorded successful pregnancies following lumbar sympathectomy, but they were dealing with hypertension of the order of 196/130, and were mainly concerned in lowering the systemic blood pressure.

Since 1930 I have maintained that eclampsia is due to faulty nutrition, together with the mechanical disadvantages which are inevitably associated with the pregnant state. It occurred to me that denervation of the internal iliac vessels might in certain cases improve the blood supply to the placenta and prevent the recurrence of toxæmic symptoms in succeeding pregnancies. This procedure, if effective, might operate: (1) by increasing the blood supply to the uterus; (2) by cutting off afferent and efferent impulses travelling from and to the uterus along sympathetic pathways.

The possible significance of afferent nervous impulses travelling from the uterus is suggested by the following facts. (a) Afferent nervous impulses occasioned by attempts at lumbar puncture in the dog provoked inhibition of water diuresis and proteinuria (Theobald, 1934). (b) The painless introduction of a small dilator through the internal os uteri of a conscious patient and the dilatation of the cervical canal under general anaesthesia may cause the blood pressure to rise by some 10 mm. Hg. Traction on the obstetric forceps during delivery commonly causes a rise in blood pressure which may on occasion exceed 60 mm. Hg. Conversely, cauterization of the uterus by the silver stick may cause a fall of blood pressure from 120/80 to 70/40, a pulse rate of 40, emesis, and a cold sweat. All these phenomena may occur apart from pain (Theobald, unpublished observations).

Lastly, it may be recalled that Franklin and Sophian (1949) and Franklin (1951) advanced the hypothesis "that toxæmia of pregnancy is, or includes, a progressively increasing tendency for the renal shunt to be

brought into operation, and that fatal bilateral cortical necrosis is the maximal, irreversible result of this tendency."

The Operation

The abdomen is opened by a midline subumbilical incision, the intestines packed off, and the peritoneum divided to expose the bifurcation of the right common iliac artery. This is cleaned with scissors and gauze dissection. Approximately the first 1½ in. (3.8 cm.) of the internal iliac artery is stripped and denervated and the corresponding portion of the internal iliac vein is then treated in like manner. After this procedure has been carried out on the left side the abdomen is closed. It must be observed that the proximal portions of the external iliac vessels are inevitably denervated.

The first two operations were performed in January, 1950, but the original patient has not yet become pregnant. In subsequent operations the stripping of the internal iliac vessels was more extensively carried out so that the obliterated hypogastric arteries were cleaned. Large amounts of nervous and other tissue removed from the blood vessels were fulgurated with the diathermy point. In some cases presacral neurectomy was performed before the abdomen was closed.

The operation is tedious, and the only danger is from haemorrhage, particularly when cleaning the veins deep down in the pelvis. Of the seven patients on whom I have operated only three have become pregnant; their histories are here reported.

Case A

This patient was aged 33. I have looked after her in all three pregnancies.

First pregnancy, 1947.—L.M.P., October 4, 1946; E.D.D., July 11. February 11: booked; 18 weeks; B.P., 140/90. April 24: 28 weeks; B.P., 200/130; alb., 6 parts; admitted. In addition to the routine dietetic and hygiene treatment, paravertebral blocks on both sides were carried out on several occasions during the first week. April 30:—eyes: right disk, physiological cupping, exudate, haemorrhage; left disk, normal. Headache, vomiting, epigastric pain. Morphine regime. May 16: slight accidental haemorrhage; B.P., 230/130; alb., 4 parts. May 17: intrauterine death of foetus. May 23: B.P., 170/110; alb., 4 parts; general condition improved. May 24: delivery, following induction of labour, of S.B. male foetus, 2 lb. 8 oz. (1.1 kg.). It was some weeks before the urine became protein-free. The B.P. subsequently varied for some months between 145/85 and 165/120.

Second pregnancy, 1948.—L.M.P., March 25; E.D.D., January 1, 1949. July 6: 12 weeks; B.P., 130/80-122/94; weight, 9 st. 1 lb. (57.2 kg.). August 23: B.P., 170/110; alb., 1 part; weight, 9 st. 6 lb. (57.3 kg.); admitted. During the seven weeks in the antenatal ward the blood pressure varied between 140/90 and 170/120. The protein disappeared from the urine, but recurred, although it did not exceed ½ part. The secretion of urine was poor and varied between 20 and 60 oz. (570 and 1,700 ml.) in 24 hours. October 9: intrauterine death of foetus. October 16: spontaneous delivery of S.B. male macerated foetus, 3 lb. 14 oz. (1.8 kg.).

Denervation of the internal iliac vessels, appendicectomy, and partial resection of right ovary were carried out on January 24, 1950. The internal iliac vessels were noticeably small—approximately half the normal size.

Third pregnancy, 1951.—L.M.P., September 5, 1950; E.D.D., June 12, 1951; weight, 8 st. 13 lb. (56.7 kg.). The blood pressure varied between 120/74 and 138/84 throughout the antenatal period until the 37th week. No proteinuria was detected. Admitted to ward in 37th week. B.P., 150/90; weight, 11 st. 1 lb. (70.3 kg.). B.P. settled in ward to 130/90. June 11: induction of labour; quinine;

artificial rupture of membranes (A.R.M.); oxytocin drip. June 13: female infant, 6 lb. 7 oz. (2.9 kg.). B.P. rose during puerperium to 160/105 and then returned to normal.

Case B

This patient was 38 years old.

First pregnancy, 1941.—Pregnancy "injected away" at 20 weeks because of "kidney trouble and blood pressure."

Second pregnancy, 1943.—Seventh month; premature S.B. foetus; "kidney trouble and blood pressure."

Third pregnancy, 1950.—L.M.P., November 12, 1949; E.D.D., August 19, 1950. February 2: 12 weeks; B.P., 150/90. March 8: 17 weeks; B.P., 110/70; weight, 9 st. 12 lb. (57.5 kg.); Hb 100%. From March 8 to June 17 the B.P. varied between 100/60 and 120/80. She then developed hypertension and proteinuria, and was kept in bed at home by her doctor. July 1: admitted to ward; B.P., 168/100. In the ward B.P. varied between 130/84 and 200/120, but during the last two weeks was in the neighbourhood of 160/120. Proteinuria, alb., 2½ parts. Maximum weight, 11 st. (69.9 kg.). August 1: spontaneous delivery of macerated female child, 4 lb. 10 oz. (2.1 kg.). Very small placenta. This patient took cod-liver oil, orange juice, iron, and calcium from the very beginning of pregnancy, and stilboestrol in the antenatal ward. August 26: B.P., 180/100.

Denervation of internal iliac vessels, presacral neurectomy, and partial resection of left ovary were performed on October 24, 1950.

Fourth pregnancy, 1951.—L.M.P., March 24; E.D.D., December 31. June 19: 12–14 weeks pregnant; B.P., 110/70; weight 9 st. 2 lb. (58.1 kg.); Hb, 75%. July 27: went cycling in Scotland. B.P. throughout pregnancy, until 36th week, varied between 110/70 and 120/80. November 30: 36 weeks; admitted, as she lives in the country; B.P., 136/90. During second week in hospital B.P. varied between 110/70 and 120/80. Labour induced at 38 weeks, as baby was considered "large enough." December 17: male infant, 7 lb. 8 oz. (3.4 kg.); weight, 11 st. 6 lb. (72.6 kg.); Hb, 75%.

Case C

Infertility patient, aged 40, married 14 years.

First pregnancy, 1949.—L.M.P., June 7; E.D.D., March 24, 1950. October 4: 12–14 weeks pregnant; B.P., 120/80; weight, 9 st. 10 lb. (61.7 kg.). November 30: 22 weeks; B.P., 170/110; alb., ++; oedema, ++; weight, 11 st. 4 lb. (71.7 kg.). Admitted. B.P., 214/120; alb., 4 parts; a few granular and hyaline casts, and red blood cells in urinary deposit; oedema of face, pitting oedema of knees; short of breath; eyes—striated greyish disks, white streaks along main vessels. "Proctocaine" was injected into broad ligaments, 6 ml. on each side. Morphine regime. December 13: blurred, misty vision; everything looked like a shadow; left eye mainly involved; weight, 10 st. 9 lb. (67.6 kg.). December 14: some oedema of retinae; tortuous vessels. December 28: intrauterine death of foetus. January 7: macerated male foetus, 3 lb. 8 oz. (1.6 kg.).

During her five weeks in hospital the blood pressure at first fell slightly, then rose steeply to 230/170. It then became stabilized at about 190/110–220/130, falling in the last week to 160/100–180/120. The blood urea reached a maximum of 30 mg. per 100 ml. Proteinuria varied from 0.5 to 4.5 parts, Esbach. The remarkable feature of this case was the constant excellent output of urine throughout her time in hospital, which reached the level of 205 oz. (5,825 ml.) in 24 hours. This in no way suggested the "Oxford shunt." On January 24 Mr. Ivor Lloyd reported as follows: "Both eyes show severe hypertensive and albuminuric retinopathy with papilloedema. I fear, however, that the retinal changes indicate severe damage to the vascular system and the kidneys, and the prognosis, as judged from the ophthalmic point of view, is not good. The blood pressure was 160/90." On November 20, 1950,

the urea clearance was 142% of normal. The electrocardiogram showed the usual pronounced left axis deviation of hypertension.

On February 12, 1951, denervation of internal iliac vessels and presacral neurectomy were carried out. Congenital absence of the left kidney was noted.

Second pregnancy.—L.M.P., August 30, 1951; E.D.D., June 6, 1952. November 19: B.P., 140/90—occasional beat at 170; weight, 9 st. 9 lb. (61.2 kg.). February 13: 24 weeks; B.P., 126/76, this was the only low reading; weight, 9 st. 12 lb. (62.6 kg.). The patient was nervous, not very co-operative, and always feared the worst. Her weight remained almost constant at 9 st. 12 lb. (62.6 kg.) for over four months. She did not look well. No proteinuria. April 9: B.P., 138/96; weight, 10 st. 7 lb. (66.7 kg.); looked better; no proteinuria. April 23: B.P., 170/106; weight, 10 st. 12 lb. (68.9 kg.); admitted; no proteinuria. April 29: B.P. had varied since admission from 150/84 to 160/100; alb., 0.5 part; foetal heart irregular. In view of the irregular foetal heart caesarean section was performed. Female infant, 5 lb. 2 oz. (2.3 kg.). On May 9 Mr. Ivor Lloyd reported: "Bilateral retinal arteriosclerosis and early retinopathy." After delivery the B.P. varied between 110/70 and 138/90. Apart from the temporary recurrence of an anxiety state the mother did well. The baby flourished.

Denervation of the Aorta, Inferior Vena Cava, and Left Iliac Vessels by Means of 5% Phenol Solution

In view of the above results it was decided to determine whether hypertension and proteinuria, once established during pregnancy, could be affected by a comparable procedure.

A primigravida aged 26 was admitted as an emergency case. E.D.D., September 17, 1951. June 28: B.P., 190/100; alb., 4 parts; blood urea, 40–65 mg. per 100 ml.; maximum concentration of urea, 2%; some oedema; foetal heart very irregular. July 3: an incision was made through the left loin, the dissection remaining retroperitoneal. The left common iliac artery and vein, the lower part of the abdominal aorta and inferior vena cava (as it was impossible to expose the right common iliac vessels without making another incision), and the left ureter were generously painted with a 5% solution of phenol: the exposed portion of the left lumbar sympathetic chain was coagulated by diathermy. The patient made an excellent recovery from the operation. From July 4 to August 17 the B.P. varied from 150/100 to 200/120; alb., 2–9 parts. August 18: labour induced at 36th week. August 19: female infant, 2 lb. 14 oz. (1.3 kg.); 36 weeks' gestation; died shortly after delivery. Numerous infarcts in the placenta. May 2, 1952: B.P., 110/76; some protein was still present in the urine.

The abdomen became extremely distended during the last few weeks of pregnancy owing to gaseous distension of the bowel, which took some time to disappear and was still present when she left hospital. It is reasonable to suppose that this distension was due to damage done to the autonomic nervous system by the phenol solution.

Water Diuresis

A Balloon in Uterus.—A rubber balloon was introduced into the uterus a few days after delivery and distended with water to a pressure of 70 mm. Hg. so that it could be felt as a tensely cystic mass reaching 3 in. (7.6 cm.) above the symphysis pubis. The distension of the uterus so occasioned did not seem to affect water diuresis, not even when a weight of 1½ lb. (0.68 kg.) was attached to the end of the balloon.

Faradic Current to Cervix Uteri.—The cervix uteri was stimulated by a faradic current which was just appreciated but did not cause pain. This procedure was tried on three patients and in no way affected water diuresis.

Normal Confinements following the Pre-eclamptic Syndrome Occurring in Pregnancy

During the past five years the few cases in which normal confinements have followed pregnancies in which the pre-eclamptic symptomatology occurred at or about the 30th week of pregnancy have been collected. They number four in all, with a doubtful fifth case (Case 5).

Case 1.—Patient aged 42, Rh-negative. *First pregnancy, 1950:* hypertension, 130/90 to 160/124; alb. varied from 0 to 1 part; usual antenatal treatment and stilboestrol; in antenatal ward five weeks. June 15, 1950: macerated female foetus, 2 lb. 6 oz. (1.1 kg.). The maternal weight increased from 7 st. 11 lb. to 8 st. 2 lb. (49.4 to 51.7 kg.). *Second pregnancy, January 9, 1951:* spontaneous delivery, female infant, 7 lb. 6 oz. (3.3 kg.). Normal pregnancy.

Case 2.—Patient aged 21. November 6, 1950: antepartum haemorrhage at home; B.P., 160/110; alb., 22 parts. November 15: severe frontal headache, photophobia. Caesarean section, male infant, 3 lb. 6 oz. (1.5 kg.), died two days later. *Second pregnancy:* slight oedema up to knees and puffiness of face. Neither hypertension nor proteinuria. February 4, 1952: female infant, 5 lb. 6 oz. (2.4 kg.), delivered at term.

Case 3.—Patient aged 28. *First pregnancy, 1951:* normal until 32nd week, then B.P. 160/100; alb., 4–5 parts. Eleven days later: headache; vomiting; B.P., 180/120; alb., 24 parts; male infant, 5 lb. 3 oz. (2.3 kg.); (36 weeks) did well. When she left hospital the B.P. was still elevated and there was 1 part of albumin in her urine. *Second pregnancy* normal in every respect, except that her blood pressure was 150/90 when she booked. This was the only abnormal reading. June 18, 1952: male infant, 7 lb. 12 oz. (3.5 kg.).

Case 4.—Patient aged 26. *First pregnancy:* booked September 12, 1950; weight, 8 st. 2 lb. (51.7 kg.); B.P., 100/60. December 28: B.P., 180/140; alb., 14 parts; generalized oedema; admitted. No improvement in antenatal ward. January 1, 1951: 30 weeks pregnant; induction of labour; male infant, 3 lb. 9 oz. (1.6 kg.); died aged 24 hours. *Second pregnancy:* E.D.D., August 8, 1952. Normal pregnancy; highest B.P., 140/80; September 9, 1952: male infant, 9 lb. (4.1 kg.).

Case 5.—Patient aged 37. *First pregnancy:* ? hypertension and proteinuria at 36 weeks; male infant, 4 lb. 8 oz. (2 kg.), died. *Second pregnancy:* twins induced at 26th week. S.B., 1 lb. 8 oz. and 2 lb. 4 oz. (0.68 and 1 kg.). *Third pregnancy, 1946, St. Luke's Maternity Hospital:* Normal pregnancy. Female infant, 8 lb. 8 oz. (3.9 kg.). *Fourth pregnancy, May 5, 1952:* Normal pregnancy; female infant, 7 lb. 6 oz. (3.3 kg.).

Living Children, but Not Quite Normal Pregnancies, following Pre-eclamptic Symptomatology

Case 6.—Patient aged 25. October 5 to November 10, 1949: hypertension, 150/100 to 170/120; alb., 2–14 parts. November 10: female infant, 4 lb. 15 oz. (2.2 kg.); died of bronchopneumonia. *Second pregnancy:* B.P. varied between 120/80 and 146/110; alb., 1–3 parts. February 5, 1952: male infant, 8 lb. 8 oz. (3.9 kg.).

Case 7.—Patient aged 27. *First pregnancy, 1947:* abortion at 11 weeks. *Second pregnancy, 1950:* emergency admission in premature labour with transverse lie; B.P., 140/108 to 160/110; alb., 14–16 parts; granular + hyaline casts, many red cells; papilloedema. June 20: S.B. female foetus, 3 lb. 5 oz. (1.5 kg.). September 8, 1951: B.P., 130/76; urine, no protein. *Third pregnancy:* hydramnios; B.P., 120/76–140/94; alb., 0.5 to 2 parts. March 16: breech, male infant, 7 lb., 6 oz. (3.3 kg.).

Case 8.—Patient aged 31. All confinements except the first in this hospital. *First pregnancy, 1941:* ? eclamptic fits; 3 lb. 8 oz. (1.6 kg.) baby; died same day. *Second*

pregnancy, 1942: hypertension up to 180/110; alb., 15 parts; S.B. infant. *Third pregnancy, 1943:* hypertension up to 150/100; no proteinuria; infant weighed 4 lb. (1.8 kg.); died after 36 hours. *Fourth pregnancy, 1944:* hypertension up to 150/95; infant, 4 lb. (1.8 kg.); lived a few hours. *Fifth pregnancy, 1947:* hypertension up to 150/85; infant, 7 lb. 12 oz. (3.5 kg.); did well. *Sixth pregnancy, 1949:* hypertension up to 176/100; no proteinuria; baby, 7 lb. 4 oz. (3.3 kg.). *Seventh pregnancy, 1951:* hypertension; alb., 7 parts; ante-partum haemorrhage; placenta praevia; caesarean section; male infant, 5 lb. 3 oz. (2.4 kg.); did well (37 weeks' gestation). It will be noted that, with the exception of the second pregnancy, all the infants were born alive.

Case 9.—Patient aged 28. *First pregnancy:* hypertension up to 160/118; no proteinuria; forceps; male infant, 9 lb. 3 oz. (4.2 kg.); maternal weight, 13 st. to 13 st. 9 lb. (82.6 to 86.6 kg.). *Second pregnancy:* hypertension, 170/120; alb., 12 parts; headache; dizziness; poor secretion of urine; caesarean section at 36 weeks; female infant, 6 lb. 14 oz. (3.1 kg.). Maternal weight: 14 st. 12 lb. (94.3 kg.) at 17 weeks, 17 st. 2 lb. (108.9 kg.) when delivered. *Third pregnancy:* emergency admission; B.P., 140/100; renal glycosuria; no proteinuria; caesarean section; male infant, 8 lb. 8 oz. (3.9 kg.). Maternal weight: 15 st. 11 lb. (100.2 kg.). The weights both of the mother and of the infants were probably significant in this case.

Case 10.—Patient aged 24. *First pregnancy:* emergency admission on February 4, 1948; three weeks in an antenatal ward; B.P., 220/140; scanty secretion of urine; alb., 20 parts; granular and hyaline casts; blood urea, 60 mg. per 100 ml.; headache; epigastric pain; vomiting. Eyes: slight retinal oedema and evidence of hypertension in arteriovenous crossings. February 24: caesarean section; male infant, 3 lb. (1.4 kg.); died on fourth day. Alb., 0.5 part, present in urine when she left hospital. *Second pregnancy:* E.D.D., January 14, 1949. Hypertension at 28 weeks; admitted. Maternal weight, 8 st. 2 lb. to 9 st. 8 lb. (51.7 to 60.8 kg.); B.P., 140/80 at six weeks; 140/76–155/95 in ward; no proteinuria. Eyes: fundi satisfactory. January 23: female infant, 5 lb. 5 oz. (2.5 kg.); did well. December 21, 1949: B.P., 140/80; neither protein nor abnormal cells discovered in urine.

Discussion of Results

I recounted the obstetric history of the second "denervation" patient, while she was still pregnant, to a colleague whose opinion is valued very highly throughout the country and asked him what chance he thought she had of a living child. He replied that her only sporting chance was a caesarean section at about the 34th week of pregnancy. She delivered herself of a healthy infant weighing 7 lb. 8 oz. (3.4 kg.), at the 38th week, after a completely uneventful pregnancy. In my judgment it is most improbable that any of these three patients could have given birth to a living child, and the fact that each of the three has a healthy infant can reasonably be attributed to the operation that was performed.

It is nevertheless necessary to exercise the utmost caution in accepting any such conclusion, and for this reason all the known relevant cases, occurring among some 30,000 deliveries during the past five years in Bradford, have been reviewed. It will be seen that four patients who developed the pre-eclamptic symptomatology at or about the 30th week of their first pregnancies did have normal second confinements. A further five such patients were delivered of healthy children at term, although the pregnancy in each case was complicated by hypertension and in three cases by proteinuria. It must also be recognized that hypertension, proteinuria, oedema, and other symptoms associated with pre-eclampsia do not have the same significance when occurring concomitantly with some forms of antepartum haemorrhage. A patient was recently delivered of a perfectly healthy infant after a normal pregnancy. Her first pregnancy was uneventful, but her second was complicated

Post-mortem Findings

The post-mortem examination was conducted thirty-two hours after death, the body having been stored at about 4° C. Externally the body appeared well nourished, there was some pallor of the lips and nail-beds, and the livid markings were light pink in colour. Needle-puncture marks were seen on the lateral aspect of each thigh, the right thigh was swollen, and the right knee-joint was enlarged by effusion. The skin of this region was tense and discoloured by patchy blue and pink markings, and there was "marbling" due to prominence of the superficial veins. The left thigh appeared normal in size and colour. The scrotum was red and oedematous. Incisions into the right thigh revealed widespread necrosis with liquefaction and gas production in the lateral group of muscles deep to the injection marks in the skin, the appearances being typical of clostridial myositis. Similar changes, but without gas production, were found in the right psoas and iliacus muscles. Several localized areas of coagulative necrosis, each deep to an injection puncture in the skin, were found in the lateral muscles of the left thigh; no necrosis of the superficial fat was present, and each necrotic area lay deeply in muscle. There was no evidence of infection in this thigh.

Considerable haemolysis was present in the general circulation, with staining of the blood vessels. Little aortic atheroma was found, but a solitary plaque was demonstrated in the upper part of the anterior descending branch of the left coronary artery, immediately below which was a recent ante-mortem occluding thrombus. No evidence of gas embolism could be demonstrated in any part of the circulatory system.

Chronic bronchitis was found, and a partially healed acute gastric erosion was seen on the posterior wall of the cardiac end of the stomach; no free blood was present. The liver was slightly enlarged by fatty change and discoloured by haemolysis. The spleen was slightly enlarged, dark red in colour, and congested. Blood-stained urine was present in the bladder. The brain was oedematous, a few cerebral petechial haemorrhages were seen, and there was blood-staining of the cerebrospinal fluid.

Microscopy.—Histological examination confirmed gas-gangrene of the muscles of the right thigh, and many Gram-positive bacilli were seen in sections. Neither clostridial lesions nor organisms were found in sections of the liver and other viscera, and the necrotic masses in the left thigh were also free from any infection.

Bacteriology.—A direct smear from the necrotic muscle of the right thigh showed pus cells and Gram-positive bacilli. Anaerobic cultures produced a heavy pure growth of *Clostridium welchii*, while aerobic cultures remained sterile. No organisms were cultured, either by aerobic or by anaerobic means, from the brain and cerebrospinal fluid or urine, and only coliform bacilli were grown from the spleen. The *Cl. welchii* was found to be resistant to penicillin and sulphonamides. Efforts to trace the source of the infection were unsuccessful. Suitable cultures were attempted from ampoules of sulphathiazole, apyrogenic distilled water, and paraldehyde, each from the same batch as that injected in this case. Scrapings from the two ward sterilizers were cultured, and the surgical spirit was similarly investigated, but no clostridia were grown.

Experimental Investigations

The pH of the sodium sulphathiazole, when made up as a 33.3% solution in sterile distilled water, is about 10.5, and it was thought desirable to investigate the growth of *Cl. welchii* in alkaline media. This investigation was deferred because of extensive structural laboratory alterations, and the original strain of *Cl. welchii* was inadvertently destroyed during the delay; subsequently three further strains of *Cl. welchii* were used.

Tubes containing 0.1% glucose broth, set up to cover a pH range of 10.5 to 4 by adding varying quantities

of concentrated sulphuric acid and concentrated sodium hydroxide, were inoculated with the clostridia. No growth occurred at pH 10 and higher or at pH 6 and lower, and the latter observation was confirmed on repeating the experiment from pH 7 and below.

In order to avoid precipitation of calcium from the media, two further experiments were performed; in the one concentrated hydrochloric acid and in the other glacial acetic acid was substituted for sulphuric acid. As growth had been shown to occur on the alkaline side of neutrality, only tubes with pH values of 7 and below were set up. No growth occurred at pH 6 and below with hydrochloric acid, or at pH 5.5 and below with acetic acid. The tubes in which no growth occurred were reinoculated and further incubated; but again there was no growth (see Table).

Effect of pH on Growth of *Cl. welchii* in 0.1% Glucose Broth

pH	Conc. H ₂ SO ₄ and Conc. NaOH	Repeat with Conc. H ₂ SO ₄	Conc. HCl	Glacial Acetic Acid
10.5	—	—	—	—
10.0	—	—	—	—
9.5	—	—	—	—
9.0	—	—	—	—
8.5	—	—	—	—
8.0	—	—	—	—
7.5	—	—	—	—
7.0	—	—	—	—
6.5	—	—	—	—
6.0	—	—	—	—

5.0	—	—	—	—
4.5	—	—	—	—
4.0	—	—	—	—

+ = Growth. — = No growth.

It thus appeared that the inhibition of growth was related to the acidity and not to calcium precipitation. We have since found references to the effect of pH on the growth of *Cl. welchii*, in which it is shown that this organism is cultured only with difficulty at low pH values (Gale, 1941; Gale and van Heyningen, 1942).

Discussion

The depth, position, and number of the necrotic foci in the muscles of the left thigh indicate the sodium sulphathiazole as the necrotizing agent in this case, and as injections of the compound were given into each thigh it is reasonable to suppose that similar necrotic lesions had been present in the right thigh, later becoming unrecognizable when the myositis developed. We have seen identical foci of muscle necrosis due to sodium sulphathiazole injections in other cases, and similar lesions are mentioned in the literature (Banks, 1940; Selbie and McIntosh, 1943). The necrosis seems to be due to the very alkaline reaction of the injection solution.

It is well known that deep necrosis of muscle is a favourable site for infection by clostridia, and the local pH in this case would have been above 7.7, though reduced from the initial high pH of the solution by buffering in the tissues and by dilution by oedema. There can be little doubt that the infection began in a sulphathiazole-induced necrotic focus in the right thigh: the organism isolated from the muscle happened to be resistant *in vitro* to penicillin and to sodium sulphathiazole; but, even had *in vivo* sensitivity to the latter been a characteristic of the bacillus, infection could still have occurred, as dormant spores might well have persisted in the tissues until the effective concentration of the sulphonamide became reduced, when active infection of the necrotic muscle would occur.

It has been shown that if an injection of *Cl. welchii* into the thigh muscles of mice is followed one hour later by injection of sulphathiazole into the same site, then only a small percentage of the mice survived (McIntosh and Selbie, 1943).

The source of the *Cl. welchii* in this case was not discovered: skin contamination from the bowel is a possibility,

the organism being a normal inhabitant of the intestinal tract of man. The customary brief skin "cleansing" with alcohol would not be sufficient to kill spores. Alternatively, the organism may have been present in any of the injection solutions or apparatus; proof of this is impossible to obtain.

Summary

Myositis due to *Clostridium welchii* infection was found in the region of injections of sodium sulphathiazole at the post-mortem examination of a man who died of acute coronary thrombosis. It is believed that the very alkaline solution of sulphathiazole was responsible for muscle necrosis, and that accidentally introduced infection of a necrotic focus led to gas-gangrene. The possible source of the infection is mentioned, and some simple experiments in the culture of *Cl. welchii* at varying pH values are described.

We are grateful to Professor H. W. C. Vines for valuable advice and to Mr. H. Neville Stafford, coroner for Westminster, for permission to publish.

PETHIDINE AND THE TRIPLE RESPONSE

BY

B. L. FINER, M.B., B.S.

AND

M. W. PARTINGTON, M.B., B.S.

(From the Department of Physiology, London Hospital Medical College)

Zuck (1951) and Pearce (1951) observed that the intravenous injection of pethidine was followed by the appearance of a wheal extending proximally along the line of the vein. Nasmyth and Stewart (1950) observed that the injection of pethidine into human skin produced a triple response which was reduced in extent by antihistamines, and suggested that pethidine was a histamine liberator. We have made similar observations. In view of the widespread use of pethidine and reports of unexpected hypotension and collapse following its administration (Giff, 1947; Butler, 1951; Zuck, 1951), it was decided to investigate the production of this triple response further. The results are reported below.

Methods

Intradermal injections (0.1 ml.) were made into the skin of the forearm with a Mantoux syringe.

The effects of intravenous injections were studied under two different sets of conditions. (1) *Venous congestion*:—A sphygmomanometer cuff was placed round the upper forearm and pumped to 70 mm. Hg. The injection (in a volume less than 0.5 ml.) was made into a small wrist vein. Immediately the needle was removed, pressure was applied with a pad of cotton-wool over the site where the vein had been punctured to

prevent blood leaking out of the vein. The pressure in the cuff was maintained for three to four minutes after the injection and then released. (2) *Circulatory occlusion*:—A sphygmomanometer cuff was placed round the upper forearm and pumped to 70 mm. Hg. This pressure was maintained for one minute to congest the vessels of the forearm and then raised to 200 mm. Hg. One minute later the injection was made into a wrist vein, and after a further five minutes the pressure was released.

The Intravenous Injection of Pethidine and Histamine

A triple response is seen over the veins in the forearm if pethidine (25–100 mg.) is injected into a wrist vein with an unrestricted circulation in the arm. The reaction is more conveniently studied if smaller doses (5–15 mg.) are used with some obstruction of the venous return as described above.

Within 30 seconds of injection under these conditions an intense sensation of itching spreads up the forearm. This is often followed by a change in the colour of the vein to a characteristic mauve or plum colour. At the same time a flare appears in the skin round the site of injection and then on each side of the vein for a distance of up to 3 cm., progressively following the vein up the forearm. Within five minutes of injection a wheal appears, localized at first to a thin strip over the vein, but later spreading a few millimetres into the skin on each side. If the vein divides, the flare and wheal follow the branches. Sometimes an unaffected area of skin is seen between the site of injection and the changes higher up in the forearm. Whealing and flaring may occur distal to the site of injection and occasionally discrete wheals form in the skin. Massive wheals are sometimes seen. The typical appearance following an injection of pethidine under these conditions is shown in Fig. 1.

Within two or three minutes of the intravenous injection of pethidine with the circulation occluded, a red reaction is seen in the skin. A number of discrete irregular red areas appear, some distal and some proximal to the site of injection. The areas lie over and on each side of the veins in the forearm. They increase in size slowly and may coalesce. When the circulation is re-established and the reactive hyperaemia has subsided the forearm is seen to be extensively whealed, and the margins of the wheals roughly correspond with the margins of the previously observed red reactions. Surrounding all the whealed areas there is a bright red arteriolar flare. On four occasions after the pressure in the cuff was released, the subject's face was seen to flush, and a characteristic metallic taste and a transitory headache were experienced, indistinguishable from those produced by injections of histamine.

All these changes, except the very large wheals, may be reproduced exactly if histamine (15–30 µg. in terms of the base) is substituted for pethidine in the above experiments.

The lymphatic vessels play no part in this response, as the following experiment shows: if pethidine or histamine

FIG. 1.—Changes in the forearm after 15 mg. of pethidine injected intravenously. Sphygmomanometer cuff (at 70 mm. Hg) at the elbow for four minutes after injection.

is injected intravenously with the veins congested, and immediately after the injection a tourniquet is applied to the forearm just proximal to the site of injection, the changes in the forearm occur in their usual sequence.

These observations can be most readily interpreted by assuming that the vein wall is permeable to both histamine and pethidine.

Effect of "Histamine Liberators" on Skin Over Vein

MacIntosh and Paton (1949) have shown that, although the injection of a histamine liberator compound into the skin is followed by a triple response, a second injection of the same substance into the same site within 24 hours produces either no response or one that is much reduced. They suggested that the original injection had reduced the normal complement of histamine in the skin, and that this had not been restored by the time the second injection was given. We have found that the skin behaves similarly after intradermal injections of pethidine (50 µg.), which supports the conclusion that pethidine is a histamine liberator.

Pethidine (10 mg.) was injected intravenously while the circulation was occluded and the areas of red reaction were outlined in ink. Twenty-four hours later pethidine (50 µg.) was injected intradermally into an area of skin which had previously shown a red reaction. The response was grossly reduced compared with an intradermal injection of the same amount into a comparable site on the other forearm. An intradermal injection of histamine had its usual effect. It seems likely, therefore, that the triple response seen after an intravenous injection of pethidine is due to the liberation of histamine from the skin.

Effects of Antihistamines

Treatment with an antihistamine drug modifies the triple response to a subsequent intradermal injection of histamine. Experiments were therefore carried out to investigate the

Effect of Pre-treatment with Diphenhydramine Hydrochloride (100 mg.) on Skin Response in Forearm after Intravenous Injections of Pethidine (100 mg.)

results of (a) the oral administration of an antihistamine drug (diphenhydramine hydrochloride) on the response of the skin to an intravenous injection of pethidine given two hours later; (b) the injection of mepyramine alone; and (c) the intravenous injection of mixtures of mepyramine and pethidine and of mepyramine and histamine.

(a) In a series of 16 cases for operation, it was arranged that half the patients received diphenhydramine hydrochloride (100 mg.) by mouth two hours before the anaesthetic was given. The patients were induced with thiopentone, and then pethidine (100 mg.) was injected into a wrist vein. The reactions in the forearm were noted and graded on a rough quantitative scale (see Table) before the observer knew which patients had received diphen-

hydramine hydrochloride. All except one of the subjects who received this drug showed either no changes in the skin or a much reduced response compared with the controls.

(b) The intradermal injection of mepyramine is followed by the appearance of a red reaction in the skin (Halpern, 1952). This reaction may be distinguished from the red reaction produced by histamine by the following characteristics: (1) the colour is a dull rather than a bright red; (2) when the red area fades there is no "speckling" at its margin; and (3) the intradermal injection of mepyramine into an arm with the circulation occluded does not give rise to a red reaction until the circulation is re-established. When mepyramine (5-10 mg.) is injected intravenously under the conditions of venous congestion a red reaction is seen in the forearm which is in every way similar to that described above as following the intradermal injection of mepyramine. This red reaction is distributed along the course of the veins in a manner similar to that of the triple response after injections of pethidine. If mepyramine is injected intravenously when the circulation is occluded no red reaction appears until the circulation is re-established. These results may best be explained by assuming that the vein wall is permeable to mepyramine.

(c) The intravenous injection of mixtures of mepyramine (10 mg.) and pethidine (5 mg.) or of mepyramine (10 mg.) and histamine (20 µg.) under the conditions of venous congestion described above produced no whealing in the forearm, but only a red reaction similar in character to that following the injection of mepyramine alone. Further, the intravenous injection of such mixtures when the circulation was occluded produced no red reaction until the circulation was re-established.

Since mepyramine does not prevent the liberation of histamine but modifies its effects by competing with it for tissue receptors (Paton and Schachter, 1951), the inhibition of the triple response in the above experiments supports the conclusion that the vein wall is permeable to mepyramine.

Effects of Pethidine on Cat's Blood Pressure

The effects of pethidine on the cat's blood pressure were found to be substantially the same as those described by Duguid and Heathcote (1940). The fall in blood pressure in cats under chloralose following the intravenous injection of pethidine (3 mg./kg.) lasted from 45 to 90 minutes (Fig. 2). Recovery from the hypotension from pethidine was not hastened by mepyramine (0.8-1.6 mg./kg.), nor did pre-treatment with mepyramine in doses up to 3 mg./kg. modify the blood-pressure response.

It follows that the hypotensive effects of pethidine in the cat cannot be explained solely on the basis of histamine liberation.

FIG. 2.—Cat, 2.9 kg.; under chloralose. Effects of pethidine (3 mg./kg.) on the blood pressure. Time of injection marked with an arrow. B, C, D, and E are successive tracings at 15-minute intervals.

Discussion

Lewis (1927) presented evidence that when a substance, other than histamine, was injected into human skin and produced a triple response, it did so by virtue of the liberation of the histamine already present in the skin but held in an inactive form. The demonstration that a triple response is inhibited by treatment with one of the anti-histamine drugs supports Lewis's conclusions. MacIntosh and Paton's (1949) observations in man that the second of two injections of a histamine-liberating compound into the same site within 24 hours fails to produce a full triple response, coupled with the work of Feldberg and Talesnik (1952) on the slow rate of recovery of skin histamine following its liberation in animals, also supports Lewis's hypothesis. It follows that if any substance (1) produces a triple response on intradermal injection in man, (2) produces a reduced triple response when the subject is treated with an antihistamine drug, and (3) fails to produce the same response when a second injection is made into the same site within 24 hours, it is likely that the substance is a histamine liberator.

The present observations show that pethidine fulfils these criteria, and so support the conclusions of Nasmyth and Stewart (1950). They also provide an explanation for the observations of Zuck (1951) and Pearce (1951), and show that the walls of the veins in the forearm are permeable to pethidine, histamine, and mepyramine. No other reference has been found to the passage of substances through the walls of veins of comparable size apart from the observation of Magendie, who in the early part of the nineteenth century applied a "spirituous extract of nux vomica" to the outside of the jugular vein of a dog and observed signs of poisoning within four minutes (Franklin, 1937).

In man, the present observations show that the appearance of a triple response in the skin after the intravenous injection of pethidine is to be expected if the injection is made into a superficial vein. Although a fall in blood pressure is common after giving pethidine intravenously (Branwood, 1943), sustained hypotension and collapse are rare. The experiments on the cat indicate that, at least in this animal, the hypotensive effect of pethidine is not due solely to the liberation of histamine. It seems likely that in man some factor other than histamine liberation is involved in the production by pethidine of severe hypotension and collapse.

Conclusions

The triple response in the skin after an intravenous injection of pethidine is due to the permeation of pethidine through the vein wall and the liberation of histamine from the skin overlying it. The walls of the superficial veins in the forearm are also permeable to histamine and mepyramine.

It is unlikely that the occasional case of vascular collapse and marked hypotension following an injection of pethidine occurs as the result of the liberation of histamine.

We wish to thank Professor J. L. D'Silva for continued advice and encouragement. Miss P. Archer kindly drew the illustration for Fig. 1.

THE "REFLUX" FACTOR IN ERYTHROCYTE SEDIMENTATION TESTS

BY

W. D. ALEXANDER, M.B., Ch.B.

(From the Gardiner Institute of Medicine, University of Glasgow)

The most popular methods of determining the erythrocyte sedimentation rate are those of Wintrobe and Westergren. The internal measurements of Wintrobe and Westergren sedimentation tubes are similar except that the length of the former is half that of the latter (2.5 mm. diameter; 100 and 200 mm. long). It was therefore surprising to find that the sedimentation rate of a specimen of oxalated blood determined in a Wintrobe tube differed from the determination in a half-filled Westergren tube. It was noticed that the period of aggregation before fall of the cells started was much longer in the Wintrobe than in the Westergren tube. The technique used to fill the tubes would seem to be the cause, since the columns of blood are identical qualitatively and quantitatively.

One way in which the method of filling the tubes differs is that in the Westergren method blood is drawn past the zero mark and then allowed to fall to it, so that a thin film of blood is left on the inside of the tube above the mark; whereas the Wintrobe tube is filled to the zero mark and the pipette withdrawn, leaving the inside of the tube above the mark free of film. In the first few minutes after a Westergren tube is set up there is therefore a reflux of cells and plasma on to the blood level at the zero mark as the blood adherent to the inside of the tube above the mark runs down to the meniscus. This reflux of blood is of course absent in the Wintrobe tube.

Since the presence or absence of this reflux of blood seemed to exert some effect on the sedimentation of oxalated blood, the effect of this factor on the classical Wintrobe and Westergren methods was investigated. The objects of this paper are: (1) to show that reflux of blood on to the meniscus is a factor frequently affecting the half-hour reading in the Wintrobe method of determining the E.S.R.; and (2) to demonstrate, in four cases in which the readings of the two classical methods were in disagreement, that if reflux of blood on to the meniscus was made to occur in the Wintrobe tube the discrepancy disappeared.

Methods

Comparisons between the readings of the standard Wintrobe and Westergren methods were made on blood from 40 unselected patients. By the Westergren method 7 showed a sedimentation rate between 0 and 10 mm., 14 between 10 and 30 mm., and 19 over 30 mm.

In four cases there was disagreement between the one-hour readings of the two methods, a raised Westergren reading being associated with a normal Wintrobe reading. Each of these patients had active organic disease, and a raised E.S.R. was expected. Blood from these four cases, and from a further 24 in which the readings of the methods were in agreement, was examined to determine the effect of reflux of blood on to the meniscus in each of the two techniques.

In the group of 24 patients in whom the standard methods gave similar readings two pairs of tubes were set up: (1) a pair of Wintrobe tubes (containing oxalated blood), and (2) a pair of Westergren tubes (containing citrated blood). In one of each pair reflux of blood on to the meniscus was allowed, in the other prevented.

Reflux of blood normally occurs when a Westergren tube is filled—in this series the blood was drawn 4 to 5 cm. past the mark and allowed to fall to it. In the tubes in which it was desired to prevent reflux the rubber tube from a W.B.C. pipette was attached to the top of the Westergren tube. Blood was sucked slowly up, and when it reached the mark was stopped by pressing the rubber tube on to the top of the Westergren tube.

Reflux does not normally occur when a Wintrobe tube is filled, the pipette being removed when the blood reaches the mark. When it was desired to cause reflux the tube was filled to the top (1 cm. above the mark), sucked back to the mark, and a small drop of blood left at the top of the tube as the pipette was withdrawn. This small drop runs back on to the meniscus.

In the four cases in which a discrepancy was known to exist between the one-hour readings of the classical methods three pairs of tubes were set up: (1) Westergren tubes (containing citrated blood); (2) Wintrobe tubes (containing oxalated blood); and (3) Westergren tubes filled to the 100 mark with oxalated blood. In one of each pair reflux was allowed; in the other it was prevented.

Results

Of the 24 cases in which the classical methods gave comparable one-hour readings, 5 showed an E.S.R. between 0 and 10 mm., 9 between 10 and 30 mm., and 10 over 30 mm.

One-hour Readings.—In each case the one-hour readings in all four tubes were comparable.

Half-hour Readings.—(a) *Oxalated blood*:—When the half-hour readings in the pairs of Wintrobe tubes were considered the cases seemed to fall into two groups—those with a P.C.V. above 37%, and those with a P.C.V. of 34% and below. The former group numbered 19, and in all these the half-hour reading when reflux was present was twice or more the half-hour reading when reflux was absent. There were five cases with a P.C.V. below 35%. In all these the half-hour readings in each pair were very similar. They were 31, 21 mm. (P.C.V. 34%); 1, $\frac{1}{2}$ mm.; 15, 15 mm.; 13, 12 mm.; 36, 36 mm. (b) *Citrated blood*:—The half-hour readings in the Westergren tubes, with or without reflux, were usually very similar; the average difference was 2.5 mm. Nevertheless in five cases the readings varied in the ratio of 2:1 or more. In all these cases the P.C.V. was 46% or more; and it is interesting to note that the P.C.V. of the blood-citrate mixture would have been 37% or more. The half-hour readings in the five cases mentioned were 3, 1 mm.; 3, 1 mm.; 2, 1 mm.; 6, 3 mm.; and 17, 7 mm.

For the four cases in which the classical methods gave dissimilar results the details of the one-hour readings are set out in the Table.

Four Cases in Which the Classical Methods Gave Dissimilar One-hour Readings

Diagnosis	Westergren		Wintrobe		Westergren Half Filled with Oxalated Blood		P.C.V.

Pyelonephritis ..	58	55	44	12	46	18	38

R.A.—Reflux of blood on to meniscus allowed.
R.P.—Reflux of blood on to meniscus prevented.

Discussion

It is clear that if the effect of a physical factor on the sedimentation rate of a blood is to be tested, the test should be made in a pair of tubes identical in every other way.

In each of the 28 cases examined a pair of Wintrobe and a pair of Westergren tubes were set up. In any pair the

blood filling the tubes was identical, and they were set up in the same stand. It seems reasonable to attribute any difference between the readings of a pair to the solitary difference between them—that the one was filled so that reflux of blood on to the meniscus occurred, the other so that it was prevented.

Fig. 1 shows the usual significance of this factor on the Wintrobe method of determining sedimentation rate. The half-hour reading is considerably affected, being greater when reflux is present, whereas the one-hour reading is affected slightly or not at all. The one-hour reading in each tube agrees well with the one-hour Westergren reading.

The position was entirely different in the four cases in which the one-hour readings of the standard methods were at variance. In them (with oxalated blood), when reflux was absent, the period of aggregation before sedimentation proper starts was greatly prolonged. In each case the difference between the Wintrobe tube filled so as to produce reflux of blood and that filled without reflux, marked at half-hour, were also present at one hour. The period of "disappearance of the discrepancy" occurred between 1 and $1\frac{1}{2}$ hours, instead of between the $\frac{1}{2}$ and 1 hour as is usual (Fig. 2).

Variation in sedimentation rate in Wintrobe tubes (each pair filled with identical oxalated blood) according as reflux is present or absent. The continuous line shows rate without reflux, the broken line rate with reflux.

FIG. 1.—Usual pattern, with half-hour discrepancy disappearing at one hour. FIG. 2.—The pattern in four exceptional cases—the half-hour discrepancy persisting at one hour and becoming insignificant only at one and a half hours.

To corroborate that this behaviour was dependent on the method of filling the tube, and not on some inherent property of the Wintrobe tube, a pair of Westergren tubes were at the same time half filled with oxalated blood, one so that reflux of blood on to the meniscus occurred, the other so that it was prevented.

The half-filled Westergren tube and the Wintrobe tube in which reflux had been prevented gave readings of a similar order. Those with reflux present gave similar readings. The latter pair were in good agreement with the classical Westergren one-hour reading, whereas the former pair gave much smaller readings.

In all 28 cases examined reflux of blood on to the meniscus did not materially affect the one-hour Westergren reading. As mentioned above, it did affect the half-hour reading in five cases. It seems from the practical point of view that here the factor can be ignored because the Westergren tube is usually filled so that reflux of blood is inevitable, and because half-hour readings (the only ones affected) are not usually made.

The point of practical importance is that if this series of patients had been examined by someone who habitually fills the Wintrobe tube to the top and then sucks out blood to the zero mark no case would have been found in which the one-hour reading differed materially from that of the Westergren method. Whereas had the cases been examined by someone who (like myself) was accustomed to fill Wintrobe tubes to the zero mark, and then remove the pipette so that reflux of blood does not occur, four cases would have been noted in which the one-hour Wintrobe reading was at variance both with the clinical condition of the patient and with the reading of the Westergren tube.

Why the difference, described above, in the filling of the tubes should be the cause of differences in sedimentation rate in a particular blood is a question of theoretical interest. It may be due to the momentum of the cells, gained by flowing down the inside of the tube to reach the zero mark, carrying them on downwards. Their momentum might act in certain circumstances as an accelerating factor on the sedimentation of rouleaux forming near the blood surface. As other suggestions can be offered, further work is required on this problem. For the present, however, it is desired to emphasize only the practical aspects.

It seems quite clear from recent papers that there is more than one cause for discrepancy between the readings of the Wintrobe and Westergren methods. Goldberg and Conway (1952) found in two cases that the discrepancy was due to the retarding effect of the oxalate. Goldberg, Glynn, and Bywaters (1952), in a preliminary note, state that the cause of discrepancy in their cases seems to have been the effect of the anticoagulant on the blood pH. In both these series the discrepancy has always taken the form of a high Westergren reading with a normal or near normal Wintrobe reading. Davis (1946) has reported cases in which a high Wintrobe but normal Westergren reading has been found.

It seems that, if the Wintrobe tube is filled so that reflux of blood on to the meniscus occurs, at least one factor causing unexpectedly low Wintrobe readings will be eliminated.

Summary

The Wintrobe and Westergren readings were compared in 40 cases and found to be at variance in four, the Westergren reading being more compatible with the clinical state of the patient.

The effect of reflux of blood on to the meniscus was examined in 28 cases, including the four in which discrepancy was noted.

This factor is of no practical importance in the Westergren method.

In the Wintrobe method it affected the one-hour reading in four cases—the cases in which discrepancy was noted. In these when reflux was present the one-hour reading agreed with the Westergren reading; when it was prevented the reading was discrepant.

One of the factors sometimes causing unexpectedly low Wintrobe readings will be eliminated if the Wintrobe tube is filled so that reflux of blood on to the meniscus occurs.

Grateful acknowledgments are due to Professor Sir John McNeer for providing facilities in the Gardiner Institute and for guidance in the preparation of this paper; also to Drs. H. Conway, A. Goldberg, and J. Cochran for their helpful advice and criticism.

A note on dahlia tubers as a source of food is contributed by Mr. S. G. Harrison to the February issue of the *Journal of the Royal Horticultural Society*. The tubers consist partly of inulin, and though not palatable either to man or domestic animals they could be a useful source of laevulose if a cheap process were devised for converting the inulin into that monosaccharide. The present small demand for inulin is being partly met by a firm which is processing three tons of dahlia tubers a year to produce it; the tubers used are normal horticultural surplus. It is thought that breeding experiments might lead to the development of tubers with a higher content of inulin than the present 9% to 13%, for the sugar content of sugar beet has been increased from about 7% sucrose to about 20%.

A SURGICAL METHOD FOR MANAGEMENT OF PATIENTS WITH PORTAL CIRRHOSIS

PRELIMINARY REPORT OF A CASE

BY

CARLO A. MONTAGNANI, M.D.

(From the Surgical Clinic of the University of Florence)

Ligation of the hepatic artery, alone or together with the splenic and left gastric arteries, has been used in recent years as a treatment for portal hypertension and its complications. Success has been claimed in a number of these cases. Ascites and bleeding oesophageal varices appear to be favourably influenced by a reduction in arterial blood supply to the liver, and liver function seems to improve.

The rational basis for this surgical method can be traced back to the studies of the intrahepatic circulation in portal cirrhosis by Kretz (1904), Herrick (1907), McIndoe (1928), and Dock (1947), and to the more recent demonstration by Montagnani and Paci (1952) of a tremendous increase in the arterial circulation in the cirrhotic liver with widespread arterio-portal shunts of varying size.

Berman *et al.* (1950, 1951) and Berman and Hull (1952) have suggested that the method works by reducing arterial blood flow and pressure in the liver parenchyma so that more blood can pass through the portal bed and portal venous pressure is lowered.

Ligation of the terminal part of the hepatic artery carried great hazard, and as a compromise the artery has been tied proximal to the origins of the gastroduodenal and right gastric branches so that a free collateral circulation is possible. Experimental studies in dogs (Montagnani, 1952) have led to the development of a method of gradual occlusion of the hepatic artery or its terminal branches by wrapping around it a "cellophane" band treated with dicetyl phosphate. This led to a fibroblastic reaction of the surrounding tissues, ending in complete obliteration of the hepatic artery. In the meantime a collateral circulation developed towards the liver through the inferior phrenic arteries and minute arterial branches along the portal vein and the common bile duct. No impairment of liver function or damage to the liver parenchyma was observed after such a procedure. No antibiotics were given at any time.

The favourable results of these experiments encouraged clinical application of the procedure in the following case.

Case Report

A man of 58 was transferred from the medical service with Laennec's hepatic cirrhosis and ascites, which had not responded to medical treatment. His father had died of hepatic cirrhosis and he himself had worked for years in a winery, drank 1.5–2 litres of wine each day, ate little, and smoked much. For two months before admission he suffered from dyspepsia, alternating diarrhoea and constipation, asthenia, and loss of weight.

On admission he was found to be wasted and breathless. The sclerae were icteric. The abdomen was greatly distended by fluid and the lower half of the body was oedematous. Distended veins were present on the lower abdomen. There were no abnormalities in the chest. The relevant laboratory findings were: total plasma protein 5.8 g.% (albumin 2.3 g., globulin 3.5 g.); prothrombin 50%. During

two months of medical treatment the loss of weight continued and ascites recurred after repeated tapping. He was transferred to the surgical side on March 22, 1952. The laboratory findings then were: total protein 6.2 g.% (albumin 2.6 g., globulin 3.6 g.); prothrombin 50%. After treatment with vitamin K and blood transfusion, peritoneoscopy was done on April 1 to confirm the diagnosis. After further fresh blood transfusion the prothrombin rose to 65%.

Operation was performed on April 16. The abdomen was entered through a right rectus incision. About a litre of clear fluid was evacuated. The liver was small and hard, with rounded borders and grossly granular surface. The gall-bladder was small and thick-walled. The hepato-duodenal ligament was carefully dissected and the hepatic artery was found and freed. Three branches were identified: the right branch, and two smaller ones directed to the left and middle (quadrate) lobes. The portal pressure measured from an omental vein was 365 mm. of heparinized saline. After occlusion of the three hepatic branches with bulldog clamps the portal pressure fell to 254 mm. The two branches to the left and middle lobe were ligated with No. 1 linen ligatures and the larger branch to the right lobe was wrapped with two turns of a cellophane band treated with dicetyl phosphate. The arteries were buried in the hepato-duodenal ligament with three stitches of 000 silk, and the abdomen was closed without drainage.

The post-operative course was uneventful except for a haematoma of the wound followed by a small dehiscence which was repaired on May 28. The abdomen was tapped once, on May 20, to avoid the danger of a post-operative hernia, and 800 ml. of fluid was withdrawn. The patient had a normal diet from the sixth post-operative day, and by the time of his discharge from hospital on June 23 he was eating well, had normal bowel movements, and a slight amount of fluid was present in his abdomen. He had gained 1 kg. in weight.

He was seen again on September 25, when he was feeling well, had gained 5 kg. in weight since discharge, and was eating well. He had slight constipation, which he corrected with some laxatives. No jaundice was present and the venous collateral circulation on his abdomen had almost completely disappeared. He had not been tapped since his discharge from hospital, and a small amount of fluid was detectable. The plasma protein at this time was 7.39 g.% (albumin 2.97 g., and globulin 4.42 g.).

The favourable result of this first case supports the belief that the method, which was developed experimentally, is worthy of further clinical application.

The physiology of vision is the subject of a dozen articles in the current issue of the *British Medical Bulletin*. Sir John Parsons, F.R.S., consulting surgeon to the Royal London Ophthalmic Hospital, contributes a preface which draws attention to some of the implications of modern research into vision. A mechanism that corrects the lens system of the eye so as to overcome chromatic aberration is the subject of an article by Professor H. Hartridge, F.R.S. Professor A. Sorsby discusses the nature of refractive errors, and Dr. Hugh Davson some problems of the formation and circulation of aqueous humour. In this connexion Sir John Parsons suggests in the introduction that further knowledge of the production of aqueous humour may have a bearing on the formation of cerebrospinal fluid and of lymph production in general. A useful bibliography of British books and periodicals concerned with the physiology of vision is included. The *Bulletin* is published by the British Council; the price of the current number is 15s.

TRICHLORETHYLENE IN LABOUR

BY

E. E. RAWLINGS, M.D., M.R.C.O.G.

Consultant Obstetrician and Gynaecologist, Hope Hospital, Salford

Browne *et al.* (1951) described the use of Steel's inhaler for administering trichlorethylene in labour. Commenting on this, the *British Medical Journal* (1951) stated: "The argument over analgesia in labour creaks on . . . Steel's inhaler . . . unfortunately does not contain all the safeguards generally considered necessary for its use . . . by a midwife." I wish, therefore, to describe the results obtained with a "Tecota" inhaler (manufactured by Cyprane Ltd.), which contains many of these safeguards and apparently fulfils most of the specifications laid down by the Medical Research Council. The machine used is readily portable and delivers a concentration of vapour of 0.45% trichlorethylene in air with

a variation of about 10% with temperature and normal breathing rates. The concentration is within these limits in all working positions and after shaking or inversion of the apparatus. The concentration falls to about 0.4% for breathing rates below a minute volume of 7 litres.

The investigation was instituted primarily to ascertain if the machine could be used safely by unsupervised midwives, and, secondarily, to attempt to assess its efficiency and detect its disadvantages. There are many drawbacks to such an investigation. On the one hand, the subjects are often extremely impressionable, and, on the other hand, one has to allow for the varying standards and enthusiasms of different observers. The present series of 400 cases is a personal one. All the patients were seen by me during labour and/or interviewed by me 24 hours later. The form reproduced here was completed for each patient by the supervising midwife immediately after delivery. The main points were that the administration was not begun until the cervix was dilated at least three fingerbreadths and was discontinued after six hours. The machine was charged with 30 ml. for each case and not refilled during that time. Chloral and bromide, and pethidine, were often used as premedication, but no drug was given once

the administration of trichlorethylene had begun. The results are presented on lines similar to those in the survey undertaken by the Royal College of Obstetricians and Gynaecologists (1947).

Type of Case

There was no selection of the 400 cases. Any patient who had been certified by the doctor as "fit for gas and air" was given trichlorethylene if a machine was available. The age incidence and the parity of the patients are shown in Tables I and II. Of all the hospital deliveries approximately 54% are primigravidae and 46% are multiparae. The reason

TABLE I.—Age Groups

Age:	20 and Under	21-25	26-30	31-35	36 and Over	Total
No.:	87 (21.75%)	138 (34.5%)	106 (26.5%)	40 (10%)	29 (7.25%)	400

TABLE II.—Parity

Primigravidae	1-para	2-para and Over	Total
295 (73.75%)	65 (16.25%)	40 (10%)	400

for the preponderance of primigravidae in the series is the fact that many of the multiparae were delivered so soon after admission that trichlorethylene was not given, or was used for less than the required minimum period of 20 minutes.

Efficacy of the Analgesia

The mothers were questioned immediately after delivery, and again 24 hours later; their opinions are shown in Table III. In 16 cases (4%) reflection caused the mother

TABLE III.—Mother's Opinion of the Efficacy of the Analgesia

Very Good	Good	Fair	Poor	Total
135 (33.75%)	155 (38.75%)	80 (20.0%)	30 (7.5%)	400

to take a more favourable view of the analgesia, and in 10 (2.5%) the reverse occurred. However, in these cases the more unfavourable opinion has been accepted for the analysis. Adequate analgesia (very good or good relief) was obtained in 290 cases (72.5%) and inadequate relief (fair and poor) in the remaining 110 (27.5%). In the observer's opinion (Table IV) adequate analgesia was obtained in 294 cases

TABLE IV.—Observer's Opinion of the Analgesia

Very Good	Good	Fair	Poor	Total
92 (23%)	202 (50.5%)	91 (22.75%)	15 (3.75%)	400

(73.5%) and inadequate relief in 106 (26.5%). Tables III and IV show a discrepancy in the numbers in the very good, good, and poor columns, although the combined figures for adequate and inadequate analgesia are very similar. This is probably due to the fact that the mother who has no previous experience to guide her is less likely than the trained observer to be addicted to moderation in her opinions.

In interpreting the results shown in Table V it must be remembered that many of the labours in which the adminis-

TABLE V.—Effect of Duration of Analgesia on its Efficacy

Period of Administration	Adequate Analgesia Very Good and Good	Inadequate Analgesia Fair and Poor	Total

More than 4 hours	34 (64.2%)	19 (35.8%)	53

Note: Cases in which trichlorethylene was administered for less than 20 minutes have been excluded from the series.

tration lasted for more than four hours were in themselves long and often complicated by uterine inertia or terminated in operative delivery, factors which in themselves would lead the mothers to take a more pessimistic view of the analgesia. On the other hand, a short administration often indicated a reasonably quick labour, with the greater likelihood of a satisfactory opinion of the analgesia.

Effect of Analgesia on Course of Labour

Co-operation of Patient.—A few of the mothers refused the trichlorethylene after a few breaths. Typical comments were: "Cannot get my breath," "Instinct told me to pull it off," "Feel as if I am choking." These cases have been excluded, as the trichlorethylene was not administered for the minimum of 20 minutes. The exact number of such cases is not known, but the estimate is between 10 and 20. Apart from this, lack of co-operation occurred in two groups of cases. In the first group analgesia was excellent, but the patient became too sleepy to push during the second stage. This occurred in five cases (1.25%). The second and larger group consisted of mothers who used trichlorethylene reasonably well until the contractions became more severe late in the first stage or during the second stage, when, owing to inadequate analgesia or slow progress of the labour, they became very restless or hysterical. There were 27 such women (6.75%), in only two of whom did the observer consider that the excitable state might have been produced by the trichlorethylene.

Delay in Labour Due to the Analgesia.—The length of labour in 400 cases having trichlorethylene is compared with a similar group of 400 women the conduct of whose labours did not include the administration of trichlorethylene. These are termed "controls" (Table VI). Of the cases of uterine

TABLE VI

	Trichlorethylene		Controls	
	Primi-gravidae	Multiparae	Primi-gravidae	Multiparae
	Hrs. Mins.	Hrs. Mins.	Hrs. Mins.	Hrs. Mins.
Length of 1st stage	20 —	12 5	19 —	11 15
" 2nd "	1 5	22 —	58 —	17 —
Total length of labour	21 5	12 27	19 58	11 32

inertia it was considered that in six the trichlorethylene probably was the major factor in production of the inertia. In all these cases the administration had begun rather early in the labour.

Forceps Rate.—Forceps were used in 1 of the 105 multiparae (1%) and in 27 of the 295 primigravidae (9.2%), a total of 28 out of 400 cases (7%). The forceps rate for the hospital is 5.3%. The increase for the trichlorethylene series can be entirely accounted for by the high percentage of primigravidae in the series.

Primary Post-partum Haemorrhage.—This is defined as a loss of more than 20 oz. (570 ml.) within 24 hours of delivery. There were 12 cases (3%). The incidence of post-partum haemorrhage for the hospital, if one excludes emergencies admitted because of post-partum haemorrhage, is 3.8%.

Conclusions.—Trichlorethylene does not appear to increase the operative delivery rate or predispose to post-partum haemorrhage. Occasionally it may cause uterine inertia if begun too early in the labour.

Ill-effects on Mother

There were no maternal deaths. No ill-effects on the respiratory rate were noted. No cases of bradycardia or arrhythmia were noted, but in three cases tachycardia was possibly connected with the administration of trichlorethylene.

Conclusion.—There was no definite evidence of any ill-effect on the mother from the administration of trichlorethylene.

Effect on the Foetus

Stillbirths.—There were 10 stillbirths among the 405 babies born, a rate of 24.7 per 1,000 total births. The stillbirth rate for the hospital is 27.4.

Neonatal Deaths.—There were 14 neonatal deaths, a rate of 35.4 per 1,000 live births. The neonatal death rate for the hospital is 36.6.

Incidence of Asphyxia.—Asphyxia was regarded as present if the baby did not cry within two minutes of birth or if it required resuscitation other than clearing of the air passages. Forty cases in which caesarean section, forceps, or other operative deliveries were carried out have been excluded, as other forms of anaesthesia were used. Using the above criteria, 28 babies showed evidence of asphyxia (7.8%).

Effect of Combination of Pethidine and Trichlorethylene in Production of Asphyxia.—Of the 28 cases of asphyxia 17 (60.7%) had pethidine in addition to trichlorethylene. In the whole series 57% had pethidine in addition to trichlorethylene. Thus it seems that, contrary to the Royal College of Obstetricians and Gynaecologists report, pethidine does not increase the incidence of asphyxia.

Premedication

A potassium bromide and chloral hydrate mixture was used in the early stages of labour followed by pethidine. By so doing, adequate analgesia was provided and the administration of trichlorethylene delayed until the cervix was dilated at least three fingerbreadths. The Royal College of Midwives allows these drugs to be administered by unsupervised midwives. No other drugs were used as premedication and no analgesic was given once the administration of trichlorethylene had begun.

Of the 228 patients who were given pethidine, 163 (71.5%) were in the "adequate analgesia" group and 65 (28.5%) in the "inadequate analgesia" group. Of the 172 patients who had trichlorethylene not preceded by pethidine, 127 (73.8%) were in the "adequate analgesia" group and 45 (26.2%) in the "inadequate analgesia" group. Pethidine can safely be combined with trichlorethylene, thereby shortening the duration of the administration of the latter, though it does not appear to improve the degree of analgesia obtained.

Conclusions

Trichlorethylene administered by the method described produces satisfactory analgesia, and it can safely be combined with pethidine without increasing the risk of foetal asphyxia. It does not increase the operative delivery rate or predispose to post-partum haemorrhage. It can safely be used by unsupervised midwives trained in the method of administration, with the following provisos: that administration is delayed until the cervix is dilated at least three fingerbreadths; that if the labour is not completed at the end of six hours the administration is stopped; and diminution in strength and frequency of the uterine contractions is an indication for discontinuing the administration.

I wish to thank the midwives for their co-operation and assistance in completing the forms.

The St. John Ambulance Association has published a booklet designed to show older children the importance of personal hygiene and the hygienic handling of food. It is intended as the basis for the association's preliminary course on these subjects. The booklet, which has been written by Dr. Guy Bousfield, may be obtained from the association at St. John's Gate, London, E.C.1, price 1s. 6d. (by post 1s. 8d.).

Medical Memoranda

A Case of Primary Red-cell Aplasia

Primary aplastic anaemia is a rare condition occurring usually before the fourth decade. All the elements of the bone marrow are depressed, and the consequent symptoms of anaemia, with mouth infection and haemorrhage into skin and mucous membrane, have been long recognized. In recent years, however, it has been demonstrated that aplasia of bone marrow can occur which involves only the red-cell element. In view of the rarity of this condition it is of interest to record the following case.

CASE REPORT

A male infant aged 11 weeks was referred to hospital on July 3, 1950, because of extreme pallor. It was stated that the pregnancy and delivery had been normal, and that he had weighed 7 lb. (3.2 kg.) at birth. The mother declared that the child had been slightly yellow on the first day of life and had remained so for two or three days. Pallor had been noticed some weeks before admission, but it had grown steadily worse. There were two other children. The first had died of pneumonia at 7 months, and the mother stated that it also had been slightly yellow on the first and second days of life. The second baby was healthy and of normal colour. The mother and father were in normal health.

The baby, which weighed 10 lb. (4.5 kg.), was seen to be very pale. There was no icterus; neither liver nor spleen was palpable, and there were no other abnormal physical signs. A green stool was passed soon after admission, but subsequent stools were normal. Blood examination on July 3 showed: haemoglobin, 16%; red cells, 630,000; white cells, 5,850, with 41% polymorphs. The red blood cells showed macrocytosis, anisocytosis, and poikilocytosis. The blood was Group O, rhesus-positive. The mother's blood was Group B, rhesus-positive. Tibial marrow examination showed "moderate cellularity, red-cell precursors almost entirely absent, an occasional normoblast (less than 0.5%), and no gross abnormality of white cells. Apparently a pure red-cell aplasia." The blood W.R. and Kahn test were negative, and x-ray examination of the long bones revealed no abnormality.

Blood transfusions were given at intervals of three to five weeks. He was also given iron and folic acid by mouth, and liver by intramuscular injection, which proved ineffective. The baby has continued to develop well, and usually seems happy until the haemoglobin drops below 40%. At the time of writing he is 18 months old and in good health, having had no illness except mild diarrhoea once in the past three months. Further bone-marrow examinations confirmed the diagnosis.

COMMENT

Clinically this case was one of severe anaemia. There was no history of blood loss, and examination of the bone marrow showed that the essential defect was failure to produce red cells, and red cells only.

Prior to 1932 three cases of pure red-cell anaemia had been described (Kaznelson, 1922; Baar, 1928; Lupu and Nicolau, 1931). Since then, however, further cases have been put on record. Diamond and Blackfan (1938) described four cases, with recovery in one case after two years' treatment with blood transfusions. Numerous substances were given by mouth in the hope of stimulating erythropoiesis, but none were successful. Splenectomy, performed at 16 months, produced a remission in one case. They thought that aetiological factors involved were probably either congenital deficiency of red-cell element of the marrow or a defect in the metabolism of the blood.

Macfarlane and Currie (1943) described a case occurring in a woman aged 22 who died of fatal pyrexia following a blood transfusion. Rinvik (1941-2) described two cases in infants between 2 and 3 months who were kept alive for long periods by blood transfusions. Robson and Sweeney (1948) described a case of red-cell aplasia arising in a child of 18 months.

Smith (1949) refers to the condition as chronic congenital aregenerative anaemia. He postulates prolonged depression of the red-cell elements of the marrow by an antibody of the red-cell elements formed during foetal life. This antibody is thought to be due to ABO incompatibility between mother and child—for example, the infant's group being A and the mother's O. The history of jaundice shortly after birth would make this theory attractive in our case, but the patient's being Group O militated against the hypothesis. Further test showed no incompatibility between the child's cells and the mother's serum.

I am indebted to Dr. R. D. C. Johnstone for permission to publish this case, and to Dr. F. Graham Lescher for his advice and encouragement.

Immediate Death after Intravenous Injection of Iodoxyl

Death following the intravenous injection of contrast media for pyelography is very rare. When it does occur it may be immediate or delayed, the immediate death being due to reaction to the drug, and the delayed death being due to pre-existing severe renal damage, which may or may not be aggravated by the injected substance. All immediate deaths hitherto reported in the literature have followed the injection of diodone (3:5-di-iodo-4-pyridone-N-acetic acid and diethanolamine), and none so far have been reported after the administration of iodoxyl (disodium-N-methyl-3:5-di-iodo-4-pyridoxyl-2:6-dicarboxylate). The following case, therefore, is of interest in that a fatal anaphylactic type of reaction occurred after the injection of this drug.

CASE REPORT

A technical mechanical engineer aged 53 was admitted to hospital on September 8, 1951, for investigation of diarrhoea, vomiting, and swelling of the left leg. These symptoms had been present for three weeks. There was nothing relevant in the past history: his general health had been good and his weight was steady.

Physical examination revealed a large fixed mass in the pelvis and gross oedema of the left leg, extending to the groin. There were no other abnormal physical signs. His blood pressure was 150/90, and Hb 92% Haldane (13.6 g.%). Urine: reaction acid, no albumin or sugar, culture sterile. Blood urea, 15 mg. per 100 ml.; serum protein, 6.48 g.%.

Sigmoidoscopy under anaesthesia revealed no growth. It seemed probable that the oedema was due to pressure of the mass on the vessels of the left leg, so intravenous pyelography was ordered to exclude ureteric obstruction by the mass.

On September 13 20 ml. of iodoxyl solution ("pyelectan") was injected intravenously. The solution had been warmed to 37° C. and was given slowly (three to four minutes). During the injection the patient was asked whether he felt any ill effects, particularly pain in the arm, which often

occurs with this preparation. The complete absence of any local reaction was remarked upon at the time. As the radiographer was about to take the five-minute picture she noticed that he failed to co-operate. He complained of dyspnoea, a tight feeling in the chest, and a desire to defaecate.

On examination he was dyspnoeic and his pulse was weak, fast, and irregular. Nikethamide, 3.5 ml., was given intravenously at once, with slight improvement, and he was returned to the ward immediately. By the time he arrived in bed (10 minutes after the injection) he had become intensely dyspnoeic and moist sounds could be heard all over the lung fields. He began to expectorate a large amount of frothy sputum. His pulse was now imperceptible and there was marked peripheral circulatory failure, with deep cyanosis. Atropine, 1/33 gr. (2 mg.), and morphine, 1/16 gr. (4 mg.), were given intramuscularly.

In spite of all efforts at resuscitation (oxygen, artificial respiration, and aspiration of the pharynx) his condition deteriorated rapidly and he died three-quarters of an hour from the time of the injection.

Post-mortem Report.—A well-nourished man. No external injuries. Heart: muscle rather flabby and fatty, otherwise normal. Lungs: acute oedema present; all air passages full of pale frothy fluid. Liver: slightly congested and slightly fatty. The spleen and kidneys were congested. The bladder was normal. In the pelvis was a small collection—a few drachms—of thick yellow pus arising from a perforated diverticulum of the rectum. There was an area of induration around the bowel, but the mucosa was normal. The stomach and intestines were otherwise normal. Oedema of the left leg was present, but no thrombosis was found. **Cause of death:** acute pulmonary oedema and myocardial degeneration accelerated by perforation of diverticulum of the rectum.

COMMENT

The empty ampoule and the remaining full ampoule of the box were returned to the manufacturers for analysis, and were found to be pharmacologically pure.

Pendergrass *et al.* (1942), in their survey of 661,800 pyelographic examinations, record 10 immediate deaths—all following the administration of diodone. Of these, three presented a clinical picture and necropsy findings very similar to the above case.

The cause of the reaction is obscure, but it is now generally agreed that it is not due to the iodine in the compound, but to some other part of the molecule. Thus, Gautot (1950) suggests that these are anaphylactic reactions, and that the sensitizing agent is diethanolamine in the case of diodone. He points out that this substance is used in the manufacture of many toilet and household preparations, and that from these sensitivity is acquired.

No reliable test for sensitivity has so far been discovered, and the prevention of an occasional very severe or even fatal reaction in a healthy patient with normal renal function seems to be impossible at present.

If the condition is recognized at once adrenaline should be given. However, in the present case it was not until the patient had developed acute pulmonary oedema that the true nature of the condition was recognized; at first, either a coronary occlusion or a pulmonary embolus appeared more likely. Even if treatment is given promptly, as it was in most of the cases so far reported, it seems to have little or no effect upon the course of the illness in the fatal case.

I wish to thank Mr. Kenneth James for permission to report this case, and Messrs. Glaxo Laboratories Ltd. for their help.

G. S. RAMSAY, M.B., F.R.C.S.,
Surgical Registrar, Gordon Hospital, London, S.W.1.

Reviews

PROGRESS IN ENDOCRINOLOGY

Ciba Foundation Colloquia on Endocrinology. Volume 1: Steroid Hormones and Tumour Growth and Steroid Hormones and Enzymes. Volume 2: Steroid Metabolism and Estimation. Volume 3: Hormones, Psychology and Behaviour and Steroid Hormone Administration. Volume 4: Anterior Pituitary Secretion and Hormonal Influences in Water Metabolism. General Editor for the Ciba Foundation, G. E. W. Wolstenholme, O.B.E., M.A., M.B., B.Ch., assisted by Margaret P. Cameron, M.A., A.B.L.S. (Pp. 1,716. 30s., 35s., 35s., and 45s. respectively.) London: J. and A. Churchill. 1952.

In recent years increasing use has been made of the colloquium to enable research workers in a particular field to discuss together their progress and their problems. The main purpose of such colloquia is the airing of difficulties, and papers submitted therefore tend to serve a rather different purpose from those published in the scientific and medical periodicals. In the colloquium, for example, the subsequent discussion of a paper may sometimes be more valuable than the paper itself. To be effective such conferences must be restricted to a relatively small number of experts and must be rather informal. Inevitably many workers in the subject will be excluded from attendance.

The Ciba Foundation in London is to be congratulated on the very successful manner in which it has organized and sponsored a series of such colloquia on various subjects and has been able to ensure a genuinely international representation. Many of these have been on matters related to steroid and pituitary hormones, and the reports of eight conferences on steroids are now published in the four volumes under review, so that the full discussions may be available to a wider audience.

The number of papers, each with its subsequent discussion, is so large that no adequate mention can be made here. The first conference is on hormones and tumour growth. Most of the papers relate to animal experiments, but two are devoted to the use of oestrogens in human cancer control, and a third to the use of cortisone and A.C.T.H. in acute leukaemia in children. In the second conference, on steroids and enzymes, many papers are concerned with the functions of β -glucuronidase in synthesis of glucuronides, but several other enzymes are discussed. In the conference on estimation of steroid hormones five papers are devoted to pregnanediol excretion and estimation, eight to the chemical methods of estimation of oestrogens, and one to the metabolism of radioactive oestrogens. Many papers also are devoted to the difficulties of extraction and estimation of urinary so-called adrenal steroids. A major conclusion in this section is that no satisfactory technique is yet available for extracting such adrenal steroids from urine and that indeed "no worker at the present time is estimating the total urinary corticoid." The reasons for such a conclusion are well discussed. The fourth conference deals mainly with the intermediate metabolism of the steroid hormones. In the conference on hormones, psychology, and behaviour the influence of hormones on sexual behaviour and drive are fully considered. Apparently sexual performance in the male is far more dependent on an intact cerebral cortex than it is in the female. An interesting study shows that the wild rat, exposed to the frequent stresses of its natural life, has far larger adrenal glands than its sheltered cousin the laboratory rat. Interesting speculations are made on the possible comparable effects of civilization on the adrenals of man. The authors of some papers discuss at length the effects of hormone therapy and of endocrine disease on personality, others study endocrine function in patients with established mental disorder. Qualitative and quantitative differences are found in schizophrenia. The sixth colloquium is on modes of hormone administration. The graphic method of displaying oestrogen action on the feathers of fowls is well illustrated in a series of plates, and several

studies are reported of the rate of absorption of steroid from implanted pellets in man. Useful clinical data are presented in this section.

The conference on anterior pituitary secretion comprises 37 papers and their discussions. It deals with the cells in the pituitary originating the various hormones, the hypothalamic paths of pituitary control, the bio-assay of the various hormones, the fate of tracer-labelled pituitary hormones, and many allied aspects. The eighth conference, on water metabolism, presents 15 papers covering excretion of sodium, water, acids and bases, and so on. It includes evidence suggesting the presence of a sodium-retaining hormone in human urine.

The very large amount of information in these volumes is of interest primarily to research workers and others interested in the technical problems concerned. Much of it is difficult to obtain elsewhere. The books are well produced, but it is disturbing to find that about two years have elapsed between the holding of many of these colloquia and their appearance in book form. In a research field as active as endocrinology this is far too long an interval, and speedier methods of publication must be found if these reports are adequately to serve the purpose for which they are intended.

C. L. COPE.

MEDICAL MYCOLOGY

Medical Mycology: An Introduction to its Problems. By G. C. Ainsworth, B.Sc., Ph.D., F.L.S. (Pp. 105; illustrated. 15s.) London: Sir Isaac Pitman and Sons. 1953.

In about 100 pages the author makes a commendable effort to introduce to students of mycology, medicine, and microbiology the history, pathogenesis, epidemiology, and clinical aspects of fungous diseases. The book is a useful introduction to classical and recent literature, but the absence of reservation when referring to certain published works may give rise to misleading impressions. Minor inaccuracies, too, arise from excessive summarization. *Cryptococcus neoformans*, for example, is described as producing no local tissue reaction, while, in fact, various degrees of subacute inflammation do occur in torulosis. Established clinical names like "tinea capitis" are criticized for being imprecise. But general terms for ringworm infections of this kind are found useful in practice, and the degrees of acuteness of inflammation produced by their various causative fungi are well recognized. Undue prominence is given to the virulence of *Candida albicans* by attributing to its invasion the death of infected children. Reference to this organism as a secondary invader in tuberculosis is unqualified. Therapeutic measures against moniliasis and aspergillosis are mentioned as if their efficacy was proved. It is more than can be expected from a work of this size, which deals with so much, that the incidence of mycotic infections in any one country could be made apparent. The author states that neither the mycologist nor the clinician alone is usually in a position to come to a correct decision on the right interpretation of fungi found in the sputum or associated with pulmonary disorders. This problem does not occur in practice. Sections are devoted to botanical taxonomy (on which Dr. Ainsworth is an accepted authority) and to serology. There is a useful chapter on allergy, and a place is found for the poisonous fungi. The structure of pathogenic fungi and the histological reactions they incite are not described.

R. W. RIDDELL.

USING THE LIBRARY

How to Use a Medical Library. By Leslie T. Morton, A.L.A. Second edition. (Pp. 44. 5s.) London: William Heinemann Medical Books. 1952.

To the student, using the library often enough means asking at the desk for a familiar book or periodical; if it happens to be "out," he grumbles and waits or chooses the next best thing. The doctor, especially if he is a research worker, is more resourceful. He has a vague idea that libraries do more than issue books, but it may take him years to learn,

in casual fashion, of the full range of services available to those who know how to ask for them. By buying this excellent little book he can anticipate experience and do himself—and librarians—a good turn. The author, formerly librarian of St. Thomas's Hospital Medical School and now information officer of the *British Medical Journal*, here provides a complete guide to all who use medical libraries—students, doctors, and research workers.

He begins by noting that work in the library is just as important as bench work—a point not always fully appreciated. Later chapters are on the geography of a library, sources of information and how to use them, the location of works not possessed by the library, references, catalogues, periodicals, and abstracts. The last chapter, based on Le Fanu's directory, is an up-to-date guide to the chief British medical libraries.

The information is comprehensive and the advice in the main sound. The style is close-knit, and most of us will have to read the book more than once to understand it—have not an easy task because of the very small type. When looking up the literature on any topic, surely it is best to get the latest review and to work back. This, so far as I know, is standard practice, but it gets three lines, as against the page or so for the appalling method of starting at the year dot and working forward. The research worker can no more delegate his bibliographic work than a surgeon can his operating—if he has any self-respect. In fairness to authors, original papers should always be studied, because abstracts are of necessity selective and do not provide a satisfactory basis for criticism of their work. The book will serve its main purpose admirably; may it also bring home to many the grievous blow medicine has suffered by the stoppage of the *Index-Catalogue*.

RAYMOND WHITEHEAD.

PSYCHIATRY AND THE STUDENT

Psychiatry and Medical Education. Report of the 1951 Conference on Psychiatric Education held at Cornell University, Ithaca, New York, June 21-27, 1951. Organized and conducted by the American Psychiatric Association and the Association of American Medical Colleges. (Pp. 164. No price.) Washington: American Psychiatric Association. 1952.

As a counter to increasing specialization in medical and scientific work it is now very fashionable to hold conferences for the exchange of views between the different branches. Advanced by the need for urgent solutions to technical problems in time of war, the method had considerable success, inspiring as it did a generous pooling of knowledge and the suppression of prejudice. It was soon recognized that it was in the preparatory commissions that the real work was done, and that the formal sessions tended to vagueness and platitudes. Psychiatric education has a good precedent in this field, and the reports of the four annual conferences of 1933-6 on this subject give a very great deal of information, even if every school has since continued to develop in its own way. This book contains a well-edited report of the conference conducted in 1951 by the American Psychiatric Association and the Association of American Medical Colleges.

The subjects under discussion included the extent to which a student should, on qualification, be able to deal with personal problems as well as those of disease, the selection and preliminary training of students from the point of view of their later contact with the social and psychological aspects of disease, and the deficiencies in the present medical curriculum. The view appears now to have been accepted that teaching on mental disorders is of secondary importance to educating the student in the psychological aspects of physical disease and of his relation with his patients. In selection, the early enthusiasm for the use of tests and selection procedures instead of traditional methods has settled down to a useful compromise in which the value of character as well as mere intellect is recognized. Some remarkable figures are given for the incidence of personality problems requiring psychiatric help among medical students,

amounting to nearly half in some studies, and it is refreshing to hear that at one school at least the students were "as a group rather hostile to psychiatric help."

The report is a readable but rather inconclusive presentation of the present situation in the United States, and it contains much experience from which we in Britain could benefit. It would be a pity if medical-school authorities expressed any strong views without first reading this book and being aware of the excellent bibliography on the subject. A selection of original papers likely to be of use to those concerned in designing the medical curriculum is given at the end of the book, and sets of these have been reprinted as a companion to the report.

ALEXANDER KENNEDY.

THERAPEUTIC THORNS

Side Effects of Drugs. By L. Meyler. Translated by Ph. Vuisje and W. Mulhall Corbet. (Pp. 268. £1 10s.) London: Elsevier Publishing Co. 1952.

There are no potent therapeutic roses without their thorns. In this work the author has attempted to enumerate all the side-effects of various drugs in common use in the hope that the book will be useful in determining whether new symptoms arising in the course of certain diseases are due to the malady suffered or to the remedy given. The ambition is laudable, and one can imagine a work of reference of this kind being of the greatest service. The present volume, however, is the most extraordinary hotch-potch of information on the subject derived partly from original articles and partly from a study of the abstracts in *Excerpta Medica*. The facts are thrown together without any plan or arrangement in an utterly higgledy-piggledy and inconsequent manner interspersed with the most erratic punctuation. The translators have a somewhat sketchy knowledge of English, derived, it would seem, from an extensive study of Mr. Jingle's pronouncements. Little or no attempt is made to indicate the relative frequency of this or that side-effect or toxic reaction, their mode of production, or their prevention and treatment. A sentence describing some of the side-effects of "antabuse" will indicate better than any description the singular style of the book:

"The patients feel very sick, they have a throbbing headache; itching erythema; glycosuria. Fatal cases have been reported. A patient died after taking 30 ml. of rum; a marked dilatation of the right heart was found. Tetany due to hyperventilation; acute nephrosis. Persons taking antabus cannot use tonics and cough medicines in alcoholic vehicles; neither can they have massage with alcohol."

While the book has a certain charm because of its ingenuous quality and the amount of odd and alarming information which it contains, it can hardly be recommended.

D. M. DUNLOP.

Among new editions of British books that have appeared recently is MacKenna's *Diseases of the Skin* (Baillière, Tindall and Cox, 42s.). The fifth edition has been prepared by Dr. R. M. B. MacKenna, son of the original author, Dr. R. W. MacKenna. It is a textbook designed to meet the needs of student and practitioner, and has been completely revised. Many illustrations are included, some in colour. Dr. C. Langton Hewer has revised his *Recent Advances in Anaesthesia and Analgesia* (J. and A. Churchill, 30s.) for the seventh edition, and added a new chapter on the induction of hypotension to minimize blood loss during operations. Many chapters have been largely rewritten. In the thirteenth edition of Dr. W. M. Frazer's *Textbook of Public Health* (E. and S. Livingstone, 42s.) the author has made many changes in order to describe the effects of the National Health Service on the public health and hospital services. New material is also included on the National Assistance Act of 1948, and on the supervision of milk supplies. In the sixth edition of his well-known textbook *Medicine: Essentials for Practitioners and Students* (J. and A. Churchill, 37s. 6d.) Dr. G. E. Beaumont writes that he has endeavoured to omit what one of his reviewers referred to as the "organic nonsense" and the "historical nonsense" of medicine, and he has added much material on recent advances. There are new articles on, among other subjects, Q fever, temporal arteritis, anticoagulant drugs, headache, and the adrenocortical hormones.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 21 1953

THE VESALIAN HERITAGE

Who are they whose work forms the foundation of scientific medicine? In judging special eminence opinions may differ, but few would dispute the claims of four men—Andreas Vesalius of Brussels (1514–64), William Harvey of Folkestone (1578–1657), Herman Boerhaave of Leyden (1668–1738), and Louis Pasteur of Dole (1822–95). On Vesalius, first of these great men in point of time, two works have appeared quite recently. One is *Three Vesalian Essays*, issued by the New York Academy of Medicine; the other, by Professor Singer, is *Vesalius on the Human Brain*, and is reviewed at p. 449.

Vesalius is a critical figure not only in the history of medicine but also in the history of thought and therefore in world history. His great book, *De Humani Corporis Fabrica* (1543), "On the Working of the Human Body," is a turning-point of the human spirit, for it set men on the task of exploring with their hands and eyes the intimate nature of living things. In it is clearly felt for the first time since antiquity the authentic and refreshing breeze of scientific research, conscious of itself and of its aims. In that book the systematic observation of Nature is set forth as a guide to the systematic control of Nature: *savoir afin de prévoir*. Foreseeing, *prognosis*, the Father of Medicine advised us more than two thousand years ago, lends peculiar confidence to the physician and peculiar power to his words. Anatomy, the only sure foundation of prognosis and the basis of all that is exact in medicine, must always look back to Vesalius. It is likely that Vesalian research and the flow of Vesalian literature will long continue, for the book of Vesalius is both enormous and difficult; it is a thing of such beauty that it must arrest attention in any library or museum; its author's life was linked with certain great movements of history; he was a spiritual wanderer between two worlds, the mediaeval and the modern. There are still many unsolved problems concerning both the man and his book, and their solution demands many kinds of knowledge seldom assembled in the same head.

For many years it had been known to a small circle that there survived some of the wood blocks of the figures in the great work of Vesalius. In 1932 the matter came to the ears of the late Dr. Samuel W. Lambert, a distinguished New York physician. On Lambert's action these blocks were ultimately discovered by Dr. Wiegand, of Munich, in the university library there. In 1934 they were used by the New York Academy of Medicine in conjunction with Munich University for their magnificent volume *Vesalii Icones Anatomicae*. This superb volume, itself a showpiece, contains all the figures associated with Vesalius and puts them within the reach of all who have access to a good library. This was none too soon. The service which the initiators of this noble tome were rendering to learning was greater than they knew, for the original blocks were utterly destroyed during the war.

A hardly less important production was Harvey Cushing's posthumous *Bio-Bibliography of Vesalius* (New York, 1943), which appeared at about the time that the blocks of Vesalius were themselves destroyed. Finally revised and certainly greatly improved by Professor John F. Fulton and his coadjutors, after Cushing's death in 1939, this work represents a constant interest of Cushing's, extended over more than 40 years. Every bibliographical detail that could be desired is included. It is an indispensable work not only for the life of Vesalius but for the study of a most eventful and critical period of cultural and political history.

Since the end of the war the rate of appearance of Vesalian literature has accelerated rather than slowed. Professors J. B. de C. M. Saunders, the anatomist, and C. D. O'Malley, the historian and Latinist, have long been collaborating in Vesalian research. In 1946 they produced an impressively documented translation of the difficult *Blood-letting letter of 1539*. Though this work of Vesalius is of little scientific significance in itself, it is perhaps the most important of all his writings for the understanding of the background of his life, his labours, and his personality.

In the same year the Wellcome Historical Medical Museum issued Professor Singer and Dr. Rabin's *Prelude to Modern Science*, a translation with running commentary of the *Tabulae Sex* of 1538, the first anatomical work of Vesalius. It displays the mental equipment with which he started on his great task and reveals much of the origin of our own anatomical nomenclature. We still lacked an English version of any considerable part of the *Fabrica*; Vesalius issued with it in the same year his so-called

Epitome of that work. This was intended not for medical but for "general" readers and perhaps especially for art students. It was rendered into English for the Historical Medical Library of Yale by Professor Lind in 1949, and is perhaps of most value for the light it throws on the adaptation by Vesalius of ancient Greek anatomical terms. It was followed in 1950 by the convenient quarto volume by Saunders and O'Malley, *The Illustrations from the Works of Vesalius*. This last contains the best account of the life of Vesalius together with translations of the captions of all the figures that he used and much other very valuable material.

The *Three Vesalian Essays* is now issued to accompany the *Icones* of 1934. In the foreword Dr. Malloch justly remarks that to many the impressions of the woodcuts in the *Icones* are even more beautiful than those in the original works from which they were prepared. The *Three Essays* open with a learned account by Dr. Lambert of the initial letters used by Vesalius. These are skilfully and often humorously decorated with human figures. They tell much of anatomical and surgical practice of the time. "Marginal Notes" by Dr. Willy Wiegand recount the story of the discovery of the lost blocks. Lastly Mr. Ivins eloquently expounds yet again his unconvincing and quite untenable theory that Vesalius was a nonentity whose sole originality was in choice of artist and that his text is of little value. In fact the Latin of Vesalius is difficult and verbose. This may explain why no substantial part of the *Fabrica* has been made available in English. However, in his *Vesalius on the Human Brain* Professor Singer has now provided a version in plain English of all on that subject that the *Fabrica* has to say. He has equipped it with an illustrated record of the debt that the account of the brain by Vesalius owed to its predecessors.

In looking at all these beautifully illustrated books the reader has constantly to remind himself that Vesalius had no means of preserving or hardening pre-structures, and that he had hardly any effective predecessors since Galen, though it is true that he acknowledges inadequately such debt as he does owe them. Professors O'Malley and Saunders have long been at work on their translation of the complete text of the *Fabrica*. Its completion and publication must still take years—perhaps many years. When in due course it appears it will crown the series of *opera magnifica* which meanwhile not unworthily commemorate the great father of anatomy whose work is the foundation of all scientific medicine.

TRICHLORETHYLENE ANALGESIA
IN LABOUR

Provision for pain relief during childbirth varies widely from country to country. At one end of the scale is Britain, with some form of analgesia available to every mother: at the other are countries where even leaders in the field of obstetrics hold the opinion—perhaps not always shared by their patients—that the pain of childbirth has a beneficial effect on mother and child and that relief is undesirable. It is sometimes held against us in Britain that so many home confinements are supervised by midwives, but a point in favour of our practice is that midwives are permitted, if not encouraged, to administer gas-and-air analgesia. This method, if it has not brought complete relief to more than a relatively small proportion of patients, at least has done few of them and their babies any harm. Moreover, ever since gas-and-air analgesia began to come into fairly general use by midwives in this country in the years immediately before the war there has been a restless search, perhaps stimulated by an insistent demand from the public, for an alternative method which could be equally easily and safely self-administered and which would be more effective in a greater proportion of cases.

Many are now pinning their hopes on trichlorethylene ("trilene"), the analgesic powers of which have been known ever since the first world war, when German workmen learnt the effects of inhaling the vapour as they leaned over degreasing vats containing the liquid. In recent years trichlorethylene has been used on an increasing scale both as an anaesthetic and as an analgesic, and its actions and effects are reasonably well understood pharmacologically and clinically. If numbers of administrations mean anything, it has proved itself a very safe anaesthetic and analgesic. A characteristic example of the careful and thorough investigations into the efficacy of trichlorethylene as an analgesic in labour is that of Seward,¹ who four years ago determined the effective concentrations of trichlorethylene in air, and concluded that it was a more satisfactory and powerful analgesic than gas and air, though he pointed out that its prolonged use might lead to some cumulation. The advisability of allowing midwives to use trichlorethylene has been under consideration for the last few years by a committee consisting of obstetricians, anaesthetists, midwives, and research workers. Difficulty has apparently arisen over which apparatus midwives should be allowed to use. Understandably, the desire

¹ *Lancet*, 1949, 2, 781.

of the committee has been to make sure that any device approved for this purpose should deliver suitable, safe, and unvarying concentrations of the vapour. So far the committee has not yet given its approval to any apparatus. Commercial interests, however, alive to the possibilities of development in this field, have put several inhalers on the market. These are not only said to administer the concentration of trichlorethylene in air which clinical observation has determined to be effective, but also have a device which automatically neutralizes the effects of changes of temperature within the inhaler. On another page in this issue Dr. E. E. Rawlings describes his experiences with one such inhaler. He comes to the conclusion that the analgesia produced by it is satisfactory, but he adds a similar caution to that of Seward in advising against prolonged administration. For this reason he delays the administration of trichlorethylene until the cervix is dilated to three finger-breadths. On the basis of these two careful investigations alone—and there are others—it seems that perhaps there is still some justification for caution before allowing midwives to administer trichlorethylene on their own, not so much on the grounds that the inhaler is not mechanically all that it should be, but rather that trichlorethylene itself, by virtue of its cumulative effects, demands skill and judgment in the administrator which not all midwives would necessarily possess. It would in any case hamper the acceptability of an analgesic if the time for beginning its administration had to be fixed by any criterion other than the patient's sensations. Pain, being subjective, can hardly be related to some objective fact such as the dilatation of the cervix. Any acceptable method of analgesia should be usable as soon as the patient desires relief from pain, the intensity and nature of which only she can judge. In the meantime there is no reason why doctors should not continue to administer trichlorethylene analgesia in labour with one of the inhalers available. The accumulation of their experience will help to clarify still further the value and place of trichlorethylene in labour.

At least one expression of opinion on this vexed question will find general agreement—that in spite of the progress that has been made the alleviation of pain in labour remains an urgent and important task for all working in this field.

LEUKAEMIA IN DOCTORS

In the U.S.A. leukaemia has been found to occur much more frequently as a cause of death among radiologists than among physicians in general, and the excess has been associated with exposure to x rays.¹ The radiologists constitute less than 1½% of the medical profes-

sion, and it would be interesting to know whether physicians who are exposed only occasionally to x rays show any increased incidence of leukaemia in comparison with other professions. In Britain evidence on this point is lacking, and the Registrar-General's report on occupational mortality during the three years round the census of 1931 gave no conclusive indication of any such excess.² In the years 1930–2 there were five deaths among 25,063 physicians and surgeons between the ages of 20 and 65 compared with an expectation of three if the rates at each age had been the same as for all males; and there were three deaths at ages over 65 in a population of 4,838. In another professional group of similar size, clergymen and other ministers of religion, nine deaths occurred at ages 20–65 in a population of 25,721 compared with an expectation of three; and there were six at ages over 65 among 10,976. These figures were not suggestive of special risk from x rays at that time, and no more recent national figures are available; the occupational mortality analysis round the census of 1951 must be awaited.

In a recent paper Peller and Pick³ have produced statistics derived from the obituary notices of physicians which appeared in the *Journal of the American Medical Association* during 1947–51, and have compared them with the official statistics of deaths in the United States in 1948. The cause of death was disclosed for a total of 11,481 physicians out of 14,516 whose deaths were reported, and 133 of the total were attributed to leukaemia and 1,426 to other forms of malignant neoplasm. The proportion of leukaemia to all causes of death among the doctors was 5% at ages under 35, 2.3% at 35–44, 1.1% at 45–54, 1.2% at 55–64, and 0.9% at ages 65 and over, compared with about 1.2, 0.8, 0.7, 0.6, and 0.4% respectively among all males according to official statistics. Proportionate mortality may be deceptive unless the death rates from all causes of the groups compared can be safely assumed not to differ appreciably. But the authors estimate that, after correcting for peculiarities in the age distribution, there was no appreciable disparity between the general death rates of physicians and the average for all males.

The Registrar-General's statistics of 1930–2 showed that in England and Wales mortality of physicians and surgeons from all causes was 8% below average at ages 25–34, 6% below at 35–44, 8% above at 45–54, and 11% above at 55–64. It is highly probable that this gradient of relative general mortality is now more pronounced than it was, and this might go some way to account for the diminution with advancing age in the proportionate mortality for leukaemia in physicians, from four times the average at 25–34 to about twice the average at 45–64. Neither this, nor the changes in the method of selecting the underlying cause of death which were made in the United States after 1949, seem to account for the excessive leukaemia death rate indicated in this study among doctors in the U.S.A. It is estimated, further, that among the physicians who were neither radiologists nor dermatologists the leukaemia

¹ Dublin, L. I., and Spiegelman, M., *J. Amer. med. Ass.*, 1948, **137**, 1519.

³ Peller, S., and Pick, P., *Amer. J. med. Sci.*, 1952, **224**, 154.

rate at ages between 35 and 74 was twice the average for all males. There remains the possibility that diagnosis and certification of leukaemia is more complete in respect of doctors than the general population, and, since this can neither be proved nor disproved, no firm conclusion can be reached at present. It is reassuring that by the same process of calculation the authors show that proportionate mortality from all other forms of malignant neoplasm among the physicians was substantially below that of all males at each age group between 40 and 75.

WORLD FOOD NEEDS

Over large areas of the world the supply of food remains less than it was before the war. This is the conclusion to be drawn from the Second World Food Survey undertaken by the Food and Agriculture Organization of the United Nations.¹ The first survey was made in 1946, when the world food position was at its worst, supplies were at their smallest, distribution most uneven, and hunger and outright famine most widespread. Since then, over the world as a whole, food production has expanded, but the increase has barely kept pace with the increased population resulting from a higher birth rate and, owing to the control of mass diseases such as malaria, a decreased death rate. Clear signs of any far-reaching changes in the scale of food production, essential for the improvement of nutrition, are lacking. In what are known as the O.E.E.C. countries—that is, the countries of Western Europe (except Spain and Portugal) and Greece and Turkey—if the total agricultural output was reckoned at 100 before the war, it is now 111. In the underdeveloped areas elsewhere in the world progress since the war ended has been much slower, and political disturbances in the Far East have hindered recovery. In striking contrast to the slow and painful progress in most of the other parts of the world, the high post-war output of North America stands out. In the United States, if again the pre-war figure be taken as 100, it is now 131, and in Canada 130. A quantitative estimate for the world as a whole shows the average food supplies, measured in calories, to be 6% lower than in the pre-war period. In the Far East, where nearly one-half of the world's population is concentrated, the decline is of the order of 10%. The large gaps between the better and the worse-fed nations have been widened. In India the calories supplied by the available food are 24% below the estimated need; in the United States 18.5% above the estimated need, and in the United Kingdom 17% above. To assess nutritional quality is more difficult than a quantitative reckoning, but surveys in most of the heavily populated regions of the world have provided evidence that diets are not satisfactory nutritionally.

The F.A.O. has worked out for each region of the world the gross quantity of foodstuffs that it should be possible to produce by 1960. One overriding consideration is that in seven years' time there is likely to be an

11% increase in world population, which is increasing by slightly more than 1% per annum. In Latin America, the Near East, and Africa the increase is about 2%, and in the Far East probably more than the 1% shown in statistics admittedly faulty. The largest increases of population are still taking place in areas where food supply is most seriously inadequate. On the other hand, the problem may be eased by the improvement in human efficiency resulting from successful public health measures. The attainment of the targets for 1960 assumes a favourable economic and political situation, financial and technical assistance for underdeveloped countries, and an immense capital investment.

FEELING THE COLD

The patient who complains of the cold may have a poor circulation through the skin or a poor metabolic heat production, as in myxoedema, muscular hypotonia, or flaccid paralysis, since the musculature is an important heat-producing tissue. Lack of subcutaneous fat, as in malnutrition or wasting disease, allows the heat produced to leak away faster, while the thicker layer of fat normally present in women enables them to stand the cold better than men. Their heat loss is 10% less under the same conditions. Their skins are colder in cold weather, but warmer in the hot by over 1° C. than those of men, because they sweat less. Clothing is an important barrier against the cold provided it is dry, absorbs sweat easily, and remains porous, so that air is trapped as stationary poorly conducting air cells. To these well-known facts must be added one sometimes overlooked: cold sensations are relative. If the left hand is placed in a bowl of water at 20° C., the right hand in one at 40° C., and then both are transferred to water at 30° C., the same water feels cold to one hand and hot to the other. This raises the question of how we appreciate cold, and it has to be admitted that there is no satisfactory explanation of all the facts.

Cold and warmth are separately appreciated.¹ Different points on the skin respond either to cold or to warmth, and peripheral sensory nerves when treated with cocaine or asphyxiated or cooled lose the power to transmit cold or hot sensations separately and under different conditions.² Cold-sensitive spots are at least 10 times more numerous than heat-sensitive ones, and it seems probable that they are fixed in location in spite of the fact that their distribution appears to change from test to test. They are not all equally sensitive to a given cold stimulus, and their individual sensitivities are constantly changing. This accounts for spatial differences found in different experiments. Certainly in the outer part of the cornea, in much of the conjunctiva, and in the glans penis—all sites which lack most of the senses of ordinary skin—cold is appreciated by histologically distinct sense organs, the end bulbs of Krause; these are small solid spheres of epithelial cells among

which the sensory nerve fibrils branch. Elsewhere in the skin, biopsy of cold-spots has not shown any special structure.

The normal temperature of exposed skin is about 30–32° C., and usually the cold-spots give rise to sensations of cold only below 30° C. Paradoxically, however, they also give rise to sensations of cold when heated to 45° C., care being taken not to warm the heat-spots at the same time. They also may respond to mechanical and electrical stimulation. Hensel has been able to show with the help of his delicate thermocouple introduced into different levels of the skin³ that warm-spots continue to signal the heat long after the warmed skin has attained constancy at the new hotter temperature, while cold-spots in the tongue continue to send cold sensations when the tongue is kept constantly cold.⁴ In fact Dodt and Zotterman⁵ have demonstrated that these temperature sense organs send impulses up their nerves with a frequency which corresponds to the constant temperature, whatever it is. Further, they find that, in the cat's tongue at least, the heat spots cease to signal at temperatures over 47° C., and it is the cold spots in their paradoxical phase which then yield the sensation of heat.

How do these end-organs act like thermometers? Possibly, as O'Connor and McCarthy⁶ have recently suggested, changes in the physical state of fatty acids in the skin with changes in temperature may have something to do with the response, but it must be remembered also that the metabolic reactions of skin and nerve, like all chemical reactions, double their velocity for every 10° C. rise of temperature. The refractory period of the sense organ will change, and also the nature and concentration of substances in the surrounding tissue fluid. There may also be changes in blood flow and sweat rate to reckon with, for the skin is an organ and not a homogeneous tissue. Hitherto most research on temperature sensations has been carried out on normal persons. Perhaps repetition of the experiments on people with metabolic and neurovascular disorders, or with skin diseases such as psoriasis, would help to clarify what is at present a complex problem.

NURSES IN HOSPITAL

A model piece of research following upon the report, published in 1947, of the Working Party on the Recruitment and Training of Nurses has been undertaken by the Nuffield Provincial Hospitals Trust in the shape of a job-analysis of hospital nursing.¹ The work has been carried out by seven field investigators under the directorship of Mr. H. A. Goddard, with the help of an advisory panel of which Sir Ernest Rock Carling has been chairman. The investigators have directed their attention to the pattern of hospital ward work, the allocation of duties among different grades of nurses, and the manner in which the needs of patients are met. Twelve general teaching hospitals, covering a wide geographical area, were taken for the purpose, and about a week was spent in each of the medical and surgical wards selected for observation.

A distinction is made at the beginning of the latest report between basic nursing—by which is meant the care required for the well-being and comfort of the patient irrespective of the disease from which he is suffering—and technical nursing, a term which describes the special care given on account of the disease. Basic nursing was found to take up rather more than two-thirds of the nurse's time, and technical nursing just under one-third. The view of those responsible for this report is that the two functions cannot be separated and assigned to different individuals. Obviously the patient's physical comfort and freedom from mental worry may be as important a factor in his recovery as any technical treatment, and his nursing needs in both respects must be met by the same person.

It is sometimes said that the doctor claims an undue proportion of the time of the ward staff, but it was found on analysis that the time spent by the nurse with doctors averaged less than half an hour per bed per week. Consultants, in this observation at least, were always escorted by nursing staff, but in the case of house officers the practice varied. Allied with this was the vexed question of early wakening in the wards. The determining factor is the routine tasks to be completed before the doctors' rounds, which may begin at 9 a.m. In 18 of the 22 wards investigated patients were wakened before 5 a.m. A study of the rounds of visits showed that of 350 rounds by consultants 43 began before 10 a.m., a few before 9 a.m., and on 21 occasions house-physicians and house-surgeons visited the wards before the earlier hour. In two-thirds of the wards consultants' rounds were between noon and 2 p.m., the peak hours for basic nursing. Some ward sisters said that they had established the precedent that there should be no rounds during patients' mealtimes.

Student nursing figures largely in this investigation. Shortages of trained nursing staff or domestic workers react on the student nurse, who has to make good most of the nursing deficiency. So long as student nurses comprise more than half the labour force in the wards it is inevitable that their training should on occasion be subordinated to administrative necessity. The term "student nurse" is misleading; she is employed in the ward, but not specifically taught. The report states that maximum use is not made of the grade of ward orderly. Many people now filling the domestic post of ward orderly would be well qualified with suitable training to hold auxiliary nursing posts. Actually 25,000 ward orderlies are employed in the hospitals in this country, and there would be no difficulty in most areas in increasing the number, whereas assistant nurses are not coming forward in as large numbers as was hoped. To avoid the present excessive dependence on student nurses it is urged that more nursing auxiliaries be recruited from the labour sources which now provide ward orderlies, and, in the words of the advisory panel, the practical work entrusted to the student nurse should be planned in accordance with her training needs and carried out in conjunction with trained staff.

REFRESHER COURSE FOR GENERAL PRACTITIONERS MISCARRIAGE

BY

JOHN BEATTIE, M.D., F.R.C.S., F.R.C.O.G.

Gynaecologist and Obstetric Surgeon, St. Bartholomew's Hospital, London

In this article the terms miscarriage and abortion are synonymous, and refer to the termination of pregnancy before the twenty-eighth week of intrauterine life. The incidence of spontaneous abortion in this country probably varies between 8 and 10% of all pregnancies. It is difficult to assess the frequency with which abortion is induced criminally, but the figure is high, particularly in the large cities, and it is this type of abortion which has the highest morbidity and mortality.

Causes

The commonest cause of spontaneous abortion is an abnormality of development of the foetus or trophoblast which is severe enough to cause death. This condition is in most cases a non-recurring factor, and the patient has an 80 to 90% chance of going to full term on the next occasion. For this reason it is safe to reassure the patient who has miscarried for the first time that her next pregnancy will most likely be uneventful. The mother is always anxious for a reason why she has miscarried, and it is safe to tell her that the most likely cause of a single miscarriage is a developmental abnormality of the foetus, so that it is as well that it did not survive. Reassurance is then given that such abnormalities are most unlikely to recur in subsequent pregnancies. Needless to say, this advice should not be given when the patient is still suffering only from a threatened miscarriage.

Probably the second commonest cause of miscarriage is an abnormality either of hormonal balance or of development of the uterus. In the former case the ratio between pituitary and placental hormones and oestrin and progesterone secretion is abnormal. In the latter case the uterus, being deficient in development, becomes more and more irritable as the cavity is stretched by the growing foetus, so that it begins to contract and retract, thus discharging its contents.

Diabetes, chronic nephritis, the acute specific fevers, and any disease which produces an acute toxæmia are less common causes of abortion. There is little evidence at present that rhesus incompatibility is a cause of miscarriage in the first three months of pregnancy. An acute emotional upset undoubtedly can cause the uterus to evacuate its contents.

A fibromyoma of the uterus may cause a miscarriage if it is submucous in distribution. However, many women with small uterine fibroids which are not submucous both succeed in becoming pregnant and in having a normal labour. Retroversion of the uterus is often associated with early pregnancy, but the malposition itself is rarely the cause of abortion. If abortion should be threatened or become inevitable in a first pregnancy, then the accompanying hypoplasia of the uterus is the more likely cause.

Thyroid deficiency may be a cause of miscarriage, but it is unjustifiable to administer thyroid unless clear evidence of deficiency is present. It is very doubtful if deficiency of vitamin E is ever a cause of infertility or miscarriage, at least in Britain.

Threatened Abortion

The symptoms of this condition are well known: bleeding from the uterine cavity, with or without a dull backache suggestive of the onset of menstruation, or even the presence of rhythmical uterine contractions. It is wise to pass a speculum with great gentleness to make sure that the haemorrhage is not caused by a mucous polypus or even a

carcinoma of the cervix. It is important to cause the patient as little discomfort as possible; a well-lubricated Fergusson, or duckbill, speculum should be passed upwards and depressed backwards until the cervix is exposed. It is common to have difficulty in finding the cervix because the speculum is passed into the anterior fornix.

The type of bleeding in threatened abortion is of interest. The haemorrhage comes from either the potential cavity in the decidua lining the uterus, which is present until the ovum fills the whole cavity at the third month, or more often from the attachment of the foetal trophoblast to the decidua basalis or the decidua capsularis. In either case the haemorrhage is at first bright in colour. If this continues to be bright red and increases in amount the prognosis is correspondingly less good. A single bright loss followed by the escape of old brown blood merely means that an initial haemorrhage has occurred but none since. It is not uncommon in threatened abortion after the third month for such a dark brown blood loss to go on for one to two weeks. This can usually be taken to mean that the foetus is growing satisfactorily; as the foetus grows it squeezes out the remaining old blood from the uterine cavity.

The amount of blood loss and pain which can occur without the abortion becoming inevitable is surprising. All cases should be treated as threatened unless there is very good evidence for saying they are inevitable.

With a threatened miscarriage the patient should stay in bed for five days after the bright red haemorrhage has ceased. The loss of dark brown blood is not a reason for keeping her in bed. There are few households now where a patient can be given a bed-pan on these occasions, and it will do her little harm if she is encouraged to use a commode or to go to the lavatory when necessary. Other-wise she should stay strictly in bed. It is important to give the patient paraffin or any mild aperient which suits her so that she does not have to strain at stool. Administration of sedatives is important. An initial dose of morphine, of ½ gr. (11 mg.), is advisable if the patient is much upset, and then phenobarbitone, 1 gr. (65 mg.) or less, three times a day, should be given for the next few days. Opinions differ so much on the vexed question of hormone deficiency in these cases that it is difficult to be dogmatic on this subject. The chances of a spontaneous recovery are high, and it is doubtful whether the administration of progesterone will be of any value, but the injection of 10 mg. on alternate days for five doses can do no harm. The use of anterior pituitary and chorionic gonadotrophic hormones is valueless.

When the patient has recovered she should be warned to take great care at the next two period times and to avoid coitus for the next three months.

Inevitable Abortion

A threatened abortion becomes inevitable when the bleeding increases greatly and uterine contractions become rhythmic and strong. The cervix then begins to dilate and products of conception may sometimes be felt protruding through the external os. Before the third month it is quite common for the foetus and trophoblast to be extruded intact when the abortion becomes complete. At about the third month the membranes often rupture and the foetus is passed, leaving the placenta behind, and all the complications of an inevitable incomplete abortion may arise.

It is of vital importance therefore to encourage complete evacuation of the uterus and to conserve blood loss

as much as possible. Everything that is passed per vaginam should be kept for examination; in this way it is often possible to establish that the abortion is complete. The passage of a decidual cast in a case of ectopic pregnancy may be mistaken for products of an intrauterine conception.

Treatment consists in complete rest in bed, which of itself lessens the amount of bleeding. An intramuscular injection of ergometrine, 0.5 mg., should be given four-hourly for three doses, and may be repeated in the next 12 hours. The use of oxytocin, 5 units (0.5 ml.), may be substituted for ergometrine, but the latter has a more prolonged effect on the uterine muscle. Posterior pituitary extract or vasopressin should never be used. Apart from maintaining asepsis as much as possible there is no other treatment to be given in a complete miscarriage other than the administration of the liquid extract of ergot, 1 dr. (3.5 ml.), thrice daily for a few days, as involution of the uterus is slow after abortion.

Inevitable Incomplete Abortion

This condition may create one of the worst emergencies that any practitioner has to deal with. It is possible for a woman to bleed so severely within the space of a few hours that the haemoglobin level drops to 20 or 30%, and often accompanying this is a severe degree of shock. If a patient is moved to hospital by ambulance before the shock is treated the latter may increase to a dangerous degree so that resuscitation becomes impossible. Such patients require immediate first aid, and if a flying squad is available this should be called upon to administer blood in the house before an ambulance takes the patient to hospital. The blood pressure should be taken and ergometrine, 0.5 mg., be given at once by intramuscular injection. The patient should be encouraged to take warm sweetened drinks and should be kept reasonably warm; the foot of the bed should be raised and morphine $\frac{1}{4}$ or $\frac{1}{2}$ gr. (16 or 11 mg.), given. When the blood pressure has reached a more normal level the patient should be transferred to hospital.

In some cases an incomplete abortion is not associated with severe bleeding, but the haemorrhage continues intermittently for many weeks and is due to a placental polypus. The uterus remains bulky and the cervix slightly dilated. Surgical evacuation of the uterus is then essential, and the patient should be admitted to hospital.

Sometimes it is difficult to decide whether prolonged irregular bleeding after a miscarriage is due to a placental polypus or to a complete abortion followed by an anovular type of bleeding from the endometrium. This may occur before the ovarian cycle is re-established normally. In either event, if the haemorrhage does not cease after a reasonable time a curettage is the best and most efficient form of treatment.

Septic Abortion

The uterine cavity may become infected before an abortion begins. This is often the result of a criminal attempt to produce abortion by an instrument in the cervical canal. The patient presents with severe suprapubic pain and a raised temperature and pulse rate. There may be no bleeding or uterine contractions and the cervical canal remains closed. There is some rigidity of the abdominal wall spreading outwards and upwards from the pelvic brim. The uterus is exquisitely tender on bimanual examination. Unlike puerperal intrauterine infections the organism in cases of septic abortion is often the staphylococcus and not the haemolytic streptococcus. Other organisms may also be present, such as *Bact. coli* and *Streptococcus faecalis*. An anaerobic streptococcal infection is not uncommon and gas-forming organisms may also be found. Massive doses of crystalline penicillin, 500,000 units six-hourly, should be given, together with a sulphonamide, until the symptoms and signs subside. It is wise to continue the antibiotic treatment for at least five days after the temperature has reached normal. A sterile throat swab should be used to

obtain a specimen of secretion either from the vault of the vagina or from the cervical canal through a vaginal speculum as soon as the patient is first seen. This is particularly necessary at present, because it is now common to find penicillin-resistant staphylococci. The swab should be sent to the laboratory at once for culture and to determine the sensitivity to antibiotics and sulphonamides. After the temperature has subsided the uterus may be left to evacuate itself spontaneously if the ovum is dead.

In cases of inevitable incomplete septic abortion the treatment may be of two kinds. First, the infection may be treated as described above and, if necessary, a blood transfusion given (with iron by mouth) to combat the anaemia. When the infection has been cured the uterus is then evacuated—by surgical means if oxytocic drugs fail. The theoretical advantage of this line of treatment is that the protecting mechanism, consisting of a zone of plasma cells and polymorphonuclear leucocytes in the uterine wall, is left intact while the infection is still present. The disadvantage is that haemorrhage may be severe, and dead placental tissue and blood clot in the uterus are excellent media for the growth of organisms, particularly of the anaerobic variety.

Secondly, it is possible to start giving the antibiotics and sulphonamides at the same time as ergometrine, and then after a short time evacuate the uterus surgically if necessary. It is common for the temperature and pulse rate to drop dramatically after the removal of a large piece of placenta which has been blocking the internal cervical os and allowing pus to collect above it.

Septic abortion, particularly in virulent infections, may be complicated by a spread of the organisms from the uterine cavity, causing salpingitis, peritonitis, parametritis, or septicaemia. In self-induced abortion the infection may reach the peritoneum directly owing to the passage of an instrument through the pouch of Douglas. If the instrument is passed into the cervical canal with the woman in the squatting position, perforation of the fundus may occur, but penetration sideways into the broad ligament is more likely to take place. This may produce an acute parametritis. A strange variety of instruments have been used in self-induced abortion, and any of these may be passed by mistake through the urethra into the bladder. In view of the dangers associated with septic abortion it is probably better to admit these cases to hospital for treatment. The medico-legal aspects of abortion have been discussed by Dr. Donald Teare in an earlier contribution to this series (see *Journal*, April 26, 1952, p. 915).

Missed Abortion

The formation of a carneous mole is uncommon. In these cases the patient usually notices a little bloodstained discharge for a day or two at about the eighth to the twelfth week of pregnancy. After this the breasts cease to be tender and swollen, but the patient often pays no attention to this. It is necessary in all cases of pregnancy to examine the abdomen at the fourth or fifth month in case the uterus has ceased to increase in size after the third month. A carneous mole can remain in the uterus for many months, and if it is not diagnosed the mother may have everything ready for the baby, only to be told late in pregnancy that the foetus died in the first few weeks. In cases of missed abortion the breasts show no signs of recent activity and the uterus ceases to grow from the date of the small haemorrhage. A pelvic examination reveals a firm uterus usually smaller than that of a three-months pregnancy. The uterus is filled with laminated blood clot with a shrunken amniotic sac in the centre. The biological pregnancy tests become negative about 10 days after the death of the ovum in these cases, and a pregnancy test should be carried out to confirm the diagnosis if this is made shortly after the vaginal haemorrhage.

All cases of carneous mole undergo spontaneous evacuation eventually, but sometimes it is many months before this happens. Massive doses of oestrogenic preparation never cause sensitivity of the uterus to oxytocic drugs when

the foetus is alive, and it is doubtful if they do so even when the foetus is dead. It is probably wiser to leave the uterus to evacuate itself spontaneously. If the patient is distressed by the knowledge that she is carrying about a dead foetus the uterus may be emptied surgically, using either laminaria tents or ovum forceps.

Vesicular Mole

This condition is one of the rarer causes of abortion, but it is of great importance because of the severe haemorrhage and sepsis which may occur and because a chorion epithelioma may develop. The patient usually begins to bleed between the eighth and the twelfth week of pregnancy. The uterus is always much larger than it should be, reaching nearly to the umbilicus, except when it is associated with a missed abortion. It is doughy in consistence and a little tender. If vesicles are seen in the blood lost from the vagina the diagnosis is established, but unfortunately these are not often found.

It is quite easy to make a mistaken diagnosis of vesicular mole. The differential diagnosis amounts to a mistake in the date of the last menstrual period, multiple pregnancy, pregnancy and fibroids, or pregnancy and an ovarian tumour. The diagnosis is established by having a quantitative biological pregnancy test performed. A morning specimen of urine should be collected and the pathologist requested to carry out the test in undiluted urine and in a dilution of 1 in 200. If the test is positive in both cases a vesicular mole is almost certain to be present. A normal pregnancy at about the third month sometimes gives a positive biological pregnancy test in a dilution of 1 in 100.

The evacuation of a vesicular mole requires great skill and judgment, and the patient should always be admitted to hospital for this. If the abortion is spontaneous it is almost the rule for some vesicles to be retained in the uterus, and it is wise to curette these patients as a routine procedure two weeks after the spontaneous evacuation. The patient is never safe until the pregnancy test is negative, and this test should be repeated at four-weekly intervals until it is so. If the test remains positive and perhaps in increasing dilutions the danger of chorion epithelioma is great. A further pregnancy should be discouraged for at least six months to avoid confusing the issue.

Habitual Abortion

By definition this refers to any case in which three consecutive spontaneous miscarriages have occurred. It can be shown statistically that a woman who miscarries for the first time has about an 87% chance of going to full term the next time she is pregnant. A woman who has had two consecutive miscarriages still has a 63% chance in the next pregnancy, but after three consecutive abortions the chances of reaching full term on the fourth occasion drop to 16%.

In habitual abortion the cause is usually of maternal origin. It has been suggested that it may be due to deficiency of progesterone secretion, and good results are claimed from the use of progesterone or, alternatively, of high doses of stilboestrol, which are believed to stimulate progesterone secretion. It is difficult to be dogmatic about these treatments, as there are many conflicting opinions on them. Vitamin E has also been tried in these cases, but there is no convincing evidence of its value. If the basal metabolic rate is below minus 10, thyroid deficiency may be the cause of abortion and thyroid should then be given.

In cases of habitual abortion a hysterosogram should be done to exclude an abnormality of development such as a septate uterus, but any such condition is seldom found to be the cause. Fibromyomata of intramural or submucous distribution should always be removed if found in a case of habitual abortion. Deep cervical lacerations may be the cause of habitual abortion. Deep cervical lacerations may be repaired. Retroversion of the uterus should be corrected, if possible before pregnancy occurs, by the insertion of a Hodge pessary so that the pregnant uterus will not drop further back into the hollow of the sacrum. Only very occasionally is a ventri-

suspension justifiable, as the retroversion is often associated with a generalized hypoplasia of the uterus, which is likely to be the real cause of habitual miscarriage.

A popular treatment at present consists in the implantation of progesterone pellets. Six pellets, each of 25 mg., are introduced below the deep fascia covering the gluteal muscles or under the fascia covering the lateral aspect of the thigh. A general anaesthetic is advisable. If the pellets are placed more superficially they will find their way to the surface. Alternatively, stilboestrol may be prescribed. The dosage begins at 5 mg. daily by mouth, starting during the sixth or seventh week (counting from the first day of the last menstrual period). The daily dosage is increased by 5 mg. every two weeks until the fifteenth week, when 25 mg. daily is given. Thereafter the daily dosage is increased by 5 mg. each week. Administration is discontinued at the end of the thirty-fifth week, since a drop in oestrogen and progesterone normally precedes the onset of labour.

Limitation of activity at the missed period times must be insisted on, and defaecation should be controlled by the use of mild aperients. Coitus must be avoided altogether.

Finally, there is much evidence for saying that there is a functional factor in cases of habitual abortion which may be largely responsible for subsequent miscarriages. It is most important therefore to reassure the patient that she still has a chance of reaching full term. The elaborate treatment so often given to these patients may be a potent factor in increasing confidence, thus promoting the chance of a successful delivery.

VESALIUS ON THE HUMAN BRAIN

Vesalius on the Human Brain. Edited and Translated by Charles Singer. (Pp. 151. £1 1s.) Published for the Wellcome Historical Medical Museum by Geoffrey Cumberlege (Oxford University Press). 1952.

This is the first book to contain a translation into English of any substantial part of that truly epoch-making work on anatomy, the *Fabrica* of Vesalius, originally printed at Basle in 1543. It was the first great work of science in the modern manner, the first to adapt exact graphic treatment to biological research, and the first to introduce a positive basis into medical education. Professor Singer has chosen the section on the brain because it is probably the most mature section of the work of Vesalius and because it illustrates the trend of medical thought at the time, prior to the work of Harvey.

There can be no doubt that the *Fabrica* depended for its success on the magnificent illustrations, more accurate than any before them except those of Leonardo, who failed to publish his researches. The drawings have a remarkable dynamic quality, and they surpass those of Calcar, who drew the illustrations for the earlier work of Vesalius, called *Tabulae Sex* and dated 1538. Professor Singer does not think that Calcar was the artist of the *Fabrica*. The letterpress in its original Latin, which the translator stigmatizes as vast, verbose, clumsy, and ill-chosen, is greatly inferior to the drawings. Nevertheless this was the best account of the brain of that time and for several generations to follow, based as it was upon observation and not on tradition. Professor Singer gives some valuable notes on previous anatomical work, and he shows how Vesalius, in dissecting the brain, followed the method he had learned in Paris. Anatomists, historians, and others may well feel grateful to Professor Singer for providing a translation of this important part of a medical classic which exercised so profound an influence on the progress of medicine.

DOUGLAS GUTHRIE.

THE HUNTERIAN BIRTHDAY ORATION

Twenty years after John Hunter's death Matthew Baillie and Sir Everard Home arranged for the delivery of an annual oration on his birthday, February 13. The latest in the long succession of orators was Mr. L. E. C. Norbury, who, before the Royal College of Surgeons the other evening, gave a discourse in which he managed to throw a kindlier light on Hunter's character than has been current in recent times. He described Hunter as emotional and quickly moved to sympathy, and with a sense of humour which came out particularly in letters to his brother William and others. Some people had a notion that Hunter's marriage was unhappy, perhaps because of the often published story of his irritation at his wife's taste for fashionable society. Hunter married Anne Home in 1771; she was 29 at the time and he was 43. She was a charming lady, and talented, too—did she not write the lines beginning "My mother bids me bind my hair"?—and she was, moreover, a good wife, devoted to her husband, and Hunter had the felicity of matrimonial success.

Mr. Norbury described Hunter as a great experimenter and observer and a great thinker above all. He read from Nature and took his science from no other source. An indefatigable worker, he was never satisfied until he thought his observations were correct. Observing many things, he tried to press a great deal into little, which perhaps was the reason for his defects as a lecturer. He was himself conscious of the difficulty of making others understand what seemed simple to himself. His writings were extensive, his first published work being a treatise on the natural history of the human teeth, dated 1771.

The lecturer concluded with a glance at some of Hunter's great contemporaries. A great legacy which Hunter left to posterity was his museum, but greater still was the spirit and tradition which had animated his disciples.

Hunterian Festival Dinner

A few hours after the Oration a large company of guests assembled at the invitation of the Royal College of Surgeons for the Hunterian Festival Dinner at the College. Mr. Iain Macleod, the Minister of Health, proposing the toast to "The College," said that since the days of John Hunter British surgery had led the world; in particular, British surgeons had been pre-eminent in operations on the lungs, heart, and brain, and in plastic surgery. Developments in the science of anaesthesia had been as splendid in this country as anywhere in the world. The great tradition of the College in research and education would certainly endure.

In response, Sir Cecil Wakeley reviewed the activities of the College and described the impressive progress that was being made with the building of the new College. The Queen, an Honorary Fellow of the College, would lay the memorial stone of the new buildings on May 5. The President also announced that the Duke of Edinburgh had accepted an Honorary Fellowship of the College, and would come to the College to receive it later in the year. Among the research activities of the College Sir Cecil mentioned particularly the new department of pharmacology which was coming into being, thanks to the generosity and interest of certain pharmaceutical firms; Imperial Chemical Industries, Limited, had agreed to finance the department to the extent of £10,000 per annum for the next seven years. The museum was about to benefit from a new trust fund—the Macrae-Webb-Johnson Fund. Lady Webb-Johnson had joined her husband as a college benefactor by making over a fund worth about £1,000 a year, to be used for the benefit of the museum on the advice of the Hunterian Trustees. This gift was made to commemorate her father and as a tribute to her husband's presidency of the College.

Sir James Paterson Ross had the formidable task of proposing the health of the many distinguished guests. After Sir Denys Lawson had replied for the guests, Sir Reginald Watson-Jones proposed the toast to the Hunterian Orator, Mr. L. E. C. Norbury, who made a brief response.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

The Metric System

SIR,—The metric system is rather like the sea serpent in that it gives rise to periodical discussion in which feelings run high. Like many other "tidy" plans, it looks admirable on paper, but actually bristles with difficulties when applied to medicine. In the first place, Professor W. C. W. Nixon and Mr. T. D. Whittet (February 7, p. 327) are not really advocating the metric system at all but the "international system of weights and measures," and this is full of anomalies. For example, a purist will hold up his hands in horror if you talk about cubic centimetres, but if you ask him what his red blood count is he will say five million per cubic millimetre. I happen to be partly responsible for the publication of a quarterly journal, and the history of this very minor matter is instructive. Some time ago we were solemnly admonished by some semi-official body, whose name I have forgotten, that it was very wrong to use c.c. and c.cs. for the singular and plural of cubic centimetres, and that the correct abbreviation was c.cm. for both. We had just got our compositors clear on this, when another notice arrived, saying that, as cubic centimetres were not a measure of volume, the correct designation was millilitres abbreviated to ml. Once bitten twice shy, and we did nothing, which was just as well, as the abbreviation was next altered to mil., which at least had the advantage of being a word in its own right. Alas, this has also gone with the wind, and we are now back at ml. Our journal now rests on the conservative platform of c.cm. This type of meddling is not only exasperating but is exploited by manufacturers. For example, the makers of one type of syringe advertised its advantage by saying that it was calibrated in millilitres instead of cubic centimetres. I believe that a syringe would have to be of at least two litres capacity to detect any difference at all.

The change-over to the new system would not be so easy as the authors suppose. They have pointed out the dangers of misplacing decimal points, but there is much more to it than this. A good deal of the method of memorizing doses is built up on the *avoirdupois* system, and all sorts of difficulties would arise. For example, any houseman knows that the usual pre-operative rectal dose of paraldehyde is 1 drachm per stone body weight, but is he going to remember it as 3.55 ml. per 6.35 kg.? If the change is to be made at all, it would have to be complete, and medical literature will be still further divorced from that of everyday life. How many people could visualize a patient 1.895 metres high weighing 64.37 kg.?

To avoid this kind of thing, agreement would have to be reached in the medical, scientific, and industrial worlds of the English-speaking nations. There is no prospect of this in the foreseeable future. For example, the last time this subject was discussed at the Engineering Section of the British Association members could not even agree that the change is desirable, let alone practicable. The view was freely expressed that, as in many fields production by Anglo-Saxon countries was greater than that of the rest of the world put together, it was unreasonable to expect the vast effort of changing over to be made. An American closed the discussion with the trenchant summary, "Your metre, my foot."—I am, etc.,

London, E.C.1.

C. LANGTON HEWER.

Emphysema

SIR,—Dr. J. Todd's letter (January 24, p. 219) puzzles me. He criticizes me because I "made no attempt to define the clinical criteria which would enable the practitioner to decide which of these cases could be given morphine with

'safe and useful' results," yet I thought my letter made it quite clear that I was asking for just that guidance. I doubt if any G.P. has enough experience and knowledge to supply it, but I did hope that possibly the author of "the erudite address," which I obviously appreciated, could do so.

Our problem may be illustrated by the example Dr. Todd offers. It is, of course, conceivable that all our cases of status asthmaticus which have benefited by morphine have really been attacks of cardiac asthma in our chronic asthmatics, but, if so, how are we to tell? Incidentally, the cough reflex he mentions is not of first importance in a man gasping for his life, but the factors I mentioned—"anxiety, distress, and the demand of the tissues for oxygen"—most certainly are. It is incontestable that vastly more lives have been saved in general practice by the use of morphine than by withholding it, and one main object of my letter was to find out how to avoid using it in dangerous cases.

We must remember that conditions in hospital are not the same as in general, especially country, practice, but it is certainly wrong to condemn potentially life-saving treatment just because it has potential dangers. The task of medicine remains, as I said in my first letter, not to damn but to define "when it is safe and useful and when it is not," and it requires much experience as well as great erudition to do so.—I am, etc.,

Winsford, Cheshire.

W. N. LEAK.

Parenteral Treatment of Crushed Abdomen

SIR,—The object of this case report is to show how modern intravenous treatment may keep both fluid and biochemical balance over a long period. Facilities for blood analysis are the only special ones necessary.

A 19-year-old man, weighing 8 st. 8 lb. (54 kg.), was crushed between two heavy vehicles. He was in a state of shock and showed signs that were those of either a ruptured gut or intra-abdominal haemorrhage. He had also a contusion of the right lung and heart. Laparotomy revealed a deeply lacerated liver that was repaired and a retroperitoneal haematoma of the right colon. On the 11th day a burst abdomen was found to be due to the effects of traumatic pancreatitis. On the 20th day a duodenal fistula appeared in the wound and persisted. Thereafter residual abscesses declared themselves by spontaneous discharge through the fistula and by discharge through a right loin incision made for that purpose. Until the 65th day his evening temperature averaged 102° F. (38.9° C.) and pulse 120. On the 65th day a painful abdominal episode associated with distension was accompanied by a sudden cessation of fever. This indicated that his major residual abscess had discharged into the gut. Then his major improved, and recovery has since been complete.

Management was based on clinical observation assisted by accurate fluid charts and blood analyses for biochemical and haematological information. Intravenous management was particularly important in the first 19 days, when 65 pints (36.92 l.) of fluid were removed from his stomach by hourly suction. During this time intravenous fluids amounted to 115 pints (65.32 l.). This consisted of calculated quantities of Ringer's solution and This consisted of glucose, saline, protein hydrolysate ("casydrol"), combinations of glucose, saline, protein hydrolysate in fluid and salt. How- and blood. At this time he was balanced in fluid and salt. However, the protein had fallen to 6.3 g. % with an A/G reversal and the potassium to 15 mg. per 100 ml. The CO₂-combining power was 75 volumes %.

From the 20th to the 26th day the duodenal fistula discharged copiously. Having forgone solid food for three weeks, it was considered necessary tentatively to introduce protein and salts considered necessary tentatively to introduce protein and salts by mouth. This, with intermittent stomach suction and continuous fistula suction, was augmented by repeated intravenous drips that included Darrow's and Ringer's solutions. By the 30th day the fistula was practically dry. There had developed, however, an alkalosis, indicated by 79 volumes % CO₂ combining power, and a blood salt reduced to 480 mg. per 100 ml. The potassium meanwhile had improved to 17 mg. %. Subsequently the diet was supplemented by potassium chloride cachets of 1 g. daily and deliberate salt consumption by the patient. It was noted how chloride continued in the urine in spite of a depleted blood salt while the alkalosis remained. Thus blood samples were essential for chloride estimation. Protein hydrolysate intravenously and by mouth assisted the recovery

of the plasma protein. By the 35th day the patient's blood chemistry was normal apart from a slightly reduced plasma protein, and he was taking increasing quantities of light diet. Until the 65th day his weight remained the same at 6 st. 12 lb. (43.2 kg.) in spite of the continued fever. During this period transfusions were also administered at about fortnightly intervals to restore his haemoglobin from 60% to 75% on each occasion. The co-operation of the patient in taking all necessary dietary supplements was achieved by keeping him informed of his requirements. Thus his nutrition remained virtually balanced for nine weeks with intravenous administrations and a small diet.

Grateful acknowledgments are due to Mr. J. H. Conyers for his encouragement in treating this young man. For the careful attention that resulted in his recovery they are due in particular to Captain Smith and Sister Lester of the Military Hospital, York.—I am, etc.,

Manchester, 6.

STEVENS DIMANT.

Bathing and Vestibular Palsy due to Streptomycin

SIR,—May I raise the question of the behaviour under water of the children who were treated in the earlier post-war years with streptomycin for tuberculous meningitis, and who may be making their first ventures into a medium entirely new, constituting a special predicament for them, denuded as they invariably are of vestibular sensation? My own belief, based on otoneurological observations at the time, is that few, if any, will have recovered from this selective paralysis, and a pronouncement by more recent workers is desirable as to whether complete immersion during swimming and diving may prove a hazard. Ordinarily, the direction of light penetration and water-pressure at body surface will be aids to orientation, but young children with bilateral vestibular palsy may be expected to panic or even drown if unattended.

I would remind physicians who have had the immense satisfaction of delivering these children from a previously fatal disease at so relatively small a cost in terms of sequelae that successful performance of the ordinary clinical neurological tests of balance can cover gross vestibular defect; they may wish to advise school health services of cases where recovery of specific vestibular function has not been established.—I am, etc.,

Bramhall, Cheshire.

H. C. PURCER SMITH.

Use of Succinylcholine in E.C.T.

SIR,—We have read the article on the use of succinylcholine in E.C.T. by Drs. D. J. Adderley and Max Hamilton (January 24, p. 195) with much interest. We should, however, like to suggest that the rise in blood pressure following the injection of succinylcholine is not due to the drug but to the fact that the patient was ventilated with a mixture of 5% carbon dioxide in oxygen. This subject, could easily produce a carbon dioxide build-up, the effect of which has been long known to cause an increase in blood pressure at least as high as that recorded in the article.—We are, etc.,

J. A. SMITH.

F. G. WOOD-SMITH.

London, W.12.

Relationship of the Suprarenal Cortex to the Differentiation of Chromaffin Cells

SIR,—As a result of our studies in several species of animals, we reported in 1951¹ that the amounts of noradrenaline and adrenaline found in the suprarenal glands seemed to bear some relationship to the relative size of the cortex. In the rabbit and guinea-pig (where the cortex is large relative to the medulla), methylation of noradrenaline to form adrenaline is almost complete, whilst in the whale and fowl (where the medulla is relatively large) only a small amount of adrenaline is found. It was suggested that the cortex might be intimately concerned with methylation of noradrenaline.

Further work indicates that methylation can occur even in the absence of intimate relation with the cortex. Both adren-

aline and noradrenaline have been detected, for example, in the rudimentary suprarenal medulla of the dogfish,² and in the organs of Zuckermandl in children aged 6 months or more,³ although both these structures are quite separate from cortical tissue. In our view there is no convincing evidence to connect the functions of the cortex with those of the medulla, though it is possible that cortical hormones may affect the degree of methylation in these chromaffin structures via the blood supply.—I am, etc.,

Dundee.

Soft-tissue Radiology

SIR,—I have read with interest your annotation on "Soft-tissue Radiology" (January 10, p. 89), with its survey of technical advances in this field. I notice that mention is made of the problem posed by the fact that x rays are absorbed by soft tissues to a uniform degree. I therefore expected to find some mention of the late A. E. Barclay's work in this respect,^{1,2} but was disappointed. His micro-radiology, a direct and more practical advance from the technique of Lamarque,³ should, I feel, receive especial mention in any discussion of soft-tissue radiology, for the technique has much to offer in many fields of medical and biological research.—I am, etc.,

Crawley, Sussex.

Measurement of Tissue Components Radiologically

SIR,—Dr. Frank Falkner and Miss Sylvia Wisdom (January 31, p. 275) did not need the tube-plate distance or object-plate distance in order to find the length of the object, because they already had the tube-shift, image-shift, and length of image. Their graph was unnecessary, therefore. Thus: O=object, I=image, TS=tube-shift, IS=image-shift.

$$O = I \times \frac{TS}{TS + IS}$$

In their formula $\frac{K-d}{K}$ is the same as $\frac{TS}{TS + IS}$

This is the formula for a length parallel to plate and plane of source of rays. It is of little use for an irregular object. I imagine it would be better to abandon calculation and instead to reproduce to scale the triangles in question, and in that way find by direct measurement the limits of the dimensions of the object.—I am, etc.,

Heath Hayes, Staffs.

P. J. O'BRIEN.

The General Practitioner and Mass Radiography

SIR,—It may interest you and your readers to know that in August last the North-west Metropolitan Regional Hospital Board set up a mass x-ray unit at the Central Middlesex Hospital as an extension of the radiological services provided by it, with the primary object of carrying out an investigation into the incidence of unsuspected chest disease in the patients attending or admitted to the hospital. It was found possible to extend the mass radiographic facilities to general practitioners in the surrounding area. Practitioners are able to refer patients direct to the mass radiography department on any weekday within normal working hours without appointment. A member of the radiological staff reports on the films within 24 hours, and a negative report is received by the practitioner within three days of the patient attending. If the report indicates suspicions of disease a large film is taken, and any of the further necessary radiological investigation is carried out in the main x-ray department and a subsequent report sent to the practitioner. Should a diag-

nosis of active, or possibly active, tuberculous disease be made, the chest physician of the area in which the patient lives is informed at the same time as the patient's general practitioner.

It is intended to publish an account of the experience gained in this scheme after a trial period of approximately a year. So far, out of the comparatively small number of 1,431 patients referred by general practitioners, 21 have had active, or possibly active, pulmonary tuberculosis, and five patients have been diagnosed as suffering from neoplasm of the lungs. It is not intended in this letter to do more than draw attention to the fact that the opportunity referred to in the final paragraph of your annotation (February 7, p. 322) has already been taken, and that in at least one area the radiological services have been extended even a stage further than that described in the very interesting article by Dr. F. A. Nash, Mr. B. Benjamin, and Dr. T. J. Lee (p. 304).—I am, etc.,

London, N.W.10.

F. PYGOTT.

SIR,—I would like to congratulate Dr. F. A. Nash and his colleagues on an excellent piece of work (February 7, p. 304), which will focus attention once more on the ever-present need for the early diagnosis of pulmonary tuberculosis. The suggestion that the services of the mass radiography unit should be employed in this fashion, however, is both impracticable and dangerous, and if adopted would constitute a disservice to the anti-tuberculosis campaign.

While it is not my purpose to attempt to devalue an excellent paper, I am struck by the relatively small number of patients attending for the first time at the chest clinics in the survey area (less than one-third the number in my own area of similar population). It is also clear that the number of patients x-rayed falls far short of the estimated needed requirements. The authors refer to the work of Toussaint, but do not mention that schemes similar to their own on a comparable scale are a common feature of many chest clinics. It is my opinion that the chest physician is best fitted to control the attack on tuberculosis. So far as diagnosis is concerned, this should be effected by a harmonious co-operation between general practitioner and chest physician. A split in the tuberculosis service between diagnosis, treatment, and prevention and aftercare has already been imposed from above, to the detriment of the patient. Let us take care that a further split does not arise, this time of our own making.—I am, etc.,

Wrexham.

E. CLIFFORD-JONES.

Reprints of Communications on Stress and the Adaptive Hormones

SIR,—In perusing the current literature with which your *Journal* is concerned, we note that an ever-increasing number of its articles deal with problems pertaining to research on "stress" and the so-called "adaptive hormones" (A.C.T.H., S.T.H., corticoids, adrenergic substances, etc.). We are writing to you because, in our opinion, the success of research in this complex and rapidly developing field largely depends upon the prompt availability and evaluation of relevant publications, a task for which we should like to solicit the assistance of your readers.

In 1950 our Institute initiated the publication of a series of reference volumes entitled *Annual Reports on Stress* (Acta Medical Publishers, Montreal) in which the entire current world literature is surveyed every year (usually between 2,000 and 4,000 publications). Up to now we had to compile the pertinent literature partly from medical periodicals, monographs, abstract journals, and partly from reprints sent to us by the authors themselves. Of all these, reprints proved to be the best source of data which we felt deserved prompt attention in our annual reports. Hence, in the past, we have sent out several thousand individual reprint requests to authors whom we knew to be engaged currently in research on stress and allied topics. Even this procedure did not give us the wide coverage which would

be desirable, because it is materially impossible to contact all these authors individually, and it often takes too much time to get the requested reprints.

It is evident that in order to ensure prompt inclusion of publications in the annual reports these surveys must develop into a co-operative effort between the authors of original papers and the reviewers. This co-operation was greatly enhanced of late by the publication of announcements, in several medical journals, encouraging investigators interested in stress research to send us their reprints for this purpose as soon as they become available. We should be grateful if, by the publication of this note, you would also bring this problem to the attention of your readers.—We are, etc.,

HANS SELYE,

Professor and Director of the Institute of
Experimental Medicine and Surgery.

ALEXANDER HORAVA,

Co-author, *Annual Reports on Stress*.University of Montreal,
Montreal, Canada.

"Pasteur's Flask" in Sydney University

SIR,—I wish to thank Dr. Lilian A. Bates for her interesting letter (November 1, 1952, p. 993) concerning the flask of bouillon or beef broth which was brought to Sydney from the Pasteur Institute in Paris in 1888. I regret my error in stating (August 23, 1952, p. 439) that the flask of broth was put up by Pasteur himself. The association interest remains, however, because, although Pasteur did not put up the flask himself, it was prepared by his nephew, Dr. Adrien Loir, in Pasteur's laboratory on Pasteur's instructions. Madame Pasteur, it appears, also came into the story, because it was her scrutiny of *Le Temps* which brought the need of the Government of New South Wales under the notice of her husband.

Sydney students will still regard the Pasteur flask as a precious exhibit, because it is one of the few links our museum provides with France, a country which has made outstanding contributions to the welfare of mankind. This flask, because of its associations, will continue to remind us of one of the noblest sons of France, Louis Pasteur, whose life and work are an inspiration to students in every land.—I am, etc.,

Sydney.

KEITH INGLIS.

Misuse of Words

SIR,—As a critic of the usage of words, is not Professor A. G. Watkins (February 7, p. 335) himself in error? Since "gynaecological" means "concerning the science of diseases of women," is it the medical student or the patient who undergoes a gynaecological examination? Similarly, since "pathological" means "concerning the science of disease," it is surely nice usage when this adjective is applied to a department.—I am, etc.,

London, S.W.10.

M. J. PURDY.

Quintuple Pregnancy

SIR,—The birth of quintuplets is still an obstetrical rarity, and it is thought that the following notes of the general practitioner's antenatal findings in such a case may be of interest.

The mother, aged 36, had previously had five full-term single pregnancies. All these births had taken place in hospital, and her last baby, now aged 6, weighed 9½ lb. (4.3 kg.) at birth. She was first seen in the pregnancy which is the subject of this report on August 25, 1952, being then about 12 weeks pregnant. Apart from varicose veins of both legs there was nothing abnormal in her condition. She was next seen on November 17, when one foetal heart was heard. The blood pressure was 120/80, and no abnormality in size or condition was noted.

The patient did not present herself for examination, as requested, in December, and she was next seen on January 6, 1953. The changes which had occurred were quite alarming. The abdomen was greatly distended, and at the twenty-eighth week appeared to be at full-term. There was a

gain in weight of 15 lb. (6.75 kg.). A foetal heart was heard in the left sacro-anterior foetal position. The blood pressure was elevated to 150/80, and there was moderate oedema of both legs and ankles, but no undue distress. On examination the uterus was tense, as with hydramnios; no foetal movements were felt. Palpation revealed the presence of many small hard protruding lumps, especially on the right side of the uterus. This would have been consistent with the presence of multiple small intramural fibroids. The urine was free of frank albumin, but the Bence Jones reaction was present.

A diagnosis of multiple pregnancy was made, with an alternative diagnosis of breech presentation and multiple small uterine fibroids. The patient was referred to hospital, where macerated male quintuplets were born nine days later within the space of three hours.—I am, etc.,

Herne Bay, Kent.

P. DE B. RANSOME-WALLIS.

Intraperitoneal Rupture of Rectovaginal Abscess Due to Proctotomy

SIR,—Although the weight of present-day opinion is in general against proctotomy for abscess in the rectovaginal or rectovesical pouch, the procedure is still occasionally recommended by writers on the subject, and rare cases occur in practice in which it seems the obvious treatment. To the numerous objections advanced we have to add another unfortunate accident.

The patient, a female aged 17 years, had an acutely inflamed unruptured appendix removed and the abdomen closed without drainage. She thereafter developed signs of a residual abscess, which was eventually located in the pouch of Douglas. In view of the degree of toxæmia, it was thought best to open this rather than wait for spontaneous evacuation per rectum. Incision was carried out under a general anaesthetic 15 days after her original operation. Only a small amount of pus was obtained. Some hours later the general condition became much worse, and obviously some catastrophe had occurred. Sixteen hours after the proctotomy a simple laparotomy and drainage was performed. The abdomen was found full of pus. The patient died later in the same day.

It seems fairly certain that rupture of the abscess into the general peritoneal cavity was caused by the sudden increase of tension when the instrument was thrust into it from the rectum. This has doubtless occurred before, though we have found no record of it even among the stock objections to the operation. Rupture of adhesions due to the collapse of the cavity consequent upon drainage has been recorded,¹ but in such a case there would be a profuse flow of pus first. Spontaneous rupture in both directions has also been mentioned by the same author; presumably it was also simultaneous.—We are, etc.,

Salisbury.

A. DUFF.¹ *Vale, C. F., Ann. Surg.*, 1940, 111, 396.

The Climacteric

SIR,—With reference to your timely annotation on "The Climacteric and Oestrogen Therapy" (January 3, p. 37), the following additional psychological aspect of climacteric disturbance needs to be more widely appreciated. The psychological reaction both to increasing age and temporary enhancement of inner tensions are sharper in those women whose cultural achievement has been severely limited; this applies to women of various social status and otherwise different personality background. Where a woman's life has previously centred almost exclusively about her domestic, motherhood, and sexual functions without any consolidated outer interests, the increasing independence of the children and the changing body image serve to evoke feelings of loss and anxiety which are especially threatening because there are no available compensations which can be more energetically utilized. In "minor" psychotherapy it is necessary to encourage the evolution of interests outside the home and to engage the attention of available social agencies so that they can help with this problem. This is

especially the job of the general practitioner, and in giving this aspect of treatment his serious attention involuntarily trouble can be averted in many cases. Of course, in some with, for example, severe obsessional character disorder and a good deal of inward guilt and tension in their personality background such "minor" psychotherapy would not be sufficient. But I feel that attention directed towards the change in the life situation of the patient in discussion with her usual physician is a very important therapeutic and prophylactic measure. Especially in the culturally restricted woman, the feeling that life has at this stage of the game lost its value, and she hers, is one to be energetically countered by her medical adviser.—I am, etc.,

Chapel Hill, North Carolina.

D. W. ABSE.

Abuse of Antibiotics

SIR,—I agree entirely with Mr. Norman Lake's letter on abuse of antibiotics (December 13, 1952, p. 1307), but I am writing to express my surprise that he reports without comment the case in which a perforated appendix was left *in situ* in the presence of generalized peritonitis. I am not surprised to learn that the patient's peritoneum was found to be full of pus at the second operation; on the contrary I would have been very surprised indeed if this had not occurred. Drainage alone in a case of perforation of the appendix is permissible only when a localized abscess is present. In a case in which generalized peritonitis is diagnosed at or before operation the appendix must be removed. Once this is done drainage is of comparatively secondary importance now that we have efficient antibiotic agents; but the actual removal of the offending appendix is absolutely essential to prevent the continuation of infection of the peritoneum.

This letter is not written in order just to criticize the management of the above case (there are, of course, possible exceptions to every rule in medicine), but to be a reminder and a warning to the more junior and less experienced surgeons, and to prevent them from adopting drainage without appendectomy as the correct treatment of generalized peritonitis due to a perforated appendix.—I am, etc.,

Georgetown, British Guiana.

The Dangers of Blood Transfusion

SIR,—The article on the D-/D- genotype (January 24, p. 198) attracted my attention merely because of the name of one of the co-authors, Dr. Ruth Sanger, whom I was glad to have seated at my table on one of my transatlantic voyages. Other readers, like myself, may find this article beyond their complete comprehension, and without the personal contact might pass it by. However, do not these highly technical articles on blood emphasize what a dangerous treatment transfusion may be? Frequent discoveries of antibodies and genotypes not previously suspected should make one wary of administering blood except as an urgent necessity. The great number of transfusions now being given on one pretext or another must enormously increase the risk of conflicting antibodies endangering life when a subsequent transfusion may be a necessity.

Statistics seem to prove that there is an immediate advantage in using whole blood, but, in view of the highly technical and skilful investigations which constantly are discovering potential dangers and which are demonstrated to us by complicated formulae, ought we not to regard a transfusion of blood, not as a routine measure, but as a dangerous major operation? The Christian pronouncement of nearly 2,000 years ago, "It is more blessed to give than to receive," may well be true as regards the giving and receiving of blood. The recipient, perhaps, is being conditioned for future unknown dangers—but what of the donor? The generous donor is willing to give blood to "save

life," but I do not think that gallons of this precious and dangerous fluid should be wasted as a routine administration in operative technique. If a pint of blood is essential for recovery, or merely the more rapid recovery, of the patient, then surely the blood cannot be obtained from the donor without cost? Wolstein said in 1791, when condemning blood-letting, the fashion of his day, "Blood is no water—it is the juice of life; a juice which after each venesection Nature replaces rapidly, but in a raw, unprepared, watery, spiritless state." We have learned much about "the juice of life" since Wolstein's day, but no doubt his clinical observation was correct, as also that of Marshall Hall, who denounced the same practice, calling the lancet "a minute instrument of mighty mischief." Some time ago when doing a short locum for a friend I saw two patients, man and wife, labelled as suffering from rheumatism. Neither had ever had any serious illness, but each appeared to be debilitated and only very slowly convalescing. They complained of great tiredness and lack of energy and indefinite aches and pains, which evidently suggested the "diagnosis" of rheumatism. They said that neither had felt well since their last donation of blood. They were universal donors and both had been called upon, and had responded willingly, many times.

I am not satisfied that the sacrifice of the donor is as harmless as is generally supposed, nor am I satisfied that a transfusion is always a good thing for the recipient. I would only submit myself and members of my own family to a transfusion if I considered it an absolute necessity, and this must be the criterion for my patients. What can I tell the would-be donors who ask my advice? I do not wish to discourage them, nor do I wish to embarrass the workers in the blood-collecting squad, but I do feel that it is time we exercised extreme economy in the use of blood, other persons' blood, and ensure that it is used only for the purpose for which most persons think they give it—to save life.—I am, etc.,

Huddersfield.

S. H. WADDY.

Treatment of Bowel Infections of the Tropics

SIR,—I would like to express disagreement with a statement made in Dr. A. R. D. Adams's article on bowel infections in the Tropics (February 7, p. 308). He says: "While emetine will unfailingly bring an acute attack of amoebic dysentery rapidly to an end, usually it will not sterilize the bowel of the infection, however unwisely the drug may be pushed or the course of treatment with it be prolonged." During the years 1942-4 I had in my care 363 cases of amoebic dysentery among British troops in India, and although the response to emetine was dramatic in most instances I encountered a number of patients who showed no response whatever. Some of these showed an immediate response to carbarsone given orally, and the history indicated that the disease had been contracted in North-east India. Conversely, there were patients from the Madras district who failed to show any response to carbarsone but reacted at once to emetine. At that time carbarsone had a high reputation in Calcutta, and one wonders whether "emetine-resistant" and "carbarsone-resistant" strains exist in India and whether Dr. Adams has been fortunate enough to work only in an area where the amoebae were "emetine-sensitive." I had hoped to gather some accurate information on the subject, but we had only just become aware of the possibility when the hospital in which I was working moved elsewhere and the unofficial "dysentery unit" ceased to exist.

Failure of emetine to sterilize the bowel, as Dr. Adams says, is well known, and the majority of the persistently relapsing cases had received treatment in the first instance of emetine only, sometimes only six injections being given. Once an adequate supply of chiniofon ("quinoxyl") became available and was given in a five-day course by mouth and as retention enemas, the obstinate relapsing cases became less frequent, and few cases who had had the full course came back as relapses. It would be interesting to know if other workers have found any evidence of strains of the entamoeba which can be differentiated therapeutically.—I am, etc.,

Keighley.

IAN STEWART.

Half-circle Intestinal Clamps

SIR,—The spring clamp illustrated was originally devised for anterior resection of the rectum. It has also proved useful in intraperitoneal intestinal resection and even in oesophago-gastric or oesophago-jejunal anastomosis. The

depth of 2 in. (5 cm.) allows enough bowel to project for anastomosis, and the maximum diameter of 3½ in. (8.75 cm.) permits haemostasis and freedom of movement in an otherwise restricted space.

I am indebted to Messrs. Down Bros. for making this instrument for me.—I am, etc.,

London, S.E.1.

GUY BLACKBURN.

Prevention and Treatment of Tetanus

SIR,—In my recent refresher course article on the prevention and treatment of tetanus (January 17, p. 150) I said that mephenesin ("myanesin") "may be given either intramuscularly or orally in doses of 0.5 to 1 g. for an adult, repeated every few hours according to the effect produced." The British Drug Houses, Ltd., comment on this as follows: "Myanesin is available for oral administration both in the form of elixir and tablets. We do not advocate the use of elixir by mouth in cases of tetanus, since myanesin possesses local anaesthetic properties, so that if the elixir is given to a case of tetanus in which dysphagia is present the local anaesthetic effect may result in abolition of the swallowing reflex with the consequent aspiration of foreign material into the trachea and lungs. The administration of myanesin tablets does not give rise to the local anaesthetic effect on the palate and pharynx, but, on the other hand, we have no records of its therapeutic efficacy in tetanus. According to our records the most satisfactory method of administering myanesin in cases of tetanus is by intramuscular injection." I think this observation is important.

Dr. L. H. Cane (February 14, p. 403) asks a pertinent question regarding the dosage of International Units for passive immunization. As he states, the 1950 I.U. is twice the potency of the 1928 I.U. Throughout the article both for immunization and treatment the dosage was expressed in 1928 I.U. It would have been more correctly and clearly expressed in 1950 I.U., the figures "1950" being added for clarity.

The question of negligence and blame for failing to give a prophylactic injection of antitoxin to a patient who subsequently develops tetanus is a very difficult one. Each case must be judged on its merits, and the types of wound enumerated which are known to have caused the disease only serve as a general guide and warning. It may be some help to remember that wounds which have never been properly cleaned but have been allowed to scab over while dirty appear more prone to harbour the organism. In my opinion whitlows in those working in earth or manure do merit antitoxin, but it is manifestly impossible and inadvisable to give prophylactic antitoxin after every trivial wound, and therein lies the chief reason for failure of the method of passive immunization to afford complete protection to the community. The degree of natural resistance in man depends on many factors and is extremely difficult to assess.

Dr. R. G. Abercrombie (February 14, p. 403) raises the difficult problem of the danger of active surgical treatment to the wound after tetanus has declared itself. In my article I emphasized the importance of minimum disturbance of tissues after a large dose of antitoxin had been given. I agree that the stress should be on the "minimum," and

nothing should be done until *after* antitoxin has been given, but with these reservations it would appear rational to try to prevent the continued production of toxin locally. I have never observed harmful effects from such limited interference, but admittedly this statement applies to patients with comparatively slight wounds. Owing to the increasing use of antitoxin in the 1914-18 war, tetanus following serious wounds in those who had not been passively immunized must have been comparatively rare after the first few months. Similarly in civilian patients they are exactly the cases to which prophylactic antitoxin is almost always given, and in the 1939-45 war tetanus was almost unknown. I have seen no example of this type from which to judge the effects of surgery. On the other hand, I have seen several on whom no surgical treatment was practised who died in spite of enormous doses of antitoxin. The answers to such questions depend a little on the definition of the word "severe" as applied to tetanus. It is only by the application of the prognostic criteria I outlined to a large number of cases that the relative values of different methods of treatment can be assessed.—I am, etc.,

Cambridge.

LESLIE COLE.

Sensitization to Local Application of an Antihistamine

SIR,—Nowadays, when ready resort is made to the various antihistamines by mouth for a variety of allergies and hypersensitive reactions, it may not be readily realized that hypersensitivity may develop to antihistamine substances themselves when applied locally in the form of ointments. The following case illustrates well this seeming paradox.

The patient developed eczema of the hands and arms in 1949. The usual ointments were applied and each produced a temporary slight improvement. In July, 1952, he was given mepyramine maleate ("anthisan") by mouth, 100 mg. three times a day for 12 days, with no improvement. On September 1 phenindamine hydrogen tartrate ("thephorin") ointment was applied and produced a dramatic improvement. On October 18 he developed impetigo of the face, which failed to respond to gentian violet. Eleven days later his face had shown little improvement, and his hands gradually became oedematous, with exfoliation of the skin of the fingers. Phenindamine hydrogen tartrate ointment and gentian violet were discontinued. Mepyramine maleate, two tablets three times a day, was given, and acriflavine emulsion was applied to the face. The oedema of the hands quickly subsided and the impetigo of the face quickly disappeared. On November 15 an eczematous rash of hands and arms reappeared, and the effect of applying phenindamine hydrogen tartrate ointment was again tried. The oedema appeared as dramatically as before, with exudation of serous fluid; and again responded quickly when phenindamine hydrogen tartrate ointment was withheld and mepyramine maleate given by mouth. Since that time the hands have shown a steady improvement from the application of zinc and castor oil.

I reported this case to Roche Products Ltd., the manufacturers of theophorin ointment, asking if a constituent of the ointment base was the cause of the hypersensitivity. I received a reply from the medical adviser stating that this was unlikely and that it was much more probably caused by the theophorin itself, as other similar cases had occasionally been reported.

It seems strange that the cure of a disease should cause the disease itself.—I am, etc.,

Bristol.

W. A. HEATON-WARD.

Medical Services for American Personnel

SIR,—It has been suggested by several British physicians, particularly those practising in the communities which are adjacent to United States bases in the United Kingdom, that information be circulated concerning the type of medical services available to American personnel and their dependants in the United Kingdom.

There are four U.S. Air Force hospitals in England: the 59th Medical Group located in Burtonwood, near Warrington, Lancs, serving the Liverpool region, telephone Warrington 3000, extensions 1070 or 1060; the 5th Hospital Group at Burdorp Park, near Swindon, Wilts, serving

the Oxford area, telephone Wroughton 391; the 3rd Hospital Group at Wimpole Park, near Royston, Cambs, serving East Anglia, telephone Arrington 381; and the 494th Medical Group, serving the London area, telephone Waxlow 4300, extensions 112, 113, or 114. All of these hospitals have the following services and facilities available: general surgery, general medicine, ophthalmology, oto-rhino-laryngology, orthopaedics, paediatrics, obstetrics, gynaecology, out-patient, laboratory, pharmacy, and radiology. In order to provide the best type of specialized medical care, certain of these hospitals have been staffed and equipped over and above the others. Therefore in the case of difficult diagnostic problems covering the following specialties patients should be referred as indicated: neuro-psychiatry—Burderop Park; urology—Burderop Park or South Ruislip; orthopaedics—Burderop Park; cardiology—South Ruislip; allergy—Wimpole Park; mortuary service—any hospitals listed or secure information from nearest American installation.

Should any British physician desire to use any of these facilities in his diagnosis or treatment of American patients, he may call on them direct or may ask the nearest hospital for assistance in securing consultation and transport facilities. X-ray examinations, all laboratory procedures, including basal metabolic rates, and electrocardiograms can be done. Prescriptions can be filled at all these and other medical establishments, such as infirmaries, although substitutes may be necessary where British and American medicines differ slightly.—I am, etc.,

L. R. BRASWELL,
Air Surgeon, Third U.S. Air Force.

Ruislip, Middlesex.

POINTS FROM LETTERS

Feeding of Babies

Dr. A. L. E. FILMER COLEMAN (Evesham) writes: I may be old and behind the times, but I am still convinced that if only we returned to starting babies off with three-hourly feeds, gradually lengthening the interval to four hours, we should not hear so much about this self-demand feeding. . . . Dr. J. Irene Rosie (January 31, p. 273) says, "The breast-feeding record is better in those babies who in the first 10 to 14 days of life are not kept on a too strict feeding régime." It is not the lack of strict régime; it is the fact that the mother, showing common sense, refuses to follow the, to my mind, silly and harmful four-hourly feeding.

"Prescribers' Notes"

Dr. F. E. S. HATFIELD (Chipping Ongar, Essex) writes: I have recently received a copy of *Prescribers' Notes*. I am fully in sympathy with the objects of this publication, but I feel that greater endeavours should be made to be objective. For instance, in this number a page is devoted to the drug "pregnenolone" which gives the impression that the drug is not only expensive but therapeutically valueless. In my experience—admittedly limited, as most general practitioners' experience of any one type of case must be—this drug gives symptomatic relief in most cases of active rheumatoid arthritis. I have had three cases in which a life of great suffering only made bearable by the constant ingestion of large quantities of tab. cod. co. was transformed by the drug. Unfortunately the symptoms relapse as soon as the drug is withdrawn, and in one case the dose had to be pushed to 10 tablets a day to get the full effect. In my opinion, rheumatoid arthritis is a disease which can cause so many years of prolonged suffering that any drug which promises relief should be fully utilized. It is common experience that costly drugs soon become cheaper if extensively used, and there has been at least one reduction of price in this case to my knowledge. If the reports in *Prescribers' Notes* are to be as biased on the one side as some of the reports of the less reputable drug firms are on the other, then it will certainly fail in its mission.

Second Attack of Chicken-pox

Dr. M. A. G. PIETRONI (Nicosia, Cyprus) writes: With reference to Dr. N. H. H. Gollidge's letter (January 17, p. 163), I have personally witnessed undoubted second attacks of chicken-pox on two occasions. I have no records of the first case, but I observed in the second patient, now aged 7½, a definite though mild attack of chicken-pox in January, 1951, which lasted only a few days and which coincided with an epidemic at her school. Her second attack occurred in January of this year. This attack was profuse enough and will probably allow the little girl to build up her immunity.

Obituary

Sir HOLBURT WARING, BT., C.B.E.
M.S., F.R.C.S.

Sir Holburt Jacob Waring, who died at his home in Gloucestershire on February 10 at the age of 86, occupied an outstanding position in British surgery for many years. He had lived since the middle thirties in retirement at Tidenham in Gloucestershire, but many in London will vividly recall him not only as a surgeon of great eminence but as a dignified Vice-Chancellor of the University and a man of high capacity in administration in many public bodies. He never lost during his long career in the south his native Lancastrian abruptness of speech and manner, but those who got behind the manner to the man found a charming personality and a real friend.

He was born on October 3, 1866, the son of Isaac Waring, of Southport, and was educated at Owens College, Manchester. He took his medical training at St. Bartholomew's, the hospital on whose staff he was to serve actively for thirty years. His university career was a brilliant one; he seemed to carry off all the prizes. He took the B.Sc.Lond. in 1888 with honours in physiology, the M.B. in 1890 with honours in medicine and forensic medicine, the B.S. in 1891 again with honours, and the M.S. in 1893, qualifying for the Gold Medal. His whole career was devoted to surgery. He became F.R.C.S. at the age of 25. In January, 1902, he was elected assistant surgeon at St. Bartholomew's, and full surgeon in 1909. He was also consulting surgeon to the Metropolitan Hospital, the Royal Dental Hospital, and to the Ministry of Pensions. His career was interrupted by service in the first European war, in which he held the rank of brevet-colonel R.A.M.C.(T.) and was mentioned in despatches. Before the war he had served in the volunteer Medical Staff Corps and had transferred to the Territorial Force when it was established in 1908.

His election in 1932, in succession to Lord Moynihan, to the presidency of the Royal College of Surgeons of England, a position which he held for three years, was the crown of a long association with the Royal College in many capacities. In 1897-8 he was Erasmus Wilson lecturer, in 1921 Bradshaw lecturer, and in 1928 he delivered the Hunterian Oration. He was a trustee of the Hunterian Collection of the College and for 10 years a member of the Board of Examiners. He was also examiner in surgery for the universities of London, Oxford, and Manchester. In the University of London he had been Dean of the Faculty of Medicine and in 1922-4, at a time of important constitutional change in the University, he held the office of Vice-Chancellor. He was closely associated with the establishment of the London School of Hygiene and Tropical Medicine, and

(Elliott & Fry, Ltd., London)

the great institution in Gower Street owes much to his business ability in the chair of the Court of Governors and as its treasurer. For many years he was the representative of his university on the General Medical Council, and there and on the Dental Board, of both of which bodies he was treasurer, his business and financial ability proved of great service.

Waring was an able if somewhat formidable teacher, and the terseness of his style was well suited to the compilation of medical textbooks. His *Manual of Operative Surgery* was first published in 1892, when it consisted of 687 pages. In the sixth edition, published in 1927, the pages ran to nearly one thousand. In 1928 he published *The Surgical Treatment of Malignant Diseases*. An early work of his, published in 1897, was *Surgical Diseases of Liver, Gall Bladder, and Biliary System*, a dissertation on which subject had gained him the Jackson prize of the Royal College of Surgeons a few years before. He also contributed to many medical textbooks and periodicals. The articles on operations on the tongue and floor of the mouth in Burghard's *System of Operative Surgery* and on surgical disease of the pancreas in the *Encyclopaedia of Medicine and Surgery* were from his pen. With the late Sir D'Arcy Power he wrote a short history of St. Bartholomew's Hospital.

Among other leading positions which he occupied from time to time were those of president of the Medical Society of London in 1925-6, president of the Section of Surgery of the Royal Society of Medicine in 1928-30, vice-treasurer of the Imperial Cancer Research Fund, vice-president of the Grand Council of the British Empire Cancer Campaign, and governor of East London College and of Christ's Hospital.

Waring was made C.B.E. at the close of his war service in 1919 and was knighted in 1925. In 1935 he was created a baronet "of St. Bartholomew's of the City of London." He was the recipient of honorary degrees of the Universities of Cairo and of Bristol and Durham, and was an honorary Fellow of the Royal Australasian College of Surgeons. He was also an officer of the Legion of Honour. Sir Holburt Waring, whose wife died in 1948, is survived by a son and two daughters.

We are indebted to Mr. J. BASIL HUME for the following appreciation: Holburt Waring, though never a very great surgeon, achieved distinction by a record of service in the profession which can rarely have been equalled. His offices, which included those of President of the Royal College of Surgeons, Vice-Chancellor of the University of London, and Chairman of the London School of Hygiene and Tropical Medicine, covered a wide field concerned with the co-ordination and advancement of medicine. With all this he never neglected what he considered to be his first duty—the care of patients at St. Bartholomew's. For thirty years he was a familiar figure in and about the hospital. The house-surgeons and dressers, all in clean white coats, awaited his arrival in the square. He was invariably punctual, and immediately led the way into the wards or the theatre. The dresser's notes were read and severely criticized, the patient was thoroughly examined, and a diagnosis or provisional diagnosis made. He hated indecision: his judgment was based on facts, and in these when duly weighed made him firm and prompt in action. The great majority of his house-surgeons held him in high esteem and many in affection. They had to pass through the stage of being "the worst house-surgeon I have ever had" to be able to graduate to competence, but, that achieved, their interests were his.

In the same way Waring was sure of himself in matters of policy. The facts had been carefully ascertained and

considered, and by his forceful speech and manner and skill in committee procedure he nearly always won his way. It is doubtful whether the new surgical block at Bart's would ever have been built if he had not forced the necessity for the building on governors and colleagues alike. Some were afraid of the cost, others that the square would be altered, but Waring had a conviction of future needs and developments that overcame all obstacles.

It is sad to recall that, with the loss of his friends Lockwood and Harrison Cripps, Waring became a very lonely man, plunging more and more actively into public affairs. That he lived to an advanced age with almost unimpaired mental powers is not remarkable when one considers the number of interests he maintained after his retirement. He came on the staff of Bart's in 1902, and is the last of the great men of the turn of the century.

W. H. GRACE, M.D., F.R.C.P.

Dr. W. H. Grace, who died at Chester on February 10 at the age of 60, was the Home Office pathologist for the north-western region from January, 1947, to March, 1952, when ill-health obliged him to resign from the appointment.

Walter Henry Grace was born in Australia on December 25, 1892, and, after graduating B.Sc. at the University of Sydney, he came to England to continue his medical studies at Guy's Hospital. He qualified M.R.C.S., L.R.C.P. in 1918 and took the degrees of M.B., B.S. of the University of London in the same year. After qualification he held a number of appointments at Guy's Hospital, including that of senior assistant bacteriologist, and then in 1922 he moved to Chester. Before leaving London he took the M.R.C.P. and the D.P.H., and in 1922 he proceeded to the degree of M.D. and took the D.T.M.&H. He was elected F.R.C.P. in 1939. At Chester Dr. Grace quickly made his mark as a pathologist of reliability, and his services were made full use of by the hospitals in the district. He became honorary pathologist and senior assistant physician at Chester Royal Infirmary, consulting pathologist to the Cheshire County Mental Hospital, and honorary pathologist to the Wrexham War Memorial Hospital and to Denbigh Infirmary. With the introduction of the National Health Service he was appointed consulting pathologist to the Chester group of hospitals. He was also part-time lecturer in forensic medicine and toxicology and examiner in forensic medicine at the University of Liverpool for some years. When the British Medical Association held its Annual Meeting at Liverpool in 1950 he served as a vice-president of the Section of Pathology and Bacteriology. On the establishment of the Chester and District Hospital Management Committee under the National Health Service in 1948 he was appointed vice-chairman, a position he held until 1952. He had also been chairman of the appointments subcommittee and vice-chairman of the staffing subcommittee.

As a Home Office pathologist Dr. Grace was often called on to give evidence in criminal prosecutions, and he appeared as an expert witness in the trial for murder of Dr. Buck Ruxton in 1936 and of Dr. R. G. Clements in 1947. As a witness his quiet, incisive voice commanded respect, and his answers to questions were uttered slowly and deliberately, without waste of words. By nature a cheerful, kindly man, he was most reluctant to give up much of his work last year, but ill-health made this inevitable. His memory will be cherished by his many friends.

Dr. GRIFFITH LLEWELYN JONES died at his home at Llangefni, Anglesey, on January 17 at the age of 80. He was born at Llanllyfni, Caernarvonshire, on October 25, 1872, and was educated at Denstone College, Uttoxeter, and St. Mungo's College, Glasgow. After obtaining the Scottish triple qualification in 1897 he was appointed house-surgeon to the Royal Infirmary, Glasgow. He volunteered for service in the South African war, and was senior medical officer to the Ladysmith, Pinetown, and Merebank camps. In 1903 he settled in general practice at Llangefni, where he remained for the rest of his life. During the first world war he held a commission in the R.A.M.C. and had charge of various auxiliary hospitals, as he also had during the last war. He was medical officer to the County Isolation Hospital for many years. An accomplished horseman for over fifty years, he was one of the most active members of the Anglesey Harriers. He married Miss Grace Rowlands, of Clegir Mawr, Anglesey, and she, with their three daughters, survives him.

Professor O. HERBERT WILLIAMS writes: Dr. Griffith Llewelyn Jones was the perfect family doctor. He had a keen and lively intelligence, unbounded energy, an understanding mind, and an inexhaustible fund of kindness, which he lavished on his patients. His response to a medical call was immediate. He used to dart along the Anglesey lanes like a swallow to see his patients, and he accomplished a prodigious amount of work in the 24 hours, but once inside the sick-room he was never in a hurry. He had that skill, which is tending to disappear, of making a remarkably accurate assessment of the patient's condition from symptoms and physical signs and with the aid of the simple armamentarium of the doctor's bag. Nevertheless, he was fully alive to the latest laboratory aids to diagnosis and made full use of them. If one of his patients was transferred to hospital or to a nursing-home he still kept in constant touch, for he considered that he was always in overall charge of the case, and kept himself continually informed of the patient's progress. No man served his generation better than did Llewelyn Jones, and no one was held in higher esteem. This was plainly shown by the mourning crowds from all parts of the island and beyond who lined the streets of Llangefni and congregated at the old church of Llangristiolus to pay their last homage to one who was indeed a "beloved physician."

Dr. N. H. Joy, who died at Chichester on January 20 at the age of 78, was the author of several well-known books on natural history. H. B. writes: Norman Humbert Joy was the son of a clever father and was himself of a rare type. As a student at St. Bartholomew's Hospital he was above the average at work and games, but his scope in both was curtailed by the need to qualify as quickly and inexpensively as possible. After a house-surgeoncy at the Southport Infirmary and a short assistantship in private practice, he became doctor to Bradfield College, an appointment for which he was well adapted. His domestic happiness and professional outlook were, however, early shattered by a motoring accident which left him a permanent cripple. Thereafter his energies were mainly confined to natural history, in which his powers of observation were extraordinary. He once said to me, "I know only part of my brain is working"; but in spite of this, and in spite of diplopia, severe headaches, and other handicaps, he had some notable achievements. He produced a large two-volume work on British beetles, illustrated by himself, which is still the standard book on the subject. He wrote also a small handbook on the identification of British birds in the field; this quickly went through several editions, and, like the beetle book, was illustrated by himself. During his lifetime he added more new species to the list of British beetles than anyone else; and once, while crossing Windsor Park, he discovered an ant new to science, named by Rothschild *laetitia* in a play on Joy's name. Among other exploits Joy made a complete collection of British butter-

flies, which he characteristically gave to a London museum. Another of his successful accomplishments which I like to remember was the photography of a cuckoo laying an egg. Through the 60 years of our friendship I have been continually inspired by Joy's brave mastery over cruel frustrations. He leaves two married daughters and a son who prospers as a doctor in the West Country. They have our sympathy with their sad memories.

We record with regret the death of Dr. E. E. PAGET-TOMLINSON at his home at Summerhill, near Ulverston, Lancashire, on January 20, at the age of 70. Edward Edmondson Paget-Tomlinson was born on April 26, 1882, the son of the late Dr. W. S. Paget-Tomlinson, of Kirkby Lonsdale. At Trinity Hall, Cambridge, he distinguished himself as an athlete, gaining a half-blue for the long jump. He also played Association football for the Corinthians, and was in a team which toured South Africa. From Cambridge he went on to the London Hospital, qualifying in 1909 and graduating M.B., B.Chir. in the following year. After holding house appointments at the London Hospital Dr. Paget-Tomlinson went into general practice in his home town of Kirkby Lonsdale, in Westmorland, and then moved to Malton, in Yorkshire, where he stayed until he entered the R.A.M.C. to serve in the war of 1914-18, much of the time in Salonika. He proceeded to the degree of M.D. in 1920 and then practised for some 15 years at Horncastle, Lincolnshire, where he was medical officer of health to the urban district council and honorary surgeon to the War Memorial Hospital and Dispensary. He left Horncastle early in 1935 and for a time lived at West Tanfield, near Ripon, and at Bedale, Yorkshire, until in 1938 he settled at Summerhill. For some years he had been in poor health, but during the last war he came out of retirement to help doctors in the Ulverston area. He was a governor of Sedburgh School and a magistrate on the Ulverston bench. He leaves a widow and one son.

We are indebted to Sir PHILIP MANSON-BAHR for the following appreciation: Dr. E. E. Paget-Tomlinson, or "P.-T." as he was known, was a friend and fellow student of mine at the London Hospital from 1905 to 1908. There are others of my contemporaries who will treasure the memory of "P.-T.'s" many lovable characteristics. He was the type of athletic student of his day, fresh from the University of Cambridge and excelling in every form of field athletics, especially in the jumps and hurdles. He was good to look upon, with his neat, well-proportioned figure and his charming, cheery smile. He was gifted with a particularly inquiring mind and would pose questions on all kinds of subjects, ending his inquiries always with a throaty chuckle. He was the most humble and modest of men, but under his diffidence there lurked a sincerity and a love of his fellow creatures. He was thus fitted with those qualities most needful to become a successful country practitioner. He filled the bill so well that his name has gone down as a household word in Lancashire and Lincolnshire, wherever he worked. He was a good naturalist and a keen observer of plant and bird life. It was always a pleasure to look forward to meeting him at reunion dinners of the London Hospital, but of recent years his visits became rare, and it is sad to think that such a fine, athletic person as "P.-T." should have suffered so much in his last long illness.

Dr. A. F. GOLDSMITH, who was for many years a greatly respected medical practitioner in Bedford, died on January 27 at the age of 82. Born at Bedford on June 18, 1870, the youngest son of the late Dr. G. P. Goldsmith, who had practised in the town for over 40 years, Arthur Frederick Goldsmith was educated at Bedford School and at St. George's Hospital, London, qualifying M.R.C.S., L.R.C.P. in 1894. Soon after qualification he joined his father and his brother, Dr. G. Harvey Goldsmith, who died in 1940, and he and his brother succeeded to the practice

when their father retired in 1904. Dr. A. F. Goldsmith himself retired in 1932 and for a time lived in Cornwall, but his home in recent years was at Biddenham, near Bedford.

Dr. H. DEAN POLLARD writes: As a contemporary colleague I would like to add a personal tribute to the late Dr. A. F. Goldsmith. I first met him when he had been in practice about three years, and we were often in contact since then. "Dr. Fred," as he was almost universally known, was a modest, unassuming, but greatly loved practitioner, one of the old school, who made friends of his patients but who did not make patients of his friends. His kindness and generosity to his poor patients were unstinted, but were known by them alone. He married, somewhat late in life, Miss Helen Rickard, a member of a well-known Bedford family, and he retired so that he could devote his whole attention to his wife, whose health was not robust. I cannot omit a reference to his zeal and enthusiasm for his church, St. Paul's, where he worked for many years in different offices, especially in connexion with the Sunday school. It irradiated his whole life and shone out in his geniality, his kindness, and his self-sacrificing hard work for poorer brethren.

Dr. WALTER SHARPIN writes: Fred Goldsmith was a contemporary of mine from my early student days at St. George's Hospital, and, although he was my senior by a year, he became one of my friends. He was known as a quiet, hard-working student and he gained the prize in anatomy for his year. When he gave up his practice in Bedford his patients felt his loss very keenly. Among his colleagues he was deservedly popular, being always cheerful, always loyal, a true friend, and one who had no enemies.

Dr. J. A. LEAHY writes: With the passing of Dr. A. F. Goldsmith, Bedford has lost a much-loved citizen and the medical profession a colleague who was held by all in terms of sincere affection and esteem. He was the last of a family of doctors, which included an ophthalmic surgeon, the late Dr. Harvey Goldsmith, who had practised in Bedford for nearly 70 years. It was my good fortune to succeed "Dr. Fred" in practice, but it was difficult to follow in the footsteps of a man whose kindness, cheerfulness, wit, and good humour were a by-word in Bedford; even a passing acquaintanceship showed him to be "full of the milk of human kindness." His old patients still talk of his skill and of his never-failing generosity, especially to the poor; and he possessed in ample measure the greatest of all virtues, Christian charity. His deep religious faith, manifest to all, enabled him to bear with Christian fortitude the infirmities which afflicted him towards the end of his days. He is buried in his beloved Biddenham close to the south wall of the church where he worshipped.

Dr. LESLIE LYNE, whose sudden and untimely death at the age of 57 occurred on February 2, was born on April 21, 1895, and educated at St. Olave's Grammar School and Guy's Hospital. As a result of this early and long association he acquired an affection for "The Borough" and its inhabitants which neither time nor separation could dull. After qualifying in 1919 Dr. Lyne held the posts of house-physician to Dr. (later Sir) Arthur Hurst and obstetric resident at Guy's. Subsequently he widened his experience by spending two years in India and Persia with the Indian Medical Service and a period as resident at Lambeth Infirmary before settling at Ascot at the suggestion of Sir Arthur Hurst. There he combined general practice with anaesthetics, being at one time on the staff of the King Edward VII Hospital, Windsor. But his real life's work began when, mainly for reasons of health, he moved to Bedford in 1934. There his sterling qualities as a man and as a physician were quickly recognized and he soon formed a large and ever-widening circle of patients, who found in him the ideal family doctor—selfless, reliable, capable, and gentle. By them he will be greatly missed, perhaps not least by the aged, whose problems he seemed to understand so

well. But in addition to the ties of a busy general practice he continued his interest in anaesthetics and held various appointments, most notably at the Sussex Throat and Ear Hospital, where he was senior anaesthetist for the past 14 years. Throughout innumerable operating sessions his quiet efficiency would allay anxieties and his unvarying good temper and charm alleviate tedium. Apart from his work, his happy family life occupied him entirely, and his joy was complete when in the same month last year his daughter graduated B.Sc. and his son M.B., B.Chir. To them and to his widow our deepest sympathy goes out in their irreparable loss.—T. S. A.

Dr. BERTRAM ROGERS, who died at Oxford on February 9 at the age of 92, spent most of his active professional life in Bristol. His father was J. E. Thorold Rogers, M.P., professor of political economy in the University of Oxford and at King's College, London. Bertram Mitford Heron Rogers was born on August 25, 1860, and was educated at Westminster School and at Exeter College, Oxford, where he gained a blue for Association football. He played at centre-half for the University against Clapham Rovers in the F.A. Cup Final at Kennington Oval in 1880. After leaving Oxford he began the study of medicine at University College, London, graduating B.M., B.Ch. in 1889 and proceeding M.D. in 1892. On going to Bristol he engaged in general practice, but was appointed physician to the Bristol Royal Hospital for Sick Children and Women, and more or less specialized in children's diseases at a time when that was very unusual, at any rate in the provinces. At the Annual Meeting of the B.M.A. in 1894 he was one of the secretaries of the Section of Diseases of Children and vice-president of the Section at the Annual Meeting in 1902. A member of the Territorial Army, he commanded a field ambulance in the war of 1914-18, and attained the rank of lieutenant-colonel. He was very active in local affairs, being president of the Bristol Medico-Chirurgical Society in 1910 and editorial secretary to its journal. He was local secretary of the British Association twice, in 1898 and 1930, chairman of the Bristol branch of the St. John Ambulance Association, and honorary treasurer of the local Royal Empire Society. As may be gathered from this record, he was highly esteemed by his colleagues, but few of them, if any, are left now to mourn his loss. After his retirement from clinical practice he worked for a time as a regional medical officer of the Ministry of Health. He married Agnes Fletcher in 1891, and had two daughters. Mrs. Rogers died in 1939.

Medical Notes in Parliament

Antibiotics for Fattening Stock

The Therapeutic Substances (Prevention of Misuse) Bill occupied the House of Lords for only a short time on its second reading on February 12.

The EARL OF ONSLOW, moving it, said that no one quarrelled with the Penicillin Act, 1947, but other substances had since come forward, and this Bill sought to regulate them so that their use should not be detrimental to the public. This applied particularly to isoniazid, which was cheap to produce, and could, if used for self-medication or without proper advice, do a great deal of harm to the person concerned. The other main purpose of the Bill was to permit the use of some of these drugs, particularly at the moment penicillin, in the feeding of pigs and table poultry. A tiny quantity of penicillin in their diet fattened them more quickly, and thus produced more pork and bacon.

The only substantial point raised in the discussion was put most succinctly by Lord O'HAGAN, although other peers spoke about it. It was to seek assurance that the effect of the inoculation of pigs by penicillin would neither be

deleterious to human beings who were allergic to penicillin when the pig-meat was eaten, nor conversely affect the effectiveness of the drug when it was properly administered to human beings.

The EARL OF ONSLOW assured them that the Agricultural Research Council and the Medical Research Council were satisfied that penicillin fed to pigs in this form could do no harm whatever.

As a footnote to this debate, an answer given in the House of Commons on February 12 stated that the Minister of Health was advised that the quantities of antibiotics needed would be minute—of the order of 2 to 20 parts in a million—and that there would remain in the meat from stock so fattened no traces of a kind that would entail any risk to the consumer.

Chemicals in Food

Mr. D. W. WADE asked the Minister of Food on February 11 what investigations he was undertaking into the use of chemicals and synthetic substitutes in the production of food, and when he would be able to publish the results.

Major G. LLOYD GEORGE replied that the Food Ministry did not itself undertake investigations of this nature. The work was carried out through continued consultation with the Health Departments and the Medical Research Council and by close co-operation with the Industrial Research Associations and other technical bodies concerned.

Mr. WADE said there had been an alarming increase in recent years in the use of chemicals in the production and processing of food, and there had been no adequate inquiry into either the short-term or long-term effects on the health of the nation.

Major LLOYD GEORGE would not accept the phrase "alarming increase." Chemicals need not necessarily be a cause for alarm; they had been used for many years in foodstuffs. Very careful investigation indeed was going on into important aspects of the matter.

Treatment of Flour

The MINISTER OF FOOD, answering a question by Mr. R. BELL on February 11 asking why, and under what authority, chalk is added to the national loaf, stated that calcium carbonate was added to National flour to ensure that total food supplies provided sufficient calcium to meet nutritional requirements. This was done under Articles 2 and 6 of the Flour Order, 1952, and Article 2 of the Bread Order, 1952. The addition of nutrients to flour was under discussion with the trades concerned, and an announcement would be made when the details had been settled.

Mr. D. W. WADE asked the Minister what progress had been made in the investigations into the existing methods of treatment of flour, and whether he would give an assurance that the process of agenization would be abandoned. Major G. LLOYD GEORGE stated that these complex and important investigations into possible alternatives to agene as a flour improver were requiring considerably more time than was originally thought necessary. They were being pursued with all possible speed, but it would be premature to take any action until they were completed.

In a further reply he said that since the investigations started one or two possible alternatives had been suggested, but it was obvious that careful research must be undertaken before either could be accepted.

Mr. G. NICHOLSON asked whether it had been accepted that agene was a contributory factor to hysteria in dogs.

Major LLOYD GEORGE said that was one of the things the committee was investigating. He also pointed out that agene had been used in bread in this country for over 30 years.

Lung Cancer

Mr. S. T. SWINGLER asked the Parliamentary Secretary to the Ministry of Works, as representing the Lord President of the Council, for a statement on the lines of research into the incidence of lung cancer among gas workers to be pursued by the Medical Research Council.

Mr. A. H. E. MOLSON replied on February 10 that the possibility of conducting further research on the incidence of lung cancer among gas workers was still under discussion by the Medical Research Council in consultation with other departments. He was therefore unable to make any statement at present about investigations which might be undertaken in the future.

London Sickness Claims

Lieutenant-Colonel M. LIPTON asked the Minister of National Insurance to what extent the number of claims for sickness benefit in the London area during December, 1952, exceeded the corresponding figure for 1951. Mr. O. PEAKE stated that the number of new claims to sickness benefit received in the offices of the Inner London region of the Department during the period of four weeks ending January 1, 1952, and December 30, 1952, were 52,770 and 77,040 respectively.

Lieutenant-Colonel LIPTON said that in view of this further evidence of loss caused by fog in London there should be more energetic action to deal with air pollution.

Elastic Stocking Prescriptions

Mr. W. W. HAMILTON asked the Minister of Health how many pairs of elastic stockings were supplied through the National Health Service on the prescription of general practitioners in the six months June–November, 1952; and what were the corresponding figures for each year since the inception of the Service.

Mr. IAIN MACLEOD, in a reply on February 6, said he regretted that when he answered a previous question on December 18 he omitted to make it clear that the figures he gave were for the hospital service only. Precise figures were not available, but it was estimated that the number of orders for elastic hosiery supplied on the prescription of general medical practitioners was at least ten times the number supplied through the hospital service. In his reply in December the Minister stated that the numbers supplied in June–November, 1952, were 16,055; in July–December, 1948, 4,788; and in the following complete years 23,331 (1949); 31,155 (1950); and 35,732 (1951).

Health Service Charges

Mr. A. BLENKINSOP asked the Minister of Health on February 12 what financial saving he estimated would result from the charges imposed under the Health Service Act, 1952, how much of this saving resulted from a fall in use of the services concerned, and how the savings compared with the estimates originally given. Mr. IAIN MACLEOD replied that the estimated amount of the charges paid or to be paid in 1952–3 by patients in England and Wales under the 1952 Act was about £2m. In addition, while figures to enable a complete estimate to be made were not available, the reduction in the demand for dental treatment and for hospital appliances for which charges were made compared with the previous year was estimated to show a saving of about £1,750,000. Comparisons could not usefully be made with estimates framed in the expectation that the charges would operate for a full year and before modifications in the original proposals were made.

Licence Duty on Cars

Lieutenant-Colonel W. H. BROMLEY-DAVENPORT asked the Chancellor of the Exchequer whether he was aware that, although veterinary surgeons, doctors, dentists, and midwives had been exempted under the Road and Rail Traffic Act (Exemptions) Regulations, 1951, from the necessity of obtaining a carrier's licence for their utility vehicles when used for carrying medicines, drugs, and instruments for use in their professional work, these vehicles were still subjected to the higher rate of Road Fund duty irrespective of ownership and use; and whether, in view of the difficulty for such

persons in obtaining small low-taxed private cars in substitution, he would take steps to ensure that the utility vehicles in question qualified for private-vehicle taxation rates.

Mr. J. A. BOYD-CARPENTER, the Financial Secretary, answered on February 12 that under section 5 of the Vehicles (Excise) Act, 1949, and s. 7 of the Finance Act, 1952, vehicles constructed or adapted for the conveyance of goods must pay duty as goods vehicles if used to convey goods for hire or reward or in connexion with a trade or business. He had no power to exempt particular classes from the general law.

Consultants in West Scotland

Sir THOMAS MOORE stated in a question to the Secretary of State for Scotland on February 10 that there was public concern in Ayrshire about the efficiency of the National Health Service and the shortage of trained medical and surgical consultants. Mr. J. STUART undertook to consider any particulars of deficiencies brought to his notice. Sir T. MOORE mentioned that there had been a disturbing number of resignations lately, especially among consultants. Mr. STUART said he was assured that the regional board were taking proper steps to replace those who had resigned. Mr. A. C. MANUEL said that doctors generally in West Scotland had expressed to him their satisfaction at the better service available since the National Health Service was begun.

Medico-Legal

LIABILITY OF HOSPITAL AUTHORITY

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

In an action for negligence against the surgical registrar of the Mayday Hospital, Thornton Heath, and the Croydon Hospital Group Management Committee in respect of the death of a patient from peritonitis after appendicectomy, a novel defence was raised on behalf of the management committee. The committee pleaded that in undertaking the care and treatment of patients they did so in pursuance of their duty to provide hospital specialist and general medical services under the National Health Service Act, 1946, that the surgical registrar was acting on their behalf in fulfilment of that duty, and that section 72 of the Act therefore relieved them of liability.

s. 72 of the Act of 1946 provides that s. 265 of the Public Health Act of 1875 shall have effect as if the authorities mentioned in it include hospital management committees. s. 265 of the Act of 1875 provides that no matter or thing done by local authorities shall, if done bona fide for the purpose of executing the Act, subject them personally to any action, liability, claim, or demand whatsoever.

But s. 13 of the National Health Service Act, 1946, provides that hospital management committees shall, notwithstanding that they may be exercising functions on behalf of the regional hospital board, be liable in respect of any liabilities incurred in the exercise of those functions, including liabilities in tort—for instance, for negligence.

This defence of the committee was tried as a preliminary issue in the action before Mr. Justice Parker on February 12.¹ In his judgment he said that it would be a very strange result if, in face of the plain words of s. 13 of the 1946 Act, the effect of s. 72 of that Act and s. 265 of the Public Health Act, 1875, absolved the committee from the Public Health Act, 1875, in *Davis v. Board of Management for Glasgow Victoria Hospitals*,² that, by reason of equivalent but not identical provisions in the statutes applicable to Scotland, the management committee could not be sued. But the decision was not binding on the English

courts and Mr. Justice Parker felt unable to follow it. He decided the preliminary issue against the management committee, but granted leave to appeal.

This is apparently the first time in England since the National Health Service Act, 1946, came into force that a hospital management committee has relied on this defence. Lawyers and management committees throughout the country will await with great interest the result of an appeal from Mr. Justice Parker's decision, which is of the highest medico-legal importance.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on January 22 the degree of D.M. was conferred on T. Stapleton and F. J. Flint.

The following reappointments are announced: A. G. McD. Weddell, M.D., Reader in Human Anatomy, from October 1, 1953, to September 30, 1960; and D. C. Sinclair, M.D., Demonstrator in Human Anatomy, and George Gordon, D.M., Demonstrator in Physiology, both from October 1, 1953, to September 30, 1958.

Among the honorary degrees the University proposes to confer at a Convocation on July 1, in connexion with the Rhodes Centenary, is that of D.C.L. on Professor W. G. Penfield, F.R.S., who was awarded the Order of Merit in this year's New Year Honours.

UNIVERSITY OF CAMBRIDGE

The establishment of the Elisabeth Storey Fund for research on leukaemia and allied diseases was announced in the *Journal of Medicine* 6, 1952 (p. 1267). The Vice-Chancellor of the University announced on January 12 that he had received a gift of £220 from Mtre Mahmoud El-Darwish for use in connexion with the fund.

Professor J. S. Mitchell, F.R.S., has been appointed representative of the University at the seventh International Congress of Radiology, to be held at Copenhagen in July.

In Congregation on December 23, 1952, the following medical degrees were conferred by proxy:

M.B., B.CHIR.—J. M. S. Grieve, H. E. Lichtenstein, T. M. O. Morris, R. D. W. Romanis, H. C. M. Walton, M. H. Bennett, R. L. Morgan, J. F. Preece, T. L. Ringrose, J. O. Winter, M. D. Heyman, P. M. H. Rack, I. F. Smith, G. D. Stones, P. A. Watt, W. M. Beatley, W. A. G. Roper, M. C. Thornton, D. A. P. Burton, A. M. B. Golding, B. S. Jay, P. L. Maybury, K. F. Morrice, F. Reiseiger, C. S. Savage, L. J. Stretton, I. Weinbren, R. K. Greenwood, H. F. Grundy, I. S. Lister, M. T. O'Donnell, I. A. Stewart, D. S. Trouton, R. C. Curry, S. H. Dallas, B. L. Hoskyns, H. S. Chen, E. M. Orton, J. T. H. Pick, J. A. M. Tudor-Hart, A. E. Wagstaff, D. W. K. Bird, W. H. Chapman, S. J. Fisher, D. B. Fox, E. P. Simkin, A. W. Warltier, F. L. S. J. Adams, L. P. Balfour-Lynn, A. N. Griffith, Whalley, C. W. M. Adams, L. P. Balfour-Lynn, A. N. Griffith, R. D. Hernaman-Johnson, T. L. Scully, J. A. Fiddian, W. G. Williams, Aileen B. Donnison, Ruth M. Turner, Mrs. Hanna French, Vera M. C. B. P. Hollyhock, Gillian G. Matthews, G. M. P. Boyes.

The Council of the Senate of the University has accepted the offer of a grant by the Nuffield Foundation of £8,650 spread over five years in support of work in experimental embryology under the direction of Professor J. D. Boyd in the Department of Anatomy, and an additional grant from the Foundation of £550 a year for the three years of the grant for work on cellular biology to be conducted under the direction of Professor David Keilin, F.R.S., in the Molteno Institute of Biology and Parasitology (see also *British Medical Journal*, November 15, 1952, p. 1106).

In Congregation on February 6 the following medical degrees were conferred:

M.D.—I. S. Hodgson-Jones.
M.B., B.CHIR.—I. M. Brown (by proxy).

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on February 12, with Sir Cecil Wakeley, President, in the chair, the death of Sir Holburt Waring (Past President) was reported and the Council unanimously adopted a resolution of condolence.

An Honorary Fellowship was awarded to Professor Reynaldo dos Santos, of Lisbon.

Mr. Geoffrey Keynes was presented with the Cecil Joll Prize.

¹ *The Times*, February 13.
² 1950, S.C. 382.

A Hunterian Lectureship was awarded to Professor Wilder Penfield, O.M., Hon.F.R.C.S., of Montreal, and a Moynihan Lectureship to Dr. H. L. Jaffe, of New York.

The Hallett Prize was awarded to Dr. A. T. Matheson (Cape-town) and the Hancock Prize to Mr. A. H. Tooley (King's College Hospital).

It was reported that gifts had been received from Lord Webb-Johnson (bringing his total contribution to the Restoration and Development Fund to £2,500), from Professor A. V. Neale, and from Professor A. J. E. Cave.

Diplomas of Membership were granted to J. R. B. Saxby and to the recipients of the diploma of L.R.C.P. printed in the *Journal* of February 7 (p. 342).

Diplomas in Public Health, in Industrial Health, and in Anaesthetics were granted, jointly with the Royal College of Physicians of London, to the candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London in the *Journal* of February 7 (p. 342).

Hospitals were recognized under paragraph 23 of the F.R.C.S. regulations as follows: North Middlesex Hospital, Edmonton, decennial revision, three surgical registrars, for a year; six house-surgeons, for six months. Warneford General Hospital, Leamington Spa, decennial revision, resident surgical officer; house-surgeon, both for six months; from January, 1954, casualty officer. Royal Victoria Hospital, Folkestone, decennial revision, resident surgical house-surgeon (until February, 1954), for six months. Lewisham Hospital, paragraph 23c, ear, nose, and throat registrar. Central Middlesex Hospital, paragraph 23c, ear, nose, and throat registrar. County Infirmary, Louth, resident surgical officer, for six months. Fulham Hospital, additional recognition, orthopaedic house-surgeon, for six months. Southmead Hospital, Bristol, additional recognition, house-surgeon (genito-urinary), for six months; from January, 1954, two casualty house officers. Royal East Sussex Hospital, Hastings, from January, 1954, casualty officer. West Norfolk and King's Lynn General Hospital, from January, 1954, casualty officer. Maidenhead Hospital, from January, 1954, casualty officer. Dreadnought Seamen's Hospital, London, from January, 1954, casualty and receiving-room officer. Ingham Infirmary, South Shields, from January, 1954, casualty officer. Chelmsford and Essex Hospital, from January, 1954, casualty officer. Wanstead Hospital, from January, 1954, casualty officer. King George Hospital, Ilford, from January, 1954, casualty officer. West Middlesex Hospital, from January, 1954, two senior house-surgeons (casualty department). Rochdale Infirmary, from January, 1954, resident casualty officer. Selly Oak Hospital, Birmingham, from January, 1954, two casualty officers (senior house officers). Worcester Royal Infirmary, from January, 1954, casualty officer (senior house officer). Walsall General Hospital, from January, 1954, casualty officer.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College held on February 3, with the President, Dr. W. A. Alexander, in the chair, the following were elected Members of the College: D. G. McIntosh, D. G. C. Whyte, M. P. Goel, L. S. C. Mendis, G. M. Baird, B. Bevan, D. P. Gupta, J. B. Gibson, A. D. Muldoon, F. C. Friedlander, L. Rabinowitz, S. A. Syed, W. Frain-Bell, J. Paul, C. Marks, C. H. Sivaraman, E. M. McLachlan, J. M. Neilson, R. H. Gosling, A. R. Somner, S. J. Cohen, D. H. H. Pullon, M. Dan, Z. H. El Massry, S. Sing, J. A. Chunn, J. L. Potter, S. J. Irani, P. Sobti.

The Services

The *London Gazette* has announced the creation of the rank of Surgeon Rear-Admiral (Dental) with effect from October 1, 1952. The announcement states that the Lord Commissioners of the Admiralty are of the opinion that the duties of the Senior Dental Officer have so increased in scope as to justify the new rank.

Surgeon Lieutenant J. I. McL. Forsyth, R.N.Z.N. (H.M.N.Z.S. *Taupo*), and Temporary Surgeon Lieutenant R. A. Rowan, R.N.V.R. (H.M.S. *Belfast*), have been mentioned in dispatches for distinguished service in operations in Korean waters.

Major A. B. Kerr, O.B.E., T.D., R.A.M.C., has been awarded the First and Second Clasps to the Territorial Efficiency Decoration.

The Air Ministry has announced the upgrading of the post of Director of R.A.F. Dental Services, which is now to be held by an officer of the R.A.F. dental branch in the rank of Air Vice-Marshal.

Vital Statistics

Influenza

In the week ending February 7 there were 446 deaths from influenza in the great towns of England and Wales. In the previous week there were 313. Since the beginning of the year there have been 1,014 deaths in the great towns as compared with 197 in 1952 and 5,914 in 1951. The increased mortality in the week reviewed was mainly confined to London and the south-eastern region, where the deaths were 123 more than in the preceding week. The deaths in the towns of the eastern region were 22 more and in the southern region 17 more; in the remainder of the country the deaths were only 19 more than in the preceding week.

Although virus B has occasionally been demonstrated, the organism mainly responsible is a virus A-prime closely related to the Scandinavian type. Probably the serological type of the virus does not in general determine the severity of the disease except in so far as it is an antigenic novelty in a community without any resistance to it.

Week Ending February 7

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,545, whooping-cough 2,571, diphtheria 16, measles 31,494, acute poliomyelitis 26, dysentery 286, paratyphoid fever 15, and typhoid fever 2.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1943-51 are shown thus -----, the figures for 1952-3 thus ———. Except for the curves showing notifications in 1952-3, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 31 (No. 4) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Infectious Diseases

With the exceptions of a rise of 4,578 in the number of notifications of measles, from 21,882 to 26,460, and 680 for acute pneumonia, from 1,349 to 2,029, only quite small variations were reported in the incidence of infectious diseases in England and Wales during the week ending January 31.

The largest increases in the number of notifications of measles were 607 in Yorkshire West Riding, from 1,182 to 1,789; 514 in Middlesex, from 1,574 to 2,088; 422 in Devonshire, from 314 to 736; 316 in Lancashire, from 1,843 to 2,159; 250 in Sussex, from 516 to 766; 241 in Durham, from 587 to 828; 223 in Surrey, from 685 to 908; 203 in Staffordshire, from 663 to 866; and 202 in Warwickshire, from 1,184 to 1,386. Only small variations occurred in the local trends of scarlet fever and whooping-cough. The number of notifications of scarlet fever was 1,850, 18 more than in the preceding week, and the notifications of whooping-cough, 2,799, were 7 more than in the preceding week. 24 cases of diphtheria were notified—an increase of 5 on the preceding week. Half of the cases were notified in two counties, Lancashire 5 (Liverpool C.B. 4) and Warwickshire 7 (Birmingham C.B. 7). The notifications of acute pneumonia were the highest for almost two years. The largest rises during the week were 74 in Middlesex, from 97 to 171, and 68 in Yorkshire West Riding, from 128 to 196.

29 cases of acute poliomyelitis were notified during the week—7 more for paralytic cases and 2 fewer for non-paralytic cases than in the previous week. The largest returns were 3 in each of the counties of Berkshire, Essex, Lancashire, and London.

The 435 notifications of dysentery were 16 more than in the preceding week. The largest returns were Lancashire 116 (Liverpool C.B. 52, Warrington R.D. 24, Salford C.B. 10), Essex 91 (East Ham C.B. 89), Lincolnshire 40 (Grimby C.B. 38), London 32 (St. Pancras 9), Yorkshire West Riding C.B. 13), Cambridge 23 (Cambridge M.B. 23), Middlesex 17 (Edmonton M.B. 7), and Kent 16 (Penge U.D. 10).

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Medical News

Hunterian Society.—The annual dinner of the Hunterian Society was held at the Savoy Hotel on February 12, when the president, Dr. B. Parsons-Smith, was in the chair. Lord Reading, in proposing the health of the Society, referred to its "long and fluctuating" history and its close connexion with the City of London. "To doctors patients are a virtue, and to some patients doctors are a vice," was one of his witty remarks. In response the president gave an account of the Society's activities in the past year. The Lord Mayor, Sir Rupert de la Bere, was welcomed in a gracious speech by Mr. J. H. Doggart. The Lord Mayor, in reply, mentioned the intensive voluntary work at the Mansion House for the flood relief fund. The toast, "The guests and kindred societies," was proposed by Dr. George Day in a witty speech which kept everyone anxiously guessing what he might say next. Sir Raymond Evershed and Dr. F. M. R. Walshe replied.

Pharmacy Bill.—The removal of the disqualification upon members of the medical profession from being registered as pharmaceutical chemists is one of the objects of the recently published Pharmacy Bill. The Bill is a private Member's Bill with support from both sides of the House. Other provisions include the creation of a single statutory register of pharmacists and the extension of the powers of the Pharmaceutical Society in connexion with the examination and registration of pharmacists.

R.S.I. Prize Essays.—The Royal Sanitary Institute is offering two open prizes this year for essays on health subjects. The prizes are the John Edward Prize of £60 for an essay on "Internal planning lay-out and equipment of dwellings to reduce domestic work without loss of efficiency and within reasonable expenditure"; and the John S. Owens Prize of £15 for an essay on "The location of industry having regard to the health of the people." Intending competitors should apply to the secretary, The Royal Sanitary Institute, 90, Buckingham Palace Road, London, S.W.1, for a copy of the conditions. The last date for entries is December 31.

Family Doctor.—In the March issue of *Family Doctor* Professor W. C. W. Nixon and his colleagues complete their series of articles on having a baby. To judge from the two pages of correspondence on the propriety or otherwise of dealing openly with this subject in a family magazine, readers have been both interested and helped. In the same issue, Dr. T. Anderson summarizes the arguments for and against whooping-cough immunization. On psychological questions there are articles by Miss Alcock on the "schoolgirl crush" and by Professor R. S. Illingworth on "family favourites." Articles of general interest include accounts of what is being done for spastics and old people, and the story of a seven-months voyage in a whaler.

New Cancer Periodical.—The first volume of *Advances in Cancer Research* has just been published by the Academic Press, New York. It is edited by Professor Alexander Haddow (Royal Cancer Hospital, London) and Dr. J. P. Greenstein (National Cancer Institute, Bethesda, Md), and is designed to present authoritative reviews on various phases of cancer research. It is international in scope; vol. 1 (590 pages) is priced at \$12.00 (£4 6s.).

Extension of Bart's.—The Court of Common Council has approved plans for the building of a 120-bed extension to St. Bartholomew's Hospital, London. The site for the new block is separated from the main hospital buildings by a street, and a tunnel will be needed to link the two together. It is not yet known when building will be begun.

Coccidioidin, Histoplasmin, and Blastomycosis Antigen for diagnostic skin tests are now obtainable from the department of pathology, St. John's Hospital for Diseases of the Skin,

Lisle Street, London, W.C.2 (Tel. Gerrard 8383, Ext. 22), instead of from the London School of Hygiene and Tropical Medicine as previously.

Colyer Prize.—The Royal Society of Medicine invites applications for the triennial Colyer Prize for the best original work in dental science during the preceding five years. The prize is valued at £20. The closing date for applications is September 21.

Refresher Course Book.—Copies of the first Refresher Course book are now available once more. The first impression, which appeared last October, sold out shortly after publication. The book contains all the Refresher Course articles printed in the *Journal* from October, 1949, to December, 1950. Each article has been revised by its author and brought up to date. Copies of the book may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1. The price is 25s.

Emergency Bed Service: Applications and Admissions.—During the seven days ending February 16 the number of applications made by doctors to the London Emergency Bed Service for admission of patients was 1,730, of whom 77.93% were admitted. A yellow warning indicating that the percentage of admissions fell below 80 was issued on February 10.

Dr. L. Justin-Besançon, professor of medicine at the Sorbonne, has been elected a member of the French Academy of Medicine.

COMING EVENTS

Robert Campbell Memorial Oration.—Dr. E. E. Pochin will deliver a Robert Campbell Memorial Oration on February 26 at 8.30 p.m. in the Whitla Medical Institute, Belfast. His subject is "The Value of Radioactive Isotopes in Medicine."

Chesterfield Medal in Dermatology.—The examination for the Chesterfield Medal will be held on March 9, 10, 18, and 19. February 28 is the closing date for entries, which should be lodged with the secretary, Institute of Dermatology, Lisle Street, London, W.C.2.

Postgraduate Examination Courses.—Courses for candidates for the D.M.R.D. and D.M.R.T. (R.C.P.Lond. and R.C.S.Eng.), commencing in October, 1953, are being organized by the Faculty of Radiologists. Further information will be found in the advertisement columns.

NEW ISSUES

Archives of Disease in Childhood.—The next issue (Vol. 128, No. 137) will be available in a week's time. The contents include:

REMNANTS OF THE VITELLO-INTESTINAL DUCT. A CLINICAL ANALYSIS OF 88 CASES. John Aitken.

OVARIAN AGENESIS OR PTERYGIUM SYNDROME. Per Skjelbred.

CHONDRODYSPLASIA WITH ECTODERMAL DEFECTS. E. J. Gallagher, M. E. MacGregor, and M. Israelski.

TYPHOID OSTEITIS IN INFANCY. Harris Jackson, I. Kessel, S. N. Jayett, and P. Kushlick.

A CASE OF OSTEOMYELITIS OF ALL THE SMALL BONES OF HANDS AND FEET. M. D. Baber.

ACCIDENTAL POISONING OF YOUNG CHILDREN. Douglas Swinscow.

THE SENSITIVITY TO ANTIBIOTICS OF STRAINS OF BACT. COLI ASSOCIATED WITH INFANTILE GASTRO-ENTERITIS. J. Smith and W. H. Galloway.

KILLED ANTITUBERCULOUS VACCINE AND HYALURONIDASE (D.V.). G. Salvioi.

OBSERVATIONS ON FOETAL HAEMOGLOBIN. C. Gardikas, D. G. Scott, and John F. Wilkinson.

TENSION PNEUMOTHORAX COMPLICATING STAPHYLOCOCCAL PNEUMONIA AND EMPHYSEMA THORACIS. DESCRIPTION OF A CASE. R. Spencer.

HAEMANGIOENDOTHELIOMA OF THE LIVER SIMULATING CONGENITAL HEART DISEASE IN AN INFANT. C. Blaxland Levick and J. Rubie.

THE INCIDENCE AND SIGNIFICANCE OF SYSTOLIC CARDIAC MURMURS IN INFANTS. W. C. Taylor.

IDIOPATHIC RENAL ACIDOSIS IN TWINS, WITH ALKALOSIS RESULTING FROM OVERDOSAGE OF CITRATE MIXTURE. John Rendle-Short.

TREATMENT OF THE SCHOENLEIN-HENOCCH SYNDROME WITH ADRENOCORTICOTROPIC HORMONE (A.C.T.H.) AND CORTISONE. A REPORT OF NINE CASES. J. N. Briggs and M. G. Philpott.

THE URINARY EXCRETION OF HISTAMINE IN CHILDREN. H. M. Adam and R. G. Mitchell.

PNEUMOPERITONEUM AS A DIAGNOSTIC PROCEDURE. J. Rubie.

THE ABSORPTION OF CHLORAMPHENICOL IN THE NEWBORN. Donough O'Brien.

TWO CASES OF CHRONIC POLYNEURITIS IN CHILDREN. J. S. Oldham.

DUPPLICATION OF THE ILEUM. W. S. Kilpack.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

Details in this column are necessarily brief. Further information and tickets where required (marked ●) should be obtained from the institution concerned.

Monday, February 23

HUNTERIAN SOCIETY.—At Mansion House, 8.30 p.m., Hunterian Oration by Mr. A. Dickson Wright: Quacks of John Hunter's Time.

INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: lecture-demonstration for postgraduates.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., pathological meeting.

UNIVERSITY COLLEGE.—At Physiology Theatre, 4.45 p.m., public lecture by Professor Jean Roche (Collège de France, Paris): Comparative Biochemistry of Iodoproteins.

Tuesday, February 24

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. P. L. Mollison: Life-span of Red Cells.

CHADWICK TRUST.—At 26, Portland Place, W., 2.30 p.m., Dr. G. Decharneux (Liège): Industrial Medicine and Hygiene in Belgium.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. L. Forman: Skin Diseases Related to Cancer.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor J. Moroney: Colonic Replacement and Restoration of the Human Stomach.

WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Dr. Colin Edwards: Neurological demonstration.

Wednesday, February 25

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Virus Diseases.

INSTITUTE OF UROLOGY.—At St. Paul's Hospital, W.C., 4.30 for 5 p.m., Mr. J. G. Sandrey: Vesical Neoplasms.

ROYAL EYE HOSPITAL CLINICAL SOCIETY.—5.30 p.m., clinical meeting: 6 p.m., film by Miss J. M. Dollar and Miss M. Savory: Exenteration of the Orbit.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Dr. James Watson Lecture by Mr. A. G. Macgregor: Thyrotoxicosis: Its Diagnosis and Treatment by Modern Techniques.

YORKSHIRE SOCIETY OF ANAESTHETISTS.—At Leeds General Infirmary, 8 p.m., Dr. G. E. Hale Enderby: Reduction of Surgical Haemorrhage by Controlled Hypotension.

Thursday, February 26

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. A. H. T. Robb-Smith: Functional Significance of Connective Tissue.

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—At Glasgow University Union, 7.30 p.m., B.M.A. Lecture by Professor Ian Aird: Modern Exercises in the Hunterian Discipline.

INSTITUTE OF CHILD HEALTH.—5 p.m., Dr. G. Stewart Prince: Emotional Problems of Puberty.

LIVERPOOL MEDICAL INSTITUTION.—4.30 p.m., Sir Russell Brain: Neurology of the Cervical Spine.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Sir Clement Price Thomas: Carcinoma of the Lungs (with lantern slides).

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Arris and Gale Lecture by Mr. L. P. Le Quesne: Management of Water and Electrolyte Administration during the Post-operative Period.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor G. A. H. Buttle: Chloramphenicol, Aureomycin, and Terramycin and the Resistance Developed to Them.

SOCIETY OF CHEMICAL ENGINEERS.—6.15 p.m., papers by Dr. C. Cockburn, Institution of Electrical Engineers, and Dr. Joan Taylor: Pathogenic Organisms in Food.

UNIVERSITY COLLEGE.—At Physiology Theatre, 4.45 p.m., public lecture by Professor V. B. Wigglesworth, F.R.S.: Chemical Aspects of Insect Physiology.

WHITLA MEDICAL INSTITUTE, Belfast.—8.30 p.m., Robert Campbell Memorial Oration by Dr. E. E. Pochin: Value of Radioactive Isotopes in Medicine.

Friday, February 27

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. D. I. Williams: Alopecia.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—4.30 p.m., Mr. N. Asherson: Mastoiditis.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—7.30 p.m., Dr. Denys K. Ford: Arthritis of Genital Origin—Treatment with A.C.T.H.

ROYAL INSTITUTE OF PHILOSOPHY.—At University Hall, 14, Gordon Square, W.C., 5.15 p.m., Dr. J. Hardland-Swann, B.Litt., Ph.D.: Nature of Mind.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Chartres.—On February 8, 1953, at Churchill Hospital, Oxford, to Mary (formerly Gaudin), wife of John C. Chartres, B.M., B.Ch., D.T.M.&H., a sister for Roger—Diana Crispin.

Cross.—On February 5, 1953, at King's College Hospital, London, S.E., to Pamela (formerly Hufeland), wife of Dr. A. F. Cross, a daughter—Melanie Jane.

Duff.—On February 13, 1953, at the Yarrowburgh Nursing Home, Southsea, Hants, to Audrey, wife of Dr. Derek R. Duff, a daughter.

Morrison.—On February 11, 1953, to Ina, M.B., Ch.B., D.Obst.R.C.O.G. (formerly Alexina Myles), wife of Dr. Leslie G. Morrison, 8, St. Catherine's Place, Edinburgh, a daughter.

Rigby.—On February 5, 1953, to Joan, wife of Dr. J. P. V. Rigby, of Huntsmoor Weir, Cowley, Middlesex, a daughter.

Wollner.—On February 8, 1953, at the Churchill Hospital, Oxford, to Sylvia Wollner, M.B., B.S. (formerly Colquhoun), wife of Leopold Wollner, M.B., B.S., a son—Mark Edward.

Wurm.—On February 10, 1953, at King's College Hospital, London, to Rhonda, wife of Roger Wurm, M.B., M.R.C.O.G., a son—Jeremy.

DEATHS

Balme.—On February 13, 1953, Harold Balme, O.B.E., M.D., F.R.C.S., D.P.H., of 64, Copers Cope Road, Beckenham, Kent, formerly of Shantung, China, aged 74.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Gastric 'Flu'

Q.—Is there such a thing as gastric 'flu'?

A.—Gastro-intestinal symptoms may occur as a complication of true virus influenza. There is, however, no evidence that outbreaks in which the symptoms are predominantly gastro-intestinal have anything whatever to do with influenza. A form of gastro-enteritis due to a filterable agent has been described and outbreaks of Sonne dysentery may also masquerade as "gastric 'flu.'" The term may be a useful label for practitioners to use, but it has no scientific basis, and its use in publications may lead to confusion.

Wheat Gluten in Sprue and Steatorrhoea

Q.—Does the exclusion of wheat gluten from the diet of adults with sprue or idiopathic steatorrhoea have the same beneficial effect as in coeliac disease in children?

A.—The effect of excluding wheat gluten from the diet in adult cases of sprue and idiopathic steatorrhoea is still under investigation. Some cases undoubtedly show improvement, but it is too early to say whether this method of treatment will prove generally effective. It does not seem likely that any form of treatment can bring about dramatic recovery in patients with many years' history of steatorrhoea and multiple deficiencies. Chronic deficiency of nutrients alone may cause irreversible structural changes which may prevent or delay complete recovery.

Aetiology of Chronic Bronchitis and Emphysema

Q.—What aetiological factors are of importance in the development of chronic bronchitis and emphysema? Are outdoor workers, such as policemen, specially liable to the condition?

A.—Factors of importance in the aetiology of chronic bronchitis and emphysema are climatic, environmental and occupational, constitutional and hereditary, and the effect of smoking. Chronic bronchitis is principally a disease of those temperate climates which are liable to spells of cold, damp, foggy weather. The environmental factor may be illustrated by the much greater frequency of bronchitis and emphysema in industrial areas, irrespective of occupation. Among occupations, those which expose the worker to dust (even apart from those dusts known to be specifically harmful) and to violent changes of temperature show a high incidence of chronic bronchitis. Heavy physical work out of doors in all weathers, such as that of navvies, is said to be a factor, though there is no evidence that outdoor occupation in itself is important. Smoking is undoubtedly important, and giving up this habit is nearly always beneficial to the chronic bronchitic. In addition to these external factors, hereditary constitution plays an important part. Many patients whose final condition is best described as chronic bronchitis and emphysema start as asthmatics and show the well-known family predisposition to allergic disorders; apart from this, chronic bronchitis itself often seems to be regarded as causing chronic bronchitis, or simply as another manifestation of the same underlying abnormality of the entire respiratory mucosa, is a matter of controversy.

Treatment of Psoriasis

Q.—Have there been any recent notable advances in the treatment of psoriasis?

A.—The treatment of psoriasis has unfortunately not altered. Year after year new treatments are introduced and praised and, before long, discarded. Undecylenic acid is now recognized to be useless; cortisone and A.C.T.H. are only of doubtful value. Other current and widely advertised treatments with proprietary remedies will, one suspects, go the way of the rest before long. Dr. R. M. B. MacKenna's Refresher Course article (*British Medical Journal*, 1950, 2, 207) still remains a complete and up-to-date summary of treatment.

Brittle Nails

Q.—What is the present informed opinion of the cause and treatment of brittle nails—that is, nails which crack and flake at the edge? One authority says it is connected with the general health, another says it is due to detergents and degreasers. It is a very common complaint among women.

A.—Both authorities are correct. There is no single cause; disturbances of general and nervous health are common causes, but external agents may be responsible, and often both factors play a part. Among external factors excessive manicuring, the use of enamels with ethyl acetate or acetone to dissolve them, and the use of alkaline cuticle removers are important. The moderate use of enamels may, however, be protective, but they should not be frequently removed. The effect of detergents and degreasers can in part be warded off by protective barriers.

Soaking in warm water and the inunction of olive oil are recommended as local treatment, together with attention to the general health.

Pyocyanea Infections

Q.—What antibiotics are effective against *Pseudomonas pyocyanea*?

A.—*Ps. pyocyanea* is totally insensitive to penicillin. It is usually resistant enough to the newer antibiotics to preclude successful treatment with them, although terramycin tends to be rather more active against it than either aureomycin or chloramphenicol. Sensitivity to streptomycin varies, some strains being highly resistant and others quite sensitive. The only antibiotic to which this organism is regularly and highly sensitive is polymyxin.

Either streptomycin or polymyxin may be used (the former assuming that the strain has been shown to be sensitive) for both the common forms of treatment called for in connexion with *Ps. pyocyanea* infections—namely, intramuscular injection for urinary infections, and local application for superficial sepsis, as in burns. The main advantage of streptomycin at present is that it is more easily obtainable, of polymyxin that it is more effective, particularly for the second purpose named. Both drugs can cause toxic effects, streptomycin on the eighth nerve and polymyxin on the kidney, but neither need be given for a urinary infection in such doses or for such a length of time that such complications need be feared. The local application of polymyxin is harmless from this point of view, as is its intrathecal injection for the treatment of meningitis.

Road Accidents

Q.—What is the best immediate treatment for a shocked patient after a road accident? Are heat and morphine still regarded as good treatment?

A.—In itself, shock is a meaningless term. Shock after a road accident should be treated according to its cause. The ill effects of road accidents may be due to fright (most commonly), to blood loss, internal injury, fracture, or fat embolism. External application of heat is impor-

tant only for the patient's comfort, or if the patient has been left out for a long time in cold weather without protection. He should be given warm fluids, such as tea. Morphine is generally most useful, particularly if there is pain: a note should always be left on the patient saying what dose has been given, since serious overdosage sometimes occurs. In the absence of serious complications, the state of stress, mental and physical, should be dealt with by making the patient comfortable and by assuring him that there is no serious complication. If it is not possible to give this assurance he should be sent to hospital and told that a more adequate examination will be made there. Should any more severe complication be present, this should be treated according to accepted first-aid principles and the patient transferred to hospital.

Enteric-coated Ferrous Sulphate

Q.—Are enteric-coated ferrous sulphate tablets absorbed by the intestine? Coating has been recommended to limit symptoms of intolerance in pregnant women, but I understand that iron is absorbed only from the pyloric end of the stomach and the first half of the duodenum.

A.—Iron is absorbed from the stomach and from the small intestine, chiefly the upper part, but there is evidence that absorption can occur from lower parts of the intestine. The usual enteric coating should ensure the liberation of the tablet's contents in the alkaline part of the duodenum, although certain proprietary forms of coating may liberate the contents after contact with fluid which is not alkaline. It may be expected, therefore, that ferrous sulphate can be absorbed from enteric-coated tablets, but positive proof of this should be easy to obtain by serial estimation of the blood haemoglobin. If a pregnant woman is intolerant of ferrous sulphate it might be worth using one of the other preparations, such as iron and ammonium citrate mixture or a colloidal iron preparation such as Liq. Ferri Dialysati B.P.C.

Toxaemia of Pregnancy

Q.—What is the present view of the aetiology and pathology of the toxaeimias of pregnancy?

A.—This question is beyond the range of a concise reply because the aetiology and pathology of toxaeimias of pregnancy remain to a large extent obscure. The present-day tendency, however, is to regard the basis of toxaeimia of pregnancy as uterine and placental ischaemia, with possibly associated imbalance of the endocrine functions of the placenta, adrenal, and pituitary.

Books of "Any Questions?"

Q.—Are copies of both the first and second books of "Any Questions?" still available?

A.—No. The first book has sold out after a total printing of 10,000 copies, but copies of the second book, published in December, 1952, are still available. Copies of the second book may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, for 7s. 6d. (postage 6d.). Please order now so as to ensure getting a copy.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Airlology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: Britmedads, Westcent, London.

ELECTROPHORESIS OF HUMAN GASTRIC JUICE IN RELATION TO CASTLE'S INTRINSIC FACTOR

BY

A. L. LATNER, M.D., M.Sc., D.I.C., A.R.C.S.

AND

C. C. UNGLEY, M.D., F.R.C.P.

With the collaboration of E. V. COX, B.Sc., M.B., B.S., E. McEVOY-BOWE, M.Sc., and LAUREEN RAINE, Ph.D., B.Sc.

From the Departments of Pathology and Medicine, King's College, University of Durham, and the Royal Victoria Infirmary, Newcastle-upon-Tyne

In the period 1929–37 Castle and his colleagues showed that normal gastric juice (intrinsic factor) administered orally to patients with pernicious anaemia would potentiate the haemopoietic effect of beef muscle (extrinsic factor). Later they showed that the extrinsic factor in beef muscle was vitamin B₁₂ or a related compound (Gardner *et al.*, 1949), and that vitamin B₁₂ itself behaved like extrinsic factor when small doses were administered orally (Berk *et al.*, 1948). Meanwhile there were many unsuccessful attempts to isolate Castle's intrinsic factor, which is heat-labile and readily inactivated by chemical procedures (see Ungley, 1951–2; Welch and Heinle, 1951; Welch and Nichol, 1952).

The methods employed in the present study were mainly physico-chemical: ultrafiltration and freeze-drying followed by preparative electrophoresis on filter paper. The techniques used were devised by one of us (A.L.L.). The method of electrophoresis has already been demonstrated (Latner *et al.*, 1952).

METHODS

These are the methods finally adopted. Their development from earlier ones is described below.

Acid gastric juice was collected from students and patients after stimulation with histamine or aminoethyl pyrazole dihydrochloride. The juice was neutralized and stored at approximately –20° C. Ultrafiltration was carried out at 0–5° C. Then the ultrafiltrate residuum was freeze-dried and reconstituted with buffer so that the gastric juice had been concentrated 150–200 times.

The filter paper used for electrophoresis was Whatman No. 31 extra thick. Each of the six strips was subdivided into 25 segments 1 cm. wide. The ultrafiltrate residuum from 500 to 800 ml. of gastric juice was applied with a paintbrush to these six strips so that each contained an approximately equal amount. After electrophoresis, separation of liquid from the segments by centrifuging gave 25 fractions labelled from 1 to 25, starting at the cathode end. A barbitone buffer at pH 8.6, used initially, was later replaced by a buffer at pH 6.35.

To test their vitamin B₁₂-binding power as a basis for grouping fractions for clinical trial, samples of 0.1 ml. from each fraction were added to 1 ml. of a solution containing 200 µg. vitamin B₁₂. Any vitamin left unbound was then estimated by plate assay using *Bact. coli* (Bessell, Harrison, and Lees, 1950). Fig. 3 shows vitamin B₁₂-binding peaks demonstrated in this way. (Figs. 1 and 2 relate to some preliminary observations in which vitamin B₁₂ was added before electrophoresis.) Later, a method used for staining protein was found equally effective for the grouping of fractions (see Experiment E).

Clinical Trials

Tests were conducted in 15 cases of pernicious anaemia. Methods are described elsewhere (Ungley and Campbell, 1949; Ungley, 1950), but certain points need re-emphasis. The diet was restricted to reduce the intake of extraneous haemopoietic factors, particularly vitamin B₁₂. Food was withheld for at least six hours before and after the administration of test material. Test material was given orally as a single dose with 50 µg. vitamin B₁₂. The administration of vitamin B₁₂ with a possible source of intrinsic factor was preceded by a test in which an equal dose of vitamin B₁₂ was admin-

FIG. 1.—Tests on fractions obtained by electrophoresis (in barbitone buffer) of gastric juice concentrated 20 times: the curve shows two B₁₂-binding peaks. Shown below is a strip of paper stained for protein. The thick line on the abscissa represents the point of application of the material.

FIG. 2.—Results of simultaneous electrophoresis (in barbitone buffer) of gastric juice and extracts of pylorus and fundus mucosa of pig's stomach. Two vitamin B₁₂-binding peaks are shown in each case.

FIG. 3.—Results of electrophoresis (in buffer at pH 6.35) of gastric juice used in Experiment A. Vitamin B₁₂ was added after electrophoresis, and the vitamin B₁₂ bound by each fraction was determined. The thick line on the abscissa indicates the point of application of material.

istered alone or with an inactive fraction. A second test was not begun until any haemopoietic response initiated in the previous period had ceased: reticulocyte counts were <2%, serial estimations of red blood cells (R.B.C.), haemoglobin (Hb), and packed cell volume (P.C.V.) were level or falling, and the marrow was megaloblastic. A further point—namely, the use of one rather than several subjects for the comparison of fractions derived from one electrophoresis—is mentioned later.

Haematological Methods

Reticulocytes were counted daily by a wet method. Multiple determinations (usually two to five) of R.B.C., Hb, and P.C.V. were made every three to five days. Only mean values determined at five-day intervals are recorded here. Reticulocyte responses were observed, but were used only as an indication of the presence or

absence of activity. For the quantitative evaluation of haemopoietic responses the rate of increase of R.B.C. and P.C.V. in 15 days was expressed in terms of the number of micrograms of injected vitamin B₁₂ which would be expected to produce a similar response (Ungley and Campbell, 1949, and unpublished).

PRELIMINARY OBSERVATIONS

In an early study gastric juice was concentrated 20 times by ultrafiltration and vitamin B₁₂ was added to the concentrate. Fig. 1 indicates the amounts of bound vitamin B₁₂ in each of the 25 fractions obtained by subsequent electrophoresis.

Two peaks of vitamin B₁₂-binding can be seen—one on the cathode side near the starting-point and one on the anode side. For comparison, a strip of filter paper from the same electrophoresis was fixed and stained for protein. Protein could be demonstrated in the region of the cathode vitamin B₁₂-binding peak, but not in the region of the anode peak. This did not necessarily mean that the vitamin B₁₂-binding compound on the anode side was not a protein, for protein may have been present in amounts too small to be demonstrated. If this were the case, the vitamin B₁₂-combining power of the compound per mg. would be very high—a possibility which we thought might indicate the presence of intrinsic factor.

This possibility was strengthened by the result of experiments in which extracts of pig's gastric mucosa (Ungley and Moffett, 1936) were subjected to ultrafiltration and electrophoresis. For when the source was fundus mucosa, which is clinically inactive, the anode peak was smaller—both relatively in comparison with the corresponding cathode peak, and absolutely, in terms of vitamin B₁₂ bound per mg. of protein in the extract—than when the source was pylorus mucosa, which in the pig is a rich source of intrinsic factor (see Fig. 2).

The findings could also be expressed in terms of the amounts of material needed to ensure that 50 µg. vitamin B₁₂ would be bound in the anode peak—namely, 500 ml. gastric juice, extract from 400 g. pylorus mucosa, and extract from 800 g. fundus mucosa. It was of interest to compare these amounts with doses used clinically—for example, a single dose of 500 ml. of gastric juice to potentiate 50 µg. vitamin B₁₂ (Ungley, 1950) and daily doses of extract from 40 g. pylorus mucosa given with yeast extract

as extrinsic factor (Ungley and Moffett, 1936). The weaker binding activity of fundus mucosa was matched by its clinical inactivity in the dosage used.

These findings encouraged us to undertake electrophoresis on a larger scale, so that the fractions could be tested clinically. Some of this work was reported at the International Congress of Biochemistry in Paris in July, 1952,* when it was stated that material with intrinsic-factor activity had been separated from other vitamin B₁₂-binding substances in gastric juice. For at this time the selection of fractions was based on the distribution of peaks of vitamin B₁₂-binding activity. Subsequently, a method used for staining and scanning protein on filter paper after electrophoresis (Latner, 1952a, 1952b) was found to be equally effective.

In these earlier experiments vitamin B₁₂ was added before electrophoresis, and barbitone buffer at pH 8.6 was used. Fractions from the cathode and anode vitamin B₁₂-binding peaks, tested in Cases 1 and 2, gave unsatisfactory results, which will not be described. About this time one of us (A. L. L.), in the course of collaborative work with Professor A. A. Harper in which paper electrophoresis was used, found that barbitone buffer at pH 8.6 could destroy the physiological activity of secretin. As it was thought that barbitone buffer might destroy intrinsic factor also, the following experiments were conducted with another buffer, the pH of which was 6.35.

MAIN OBSERVATIONS

Experiment A

The ultrafiltrate residuum from one litre of gastric juice was applied to paper strips and separated into 25 fractions by electrophoresis. The vitamin B₁₂-binding power of these fractions is shown in Fig. 3. Two or possibly three peaks were visible on the cathode side and four on the anode side of the line of application of the concentrate. As a first step towards determining where the intrinsic-factor activity lay, the 25 liquid fractions were separated into two groups. The group from the anode side was tested in Case 3, the cathode group in Case 4.

Case 3 (a Female Aged 62). Anode

In a preliminary period 50 µg. vitamin B₁₂ administered orally alone produced merely a slight reticulocytosis of 4.2% without a rise in R.B.C. or P.C.V. When the same dose of vitamin B₁₂ was given with the liquid fractions from the anode side, reticulocytes rose on the third day and reached a peak of 17.6% on the sixth day (Fig. 4). Clinical improvement was evident and R.B.C., Hb, and P.C.V. increased as follows:

Days:	0	5	10	15
R.B.C. (10 ⁶ per c.mm.)	2.00	2.24	2.44	2.68
Hb (g. per 100 ml.)	9.3	10.1	10.5	10.5
P.C.V. %	21.5	24.0	27.0	29.0

Values continued to rise up to 81 days.

The increase of R.B.C. and P.C.V. in 15 days was slightly less than that which would be expected from an injection of 5 µg. (Ungley and Campbell, 1949, and unpublished). This result falls within the lower range of responses obtained with 50 µg. vitamin B₁₂ and 500 ml. of gastric juice (Ungley, 1950).

Case 4 (a Female Aged 63). Cathode

The liquid fractions from the cathode side were administered orally together with 50 µg. vitamin B₁₂. There was no haemopoietic response. Subsequently a good response

*Unfortunately, an account does not appear in the abstract, which was submitted long before the meeting.

to the injected vitamin was obtained, but unfortunately the response to a potent oral preparation was never observed, so that the patient may have been resistant to oral therapy. Results reported later indicate that liquid from the cathode side usually does in fact possess some intrinsic factor activity. At this stage, however, we knew only that liquid from the anode side possessed such activity, whereas liquid from the cathode side might or might not be active. For this reason in the next three experiments, B, C, and D, only material from the anode half of the papers was tested clinically. In each instance material derived from 800 ml. of gastric juice was applied to six strips of paper.

FIG. 4.—Clinical response to anode fractions in Case 3 (Experiment A).

Experiment B

Segments 1 cm. wide were drawn on the anode side of the line of application of material and numbered from 1 to 15. Liquid from segments 2, 3, and 4, which represented the B₁₂-binding peak on the anode side nearest to the starting position (see Fig. 5), was tested in Case 5.

FIG. 5.—Vitamin B₁₂-binding in fractions obtained by electrophoresis of gastric juice used in Experiment B, in which only the anode side was tested.

Liquid fractions from the rest of the anode side were tested in Case 6. In this and subsequent experiments the anode and cathode peaks nearest to the line of application of concentrated gastric juice are referred to as the "first anode peak" and "first cathode peak" respectively.

Case 5 (a Female Aged 72). First Anode Peak

There was no reticulocyte response to 50 µg. vitamin B₁₂ administered orally alone and the absolute values fell.

When the same dose of vitamin B₁₂ was given with the liquid from segments 2, 3, and 4, reticulocytes rose to a maximum of 10.3% on the sixth day. The R.B.C., Hb, and P.C.V. changed little:

Days:	0	5	10	15
R.B.C.	1.48	1.54	1.64	1.48
Hb	6.2	6.2	7.3	6.5
P.C.V.	15.0	16.5	19.0	17.5

There was subsequently a considerably greater response to a single oral dose of 3,000 µg. vitamin B₁₂.

Case 6 (a Male Aged 64). Rest of Anode Material

There was no response to 50 µg. vitamin B₁₂ administered orally alone. An equal dose of the vitamin was then given together with the liquid from segment 1 and segments 5 to 15. Reticulocytes rose only to 2.8%, but there was some increase in absolute blood values.

Days:	0	5	10	15
R.B.C.	2.20	2.42	3.12	2.92
Hb	10.4	11.3	13.1	11.4
P.C.V.	31.0	35.0	37.0	35.0

Unfortunately, liquid from segment 1, which was erroneously included, might have had sufficient intrinsic factor activity to account for these changes. Desiccated stomach, 40 g. daily, subsequently produced a satisfactory increase in absolute values without a reticulocytosis.

Our conclusion from Experiment B was that the material corresponding to the first B₁₂-binding peak on the anode side had some intrinsic factor activity. The rest of the material from the anode side (which may have included part of the first peak) perhaps also had some intrinsic factor activity.

Experiment C

Fractions from this electrophoresis caused no response in Cases 7 and 8. Either the patients were resistant to oral therapy or any intrinsic factor present had been inactivated.

Experiment D

In this experiment a 1-cm. segment on the cathode side was included, together with the first four on the anode side, and tested in Case 9. Liquid from the rest of the anode side was tested in Case 10.

Case 9 (a Male Aged 38). First Anode Peak

There was no reticulocyte response to 50 µg. vitamin B₁₂ administered orally alone, and absolute values fell slightly. When this amount of vitamin was given with the first anode peak (and one segment from the cathode side) reticulocytes rose to 8.6% on the fifth day. Absolute blood values (R.B.C., 1,200,000; Hb, 5 g.; P.C.V., 13.0%) showed little change. There was subsequently an excellent response to injected vitamin B₁₂.

Case 10 (a Female Aged 59). Rest of Anode Material

There was no response to 50 µg. vitamin B₁₂ given orally alone. When 50 µg. was given with liquid from the rest of the anode side the response was negligible. There was no reticulocytosis, and the increase in absolute values was insignificant. The patient responded to desiccated stomach and later to injections of vitamin B₁₂.

FIG. 6.—Intensity of protein staining in 25 fractions obtained by electrophoresis of aliquots of a large pool of gastric juice, and tested in Cases 13, 14, and 15 (Experiments F, G, and H).

Our conclusion from Experiment D is that any intrinsic-factor activity in the liquid from the anode side was mainly concentrated in the first anode peak, which in this case included one segment from the cathode side. There was little or no intrinsic-factor activity in the remainder of the anode side.

Experiment E

Neither of the patients (Cases 11 and 12) responded to the fractions administered. The same remarks apply as in Experiment C.

We now reached the conclusion that testing the various fractions from one electrophoresis in different patients was not completely satisfactory since individuals differ in their responses, especially to oral therapy. It was decided to test the fractions successively in the same patient, who then acted as his or her own control. We also reverted to our original procedure of testing fractions from both the anode and the cathode side of the starting position.

The three final experiments were carried out with a single pool of concentrated gastric juice. The aliquots taken for each electrophoresis corresponded to an original volume of 800 ml. The fractions after electrophoresis were tested not only for vitamin B₁₂-binding power but also for protein content. For the latter purpose 0.02-ml. portions of each fraction were placed in line on a strip of filter paper. The spots were fixed in the oven and stained by a technique already described (Latner, 1952a). The stain used, naphthalene black, is not necessarily specific for protein. The density of each stained spot was determined with a modified Spekker absorptiometer (Latner, 1952b), and plotted graphically as shown in Fig. 6. The peaks so obtained agreed fairly closely with the peaks of vitamin B₁₂-binding obtained microbiologically. Since the staining method was less arduous and gave smooth, easily reproducible curves, it was used henceforth as the guide for grouping fractions for clinical trial.

Experiment F

Several peaks were demonstrated by the staining method (Fig. 6, Case 13). The material was subdivided into three groups of fractions corresponding to the first anode peak, the first cathode peak, and the rest of the material. These were tested in successive periods in Case 13. Disappointingly, there was no response to any of them. A review of the technique suggested that there may have been undue warming during manipulation. In subsequent experiments, therefore, special care was taken to keep the material cool at all stages and in particular during centrifuging.

Experiment G

The peaks demonstrated by staining are shown in Fig. 6, Case 14. This material was also subdivided into three groups of fractions and tested in successive periods in Case 14 (see Fig. 7).

Case 14 (a Male Aged 60)

In the first period 50 µg. vitamin B₁₂ was given with liquid from segments 1 to 6 and 18 to 25. There was no response. In the second period the same amount of the vitamin was given with liquid from segments 7 to 10 (the first cathode peak). Reticulocytes rose to 15% on the fifth day and absolute blood values increased.

Days:	0	5	10	15
R.B.C.	1.52	1.60	2.12	2.02
Hb	5.9	6.4	7.7	7.7
P.C.V.	15.0	18.2	24.6	24.2

In the third period, when liquid from segments 11 to 17 (first anode peak) was given with 50 µg. vitamin B₁₂, there was a further reticulocytosis of 8.6% on the seventh day. Because of the higher initial R.B.C. level, this reticulocytosis is as significant as the peak of 15% in the preceding period. For similar reasons the increases in absolute blood values were also more significant.

Days:	0	5	10	15
R.B.C.	1.94	2.00	2.92	2.96
Hb	7.4	7.8	10.1	10.4
P.C.V.	23.5	25.5	34.0	32.5

FIG. 7.—Clinical trial in Case 14; responses to first cathode peak (segments 7-10) and first anode peak (segments 11-17), but no response to rest of material (segments 1-6 and 18-25).

The increases of P.C.V. and R.B.C. in the second period were much less than would be expected from an injection of 5 µg. vitamin B₁₂. In the third period the increases were equivalent to those which would be expected from an injection of 5-10 µg.

Our conclusion from Experiment G is that the material corresponding to the first anode peak had a substantial amount of intrinsic-factor activity. It was particularly rich in terms of activity per mg. of stained material. Some intrinsic-factor activity stayed with the first cathode peak, but the activity of this region per mg. was much less than that of the first anode peak.

Experiment H

This experiment was similar to the previous one. The peaks demonstrated by staining are shown in Fig. 6, Case 15. The various fractions were tested in Case 15.

Case 15 (a Female Aged 56)

In the first period 50 µg. vitamin B₁₂ was given with liquid from the outer segments of cathode and anode sides (segments 1-6, 18-25). Reticulocytes rose only to 4.4% on the sixth day, and absolute blood values remained unchanged.

In the next period 50 µg. vitamin B₁₂ was given with the liquid corresponding to the first cathode peak (segments 7-10). Again reticulocytes rose to only 4.2% on the sixth day, although this time there was a very slight increase in absolute values.

Days:	0	5	10	15
R.B.C.	1.76	1.68	2.16	2.16
Hb	7.8	7.8	8.7	8.4
P.C.V.	22.0	22.0	26.0	26.0

In the third period 50 µg. B₁₂ was given with the material corresponding to the first anode peak (segments 11-17). Reticulocytes rose to 7.2% on the sixth day, and the increase in absolute values was more significant.

Days:	0	5	10	15
R.B.C.	2.40	2.81	3.08	2.88
Hb	9.6	10.8	11.1	10.8
P.C.V.	25.7	31.0	31.0	29.0

The same conclusions were drawn from this experiment as from Experiment G. The liquid corresponding to the first anode peak was the richest in intrinsic factor, especially in terms of activity per mg. of stained material. Some activity stayed with the liquid corresponding to the first cathode peak.

Discussion

It has thus proved possible to fractionate intrinsic-factor activity in human gastric juice by preparative paper electrophoresis. Vitamin B₁₂-binding and later a method of protein staining were used as aids to the grouping of fractions for clinical trial.

When highly concentrated gastric juice was used, a "protein" peak could be detected in association with every vitamin B₁₂-binding peak. This suggests that our inability to demonstrate such a peak corresponding to the anode vitamin B₁₂-binding peak in an earlier experiment (see preliminary observations) was probably due to insufficient concentration of the gastric juice. It will be remembered that in this experiment the juice was concentrated only 20 times.

In experiment A, intrinsic-factor activity was clearly demonstrated in the anode fractions. But the absence of response to the cathode fractions did not necessarily mean absence of intrinsic-factor activity, for the recipient (Case 4) may have belonged to a group of patients who respond poorly to orally administered material. Of 10 patients with pernicious anaemia to whom 50-80 µg. vitamin B₁₂ was administered with 500 ml. gastric juice, no fewer than three had very trivial responses, and one failed to respond (Ungley, 1950, and unpublished).

It is interesting to note that in the last two experiments, G and H, when larger quantities of gastric juice were used, tests showed the presence of some intrinsic factor in material corresponding to the first cathode peak as well as to the first anode peak. The reaction to the anode peak material seems to be the more significant, for its activity is as great as or greater than that of the cathode peak material although the former contains much less protein.

In view of our finding that intrinsic-factor activity is associated with material corresponding to two peaks, it is interesting to speculate that the substance may exist in gastric juice both in a free and in a combined state. The former might be represented by the first anode peak and the latter by the first cathode peak. We already have evidence that the material of the first anode peak contains either a mucoprotein or a mucopolysaccharide, and that heparin, a related substance, has significant vitamin B₁₂-binding power. These facts will be reported in greater

detail elsewhere. We have also shown that the material of the first cathode peak, although it contains much more mucoprotein, has less intrinsic-factor activity. This may well represent the fraction isolated by Glass *et al.* (1952). It is possible, however, that the activity of the cathode peak material may have been due not to a chemical combination but to overlap of the peaks or to some physico-chemical phenomenon associated with the electrophoresis on filter paper of concentrated and highly viscous solutions.

In Experiments G and H the weight of organic material from the first anode peak was of the order of 40 mg. It would be misleading to compare this quantity with the daily dose of 0.6 mg. with which Welch and Heinle (1951) produced a response in one case. Our method has been to give a single dose orally and to evaluate the result on the rate of increase of R.B.C. and P.C.V. in 15 days (Ungley, 1950). Reticulocyte responses may provide evidence of the presence or absence of activity, but they are not a satisfactory basis for quantitative assessment (Ungley and Campbell, 1949). As determined by reticulocyte response, even 10 ml. of gastric juice daily was enough detectably to potentiate an oral dose of 5 µg. vitamin B₁₂ (Schilling *et al.*, 1950; and Castle, 1951, personal communication). Until details of their case are published it cannot be assumed that the 0.6 mg. of material used by Welch and Heinle (1951) had any greater activity than 10 ml. of gastric juice.

In Experiments G and H our material produced not only a reticulocytosis but a significant increase of R.B.C. and P.C.V. within the range of responses we have obtained with a single dose of 500 ml. gastric juice and 50 µg. vitamin B₁₂ (Ungley, 1950, and unpublished). The magnitude of these responses makes it reasonably certain that appreciably smaller doses, perhaps differing little from those used by Welch and Heinle in the single case referred to above, might have sufficed to produce a reticulocytosis alone.

But, whatever the basis of haematological assessment, allowance must be made for the wide scatter in the responses of different patients to equal dosage. This scatter is wide even when vitamin B₁₂ is administered parenterally, especially if the dose is less than 10 µg. (Ungley and Campbell, 1949, and unpublished). The scatter is even wider when the vitamin is administered orally, for increases of R.B.C. and P.C.V. tend to be small and individual differences in absorption are great. When different observers are concerned there are certain also to be differences in strictness of control, limitation of diet, and so on. Because of all these variables, attempts to compare the activity of our material with that of others might involve errors of several hundreds per cent.

Even an approximate comparison would call for many more clinical trials—preferably trials in each of which the two materials would be tested serially in one patient, as in our Experiments G and H. Alternatively, activities could be compared by the technique of Welch, Scharf, Heinle, and Meacham (unpublished data cited by Welch and Nichol, 1952). These authors measured the radioactivity of the stools of patients with pernicious anaemia in remission after administration of radioactive vitamin B₁₂, at first alone and then together with a source of intrinsic factor.

Welch and Nichol (1952) remark that a daily dose of 3 mg. of a crude concentrate of hog's stomach will promote the absorption of 0.5 µg. radioactive vitamin B₁₂. It is possible, however, that 10 times this daily dose of their intrinsic factor concentrate might be needed to potentiate 5 µg. vitamin B₁₂ administered orally to patients with pernicious anaemia in relapse.

Summary

Concentrated human gastric juice was subjected to preparative electrophoresis on filter paper. Several peaks were demonstrated by a protein-staining method. All had vitamin B₁₂-binding activity. Material from two of them—one on the cathode side and one on the anode side of the starting-point—was shown clinically to possess intrinsic-factor activity. Material correspond-

ing to the anode peak, which appeared to be the more active of the two, has been shown to contain either a mucoprotein or a mucopolysaccharide.

This work was assisted by grants from the Medical Research Council and the Lady Tata Memorial Trust. One of us (E. V. C.) was working under the tenure of a Luccock Fellowship from the Medical School, King's College, University of Durham.

We are particularly grateful to Professor J. B. Duguid and Professor F. J. Natrass for their encouragement and advice. We wish to thank students and patients who gave their gastric juice, and colleagues in this and other hospitals who provided facilities for its collection. We are also grateful to the nursing and non-medical staff of the hospital and medical school, and to many general practitioners for their co-operation. The aminoethyl pyrazole dihydrochloride was kindly supplied by Eli Lilly and Company.

THE DEFINITION AND ASSESSMENT OF
RESPIRATORY FUNCTION*

BY

K. W. DONALD, D.S.C., M.D., F.R.C.P.

Reader in Medicine in the University of Birmingham

PART II

FACTORS AFFECTING THE TRANSFER OF
OXYGEN IN THE LUNGS

It has already been emphasized that the main function of the lungs is the transfer of adequate quantities of oxygen to the blood to maintain a normal oxygen tension and content in the blood flowing to the body, no matter what the degree of activity or how great the oxygen utilization of the tissues. The removal of excess carbon dioxide from the blood rarely presents any difficulty in disease, except in a few special circumstances. I will therefore confine my main discussion to the problem of oxygen transfer.

Distribution of Blood and Gas to the Alveoli

The alveolus is the unit of lung anatomy and lung function. All aspects of structure and function are subservient to the proper supply of each alveolus with blood and gas in correct quantities so that an adequate oxygen tension gradient and gas transfer between them is maintained. In a theoretically perfect lung the inspired air that passes the anatomical dead space would be equally divided among all alveoli. In other words, if there were, for argument's sake, one million alveoli, then each would receive one-millionth of the effective inspired air that enters the alveoli. Similarly in such a lung each alveolus would receive one-millionth of the cardiac output. Such a state of affairs would repre-

*Adapted from the lectures given in the "Science and Medicine" series, Postgraduate Federation (London University), 1950-1. Part I was published in last week's issue, p. 415.

sent perfect blood and gas distribution and each of the million alveoli would have the same ratio of ventilation and perfusion as all the other alveoli and the total lung itself. The resultant gas and blood tensions in each alveolus would be similar to all other alveoli, and each will be a miniature lung in all respects.

It is easy to imagine various disturbances of blood and gas distribution that could occur. Certain alveoli could receive less than their "share" of ventilation and yet be perfused with their normal "quota" of mixed venous blood. The blood leaving such alveoli and joining the left heart outflow would be inadequately oxygenated.

Next there could be imperfect distribution of blood; this would result in alveoli which are adequately ventilated no longer receiving their quota of mixed venous blood from the right heart. Such blood-distribution defects would not cause any deficiency of blood oxygenation but would manifest themselves in the expired air, which would contain a larger-than-normal percentage of unchanged inspired air.

We shall see later how near normal and diseased lungs come to these entirely theoretical concepts of perfection and imperfection of blood and gas distribution.

Oxygen Transfer (Diffusion) in the Lungs

The diffusion characteristics of a membrane, in regard to a particular gas such as oxygen, can be described by the quantity of oxygen that passes across it in unit time when there is a unit pressure gradient of oxygen across the membrane. This quantity of gas, or the diffusion coefficient, will depend on a number of fairly obvious factors—surface area, thickness, and physical characteristics. If we wish to consider the diffusion characteristics and coefficient of the pulmonary membrane, we must remember that we are dealing with a very complicated structure. It will include all the tissues and fluids between alveolar gas and the haemoglobin molecule in the red blood cells in the pulmonary capillary. It is also possible that the effective area of this "membrane" may vary greatly in the normal lung during various degrees of activity. Marie Krogh (1915) attempted to measure the oxygen diffusion coefficient of the lungs in normal subjects by the use of carbon monoxide. This gas was used because it is taken up by haemoglobin with such avidity that its tension in the pulmonary capillary blood (amount in simple solution) was assumed to be zero at all times. The diffusion coefficient of oxygen was easily determined from these data, as the coefficient of each gas is a simple function of its solubility and molecular weight.

Since that time little definitive work has been done on this subject, but attempts have recently been made to measure the diffusion coefficient of oxygen more directly during normal respiration (Lilienthal *et al.*, 1946). This presents great difficulty even in the normal lung, where it can be reasonably assumed that the alveolar oxygen tension is fairly constant through all alveoli. If the alveolar oxygen tension is known, then the initial pressure gradient between this and the mixed venous blood entering the alveoli can be determined by cardiac catheterization. However, the determination of the final and mean gradient between the alveolus and capillary blood presents more difficulty. These difficulties are even greater in subjects with lung disease, in whom the alveolar oxygen tension may also vary greatly. The diffusion coefficient cannot be measured unless the mean alveolar capillary oxygen tension gradient is known.

Alveolar Gas Tensions. The Concept of Ideal Alveolar Gas Tensions

The determination of the actual gas tensions in the alveoli during normal respiration presents great difficulties. Without this information the analysis of blood and gas distribution and gas transfer would seem impossible. The Haldane (1915) technique of making a subject expire deeply and collecting the sample at the end of expiration has long been used for this purpose. There is no certainty that the gas obtained in this way is an accurate, statistically repre-

sentative sample of the gases actually present in the alveoli. Further, this method of sampling interrupts the normal rhythm of respiration and alters the very values it is attempting to determine. Various devices for aspirating a small quantity of gas from the end of each normal expiration over a period have been used; this avoids upsetting the natural respiration and gives far more repeatable results in normal subjects (Rahn *et al.*, 1946). However, the underventilated alveoli will not be adequately represented in such a sample. Recently new concepts and methods have partially solved these difficulties. Fenn *et al.* (1946) pointed out that, in the steady state, the difference of pressure of oxygen and carbon dioxide in the alveoli and the inspired air was a measure of the quantities of these gases being absorbed and excreted by the lungs. Now these quantities of gases are related, their ratio being the respiratory quotient, which is easily determined by the analysis of expired air collected over a period thus:

$$\text{Respiratory quotient} = \frac{\text{CO}_2 \text{ excreted}}{\text{O}_2 \text{ absorbed}} = \frac{\text{Pressure gradient of CO}_2 \text{ between alveoli and inspired air}}{\text{Pressure gradient of O}_2 \text{ between alveoli and inspired air}}$$

As the pressure of CO₂ in the inspired air is negligible the equation becomes:

$$\text{R.Q.} = \frac{\text{Alveolar pCO}_2}{\text{Insp. pO}_2 - \text{alv. pO}_2}$$

$$\text{or Alv. pO}_2 = \text{Insp. pO}_2 - \frac{\text{alv. pCO}_2}{\text{R.Q.}}$$

It will be obvious that to define the alveolar gas in a single equation, in which the body R.Q. describing total gas exchange is employed, is to assume that all alveoli are equally ventilated and perfused and have the same R.Q. and gas tensions. It would seem that this equation gives little advantage, as the alveolar pCO₂ is now needed to determine the alveolar pO₂.

Riley *et al.* (1946) pointed out that the arterial pCO₂ could be regarded as accurately representing the alveolar tension of carbon dioxide (pCO₂), as, owing to the extremely high rate of diffusion of carbon dioxide in fluids, there must be almost absolute equilibrium of this gas between alveolar gas and blood leaving the alveoli. Again, this would be valid only if the distribution of the blood and gas were perfect. Yet Riley and Courmand (1949, 1951) pointed out that even if there is considerable underventilation of normally perfused alveoli (poor gas distribution) the arterial pCO₂ will differ but little from that which would obtain in a perfect lung with perfect blood and gas distribution. The reason for this superficially surprising fact is that there is only 4-5 mm. difference in the pCO₂ of normally ventilated and of unchanged mixed venous blood, owing to the enormous capacity of the blood for this gas. Thus in most patients with diseased lungs the increase of the arterial pCO₂ above what would be found in the same patient with ideal lungs and perfect gas and blood distribution is rarely significant. This is a most important observation and the key to many advances. It means that the "alveolar oxygen tension" as calculated from the inspired oxygen tension and the arterial pCO₂ and body R.Q. is, even in abnormal subjects, very close to what the alveolar tension would be if the lungs were "ideal" and had perfect distribution of blood and gas and all alveoli had similar gas tensions. It is therefore an easily obtained arbitrary measure of perfection, and the deviation of gas and blood coming from the lungs from this theoretical figure gives much information concerning any departure from complete homogeneity of the ventilation-perfusion relationships of the alveoli.

Venous Admixture Effect

The effect of underventilation of alveoli on the arterial oxygen tension is considerable, as the difference in oxygen tension between mixed venous blood and adequately venti-

*Corrected for change in volume as in oxygen-consumption determination from analysis of expired air.

lated blood is of the order of 60 mm. Hg. Riley and Courmand (1949) therefore attempted to assess the underventilation of alveoli in the following manner. They studied a normal subject in the steady state and determined the inspired air oxygen tension, the body R.Q., and the arterial pCO₂. From these data they could calculate by the above equation the only alveolar oxygen tension that was possible if all alveoli were homogeneously ventilated and perfused. They then calculated what the percentage oxygen saturation of arterial blood would be if it had all passed through homogeneous "ideal" alveoli. For good reasons, which will be discussed later, they assumed that there was virtual equilibrium of oxygen tension between alveolus and blood in normal subjects when breathing air.

They then compared this arterial percentage oxygen saturation with that actually found in the subject. Any passage of blood through underventilated alveoli or systems unrelated to air spaces would cause the arterial saturation to be lower than the calculated ideal figure. They then expressed the drop of percentage oxygen saturation from the ideal as a certain percentage of unaltered mixed venous blood being added to ideally ventilated blood. This figure, stated as *percentage venous admixture*, is a measure of perfusion of poorly ventilated alveoli or of direct venous addition (bronchial veins, thebesian veins, etc.) to the blood in the left heart. It is in fact an integration of all degrees of imperfection of ventilation of blood passing through the lungs into ideal ventilation and complete lack of ventilation. In normal subjects studied the arterial oxygen tension is only a few millimetres below the "ideal" figure and the percentage venous admixture is usually well below 5%, over 95% of the cardiac output being perfectly oxygenated. This emphasizes how remarkably near to perfection the distribution of blood and gas is in the normal lung. It is not yet known whether the "venous admixture" is due to anatomical venous admixture, to a slight degree of alveolar underventilation, or to a combination of the two.

Dead-space Effect

Just as poor gas distribution, or alveolar underventilation, is studied by its effect on the arterial blood, so inefficient blood distribution, or alveolar underperfusion, can be assessed by the analysis of expired air. It is now well established that in a normal person two-thirds or more of the tidal air passes the conducting air passages in which significant gas exchange does not occur and enters the alveoli. As all the gas leaving the alveoli has been in virtual carbon dioxide equilibrium with the blood leaving the alveoli, then this gas will have a similar carbon dioxide tension to the arterial blood. In an ideal lung, which the normal closely approaches, all alveoli will be equally ventilated and perfused and thus the expired gas will have a carbon dioxide tension which is at least two-thirds of the arterial carbon dioxide tension, as two-thirds will be from the alveoli and not more than one-third returned unchanged from the anatomical dead space. The small amount of air leaving poorly ventilated alveoli will, for reasons already given, have a pCO₂ very close to the arterial pCO₂ and have little effect on the expired pCO₂. However, if there is poor distribution of blood to alveoli and a number are well ventilated but not perfused with venous blood, then the gas leaving these alveoli will be unchanged inspired air. Similarly, if the blood perfusing ventilated alveoli is reduced then less oxygen will be extracted and less carbon dioxide will be added to the alveolar gas. This will result in the gas leaving the alveolus being nearer in composition to inspired air than that from normally ventilated and perfused alveoli.

Now, many studies in various lung diseases have shown no significant increase of the anatomical dead space. Thus if the pCO₂ of the expired air is less than two-thirds of the arterial pCO₂ then this is regarded as good evidence of the ventilation of unperfused and poorly perfused alveoli. The overventilation of normally perfused alveoli will also add to this so-called "dead-space effect." This is an extension of Bohr's concept of the physiological dead space, which

again integrates the various degrees of imperfection of distribution into absolute lack of alveolar perfusion and ideal ventilation and perfusion. The dead-space effect can be stated as a percentage of tidal air or of total ventilation. It is estimated as follows:

$$\text{Dead-space effect (as \% tidal air or total ventilation)} = \frac{\text{Arterial pCO}_2 - \text{Expired pCO}_2}{\text{Arterial pCO}_2} \times 100$$

Diffusion Gradients in the Alveolus

It will be remembered that so far in this discussion it has been assumed that when a normal subject breathes air the transfer of oxygen across the pulmonary membrane is so efficient that there is no appreciable oxygen tension gradient between the alveolar gas and the blood leaving the alveolus, and that the diffusion factor did not contribute in the normal subject to the slight depression of arterial oxygen tension below the theoretical ideal. Let us return to the question of whether it is reasonable to assume that this depression of the arterial oxygen tension is due only to so-called "venous admixture" or distribution disturbance.

Lilienthal *et al.* (1946) studied the alveolo-arterial oxygen tension gradient in normal subjects breathing low percentages of oxygen. Under these conditions the effect of alveolar under-ventilation becomes insignificant and the whole of the alveolo-arterial oxygen tension gradient can be safely assumed to be due to the final alveolo-capillary gradient in the alveoli (final diffusion gradient). This allowed the mean oxygen tension gradient between the alveolus and capillary to be calculated, and from this the diffusion gradient (O₂ uptake per minute mean diffusion gradient). By applying this diffusion coefficient to the data obtained while the subjects were breathing air, they showed that under these conditions the mixed venous blood reaches that under these conditions with the alveolar gas when it oxygen tension equilibrium with the alveolar gas when it is about halfway through the alveolar capillary. They were thus able to state that the slight alveolo-arterial oxygen tension gradient in normal subjects when breathing air was due to slight distribution disturbances—that is, venous admixture.

The application of this "two-level" technique to abnormal patients presented many great difficulties. A smaller degree of anoxia was advisable, and it could not be assumed that distribution or diffusion gradients were negligible at any particular level of oxygen breathing. These difficulties were overcome (Riley *et al.*, 1951), and the resultant studies (Donald *et al.*, 1952) have allowed the disturbances of blood and gas distribution and of alveolo-capillary oxygen diffusion, and their role in arterial desaturation, to be more precisely assessed in various lung diseases. The most important findings can be briefly outlined.

Two main groups of patients were studied by this technique. Those in the first group were suffering from pulmonary disease in which the pathological processes involved the alveolar walls and in which interference with the diffusion of oxygen across the pulmonary membrane was suspected (Baldwin *et al.*, 1949a). The second group consisted of patients with pulmonary emphysema in whom impairment of the efficient distribution of blood and gas to the alveoli was thought to be the main disability.

Pulmonary "Infiltration," or "Pneumonitis"

These patients complain of severe shortness of breath on very slight exertion. All show radiological evidence of widespread pulmonary infiltration. Although the physiological findings are remarkably constant, there is a very wide range of diagnoses. These include beryllium granuloma, asbestosis, scleroderma, Boeck's sarcoid, reticuloses, "interstitial pneumonitis," and various unclassified granulomata. In those patients coming to necropsy the occurrence of pathological tissue in the alveolar walls can be demonstrated. All the patients studied had no spirometric evidence of ventilatory obstruction, and the residual volumes were equal to or less than the predicted normal range. The normal or nearly normal ventilatory capacity (M.B.C.)

in all cases was further evidence that emphysema was not present. At rest the arterial blood saturation was normal or only very slightly depressed, whereas on very mild exercise marked arterial blood desaturation associated with considerable dyspnoea occurred, despite the unimpaired ventilatory capacity.

In some of these patients, studied at rest, the gas and blood distribution in the lungs was normal, as shown by the normal dead space (33%) and the normal venous admixture effect (6%). Yet the mean oxygen diffusion gradient (mean alveolo-capillary oxygen tension gradient) was about twice that found in normal subjects (normal, 20 mm. Hg), the diffusion coefficient being abnormally low (normal, 15 ml./mm./minute). Thus the interference with the transfer of oxygen across the alveolar membrane, despite the relatively efficient distribution of blood and gas to the alveoli, which had been previously suspected in these cases, was now definitely demonstrated. This interference with the oxygen diffusion necessitated an increased oxygen tension gradient between alveolus and capillary to maintain the transfer of even the resting oxygen requirements.

Let us contrast these patients with normal subjects. It has been pointed out already that, under resting conditions, the blood in the normal alveolar capillary reaches almost complete oxygen equilibrium with the alveolar gas in just over half the capillary length. Further, when a normal subject exercises there is probably a considerable increase in the diffusing capacity of the lung due to this expansion of the alveolar capillaries or the opening up of new capillaries. Even if this mechanism is greatly limited the "reserve" distal half of the lung capillaries will allow a large increase in capillary blood velocity, even with the same or increased mixed venous blood desaturation, without any risk of incomplete oxygenation of the blood leaving the alveolus.

In this group of patients a measurable oxygen tension gradient between the alveolar gas and the blood leaving the alveolus could be demonstrated when air was breathed in the resting state. Thus the normal reserve of lung capillary was no longer available. It is probable that the ability to expand the pulmonary capillary bed and increase the diffusing capacity was also much impaired. More important is the fact that any increase in the velocity of blood through the lung capillary will inevitably increase the final alveolo-capillary oxygen tension gradient, and thus the blood leaving the lungs and entering the systemic circulation will be considerably desaturated. In more simple terms these patients show marked cyanosis and distress on exercise because they have no reserve diffusing capacity.

In the more severely affected patients not only was the diffusion of oxygen even more impaired but the dead-space and venous admixture effects were greatly increased. It was considered, in the absence of emphysema, that this was probably due to such severe involvement of the alveolar membrane in certain portions of lung that no significant gas exchange was possible, and that gas and blood were returned unchanged from such areas.

Pulmonary Emphysema

The patients investigated all had clinical and radiological evidence of emphysema. Lung-volume studies showed the usual increase of residual volume and decrease of maximum breathing capacity. A number of these patients showed moderate arterial blood desaturation at rest and considerable desaturation on exercise. Raised arterial blood carbon dioxide tensions were found in some cases.

It has been demonstrated in many ways that the distribution of inspired air throughout the lungs is exceedingly uneven and inefficient in this disease. The uniform distribution of blood is probably also impaired in emphysema owing to the damage to the finer branches of the pulmonary vascular tree; but there is so far only indirect evidence of this, such as histological and injection studies, and haemodynamic studies of the pulmonary circulation during rest and exercise.

In this investigation considerable increase of the dead-space effect (ventilation of underperfused and unperfused alveoli) and of venous admixture effect (perfusion of under-ventilated or unventilated alveoli) was demonstrated. In some patients the dead-space effect was well over 60% of the tidal air, the upper limit of normal dead space due to the conducting passages being about 33% of the tidal air. Similarly, venous admixture effects of nearly 50% of the cardiac output were found. Such findings indicated gross upset of the normal distribution of blood and gas to the alveoli and of the efficient correlation of alveolar ventilation and circulation. It must be remembered that, as it is impossible to describe the almost infinite variations of ventilation-perfusion relationships, the present method integrates all departures from homogeneity into ideal ventilation-perfusion relationship and into the return of unchanged gas and blood from the lungs.

It was also found that an increase of dead-space effect was not always associated with a similar increase of the venous admixture effect, and vice versa. This is an important finding, as it means that emphysema may interfere predominantly with alveolar ventilation in certain cases and with alveolar circulation in others. It may also explain the remarkable variation in disability and prognosis in this disease.

A somewhat unexpected finding in a number of these patients was a greatly increased oxygen diffusion gradient (mean alveolo-capillary oxygen tension gradient) and a decreased diffusion coefficient. Histological studies in emphysema do not suggest any structural interference with the diffusion of oxygen across the alveolar membrane. However, it must be remembered that lung which is ventilated but not perfused, or perfused but not ventilated, is as functionless as lung that receives neither blood nor air. Thus these distribution disturbances will render large amounts of lung quite functionless, and the effective blood-gas interface where blood and gas meet and there is an adequate gas gradient between them will become less and less as these disturbances increase.

In confirmation of this, the most pronounced impairment of diffusing capacity was found in those patients with the largest combined venous admixture and dead-space effects. Just as the area of the pulmonary membrane and the diffusing capacity will become less and less in patients whose lungs are being progressively destroyed by infection or cystic disease, so increasing disturbances of alveolar ventilation and perfusion will also reduce the amount of effective lung and diffusing capacity.

The findings further suggested that deficient arterial blood oxygenation at rest in emphysema is mainly due to alveolar underventilation, whereas marked arterial desaturation on exercise, as in the previous group described, was due to the limited diffusing capacity of the lung.

Practical Considerations

The methods required in such studies need a large trained team and generous facilities. These studies are necessary for furthering our knowledge of lung function but are quite impracticable as routine investigations. However, without such experiments the value and significance of the more simple tests which can be used in clinical medicine will remain obscure.

Arterial Blood Studies

In routine clinical work the commonest cause of severe cyanosis is severe congestive cardiac failure due to rheumatic heart disease. These patients have greatly reduced cardiac outputs, and their cyanosis is caused by the inevitable extraction by the body tissues of an unusually large percentage of oxygen from the reduced amount of circulating blood. Yet they have normal or nearly normal arterial blood oxygenation. Again, many patients with congenital heart disease and arterial blood desaturation have considerable polycythaemia, and their cyanosis is further increased because of this.

In most patients with lung disease the cardiac output is normal and marked polycythaemia is not present. In such patients it is most difficult to assess the degree of arterial blood oxygenation by visual inspection, and they may be dangerously anoxaemic with only what seems to be very slight cyanosis. Although the difference between "peripheral" and "central" cyanosis has been long appreciated, the difficulty of assessing the latter, particularly if acute, and its sinister import if marked, is not so clearly understood. In all cases of respiratory disease, whether acute or chronic (apart from pneumonia responding rapidly to treatment), the determination of the arterial blood oxygenation is as essential and obvious an investigation as the determination of the blood urea in kidney disease.

With practice arterial puncture is a smooth, easy, and painless procedure. The brachial artery is almost always used in respiratory studies, as most patients are conditioned to assault in this region and are not disturbed. It is not justifiable to risk damaging the femoral artery in middle-aged and elderly patients, as the circulation is always more precarious in the leg than in the arm. Further, the patient can be exercised without disturbing the needle. The best needle for this type of work is the Riley modification of the Courmand indwelling arterial needle, although, if only a single sample is needed, any medium-sized needle can be used, providing the bevel is kept short. The arterial blood is collected into a heparinized syringe and sealed after a drop of mercury has been added to facilitate mixing. It is quite incomprehensible why a number of workers continue to transfer these beautifully sealed blood samples to another vessel under oil. It is not only messy but an unnecessary additional manipulation. Further, the carbon dioxide diffuses through the oil at a high rate and is lost to the atmosphere. There is therefore a variable loss of this gas and change in the pH of the blood. Even more serious is the fact that when the sample is left to stand sedimentation of red cells occurs. Most vigorous stirring under oil will not give homogeneous red cell distribution, and thus samples taken for analysis may vary considerably and contain a greater concentration of red cells than in the original sample (Donald and Wade, 1952). A sealed syringe can be placed on a conical roller and the blood will remain well mixed until the analysis.

The most accurate method of determining the oxygen and carbon dioxide content of blood is the Van Slyke and Neil manometric technique (Peters and Van Slyke, 1932). The Haldane blood-gas analysis method is also satisfactory for determining the oxygen content if the Courtice and Douglas (1947) modifications are used. It takes less time than the Van Slyke method. However, the reliability of all methods is checked against Van Slyke determinations, and if several of these instruments are used, and all concerned are trained in its use, then the more reliable and accurate method can be employed without undue loss of time. An important point is that the oxygen capacity of arterial blood varies in different states and exercise will cause it to rise considerably. The use of a resting capacity in exercise studies may cause considerable errors.

If more precise and fundamental work is being done then it is necessary to measure the arterial blood-gas tensions. This procedure, although not yet suitable for routine clinical studies, is essential in the study of blood oxygenation in lung diseases. A glance at the oxyhaemoglobin dissociation curve will show why tension studies are so necessary for more precise work. It will be seen that, provided the blood pH does not alter, a fall in blood oxygen tension from 100 to 62 mm. Hg involves a drop of haemoglobin saturation of only 97 to 90%. Thus disturbances in alveolar ventilation or oxygen transfer have to be quite gross before pronounced arterial blood desaturation is obtained.

The bubble equilibration method of Riley, Proemmel, and Franke (1945), although not perfect and demanding great skill, is an essential weapon in modern respiratory research. Without it, as already emphasized, only the most severe disturbances in blood oxygenation can be demonstrated. It is unwise to attempt to develop this technique without first seeing it done by a worker who is trained in the method.

When arterial blood is being taken for gas-tension studies it is necessary to collect the expired air at the same time,

so that the expired-gas tension and respiratory quotient can be determined. This allows the ideal alveolar oxygen tension to be calculated and thus the gradient between this and the arterial oxygen tension. This is the most accurate and delicate method of expressing how far arterial blood oxygenation falls short of perfection.

Finally, let us consider the value of studying the oxygen and carbon dioxide content of arterial blood in various lung diseases.

Resting Studies

The arterial blood desaturation in emphysematous subjects at rest is never of the extreme order seen in many cases of congenital heart disease, unless there is extreme interference with alveolar ventilation due to acute bronchitis, severe asthma, or pneumonia. Figures below 85% saturation are unusual, but even this is roughly equivalent to 40% of the blood from the right heart passing through the lungs unchanged. This would again emphasize how relatively insensitive arterial blood saturation is as a measure of defective alveolar ventilation. It may also explain why marked polycythaemia is not often encountered in this disease. In fibrosis and pathological infiltrations of the lung there is rarely any significant arterial desaturation at rest.

Speaking in general terms, the arterial desaturation at rest is due to the venous admixture effect from under-ventilated alveoli and is not caused by any limitation of the diffusing capacity, which is adequate in the resting state even in patients with severe diffusion disturbances.

Patients may suffer severe anoxaemia after intrathoracic operations. This is due to acute and severe interference with alveolar ventilation caused by oedema, bronchial irritation and blockage, collapse, and effusions. Such patients are usually obviously cyanosed, and oxygen therapy is given until cyanosis is relieved. However, precise measurement of the arterial blood saturation in these patients can be of great help in the conduct of such cases. More studies of post-operative arterial oxygenation are needed to increase the knowledge of the hazards of various surgical procedures.

Again, arterial blood studies are most useful in the treatment of patients with chronic respiratory diseases who are suffering from acute pneumonic infections. The carbon dioxide content or tensions are particularly valuable in helping to assess the risk of carbon dioxide retention when oxygen therapy is given (Donald, 1949).

Finally, the only method of demonstrating deficient blood oxygenation at rest in early and moderate emphysema is that of measuring the alveolar-arterial oxygen tension gradient. This is greatly increased even in patients with what seems to be relatively normal arterial blood saturation (90-94%).

Exercise Studies

The fact that considerable alveolar underventilation or limitation of the oxygen diffusing capacity causes only very moderate depression of the arterial blood saturation at rest would appear to make this approach unfruitful if blood-tension studies are not available. However, it is fortunate that limited diffusing capacity can be demonstrated by increasing the oxygen demands of the body by brisk exercise. Any inability to increase oxygen transfer in the face of increased oxygen demands will cause dramatic arterial-blood desaturation. This inability to transfer increased quantities of oxygen to the blood is due to a decreased effective blood-gas interface or, more rarely, interference with oxygen diffusion into the alveolar capillary. Thus marked arterial desaturation on exercise may be due to faulty gas or blood distribution, rendering large amounts of lung relatively functionless (emphysema, bronchial obstruction), by disease destroying large amounts of lung tissue (extensive tuberculosis, cystic disease, etc.), or by pathological infiltration of the alveolar wall. The ability to maintain normal arterial oxygenation in the face of increased oxygen demands is therefore a remarkable test of overall respiratory effi-

ciency and actual amount of functioning lung. Arterial blood studies are carried out during various standard exercises (walking, step-test, treadmill), but this relatively simple method of assessing overall lung function is still in its infancy. As in this method study is made of the change or otherwise of arterial saturation, it is likely that oximetry may be of great help and render the test even more accessible to the practising physician.

Finally these various functions of the lungs can now be studied and to some extent assessed quantitatively. Nevertheless, although great progress has been made, mainly by academicians, the true value of these various concepts and methods of assessment of respiratory function will not be known until they are understood and used by practising chest surgeons and physicians, who can then reject, endorse, and advance in the light of real practical experience.

General Summary

The function of the lungs is defined. The importance of lung ventilation and circulation bringing blood and gas in close contact in all alveoli so that efficient gas exchange occurs is emphasized.

The various methods of assessing ventilatory function are discussed. The determination of the lung volumes and ventilatory capacity is described and the greater value of the more dynamic measurements emphasized. The relationship of the volumes ventilated to the ventilatory capacity present in the causation of ventilatory discomfort or dyspnoea is discussed.

The important features of the pulmonary circulation are detailed and the disturbances of this circulation in lung disease, and their effect upon the right ventricle, are described.

Finally, the problem of oxygen transfer and blood oxygenation is considered. It is emphasized that this depends upon the efficient distribution of gas and blood and the proper correlation of alveolar ventilation and circulation throughout the lungs. The diffusion of oxygen across the pulmonary membrane is considered. The theoretical concept of ideal distribution of blood and gas is elaborated and the application of this concept to the measuring of the efficiency of the lungs in this respect, both in health and in disease, is described. The diffusion gradients in the alveoli and the diffusing capacity of the lungs are also considered in both normal and abnormal subjects. The value and future of arterial blood studies in pulmonary disease is discussed.

THROMBO-ANGIITIS OBLITERANS

CLINICAL DIAGNOSIS AND CLASSIFICATION OF CASES

BY

R. L. RICHARDS, M.D., M.R.C.P.Ed.

(From the Gardiner Institute of Medicine, University of Glasgow)

"Thrombo-angiitis obliterans is a segmental, inflammatory obliterative disease of the arteries and veins which occurs almost exclusively in young men, involves the extremities, and rarely the viscera also, and produces ischaemia of tissues and frequently gangrene."—Allen, Barker, and Hines (1946).

In 1908 Buerger suggested the name thrombo-angiitis obliterans for a disease of the peripheral arteries which he had studied in eleven lower limbs amputated for "pre-senile spontaneous gangrene." He did not claim that he had described a new disease, but gave due credit to earlier writers, notably von Winiwarter (1879), who had described the condition under other names. Nevertheless it was largely due to Buerger's (1908, 1924) publications that the disease became a recognized clinical entity, and the name which he suggested, or its eponymous alternative "Buerger's disease," came to be generally used. Since 1908 the literature on thrombo-angiitis obliterans has become extensive; among the more important contributions are the American monograph by Brown and Allen (1928) and, in this country, the papers by Parkes Weber (1916), Telford and Stopford (1924, 1935), and Telford (1937).

As a result of the attention thus focused on the disease it has become customary to classify patients with symptoms of occlusive disease of the arteries of the limbs into two groups: (1) a group of young patients in whom the diagnosis is thrombo-angiitis obliterans, and (2) an older group in whom the arterial occlusion is thought to be secondary to atheroma (arteriosclerosis obliterans). Although the patient's age is regarded as an important factor in deciding his grouping, it is recognized that there are other fundamental differences between the two conditions (Table I). There is, however, no unanimity

TABLE I.—Differential Diagnosis of Thrombo-angiitis Obliterans and Arteriosclerosis Obliterans

Feature	Thrombo-angiitis Obliterans	Arteriosclerosis Obliterans
Age at onset of symptoms	Usually under 35 years; rare over 40 years	Usually over 50 years
Sex	Almost exclusively males	Preponderantly males, but not rare in females
Distribution	Upper limbs often involved	Upper limbs seldom involved
Venous involvement	Superficial phlebitis in about 40% of cases	Rare
Blood pressure	Normal	Frequently elevated
Association with diabetes	Rare	Frequent
Radiography	Vessels seldom calcified	Vessels often calcified
Biochemistry	No constant abnormality	Blood cholesterol and total fats often high
Pathology	Acute or subacute "inflammatory" lesions	Degenerative lesions with benign thrombosis

regarding the age which separates the two groups. Buerger (1924) described thrombo-angiitis obliterans as a disease which begins in the twenties or early thirties, and the average age at the onset of the disease in his cases was 32 years and 5 months. Brown and Allen (1928) stated that 90% of cases of thrombo-angiitis obliterans occurred between the ages of 20 and 50 years. The average age in Telford and Stopford's (1935) series of 48 cases was 45 years, and Telford (1937) said, "A diagnosis of thrombo-angiitis obliterans may be made with some confidence in patients up to 45 years or even 50." Lewis (1936) thought that the onset of thrombo-angiitis usually occurred in the thirties, Homans (1939) stated that the disease occurred in young men between the ages of 20 and 40 years, and Wright (1948) said that all patients have symptoms before 55 and most before 45. The opinion of Allen *et al.* (1946) was that "it is fairly safe to consider that if the symptoms of chronic occlusive arterial disease begin after the patient is 50 years of age the lesion is arteriosclerosis, and if they begin before the age of 40 years the lesion is thrombo-angiitis obliterans."

Current views regarding the differential diagnosis between the two groups may be summarized as follows: a diagnosis of thrombo-angiitis obliterans may be made with some certainty in the case of a male patient suffering from occlusive arterial disease who was under the age of 35 years at the time of his initial symptoms, gives a history of superficial phlebitis, and has involvement of the arteries of the upper limbs; if the patient is over 50 years, if the disease is confined to the lower limbs, if there is some degree of hypertension, and if radiographs of the affected limbs reveal calcification in the walls of the arteries, then arteriosclerosis may be diagnosed confidently. There are many patients with occlusive arterial disease in whom the clinical picture is not sufficiently clear-cut to permit of these definite diagnoses. These patients are in the age group between 35 and 45 years; although their blood pressure is normal and they do not have calcified vessels, they do not give a history of

phlebitis and the disease is apparently confined to one or both lower limbs. Hitherto the tendency has been to regard these patients as suffering from thrombo-angiitis obliterans rather than arteriosclerosis obliterans, although the natural history of their disease is often different from that observed in younger patients who show all the classical features of thrombo-angiitis obliterans.

An attempt to clarify this situation has recently been made by Boyd and his colleagues (Boyd *et al.*, 1949; Boyd, 1950), who have proposed a new classification of obliterative arterial disease of the lower limbs:

1. Traumatic Arterial Thrombosis.

2. Juvenile Obliterative Arteritis.—"This comprises a group of cases corresponding to those described by Buerger, and the condition may be a pathological entity."

3. Primary Popliteal Thrombosis.—A benign condition in which a local thrombosis develops in the popliteal artery as a result of trauma to the vessel where it runs behind the knee-joint.

4. Senile Obliterative Arteritis.—An inclusive term which covers all forms of arterial disease generally referred to as arteriosclerosis; it accounts for 95% of all cases of occlusive arterial disease, and the cases may be subdivided into the following groups: (a) diffuse obliterative arteritis; (b) secondary popliteal thrombosis; (c) secondary femoral thrombosis; and (d) distal type.

It is apparent that many cases which would be regarded by most authorities on peripheral vascular disease as instances of thrombo-angiitis obliterans are classified by Boyd under the headings of primary popliteal thrombosis and senile obliterative arteritis.

Clinical Material

Consideration of these facts has led me to review the case histories of 85 patients who were first seen between 1941 and 1947, and in whom a diagnosis of thrombo-angiitis obliterans was made. There were 84 males and one female in the series and their ages ranged from 21 to 56 years. All were smokers, but few could be regarded as heavy smokers. The majority of the patients were Scots, but the series included a Belgian, a Dutchman, and an Italian; only one patient was of the Jewish race. Many of the cases have been included in the recent clinical review published by Lynn and Burt (1949); most of these have been followed for several years, and the natural history of their disease is therefore known. Lynn and Burt dealt with the clinical features, the treatment, and the results of treatment, and these aspects will not be reconsidered.

Because of the importance which has been attached to the patients' age in regard to the diagnosis of thrombo-angiitis obliterans the cases have been divided into three groups according to their age at the onset of the disease (Table II). Superficial thrombophlebitis occurred in 27

TABLE II.—Clinical Material

	Age Group			Totals
	Under 35	35-45	Over 45	
No. of cases	39	37	9	85
No. with superficial phlebitis	12	13	2	27
No. with involvement of upper limbs	15	8	2	25
No. with hypertension (B.P. 150/90)	4	8	3	15
No. with pathological confirmation of diagnosis	12	8	2	22

cases, an incidence of 32%, which is similar to that usually quoted (Buerger, 1924; Allen *et al.*, 1946; Edwards, 1949). In 25 cases (29%) there was clinical evidence of involvement of the arteries of the upper limbs, a lower incidence than that given by Allen *et al.* (1946) and Farber and McLain (1951).

Fifteen patients had a blood pressure higher than 150/90 mm. Hg; the highest pressure was 190/100 in a patient in whom the diagnosis of thrombo-angiitis obliterans was confirmed. In most of the cases, and in all patients over the age of 40, radiographs of the affected limbs were taken; these did not reveal calcification in the walls of the arteries. Pathological confirmation of the diagnosis was obtained in 22 cases—by examination of material obtained by amputation (18 cases), at necropsy (3 cases), and by biopsy of a thrombosed vein (1 case). In two other cases necropsies performed since 1947 have shown that the arterial lesions were due to atheroma and not to thrombo-angiitis obliterans.

Clinical Classification

Several clinical classifications of cases of thrombo-angiitis obliterans have been suggested. Brown and Allen (1928) described 12 clinical types, Learmonth (1937) stated that cases could be divided into four groups, and Allen *et al.* (1946) mentioned nine clinical types and four groups according to the course of the disease. None of these classifications was entirely satisfactory for the present series, which has been subdivided into five groups (Table III).

TABLE III.—Clinical Classification

Clinical Type	Age Group			Totals
	Under 35	35-45	Over 45	
Acute	8	4	1	13
Episodic	16	11	1	28
Slowly progressive	7	11	7	25
Acute arterial occlusion	5	10	0	15
Upper limbs	3	1	0	4

1. An "Acute" Group (13 cases).—In this group the disease began either suddenly or insidiously and progressed rapidly; within a year of onset gangrene was extensive enough to necessitate either a major amputation or the loss of more than digits.

2. An "Episodic" Group (28 cases).—The history of the disease was punctuated by a series of episodes separated by months or years, each episode corresponding to a wave of thrombosis, either venous or arterial. Between the episodes the disease was quiescent and the patients were apparently well except for such residual disabilities as were left by the previous wave of thrombosis.

3. A "Slowly Progressive" Group (25 cases).—Intermittent claudication affecting the muscles of the leg was the first symptom of the patients in this group. The condition progressed slowly with gradual shortening of the "claudication distance"; nutritional changes and gangrene were late manifestations.

4. An "Acute Arterial Occlusion" Group (15 cases).—The onset was sudden and indicated that the patient had suffered an acute occlusion of either the femoral or the popliteal artery. This did not result in gangrene, but thereafter the patient had intermittent claudication in the affected limbs and the foot blanched unduly on elevation.

5. An "Upper Limbs" Group (4 cases).—In this group the disease was either confined to the upper limbs or the symptoms in the hands were of major importance and only minimal signs of disease were found in the lower limbs.

The first three groups represent well-recognized types of thrombo-angiitis obliterans. It will be noted that the incidence of the acute and episodic cases was greatest in patients under 35 years of age, and that in only one patient in each group did the disease begin after the age of 45. The age distribution of the slowly progressive type of case was different: the cases were more evenly distributed throughout the three age groups, and the greatest incidence was in the 35-45 period. The incidence of superficial phlebitis in these cases was low (only 3 cases out of 25), and none of the patients had involvement of the upper limbs. There is therefore some reason for questioning the diagnosis of thrombo-angiitis obliterans in these cases.

The fourth clinical group is of particular interest. Ten of the 15 cases in this group were in patients whose ages were between 35 and 45 years, and it is in patients of that age that the problem of diagnosis is most difficult. Opinions differ on whether acute occlusion of a major artery occurs

in thrombo-angiitis obliterans. Telford (1937) gave an excellent description of this type of case, and expressed the opinion that the occlusion was due to an embolus—"the embolus having been derived from some patch of atheroma or calcification in a vessel proximal to the popliteal. That they are not true thrombo-angiitis obliterans is evident from the fact of the sudden very painful onset and from the observation that the other leg is apparently normal." Klostermeyer (1941), on the other hand, suggested that many cases of thrombo-angiitis obliterans begin with occlusion of a major artery. Allen *et al.* (1946) recognized a type of thrombo-angiitis obliterans with sudden arterial occlusion, but they also stated that "cases in which acute and extensive arterial occlusion occur are uncommon." According to Boyd's classification, cases of this type would be examples of primary popliteal thrombosis or of senile obliterative arteritis with secondary thrombosis of the femoral or popliteal arteries.

At least some of the patients over the age of 35 who presented with signs of an acute arterial occlusion probably do belong to the latter category. The five patients under the age of 35 are more difficult to classify. Three of these cases were reported by Learmonth *et al.* (1944) as instances of "localized arterial thrombosis of undetermined origin." The fourth case, which we reported at that time, is now included in the upper-limb group because the brachial artery was affected. The subsequent histories of these four patients are illuminating: two (Cases 1 and 4) have had further episodes of thrombosis, both venous and arterial, and therefore would now qualify for inclusion as cases of thrombo-angiitis obliterans with an episodic course; of the other two, one (Case 2*) has had no further trouble, and the fourth (Case 3) is untraced. The natural history of these cases is therefore different from Boyd's conception of primary popliteal thrombosis; he regards the latter as a benign condition, and states that he has followed patients for ten years and found no further evidence of arterial disease (Boyd, 1950).

Most writers agree that involvement of the upper limbs occurs more often in thrombo-angiitis obliterans than in arteriosclerosis obliterans. Boyd *et al.* (1949), however, state that juvenile obliterative arteritis (which they regard as corresponding to Buerger's original description of thrombo-angiitis obliterans) is confined to the lower limbs, and that involvement of the upper limbs is more characteristic of senile obliterative arteritis. In the present series 25 patients had symptoms or signs of arterial disease in the upper limbs (see Table II). In four patients the symptoms and signs in the hands were of major importance, and evidence of the disease in the lower limbs had to be sought; three of these patients were under 35 years of age and one was in the 35-45 age group. All were found to have occlusive arterial disease in the lower limbs, but only one gave a history of an attack of superficial phlebitis.

Classification According to the Site of the Arterial Lesion

An alternative method of classifying cases of occlusive arterial disease is according to the site of the arterial lesion. Clinically it is possible to recognize two distinct types (Boyd, 1938). (1) A proximal type: in this group the occlusion is in the main artery of the limbs, claudication in the calf muscles is the main symptom, and postural colour changes in the foot are pronounced. (2) A distal type: the disease appears to begin in the arteries of the foot, pain in the foot either on exertion or at rest is the presenting symptom, the progress of the disease is more rapid than in the preceding group, and ulceration and gangrene are common.

When an attempt was made to divide the cases in the present series into these two types it was found that, although some cases could be allocated to one or other of the groups with certainty, there were a larger number

in which the clinical findings and special investigations indicated that both proximal and distal vessels were occluded. These cases therefore constitute a third group, which may be called the "mixed type" (Table IV).

TABLE IV.—Classification According to Site of Lesion

Site of Lesion	Age Group			Totals
	Under 35	35-45	Over 45	
Proximal type	7	9	3	19
Distal "	18	11	1	30
Mixed "	14	17	5	36

1. *The Proximal Type* (19 cases).—The outstanding feature of the cases in this group was that at the initial examination the disease appeared to be confined to one lower limb. Fourteen of the patients presented clinically as instances of acute arterial occlusion (see Table III); the remainder gave a history which suggested that the disease was slowly progressive, but examination indicated that they had a localized block in a main artery.

2. *The Distal Type* (30 cases).—In 22 cases both lower limbs were affected when the patient was first seen; in eight cases the disease was unilateral. The cases were evenly distributed through the acute, episodic, and slowly progressive clinical groups.

3. *The Mixed Type* (36 cases).—In all the cases in this group the disease was bilateral; in some, distal vessels only were occluded in one leg and both distal and proximal vessels in the other lower limb. As in the second group, the cases were distributed throughout the acute, episodic, and slowly progressive clinical groups, but the greatest number (15) were in the episodic group.

Buerger's (1908, 1924) descriptions of thrombo-angiitis obliterans clearly indicate that he regarded the disease as one which affected principally the arteries of the foot and leg, and which tended to spread proximally, often with a patchy distribution to involve the popliteal and, occasionally, the femoral vessels. Certainly the majority of cases of thrombo-angiitis obliterans begin as a distal arteritis, although often in the early stages the correct diagnosis is not made, and by the time the true condition is recognized the disease has spread to the proximal vessels. It is unusual for the initial symptoms to be those of acute occlusion of a main vessel, and when this occurs the diagnosis is more likely to be arteriosclerosis obliterans. Nevertheless, experience with some of the cases in the proximal group has shown convincingly that thrombo-angiitis obliterans does occasionally present in this manner: if the patient with an acute arterial occlusion is under 35 years of age the possibility that the cause is thrombo-angiitis obliterans should not be too readily dismissed. If, when the patient is first seen, both distal and proximal vessels are occluded it is often impossible to determine the level at which the obliterative process began, and clinical diagnosis is more difficult.

Conclusion

It is apparent from this study that the clinical diagnosis of thrombo-angiitis obliterans is not a simple problem. Much of the present confusion is due to the fact that Buerger used the term "thrombo-angiitis obliterans" in the first instance to describe the pathological lesion which he found in the arteries of the original eleven amputated limbs; only later did he apply the name to a group of clinical cases. It was assumed by Buerger (1924) and others that all patients presenting features similar to those of his original cases were suffering from the same disease. The symptoms and signs of obliterative arterial disease, however, depend not so much upon the pathological nature of the occlusive process as upon the distribution and extent of the lesions in the arterial tree. With the possible exception of superficial phlebitis none of the clinical features of thrombo-angiitis obliterans is pathognomonic. The diagnosis therefore must often depend upon the natural history of the patient's illness. In the past too much emphasis has been placed upon such criteria as race, age, and involvement of the upper limbs.

Buerger's original contention that the disease occurred most frequently in the Jewish race has long been disproved. Pathologists have often commented upon the fact that atheromatous changes are sometimes found in the arteries of young adults who come to necropsy as a result of fatal accidents and other conditions which do not primarily affect the cardiovascular system. If proof were required that such changes can be the basis of obliterative arterial disease it is amply provided by the studies of Newman (1946, 1951) and Poe (1947) on cases of coronary artery occlusion in young adults. Newman reviewed 100 cases of coronary occlusion which occurred in patients under 35 years of age, and found that in all of them the pathological changes in the coronary arteries were similar to those found in older patients—namely, atheroma. What happens in the coronary arteries may also occur in the arteries of the limbs, and therefore the possibility of arteriosclerosis obliterans, the pathological basis of which is atheroma, cannot be dismissed merely on account of the patient's youth. Involvement of the arteries of the upper limbs is not uncommon in cases of arteriosclerosis obliterans. The two criteria which remain as reliable indications for a diagnosis of thrombo-angiitis obliterans are its constant association with tobacco-smoking and its predilection for the male sex. The value of these criteria is lessened by the fact that smoking is an almost universal habit, and that, except in diabetics, all forms of obliterative arterial disease are commoner in men.

In its classical form thrombo-angiitis obliterans presents as an acute or episodic type of obliterative arterial disease occurring in a young adult male who smokes; it begins in the arteries of the lower leg or foot, may be preceded or accompanied by superficial migratory phlebitis, and is often associated with fungus infection of the feet. In cases of this type pathological examination of the affected arteries or veins almost invariably reveals lesions similar to those found by Buerger in his original cases. Many cases do not conform to this classical picture, and the clinical diagnosis can then be only a tentative one. Nevertheless, as Buerger (1924) states, "a careful clinical study of thrombo-angiitis obliterans will dissipate all doubt as to the possibility of separating this disease, as a clinical entity, from the other types of organic vascular disease as well as from all those neurogenic varieties of vasomotor and trophic disorders that may be clinically confounded with it."

Summary

The criteria necessary for a clinical diagnosis of thrombo-angiitis obliterans are reviewed with particular reference to a personal series of 85 cases. The view is put forward that the diagnosis should be based principally upon knowledge of the natural history of the disease and that such factors as race, age, and involvement of the arteries of the upper limbs are of secondary importance.

The majority of the patients were under the care of Sir James Learmonth, to whom I am indebted for the opportunity to study them. I wish to thank Dr. C. C. Burt for help in case-taking and for providing me with follow-up data on many of the cases.

SIMPLIFIED METHOD OF DRUG TREATMENT FOR THYROTOXICOSIS USING A UNIFORM DOSAGE OF METHYL- THIOURACIL AND ADDED THYROXINE

BY

RUSSELL FRASER, M.D., F.R.C.P.

AND

M. WILKINSON, M.R.C.P.

(From the Department of Medicine, Postgraduate Medical School of London)

The thiouracil drugs are now used widely both for the pre-operative management and for the prolonged medical control of thyrotoxicosis. The use of these drugs over long periods carries two potential disadvantages; first, the possibility of overdosage, which will cause further goitre enlargement and worsening of the eye signs along with subclinical or obvious myxoedema; and, secondly, the remoter risk of agranulocytosis or other lesser toxic effects. It is known from animal experiments that goitrogenesis during antithyroid drug administration depends on the increased output of pituitary thyrotrophin which is induced when the level of thyroid secretion is lowered, for it can be avoided by giving enough exogenous thyroxine (Purves, 1943; Astwood *et al.*, 1943) or by hypophysectomy (Griesbach *et al.*, 1941). The worsening of the eye signs of Graves' disease, which may also be seen as a manifestation of overdosage during thiouracil treatment, probably depends on the same mechanism. Thus the risks of thiouracil overdosage are those of its over-suppression of thyroid function.

Clearly these risks of overdosage should be avoidable either by adjusting the thiouracil dosage to levels just short of those which over-suppress thyroid function or merely by daily supplemental administration of thyroxine or thyroid. The former is the basis of the usual clinical practice of adjusting the thiouracil dosage to the patient's individual requirements; but this requires frequent and careful supervision, which can readily worsen the nervous state of such patients. We have therefore attempted to evolve a simpler procedure by giving the thyroxine with the methylthiouracil and so adopting the latter method of avoiding the risks which may follow undue suppression of thyroid function. A uniform basic dosage scheme giving both drugs should suffice, unmodified, for most cases if it provided enough methylthiouracil to block thyroid hormone production

*Case numbers refer to those used by Learmonth *et al.* (1944).

adequately in all cases and also supplied enough thyroxine for the normal daily needs of thyroxine. If the basic or standard dosages were correctly chosen the drug control should consist simply in watching the goitre size and adding thyroxine if goitre enlargement appears; while, to the occasional cases in which thyrotoxicosis does not seem controlled by this basic dosage, extra methylthiouracil could be given without any added risk of goitrogenesis. We have combined the basic dosage scheme into a single pill, so that one methylthiouracil co. pill is given thrice daily during the maintenance phase; and extra thyroxine is prescribed if goitre enlargement appears.

Present Investigation

A trial of this procedure seemed necessary to ascertain not only the optimal dosage schedule and whether it avoided the risks of thiouracil overdosage, but also whether its avoidance of over-suppression of thyroid function altered the frequency of permanent remissions after termination of the treatment. We have analysed the preliminary results of this treatment in our first 51 patients, particularly as regards the avoidance of goitrogenesis and of worsening of the eye signs during treatment, and the remission rate obtained after completion of treatment, comparing these with the published results of other methods of prolonged thiouracil treatment.

Selection of Cases.—This analysis concerns all our 51 patients (10 male, 41 female) who started this prolonged thiouracil treatment before August, 1951, and completed it before February, 1952; in all patients the diagnosis of thyrotoxicosis had first been confirmed by radio-iodine excretion test (Fraser *et al.*, 1952). All cases have been followed for one year or more after treatment ceased. The ages of these patients ranged from 11 to 68 years, with an average of 37.7 years. At first all cases of thyrotoxicosis were treated with methylthiouracil co. unless the patient expressed a preference for surgery. Later, radio-iodine treatment was used for all patients over 45 years of age and for a few younger subjects judged to have a life expectation of less than 20 years. Also, with increasing experience, surgical treatment was preferred for young patients with an initially large or nodular goitre or with evidence of a marked allergic diathesis, and for those patients considered insufficiently reliable for a prolonged drug treatment which needs precise regularity.

Methods

For the treatment two strengths of methylthiouracil co. pills were used—100 and 50 mg. During the evolution of this procedure there has been a change in the amount of thyroxine added to these pills, and so in the need for added thyroxine. We now believe that the new methylthiouracil co. pills, containing 0.1 mg. of L-thyroxine against the 0.075 and 0.05 mg. of the "old" methylthiouracil co. pills, provide the optimal added thyroxine (0.1 mg. t.d.s.) for the basic maintenance dosage schedule; clearly, giving the same dosage of these two drugs separately should provide equivalent control.

During the induction phase the patients received two 100-mg. methylthiouracil co. pills thrice daily until they were considered to be restored to a euthyroid state; this phase usually lasted six to eight weeks. They were then put on a maintenance dosage of either 50 mg. or 100 mg. (usually the former) of methylthiouracil co., taken in each case three times daily. Additional thyroxine was given at the first sign of enlargement of the thyroid gland and sometimes if the eye signs were initially severe.

Most cases were treated as out-patients, but in a few instances treatment was begun in hospital. Patients were seen at intervals of one to three months, when progress was assessed mainly from the body weight, the state of the circulation, the eyes, and the size of the thyroid gland. All patients were warned to report to hospital if a sore throat or other illness supervened. A white-cell count was done at the start of treatment but was not repeated unless any such symptoms developed.

The course of treatment was for a minimum of nine months, but was prolonged if the patient's physical state was unsatisfactory or if worries or stress were known to exist. Patients completing the course were treated for one month with thyroxine, 0.1 mg., and potassium iodide, 1/6 gr. (11 mg.) daily, the former to depress thyrotrophic hormone production during the restoration by the latter of the thyroid's depleted iodine store. All patients were reassessed clinically at three and twelve months after treatment, on one or both of which occasions a radio-iodine test was performed.

Results

The subsequent analysis concerns the 32 patients who completed a full course of nine months' treatment; 19 failed to complete a full course for the following reasons:

Agranulocytosis (later recovered)	3
Patient ceased attending	9
Other treatment preferred	7
Chosen for I^{131} therapy	3
Surgery for large goitre	3
Surgery because of cardiac state	1

Status After Ceasing Treatment (Remission Rate).—The results are shown in Table I; all of the 18 remitted cases have been observed for 12 or more months. They

TABLE I.—Clinical Status Six Months or More after Finishing Prolonged Treatment with Methylthiouracil Co.

Well, and normal I^{131} test	9 (28%)
" but residual eye signs	6 (19%)
" but abnormal I^{131} test	3 (9%)
Thyrotoxicosis relapsed	14 (44%)
Total	32

appear to be quite well and free from clinical signs of thyrotoxicosis, though the radio-iodine test suggested that three had hyperactive thyroids. One of these patients also had nervous symptoms, associated with an unhappy domestic situation. In six patients there were residual eye signs—two had minor ocular paresis and four had only slight degrees of exophthalmos or lid retraction. Of the 14 (44%) patients who relapsed, six did so in the first six months, six between 6 and 12 months, and two later. It seemed that the relapsed cases had had a longer illness before treatment, that they included more patients with

nervous or unstable personalities, and that they had more often (in 9 out of 14) had some persisting cause for anxiety during the period after ceasing treatment.

Control of Goitre Size.—As is shown in Table II, the size of the goitre increased temporarily during treatment in almost half the cases (14 out of 32), but when extra thyroxine was given the added enlargement almost always subsided. In only one case did the goitre size at the end of treatment exceed that noted at the start of treatment, and in 25 out of the 32 cases the goitre was then judged to be less than two and a half times normal size. Among the 19 patients not completing a full course of treatment there were three who had surgical treatment for a large goitre. All of these patients had initially large goitres which had at first further enlarged during thiouracil treatment; one case is of particular interest in that the goitre continued to enlarge despite the administration of L-thyroxine totalling 0.6 mg. daily. After surgical removal the thyroid in this case was found to weigh 300 g. This was the only case in the whole series in which thyroxine up to this dosage failed to prevent further goitre enlargement.

The Eyes During Treatment.—Eye signs were initially present in 23 patients: in 17 they were mild and in six severe (that is, including ocular palsy and/or obvious conjunctival congestion). As shown in Table II, in no case did eye signs develop or worsen significantly during treatment. The possible worsening noted at some stage in three patients was only temporary and slight. At the end of treatment relatively minor eye signs persisted in all six of those patients who had originally had severe eye signs and in four other patients. In six of these ten cases this was either mild exophthalmos or lid retraction, though two still had some diplopia and one had slight ptosis. Extra thyroxine was given to three of the patients with initially severe eye signs, so that their total daily thyroxine ranged from 0.3 to 0.6 mg.

Adequacy of Basic Dosage Schedule.—**Suppression of Thyrotoxic Features.**—During treatment these features were controlled in all patients, though in a few the usual maintenance dose of 50 mg. of methylthiouracil co. three times a day had to be increased to 100 mg. to achieve this. In one patient there was at first some doubt whether control was satisfactory; but as the symptoms persisted despite 7.2 g. of methylthiouracil daily it was concluded that these symptoms were of nervous and not thyrotoxic origin. **Use of Extra Thyroxine.**—At some stage 18 patients were given 0.1 to 0.3 mg. of additional thyroxine daily, apart from that included in the old compound tablets. This was prescribed in 15 instances because of goitre enlargement and in three because of severe eye features. In three patients this additional thyroxine was continued because pregnancy supervened. Extra thyroxine was given for less than three months in five cases and for longer periods in the remainder. Only five patients had received an average daily total of more than 0.3 mg. of L-thyroxine, which is the amount they would have received using only the new compound tablets now in use.

Control During Pregnancy.—Pregnancy occurred successfully in three patients. One patient, however, gave birth to a child with a large goitre, but this subsided rapidly with small doses of thyroxine for three months, and the child has since developed normally. The mother in this case had been maintained throughout most of her pregnancy on methylthiouracil co., 100 mg. t.d.s. (which included 0.225 mg. L-thyroxine daily) with 0.1 mg. t.d.s. of extra thyroxine until the last four weeks before delivery, when by accident the extra thyroxine was omitted. After this experience we have been careful to maintain pregnant patients on small doses of methylthiouracil co. (usually 50 mg. t.d.s.) with relatively large doses of added thyroxine (usually 0.3 mg. daily), and the results have been satisfactory. Only one child was breast-fed, and during the period of lactation the mother was maintained on methylthiouracil co., 50 mg. t.d.s., with 0.3 mg. of extra thyroxine daily.

Discussion

This preliminary report has been made on a small series because it suggests that control of thyrotoxicosis is possible by this fairly standardized and simple procedure, using methylthiouracil combined with thyroxine.

With one exception, which required surgical treatment, goitrogenesis has been adequately averted—provided extra thyroxine was prescribed if indicated. In no cases have the eye signs significantly worsened during or after therapy. Very few other reports give more than brief mention of the effects of prolonged antithyroid drug treatment on the goitre size and eye signs. Williams (1946), however, found that thyroxine was necessary because of goitrogenesis or worsening of the eye signs in 31 out of 247 cases treated with thiouracil; and among those patients receiving prolonged treatment the goitre enlarged in 7%. Dunlop and Rolland (1950) found that slight goitre enlargement "was not uncommon" during methylthiouracil treatment, while Frisk (1948) reported enlargement in 50% of cases. Obviously the frequency of goitre enlargement will depend on the degree of thyroid suppression attained. Astwood (1948) has suggested that it is better to keep the patient at a slightly hypothyroid level; if this is attempted goitrogenesis will probably be a very definite problem.

With this group of cases extra thyroxine was often necessary (in 14 out of 32) to avoid goitrogenesis. Our current practice, however, is to give a larger basic or standard dosage of thyroxine, to provide 0.3 mg. a day. The compound tablets now each contain 0.1 mg. of L-thyroxine with either 100 mg. or 50 mg. of methylthiouracil, so that either strength given thrice daily should provide a maintenance dosage. With this modified or "new" standard dosage extra thyroxine is rarely needed. There should be no hesitation about giving this extra thyroxine (0.1–0.3 mg. a day) in doubtful cases. The thyrotoxic features have usually been controlled with the 50 mg. of methylthiouracil co. thrice daily and always with the 100 mg. strength thrice daily. Thus the compound thiouracil tablets have provided satisfactory control in every case, and the use of these tablets does simplify the treatment. Ordinarily the patients follow a routine schedule and are maintained on 50 mg. of methylthiouracil co. three times a day. If the control of thyrotoxicosis then seems defective this is changed to the stronger compound tablets, 100 mg. three times a day, the only other dosage control required being to give extra thyroxine if goitre enlargement is noted. In a straightforward case there is no necessity for the patient to be seen more often than at three-monthly intervals during maintenance treatment.

When one considers the relapse rate there is less cause for satisfaction, though our results are probably similar to those achieved with the usual prolonged thiouracil treatment. Admittedly the results reported in the literature vary widely, and it is difficult to know which figures to choose for comparison. Starr *et al.* (1949), using propylthiouracil, failed to achieve a single lasting remission, whereas Frisk (1948), using methylthiouracil, claims a remission rate of 90%, though some of his patients had been followed for only six months after treatment, and several patients had required two courses of treatment. Williams *et al.* (1947) and Dunlop and Rolland (1950) followed patients for a year or more after prolonged thiouracil treatment, and reported remission rates of 46% and 47% respectively, which compares with our remission rate of 56%. Other recent reports claim remissions in 41% (Stirrett *et al.*, 1952), 70% (Murray, 1950), 85% (Astwood, 1948), and 88% (Iversen, 1951, but here relapses within six months of stopping treatment were excluded).

Final evaluation of these drugs must await further experience; possibly both case selection and variations in the technique of using thiouracil may have contributed to the varying results. A drug treatment is needed for those

TABLE II.—Goitre Size and Eye Signs During and After Prolonged Treatment with Methylthiouracil Co.

Grading Before Treatment:	Goitre Size			Eye Signs of Graves's Disease		
		Less Than 2½ Times Normal (21)	More than 2½ Times Normal (11)		Severe (6)	Mild (17)
Temporary change during treatment	Enlargement controlled by extra thyroxine	(7)	(7)	Possible worsening	(2)	(1)
Status on finishing treatment	Smaller than initially, and: Less than 2½ times normal	20	5	Nil	—	13
	More than 2½ times normal	—	6	Mild (lid retraction or mild exophthalmos)	—	3
	Larger than initially	1	—	Severe:	3	—
				Ptosis only	—	1
				Muscular paresis	3	—
				Significant worsening	—	—

patients who do not desire surgery and cannot have radio-iodine, and is used with many other patients for varying reasons.

We would suggest that the procedure outlined above, while simplifying the management of such cases, diminishes the risk of goitrogenesis and of worsening of the eye signs without impairing the therapeutic effects.

We should expect the procedure to be similarly suitable for preparing the thyrotoxic patient for operation, provided iodide is given in addition over the last two weeks. We are at present investigating the latter method.

Summary

A preliminary report is made of the practicability of treating thyrotoxicosis with both methylthiouracil and thyroxine to simplify the control of dosage. The results were apparently as satisfactory as the published results obtained with antithyroid drugs alone.

A basic standard dosage was used (enough methylthiouracil to control all but exceptional thyrotoxicosis and the minimal normal thyroxine requirements—that is, methylthiouracil, 50 mg., and L-thyroxine, 1 mg., thrice daily); this standard dosage, unaltered, suffices for the maintenance treatment of most patients, provided signs of goitre enlargement are sought and when seen are countered by giving additional thyroxine. If the adequacy of the control of thyrotoxicosis is doubted the methylthiouracil dose can be increased.

Among the first 32 cases completing a course of nine or more months of such treatment, in 18 (56%) the thyrotoxicosis was still fully remitted one year later, in no case had the eye signs significantly worsened, and in all except one the goitre size had decreased.

We are indebted to Glaxo Laboratories Ltd., who supplied the pills for this trial.

Aided by a grant from the National Institute of Mental Health of the United States Public Health Service, the Yale Centre of Alcohol Studies recently surveyed current American work on alcoholism. Their findings, originally printed in the *Quarterly Journal of Studies on Alcohol* (1952, 13, 421-511), have now been published as a separate booklet entitled "Alcoholism, 1941-1951: A Survey of Activities in Research, Education, and Therapy." Although the main emphasis is naturally on American studies in this field, much of the material included in the book is of general application and likely to interest workers elsewhere. The book is comprised of six sections each written by members of the staff of the Yale Centre, and with an introduction by the Director of the Centre. The sections are entitled: Sources of Scientific Information; the Status of Physiological Knowledge; Social Science Research; the Treatment of Alcohol Addiction; Programmes on Alcoholism in the United States, 1952; and Activities of State Departments of Education concerning Instruction about Alcohol. Copies of the book may be obtained from: *Quarterly Journal of Studies on Alcohol*, 2162 Yale Station, New Haven, Connecticut, price \$1 per copy.

PITYROSPORUM OVALE AND SOME SCALY CONDITIONS OF THE SCALP

BY

F. A. WHITLOCK, M.D., M.R.C.P.

Dermatologist, West Cornwall Clinical Area

The part played by the organism *Pityrosporum ovale* in the aetiology of a number of conditions of the skin has been much debated. By some it is held to be the prime and only cause of dandruff of the scalp and "seborrhoeic" eczema of the body; by others it is denied that the organism is anything but a harmless saprophyte which thrives under the cultural conditions provided by certain diseases. The problem is not made any easier by the confused and confusing terminology which has been applied to the group of conditions variously labelled as dandruff, pityriasis capitis, seborrhoea, seborrhoeic eczema, pityriasis circinata, the eczemas, etc.; the list could be made very much longer. So far as this paper is concerned, I hope to avoid lengthy discussion of the problems of seborrhoea, male-pattern baldness, and seborrhoeic eczema, and to confine my attention to certain scaly conditions of the scalp. It is not entirely possible to do this, as the three diseases often coexist with the subject under consideration.

Review of the Literature

Sabouraud (1902) held quite firmly that the cause of dandruff, or pityriasis simplex of the scalp, was infection with *P. ovale*. In addition, when the scalp became infected with an organism variously named the polymorphic coccus of Cedercreutz or the morococcus (Unna), but which seems to be the same organism as the *Staphylococcus epidermis albus* of Welch, the nature of the scaling changes from a dry condition to one which appears to be greasy, and is termed pityriasis steatoides or serosa. To add to the problem the scalp might also be affected with the acne bacillus, held by Sabouraud to be the cause of increased sebaceous secretion on the skin, thus causing an oiliness of the scalp, with an aetiology differing from the supposed greasiness of pityriasis steatoides.

Darier (1920), however, propounding his doctrine of "kerose," was of the opinion that pityriasis capitis is but a manifestation of the underlying state which is characterized by a brownish dirty-yellow complexion, slight thickening and hyperkeratosis of the skin of the centre of the face, scalp, and other areas, and enlargement of the pilosebaceous follicles with hyperkeratosis of their openings. He regarded the kerosé as a constitutional condition normal to certain types of person rather than a disease, and that *P. ovale*, the acne bacillus, and the polymorphic coccus grew best on this type of "soil," but were in no way responsible for any disease or for the varying manifestations of kerosé.

Sabouraud was not able to culture *P. ovale*, but Macleod and Dowling (1928) cultured an organism which they thought to be *P. ovale*, and which they believed to be the cause of dandruff of the scalp. In addition, by inoculation experiments with their culture on the normal skin they produced lesions which they thought were identical with those of seborrhoeic eczema. However, it was later realized that the organism was not *P. ovale* but *M. pinoyi*, a fact acknowledged by Dowling (1939) himself. Unfortunately the original experiments are still cited in many modern textbooks of diseases of the skin and hair as if they are the proof positive that *P. ovale* is the cause of seborrhoeic eczema and dandruff. Why the later repudiation by Dowling

is not more widely known is difficult to understand, but Savill (1952), a strong supporter of Sabouraud, still writes as if it had never been made.

Templeton (1926) managed to culture the organism and made some scrapings from "normal" scalps and from scalps affected with pityriasis simplex and with oily dandruff. Of the 26 normal scalps it is significant to note that 13 were those of children under 15 years of age. *P. ovale* was present in 69% of these cases which were devoid of dandruff, in 27 out of 28 cases of pityriasis simplex, and in 85% of cases afflicted with oily dandruff. Templeton had some difficulty in deciding where dry dandruff ended and oily dandruff began, and I would agree with his conclusion that the two merge together imperceptibly. It is by no means easy to distinguish the minute details described by Sabouraud, and I suspect that many who describe his classification have difficulty in doing so themselves. Dry dandruff, or pityriasis simplex, is easy to recognize; so also is dry dandruff made greasy by sebaceous secretion. On the other hand, I am by no means convinced of the separate existence of pityriasis steatoides or serosa, which seems to be, as described by Sabouraud, an eczematous condition of the scalp more often to-day called seborrhoeic eczema.

Ota and Huang (1933) cultured *P. ovale*, and, after pointing out that the organism grown by Macleod and Dowling was not the same as their own, they attempted to repeat their experiments. They concluded that *P. ovale* was not the cause of seborrhoeic eczema, as they were unable to obtain more than a transient erythema with their inoculations. Moore and his colleagues (1936) cultured *P. ovale* and believed that they were able to produce lesions of seborrhoeic eczema by percutaneous inoculation, and could recover the organism later from the lesions. Unfortunately it was by no means clear (a) why some inoculations "took" and others did not; (b) what were their criteria for seborrhoeic eczema; and (c) whether the organisms they recovered were the same as those they inoculated or those which were on the skin of the patient before the experiment was started. Kile and Engman (1938) were able to find *P. ovale* in 21 out of 24 cases of seborrhoeic blepharitis, and thought that by inoculation of cultures on to scalps "clinically free from seborrhoeic eczema" they were able to cause scaling, itching, and lesions "like seborrhoeic eczema" after an interval of two weeks, during which the scalp remained unwashed. Unfortunately, again there was a total absence of control experiments, and the results cannot be held to be in any way conclusive.

Bigham (1937) made scrapings and cultures from patients with various scaly dermatoses and scalps, and detected the presence of *P. ovale* and a "yeast-like organism." He was able to find *P. ovale* in 20 control "normal" scalps and in all of seven cases of seborrhoeic eczema. He was also able to recover the organism from the scalps of patients affected with diseases such as psoriasis and pityriasis rosea, so he concluded that the *P. ovale* was not the cause of seborrhoeic eczema. Mackee *et al.* (1938) examined the flora of the scalps of 100 unselected persons and were unable to find any correlation between the incidence of *P. ovale* infection, seborrhoeic eczema, and normal scalps. In further studies Mackee *et al.* (1939) were unable to show any relationship between the type of skin and the presence or absence of various organisms, including *P. ovale*.

Barber (1948) concludes that *P. ovale* is the cause of simple dandruff and also says that dandruff is very rare before the age of 9-10. He believes that circulating androgen is necessary for the active growth of *P. ovale* and that oestrogen inhibits its growth. He also states that the administration of oestrogen to males with acne causes cessation of dandruff and diminution of seborrhoea, and that the local application of oestrogen diminishes dandruff. From these observations one assumes that Barber regards androgen and oestrogen as having a direct stimulating or inhibiting action on the growth of *P. ovale*. Unfortunately he is not precise on this point, as, after outlining Darier's views on kerosé, he considers that many of the complications

of this state, such as acne and increased sebaceous secretion and pityriasis capitis, are a direct androgen effect without the need for any organism such as *P. ovale* to cause the increased desquamation from the scalp. Again one does not know whether any of these views are supported by crucial experiments. Eller and Eller (1949) were unable to detect any changes in the skin of normal young women or in men after the inunction of oestrogen ointment, but they did not carry out their experiments on the scalp. If oestrogen has a direct inhibiting action on *P. ovale* one would expect that the organism would be absent during pregnancy. That this is not the case is shown under Survey 3 below.

Survey 1

Examination was made of scrapings taken from 200 normal scalps selected in such a way that the scalps were devoid of any active lesion or inflammatory condition other than dandruff or sebaceous secretion. Also, apart from diffuse thinning or male-pattern baldness of the hair, no abnormality of the hair was included in the series. The sexes were represented equally and were divided into ten-year age groups, from 0-9 to 80+ years. Each of the first eight groups contained 12 cases of each sex; the last group had four of each sex.

Method.—The scalps were examined and the presence or absence of dandruff was noted, as was the state of the hair, degree of hair loss, and degree of seborrhoea.

With a small Meibomian scoop scrapings were taken from six different areas of the scalp radiating in linear fashion from the vertex. The material collected was placed on a slide, mixed with 90% alcohol to facilitate spreading, heat-fixed, stained with methylene blue, and examined microscopically with the 1/12-in. objective lens. The slides were examined for the presence of *P. ovale*, and, depending on the numbers present, the findings were classified as follows:

- P.O.—: After an extensive survey of many fields the organism was not seen.
 P.O. scanty: The organism was found in numbers up to about 10 after a prolonged search of the slide.
 P.O.+ : The organism was present, a few being seen in most fields examined.
 P.O.+++ : Present in all fields in numbers up to about 20 in the majority of fields.
 P.O.++++ : Present in large numbers in most fields examined.
 P.O.+++++ : Present in large numbers and clumped together in masses in many of the fields examined.

This classification is admittedly an arbitrary one, depending in some degree on the person examining the slides. Nevertheless it seemed to work, and after a little experience it became a simple matter to assign a case to its proper category. Although this classification was useful when it came to assessing certain individual factors, such as greasiness of the scalp correlated with the number of organisms present, it was found simpler to group together the first three subdivisions as category A and the second three as category B for the purposes of recording the overall results.

The dandruff findings were recorded as follows:

- D—: No scaling or flaking seen on any part of the scalp.
 D slight: Fine white powdery scaling seen in a few areas on the scalp.

D+: White powdery scaling seen with ease, but not in large quantities.

D++: Large amounts of scaling and flaking present, with, in some cases, adherent greasy scaling over much of the scalp.

Results.—*P. ovale* was absent or scanty in 12% of cases—14 male and 10 female. Dandruff was absent or slight in 56.5% of cases—67 male and 46 female. Of these, 48 male and 33 female cases came into category B when the dandruff findings were correlated with those of *P. ovale*. Nine male and nine female cases with the finding "dandruff +/++" came into category A for the *P. ovale* result. Thirty cases showed "seborrhoea" of the scalp. Of these, all except one had infection with *P. ovale* in the range of category B, and nine of these showed the organism clumped in large masses (P.O.+++). Some degree of hair loss, ranging from diffuse thinning to severe Hippocratic baldness, was seen in 49 cases: 38 of them fell into category B for the *P. ovale* finding. The results when divided up into age groups were as follows:

0-9 years	P.O. Category B	33.3%	Dandruff +/++	16.5%	of cases
10-19	"	83.0%	"	58.3%	"
20-29	"	71.0%	"	46.6%	"
30-39	"	83.0%	"	50.0%	"
40-49	"	87.5%	"	50.0%	"
50-59	"	79.0%	"	41.5%	"
60-69	"	82.0%	"	37.5%	"
70+	"	72.0%	"	47.0%	"

These results may conveniently be plotted as a graph, as shown on the previous page.

Survey 2

It is known that *P. ovale* is a lipophilic organism, and during the course of the first survey of scalps it soon became clear that those cases having oily or greasy scalps would show the organism in abundance. In short, it seemed that the presence of sebaceous secretion was the ideal basis on which the organism could flourish. In order to make this point more evident scrapings were taken from the nose and naso-labial folds and from the eyelids of 20 patients. The skin of the nose is rich in sebaceous glands and secretion, whereas the eyelids appear to remain comparatively free from grease. The two areas are contiguous, so it would be perfectly possible for the organism to spread from one site to the other or be transferred by the fingers of the individual or by washing.

Results.—(1) Nasal scrapings gave the following results: P.O. +, 9; P.O. ++, 9; P.O. +++, 2. In all these cases the organism was found without much difficulty. (2) Eyelid scrapings gave the following results: P.O. -, 3; P.O. very scanty, 13; P.O. +, 3; P.O. ++, 1. In 16 cases (80%) the organism was not found or only found with considerable difficulty after a prolonged search of the slide.

Survey 3

As mentioned earlier in this paper, it has been suggested that under the influence of oestrogenic stimulation the infection of the scalp with *P. ovale* diminished. That there was no significant difference between the degree of infection in male and female cases in the first survey would seem to disprove this thesis, but in order to attempt to settle the matter examination was made of the scalps of 32 pregnant women attending an antenatal clinic, their ages ranging between 17 and 42 years.

Results.—(1) *P. ovale* was present in all cases, and, except for two who showed P.O. +, all the cases came into category B. (2) Dandruff was absent or slight in 19 cases and +/++ with some degree of seborrhoea in 13. (3) If these cases are grouped into age groups 17-29 and 30-43, and compared with non-pregnant women in the first survey of similar ages, the following results are obtained:

P.O. Category B:	Pregnant cases, aged 17-29	22 out of 23 (96%)
"	Non-pregnant cases, aged 17-29	12 " " 16 (75%)
"	Pregnant cases, aged 30-43	8 " " 9 (89%)
"	Non-pregnant cases, aged 30-43	17 " " 18 (94%)

Thus, so far as the first of these age groups is concerned, there seems to be a definite increase of infection in the pregnant cases; and in the second group the difference is not

sufficiently great to be of significance. Certainly there is nothing in these results to suggest that increase of circulating oestrogen diminishes the degree of *P. ovale* infection. The great majority of these women were in the last trimester of pregnancy, when the quantity of oestrogen would have been at its highest and when the stimulation would have lasted for not less than six months. I conclude, therefore, that circulating oestrogen plays no part in determining the degree of infection of the scalp with *P. ovale*.

Survey 4

It has already been suggested that *P. ovale* thrives best in a medium containing sebaceous secretion. This supposition is given support by the findings in nine cases of tinea amiantacea. All these cases showed a dry silvery scaling of the scalp, fine and adherent, in some cases covering most of the hair-bearing area, in others more patchy in distribution. In addition, some cases showed flexural lesions of the seborrhoeic type. *P. ovale* was not found in two cases, was found with difficulty in very small numbers in six, and was classified as P.O. + in the remaining case. It would seem that the excessive dryness of the scalp was a factor responsible for the very low degree of infection with the organism. In parenthesis it should be said that I would agree wholeheartedly with the thesis put forward by Brown (1948) that the disease is due to underlying emotional factors, and I would prefer the title of "neurodermatitis of the scalp" to the outmoded one of tinea amiantacea.

Survey 5

During the course of these investigations 17 cases of psoriasis of the scalp were seen and scrapings taken.

Results.—*P. ovale* was absent in 11 cases, scanty in one case, + in three cases, and +++ in two. Of these last two, one had a very greasy scalp and the other had such a slight degree of scaling that it could be differentiated from ordinary dandruff with some difficulty. In the main, the scalps examined were dry and the scrapings were taken from the centres of obvious and well-demarcated patches of psoriasis. Once again it seemed that the dryness of the lesion and the absence of sebum was the cause of the slight degree of infection with *P. ovale*.

Survey 6

In the past, claims have been made that inoculation of the skin with cultures of *P. ovale* would produce lesions of seborrhoeic eczema. As has already been indicated, the methods used are open to criticism, and conflicting results have been obtained when scrapings from "seborrhoeic" lesions have been examined for the presence of the organism.

In the course of this investigation 16 cases were diagnosed as suffering from seborrhoeic eczema. Eight cases showed generalized flexural lesions involving the scalp, ears, neck, axillae, breasts, umbilicus, perineum, and intergluteal fold. In six scalp scrapings *P. ovale* was absent or scanty in five and + in one. In 20 scrapings from behind the ears and other body areas mentioned, the organism was scanty in one retro-aural scraping and absent in all the others, although a monilia-like organism was present in one specimen taken from an intergluteal lesion. Scrapings taken from four cases of pityriasis circinata of the chest showed the organism to be absent in three cases and scanty in one. In four cases having seborrhoeic eczema of the ears and scalp five scrapings were taken—one showing P.O. ++, one scanty P.O., and three negative.

From the findings in the admittedly rather small number of cases one would not deduce that *P. ovale* was the cause of the disease. Unless secondary infection was present—and cultures invariably produced a pure growth of coagulase-positive *Staphylococcus aureus*—the lesions were red, scaly, and remarkably dry, an observation much in keeping with that of Percival (1936), who comments on the lack of seborrhoea in cases of seborrhoeic eczema.

Discussion

It has been the aim of this investigation to support the thesis that *P. ovale* has nothing to do with the cause of dandruff, seborrhoea, or seborrhoeic eczema. In consequence I would strongly support the conclusions reached by Martin-Scott (1952), which were backed by cultural and inoculation studies.

In the first survey of 200 "normal" scalps one of the most striking findings was the sharp rise in the incidence of dandruff and degree of *P. ovale* infection at puberty. Another point of interest was the greater degree of dandruff and slightly larger number of heavy *P. ovale* infections in the female than in the male. The sudden increases of dandruff and heavy *P. ovale* infection at puberty might lead one to suppose that the two conditions are causally associated, but other factors must be considered, notably the increase of sebaceous activity at that age.

It was noted that of 30 cases with "seborrhoea" of the scalp all except one showed a heavy *P. ovale* infection, and that 38 out of 49 cases with some degree of hair loss showed the same finding. Sabouraud thought that increased sebaceous secretion led to hair loss, and more recently Flesch (1951) has shown that squalene, a normal constituent of sebum, will cause loss of hair when applied to the skin of rabbits. In short, it seems that it is the heavy sebaceous secretion which permits *P. ovale* to flourish in these cases—a reasonable conclusion, as the organism is very lipophilic. The later surveys of nose and eyelids and of various dry scaly conditions of the scalp and body all tend to support this view, and in consequence the increased infection at puberty is to be expected owing to the increased greasiness of the skin at that time.

For additional proof that *P. ovale* does not cause dandruff I would point to the 48 males and 33 females who showed slight or no dandruff in the presence of heavy *P. ovale* infection. In addition it was possible to find comparable degrees of infection on the skin of the nose without any sign of scaling or abnormality of the surface.

This, of course, does not lead us any nearer to understanding the precise cause of dandruff, but I would suggest that it is the normal desquamation of the scalp, similar in every respect to the "invisible" scaling on other parts of the skin caused by the normal replacement of cornified of the hair of the scalp—a suggestion which might seem to derive support from the shorter hair and more frequent scalp-washing in the male, who shows a lower incidence of heavy dandruff when compared with the long-haired female, whose scalp is washed less often lest her "waves" should cease to remain permanent.

The suggestion that androgen increases and oestrogen decreases the degree of dandruff would seem to be unsupported by the findings in the 32 pregnant cases, and also by the greater incidence in the female than in the male. Nevertheless it is difficult to resist the conclusion that endocrine factors must have something to do with the sharp increase at puberty, although I would not agree with Barber's statement that dandruff is rare before the age of 9-10.

This paper, it must be admitted, is largely iconoclastic and offers little constructive suggestion to explain some of the conditions described. However, to attempt to explain the causes of seborrhoeic eczema and neurodermatitis of the scalp would take me far beyond the scope of this investigation, as many factors other than the bacteriology of the scalp would need to be considered. Nevertheless it is hoped that *P. ovale* will no longer be regarded as the major or only cause of the conditions discussed, and, although many of the findings are of a negative type, I have yet to read of any convincing evidence in the shape of inoculation studies which would support the thesis that *P. ovale* is the cause of dandruff or seborrhoeic eczema.

Summary

Some of the problems concerning the relationship of *Pityrosporum ovale* to dandruff and other "seborrhoeic" conditions of the scalp and body are discussed and the literature on the subject is briefly reviewed.

Examination was made of 200 normal scalps and the degree of infection with *P. ovale* was correlated with the degree of dandruff present. From the findings it was considered that there was no evidence to justify the theory that *P. ovale* caused the dandruff. Instead it was suggested that the degree of infection was influenced by the quantity of sebaceous secretion, and that the increased flow of sebum at puberty would explain the rise in the incidence of infection at that age. It was also noted that the amount of dandruff was heavier in the female than in the male.

The suggestion that sebaceous secretion was the main factor influencing the degree of infection with *P. ovale* was supported by the findings in scrapings taken from the skin of the nose when compared with scrapings from eyelids in 20 cases. Further support was given by the findings in nine cases of tinea amiantacea, 17 cases of psoriasis of the scalp, and 16 cases of seborrhoeic eczema of the scalp and trunk. In most of these dry scaly conditions the organism was absent or was found only in small numbers.

The suggestion that oestrogens diminish the degree of dandruff and *P. ovale* infection receives no support from the findings in the 100 male and 100 female normal scalp scrapings. Examination of the scalps of 32 pregnant women, most of whom were in the last trimester, showed a rather greater degree of infection when compared with non-pregnant women of the same age groups.

It is concluded that *P. ovale* is not the cause of dandruff but is a harmless organism on the scalp which thrives best in the medium provided by a heavy flow of sebum.

The county health department of Cheshire has performed a useful service in publishing *A Cheshire Index*, a booklet listing in alphabetical order and in five sections (a) the county districts and civil parishes, (b) civil parishes with place-names therein, (c) place-names of the administrative county, (d) county boroughs and place-names therein, and (e) place-names outside Cheshire with a Cheshire postal address. In a modestly worded preface the department invites the correction of any error of omission or insertion. Similar lists of the place-names of the other counties in the United Kingdom would be a boon to all those who have to verify the names of villages, hamlets, and district localities in larger towns.

A CASE OF PRIMARY OVARIAN PREGNANCY

BY

R. G. WHITELAW, M.B., Ch.B., M.R.C.O.G.

Formerly Senior Obstetrical and Gynaecological Registrar,
Beckenham Hospital and Beckenham Maternity
Hospital, Kent

Primary ovarian pregnancy is an obstetrical rarity. Courtiss (1942) gave its incidence as 1 in 25,000 pregnancies and, using the figures of the Mayo Clinic, stated that it occurred in about 0.5% of ectopic pregnancies. Eckerson (1941), basing his estimate on the statistics of St. Luke's Hospital, reckoned that it occurred in something like 0.2% of ectopic gestations. Just over 100 cases have been reported in the English language, and a perusal of the relevant British, American, and Dominion obstetrical and gynaecological references leaves one with the impression that some of these may be spurious, as they seem to be backed by inadequate information.

Spiegelberg (1878) established four criteria upon which the diagnosis is to be based. He stated that if a case is to be accepted as one of primary ovarian pregnancy: (1) the Fallopian tube on the affected side must be intact and separate from the ovary; (2) the gestation sac must occupy the position of the ovary; (3) the gestation sac must be connected to the uterus by the ovarian ligament; and (4) ovarian tissue must be found in the wall of the sac. Since the following case seems to comply with these standards, it is submitted as an addition to the existing literature on the subject.

Case Record

A woman aged 37 was admitted on August 13, 1951, complaining of dull aching left-sided pain of some hours' duration. A similar but less severe attack had occurred one week previously, but had passed off in a few hours. Both attacks had been accompanied by nausea and retching, but there was no vomiting. The pain did not radiate and was not aggravated by movement. The last menstrual period had started on June 29.

The patient had been married for 17 years, but had never been pregnant. In 1942 she and her husband had undergone a series of investigations by a "specialist" in infertility. The scope and nature of these investigations were not clearly revealed by the patient, but she was emphatic in stating that no apparent cause for her failure to conceive had been advanced.

At the time of her admission she had been attending regularly at the out-patient department of the Maudsley Hospital, where she was being treated for what she called "nerves." Her history was otherwise without significance.

Examination showed that the patient's general physical condition was good. Her pulse rate was 80 a minute, regular, and of good volume. Her blood pressure was 105/65 mm. Hg. Examination of the cardiovascular and respiratory systems revealed no abnormality. The abdomen moved freely with respiration and there was no rigidity. Some guarding was noted in the left iliac fossa, where tenderness was elicited on deep palpation. No mass was, however, felt by the examining hand. On bimanual examination the uterus was found to be normal in size and consistence and to be acutely anteverted. No palpable mass could be detected, but tenderness was very acute in the left fornix. A presumptive diagnosis of ectopic pregnancy was made and the patient prepared for laparotomy. Two pints (1.1 litres) of cross-matched blood of the appropriate group was held in readiness.

Operation.—Under thiopentone, nitrous oxide, oxygen, and cyclopropane anaesthesia the abdomen was opened through a subumbilical midline incision. The uterus was found to be normal in size and to occupy the position disclosed by vaginal examination. A few tenuous adhesions were found on the posterior uterine wall, but no evidence of gross inflammation or of endometriosis was detected. The right tube and ovary were normal in appearance, as was the left tube. At the site of the left ovary was a tumour, about 2½ cm. in diameter, which appeared to consist of the ovary in addition to an adherent mass of blood clot. There was no free haemorrhage in the peritoneal cavity. Left oophorectomy was performed and the specimen submitted to the pathologist, Dr. J. H. H. Keale, for histological examination. The abdomen was closed in the usual manner, and the patient made an uninterrupted recovery, being discharged from hospital 14 days later.

Pathological Report.—Microscopic examination of the tissue was performed by Dr. Keale, who reported: "A fibrocystic ovary to which was attached a circular mass of tissue fully 2 cm. in diameter containing a small ragged haemorrhage. Contained in the haemorrhage and lying centrally was a small mass of tissue which was considered to be a very early foetus. A section of this circular mass of tissue showed fibrous tissue, and on the inner edge was a haemorrhage with chorionic villi. A section of the ovary proper displayed a few follicular cysts only." The pathologist concluded that the specimen submitted was "an ovarian pregnancy."

The normal appearance of the left tube, the location of the foetal sac at the site of the left ovary, the fact that the mass was connected to the uterus by the ovarian ligament, and the presence of chorionic villi situated in close relation to ovarian tissue, mark this case as satisfying Spiegelberg's criteria and enable one to classify it as a case of primary ovarian pregnancy.

Discussion

The cause of primary ovarian pregnancy has evoked much speculation, but little that is definite is known concerning it. As recently as 1888 Lawson Tait gave it as his opinion that no such condition existed. When, however, irrefutable evidence to the contrary was repeatedly submitted, challenging medical opinion to explain this phenomenon, endometriosis of the ovary was initially invoked as a convenient and plausible basic cause. In the above case (as in many other cases in the literature) there was no evidence of endometriosis on naked-eye examination of the pelvis, and histological examination of the ovary revealed neither endometriosis nor decidual reaction to implantation.

It is known that fertilization and implantation may occur initially in the Fallopian tube, and that the foetal sac subsequently becomes dislodged, to achieve a secondary implantation in the ovary (secondary ovarian pregnancy). It is possible also that even when the tube on the affected side presents a normal appearance it nevertheless is the primary site of implantation in certain cases hitherto classified as primary ovarian pregnancies. Not all cases can, however, be explained away in this fashion, as fastidious

Ovarian mass split to reveal gestation sac of very early foetus.

histologists have in many instances subjected the apparently normal tube on the affected side to serial histological examinations and in the end have been compelled to concede it normal upon the basis of a complete absence of chorionic tissue.

Curtis (1941) suggested that in certain cases the ovum, after becoming fertilized in the Fallopian tube, may "slide downwards to the gaping recently ruptured ovary, there to develop." Other writers, like Mann *et al.* (1941) believe that "the ovum becomes fertilized while remaining in the follicle and develops its sac from contiguous ovarian tissue." Each of these views has the merit of plausibility, and it is not improbable that both processes may occur.

In view of the unfavourable nature of the implantation site it might be supposed that ovarian pregnancies generally would come to an abrupt and early termination. Statistics, however, do not support this view, and Dale (1947) collected from the literature 38 cases in which the pregnancy had proceeded beyond seven months, and from which 12 living infants had been produced.

Lithopaedion formation has been recorded in several cases of ovarian pregnancy, and De Lee (1943) reports an ovarian hydatidiform mole. The coincidence of ovarian pregnancy and eclampsia reported by Pride and Rucker (1942) may, however, claim distinction as a rarity of rarities.

Many writers have stressed the relatively slight danger of alarming haemorrhage in ovarian pregnancy as compared with the tubal variety, and the above case in this respect conforms to type. Indeed, it stands out in my experience as one of the very few cases of ectopic pregnancy in which the administration of a blood transfusion would have been completely without justification.

Summary

The relative rarity of primary ovarian pregnancy is stated, with statistical support.

Spiegelberg's criteria of primary ovarian pregnancy are quoted and a case is reported which seems to satisfy these criteria.

Various views on the aetiology of primary ovarian pregnancy are mentioned, with brief comment.

The unexpectedly high proportion of viable infants resulting from ovarian pregnancy is mentioned.

The relative infrequency of severe haemorrhage attendant upon this type of ectopic gestation as compared with tubal pregnancy is stressed.

I am indebted to Mr. Douglas M. Lindsay for permission to report this case, which occurred in his unit at Beckenham Hospital.

DELAYED CHLOROFORM POISONING IN OBSTETRIC PRACTICE

BY

R. L. LUNT, M.B., M.R.C.O.G.

Senior Registrar, Royal Berkshire Hospital, Reading

Cases of delayed chloroform poisoning in obstetric practice have been reported by numerous writers. The outcome in many of the cases was fatal. Nine of the 10 cases reviewed by Gibberd (1935) were fatal. Stander (1932) reports a mortality of 80% in five cases. This figure is regarded as too pessimistic by Sheehan (1940), since his last six cases recovered and two of them were very severe. Clinical histories of three patients who developed delayed chloroform poisoning are here briefly described.

Case 1

The patient, aged 24, was admitted to hospital on January 10, 1947, following a difficult forceps extraction under chloroform anaesthesia at home 48 hours previously. This was her first confinement and followed a normal antenatal period. The duration of labour was 83 hours. The food and fluid intake had been insufficient during this time, and the patient had experienced troublesome vomiting.

On admission she was drowsy and slightly jaundiced. There was no vomiting. Her blood pressure was 130/85 and her temperature 99.8° F. (37.7° C.). Prophylactic penicillin had been given since delivery. There was no liver tenderness or enlargement. Shortly after admission she became very restless and cried out as if in pain. This was associated with muscle-twitching. Periods of extreme restlessness occurred during the next three days, and on occasion she became almost maniacal. The jaundice deepened during this time. No vomiting occurred and sips of fluid were taken. Her condition then gradually improved, and a slow, steady recovery was made.

Retention of urine before and after admission into hospital necessitated catheterization. The urine output was always satisfactory. A bacteriological examination of the urine showed a *Bact. coli* infection, and the cervical swab yielded a growth of haemolytic streptococci. The blood culture was negative. Pyrexia persisted for several days after admission, but responded to penicillin and sulphonamide therapy.

Intravenous dextrose therapy was given on admission and continued for five days. In each 24 hours two litres of 5% dextrose and one litre of 4.3% dextrose in 0.18% sodium chloride were given. Five units of soluble insulin twice a day, 20 ml. of 10% calcium gluconate intravenously, and vitamin B by injections were given each day. Intramuscular paraldehyde was administered when necessary to control the restlessness.

Laboratory Investigations.—On January 11 (third day after delivery) an immediate positive van den Bergh reaction was given by the serum. The indirect van den Bergh reaction was 5.8 units; this increased to a maximum of 10.3 units on January 13. The alkaline phosphatase was 21.4 King-Armstrong units on January 11 and 22.3 on the 15th; it then slowly returned to a normal level. At all times the colloidal gold test showed no precipitation (0). The Takata-Ara reaction did not show a positive result, and the serum thymol turbidity varied between 0 and 3.2 units. Other blood chemistry estimations on January 11 showed the alkali reserve 34 vols. CO₂ per 100 ml., with the chlorides and total protein within normal limits. The blood urea was 108 mg. per 100 ml., and remained raised for several days. On January 15 the blood urea was 104 mg. per 100 ml., and then returned to a normal level. The urine contained bilirubin and urobilin. The Rothera test was negative on all occasions before and after the beginning of intravenous dextrose therapy. The blood-sugar level of 135 mg. per 100 ml. of blood on January 13 was probably influenced by the dextrose therapy.

Reviews

BRONCHOSCOPY AND OESOPHAGOSCOPY

Bronchoesophagology. By Chevalier Jackson, M.D., and Chevalier L. Jackson, M.D. (Pp. 366; 263 illustrations. £3 3s.) Philadelphia and London: W. B. Saunders Company. 1950.

This is a fourth edition, considerably revised and under a new title, of a well-known and very successful book. It is based, essentially, on the fundamental work of Chevalier Jackson senior, whose name will always be associated with the development, organization, and establishment of safe bronchoscopic and oesophagoscopic methods. As a pioneer in this field he is unequalled. His son and co-author carries on his father's good work. The horrid title is defended by the explanation that the book sets out to do more than present the bare bones of endoscopy and tries to give the whole picture of the diseases of the bronchi and oesophagus.

The most important part of the book is the presentation of technical methods. The Philadelphia school of endoscopists, led and inspired by Chevalier Jackson, have justly achieved a world-wide reputation for their efficiency, skill, and dexterity. Your reviewer was privileged, 22 years ago, to work at the Chevalier Jackson Clinic at Jefferson Hospital under the tutelage of Dr. L. H. Clerf, and will be ever grateful for the kindness and proud of the splendid training received. A lasting knowledge can be rapidly obtained when one is taking part in some 100 examinations a week. The memory is still vivid of the effortless and rapid dexterity of technique, especially in removal of foreign bodies. Objects that had perhaps already defeated several attempts at removal elsewhere would be extracted in some two minutes by the stop-watch.

The vast experience of the Philadelphia schools in removing foreign bodies of every conceivable type from the bronchi and oesophagus is unique and probably always will be. In this book the reader can learn from this accumulated experience; he can use it as a textbook or as his reference book when faced with the problem of dealing with a foreign body. An interesting development is the use of the magnet; less attractive is the account of extraction of foreign bodies by external puncture. One wonders also how often the elaborate technique of removing small pins, etc., from peripheral bronchi is really justified. Most of these small foreign bodies are better left alone.

The authors take great care in describing the position of the head and shoulders in introducing the bronchoscope or oesophagoscope, and the necessary alterations during further passage of the instruments. The Jackson contribution in these matters is classic. As my own knowledge rests entirely on what I learnt in Philadelphia I am hesitant about calling attention to the position of the head as depicted diagrammatically in Fig. 30c and other diagrams. It does not seem anatomically possible, if the neck is fully flexed on the trunk, for the head to be hyperextended on the neck. I have always remembered the instruction that for exposure of the larynx the plane of the face should be *parallel* to the plane of the body surface and as much above it as possible. These diagrams showing the head hyperextended will encourage the inexperienced operator to try to introduce the bronchoscope with the head thrown back and the neck not flexed on the trunk. It would be an advantage if diagrams such as this were either replaced by or supported by actual photographs. The numerous photographs of the grouping around the patient at endoscopy do not show the head position clearly.

Incidentally, in all the photographs the members of the team wear their mask with the nose uncovered. Quite apart from the risk of contamination from the operator, there is the grave risk of infection of the operating team by the patient. This also should be altered in future editions. Spectacles are recommended, and a nurse to stand by and change the spectacles as they become soiled. The Negus

face-shield not only gives much more protection, but also dispenses with the need for a nurse to stand by.

Chevalier Jackson's valuable contribution in describing so clearly the various check-valve actions in bronchial obstructive lesions is well known and is fully explained, but the frequent repetition of description and of diagrams illustrating it becomes rather tedious and might with advantage be lessened. Physicians would do well to pay attention to the counsel: "Every medical student should be taught that no physical examination of the chest is complete without listening at the patient's open mouth for a wheezing sound." This invaluable sign often provides more information and in a much shorter time than can be achieved with percussion and the stethoscope.

The account of lung abscess leaves much to be desired, especially the suggestion that acute post-tonsillectomy lung abscess "is a distinct type." The claims for a high degree of success in bronchoscopic therapy are less enthusiastically pressed than in the past—a change that should meet with general approval. The claims of bronchoscopy in diagnosis and examination are ably set out.

The value of examining aspirated bronchial secretions for malignant cells in the diagnosis of bronchial carcinoma is fully presented, but a notable omission is any reference to Dudgeon's wet-film method, evolved at St. Thomas's Hospital, which forms the basis of this investigation. Surely his contribution should be acknowledged.

In describing the dangers of oesophagoscopy more emphasis should be placed on acute perforation of the oesophagus and the need for prompt thoracotomy and closure of the rent by suture. A special account of this disaster and its management should be given. Too much is said of treatment of residual abscess and too little of immediate recognition of the disaster and its reference to a surgeon; many patients with perforations never live to develop a residual abscess.

These criticisms are not meant to be derogatory and are almost trivial in relation to the vast amount of first-class information clearly and authoritatively presented.

There is, however, one big criticism that must be made; it is not meant to belittle, and in some ways it is embarrassing to make it in view of the ripe experience of and the respect due to a pioneer of the quality of the senior author. It is now well over a quarter of a century since the bronchoscopic and oesophagoscopic technique, as described in this book, was established at Philadelphia. It was a triumph of organization and performance, allowing safety and success to be achieved. Very large numbers of pupils have been taught these methods with great advantage to everyone. Yet there has been almost no significant change in the basic technique and in the instruments used. The elaborate head-holding technique, for instance, is a quite unnecessary waste of man-power, and rather pathetic when one sees it slavishly followed by devotees in many places. It seems to be in danger of becoming a traditional ritual indulged in by the disciples of the Jackson school.

The same criticism applies to the bronchoscopes and oesophagoscopes used. These also have remained unchanged throughout the years, presumably because they are thought to have achieved perfection. The jealous guarding of their design is also fast becoming a tradition, for they have been outdated and outmoded by other instruments just as the motor-cars of the same vintage have been replaced by later and more efficient models. The continued, unquestioned acceptance of these obsolete instruments by the devotees is somewhat remarkable. If this state of affairs continues much longer, the Jackson type of bronchoscope and oesophagoscope will attain a dignity due to custom and usage only comparable to that of a sacramental weapon or staff. Sooner or later the break will have to come unless it is to remain as unchanged as Holy Writ.

The bronchoscopes are very wasteful of space. The wall is unnecessarily thick compared with the lumen, and even the effectiveness of this is further encroached upon by the excessive projection of the light-carrier channel. The lip of the instrument is also too big and clumsy, especially in the smaller sizes, when every fraction of a millimetre counts. The Negus type of instrument, which has been used for

many years in Britain and has almost completely displaced the Jackson instruments, has none of these disadvantages; the size and construction are as economical as possible and give a much more generous view and operating space. The objections to the Jackson type of oesophagoscope are less serious, but the Negus type of instrument is similarly much more efficient.

Your reviewer is anxious to repeat that these criticisms are made only with a full sense of the respect due to the great contributions and pioneer work of the Jackson school and are not meant to be unkind or disparaging. The book itself should be familiar to all those, whether thoracic surgeons or physicians or "bronchoesophagologists," who have to deal with the oesophagus and air passages.

R. C. BROCK.

PRACTICAL DERMATOLOGY

Practical Dermatology for Medical Students and Practitioners. By Professor George M. Lewis, M.D., F.A.C.P. (Pp. 328; 99 plates. £1 17s. 6d.) Philadelphia and London: W. B. Saunders Company. 1952.

This is a simple presentation of dermatology for students and general practitioners. It is an admirable book, easy to read, well produced, and excellently illustrated in black-and-white. With no more than six pages of introduction the author gets into the heart of his subject, discussing with much common sense the various groups of dermatological ills in a manner that any doctor can understand. Though the introduction deals with the special features of dermatology, it is mostly devoted to the taking of an adequate history, performing a thorough physical examination (not limited to the skin), and verifying clinical assessments by laboratory tests.

There is a pleasing and judicious use of heavy type to emphasize the essentials in each paragraph. The balance and proportion of the work are excellent, and there is no section that falls short of this high standard. The presentation of psoriasis and the summary of the problem of eczema are admirable. There is also a section on the acute specific fevers. Only very occasionally is the variation of American from British experience felt, as in the presentation of tuberculosis and erythema nodosum and the scant attention to chilblains. The section on fungous diseases is particularly good and there is here a warning against excessive treatment.

The author is clearly a sound and experienced physician, and there are few criticisms to be made of his work. He does not mention the course and prognosis of dermatitis herpetiformis, the fact that black hairy tongue often results from sucking penicillin lozenges, or that ichthyosis may respond to large doses of vitamin A. The treatment of rosacea is perhaps a little inadequate, but these are small points. How true are such injunctions as that "sympathetic listening, allowing the patient to ventilate his problem, is often an important part of treatment," and that "acne should be taken seriously and the patient treated with sympathy and understanding." In the account of pyoderma there is a warning against the use of antibiotics in a routine fashion; each case should be treated on its merits.

This is a most important and valuable addition to the literature and is just the type of work which the student and practitioner require.

J. T. INGRAM.

CHEMICAL INDUCTION OF CANCER

Chemical Induction of Cancer. By George Wolfe, B.Sc., D.Phil. Foreword by Professor Alexander Haddow. (Pp. 250. 17s. 6d.) London: Cassell and Co. 1952.

This work is a general compilation of all that is known on the induction of cancer by substances of known constitution. Professor Alexander Haddow in his introduction says: "So far as concerns the experimental reproduction of the disease and the understanding of the biological process involved, no more useful or more succinct general account can be recommended than that in the pages which follow," and the reviewer could not improve on this statement.

The book can be recommended for the general medical and biological reader who wishes to have exact information on this subject. Very wisely, the author begins with a readable general account of the structure of condensed carbon ring compounds; it will certainly be useful to the general reader. He then, through subsequent chapters, reviews the various types of compounds with carcinogenic activity, and discusses in other chapters their possible mode of action, effects on enzyme systems, and their metabolism in the body. The work is well indexed and will be valuable in any medical or biological library.

E. C. DODDS.

MOLLUSCIDES

Molluscicides. By Alan Mozley, D.Sc., Ph.D., F.R.S.Ed. (Pp. 88; illustrated. 9s.) London: H. K. Lewis and Co. 1952.

This manual should be of interest to readers who wish to learn the main facts about molluscicides and how they are applied. The author outlines their importance in controlling diseases of man and animals caused by trematode parasites and discusses their toxicity (to organisms other than snails), the preliminaries to application, and the different methods of applying them. Three kinds of molluscicides are recognized—those of vegetable origin, synthetic organic substances, and inorganic salts. The fruits of some species of *Balanites*, *Swartzia*, and *Sapindus* contain saponins which are toxic to snails. The roots and rhizomes of *Derris* spp. and the leaves and flowers of *Tephrosia* spp. also contain molluscicidal substances. The author thinks that neither these nor the synthetic organic substances—the latter are the subject of much research at present in America—include the ideal molluscicide. He favours the salts of copper, especially the sulphate and the carbonate, but considers that members of the other two groups may be used advantageously in conjunction with copper salts.

In four appendices the author describes briefly the life cycles of *Schistosoma* and *Fasciola*; gives directions for finding snails and examining them for infection; reports a field experiment conducted by himself in Southern Rhodesia; and gives practical instructions for treating a pond, pool, tank, or swimming bath with copper sulphate.

J. J. C. BUCKLEY.

RHEUMATIC DISEASES

Rheumatic Diseases: Diagnosis and Treatment. By Eugene F. Traut, M.D., F.A.C.P. (Pp. 942; 192 illustrations. £7 10s.) London: Henry Kimpton. 1952.

This is an ambitious and well-produced volume intended to review the whole field of the rheumatic diseases. It is produced by a group of physicians working in and around Chicago, but appears in places to reflect their personal preferences and prejudices rather than, as is their avowed intention, current world opinion. There are indeed very few references to work published outside the United States. Examples of these personal views will be found in the advocacy of vaccine treatment, the statement that gold salts cannot be recommended as a safe therapy, and the importance still placed on focal infection. The arrangement and nomenclature of the chapters will also prove rather puzzling to English readers; for example, although Chapter 3 is entitled "Psychologic Factors in Rheumatoid Arthritis," there is no separate chapter on adult rheumatoid arthritis, nor on osteoarthritis, although these entities are naturally well covered, incidentally, in the text.

This is one of those books that one feels would have been a great deal better if the editor had been content with half its present size. It is nevertheless a valuable acquisition for the rheumatologist's library, since it provides an interesting and somewhat unusual viewpoint of the subject and is extremely well illustrated.

W. S. C. COPEMAN.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 28 1953

FIRST WORLD CONFERENCE ON MEDICAL
EDUCATION

As has already been announced in this *Journal*¹ the First World Conference on Medical Education will be held in London in August of this year, under the presidency of Sir Lionel Whitby, Vice-chancellor of Cambridge University; the deputy president is Professor W. Melville Arnott, of Birmingham University. The Chancellor of the University of London, the Secretary of State for Scotland, and the Ministers of Education and Health for England and Wales have kindly agreed to act as patrons. Elsewhere in this issue (p. 503) we give details of the programme.

The work of the Conference will be carried on in the four principal sections meeting simultaneously throughout the week, under the chairmanship of the four vice-presidents of the Conference: Dr. Victor Johnson, Director of the Mayo Foundation, Sir A. T. Mudaliar, of the University of Madras, Professor Alberto Hurtado, of the University of San Marcos, Lima, and Professor René Sand, of the University of Brussels. They will be in charge respectively of the following sections: "Requirements for Entry into Medical School," "Aims and Content of the Medical Curriculum," "Techniques and Methods of Medical Education," and "The Teaching of Preventive and Social Medicine." Doctors from many countries have already accepted invitations to speak at the Conference, which promises, therefore, to provide a real opportunity for an international exchange of views on the important topic of medical education.

The World Medical Association initiated the Conference, and it is being held under its auspices, the British Medical Association, as a member of the W.M.A., acting as the host organization and making itself responsible for the local arrangements. The World Health Organization has joined with the W.M.A. in sponsoring the Conference and has a

special interest in the fourth section of the programme—"The Teaching of Preventive and Social Medicine." The C.I.O.M.S. (Council of International Organizations of Medical Sciences) has also been of great help to the Organizing and Programme Committees, as, too, has the I.A.U. (International Association of Universities).

In the conception and planning of the Conference, therefore, three international organizations under the W.M.A. have taken an active part and will continue to do so; it is hoped the outcome will be of value to those responsible for medical education in different parts of the world. Limitations of time and money will unfortunately make it difficult for medical educators from far distant countries to be present in London in August, but there will be as wide a representation as is possible in the circumstances. The three official languages of the meetings will be English, French, and Spanish, and simultaneous translation will be available in every session. The Conference will be open to members of the medical profession and also to non-medical teachers who may have a special interest in some of the subjects of the programme.

The general theme of the Conference is undergraduate medical education, and no attempt will be made to go beyond this into discussions on post-graduate education—which one of these days may well be the subject of another congress. As the titles of the themes given in the programme may suggest, the aim will be to concentrate on principles and methods rather than on the minutiae of the medical curriculum. It would, in fact, be impossible to try to draw up in August this year the details of a curriculum which would satisfy even the different medical schools of Britain. The title of Sir Lionel Whitby's Presidential Address, "The Challenge to Medical Education in the Second Half of the Twentieth Century," provides the keynote of the meeting. In the programme there are, of course, certain well-worn themes of medical education, and it is hoped that the principal speakers at the Conference will not hesitate to challenge some of the conceptions that traditionally lie behind these. There will, too, be discussion on themes that are new, or at least new in relation to present medical curricula in the various countries. In the section "Requirements for Entry into Medical Schools," schoolmasters and medical men will exchange views on the subject "General Education in an Age of Science." The type of human being the future doctor will be will depend to a large extent on the kind of education he has

at the secondary school stage. Reports on medical education so often pay lip service to the need for a broad education in the humanities, and then we see our ancient universities in this country insisting that a boy or a girl should pass the First M.B. before going, for example, to Oxford or Cambridge. This often forces the schoolboy into specialization in the basic sciences, and the schoolmaster, with the examination hurdle in mind, finds it difficult to provide an education that will fit the boy to be an intelligent citizen of the world. The programme, too, suggests a different approach to the First M.B. itself in providing for a discussion on "The Teaching of the History of Science" and of "The Scientific Method," and on "The Introduction to the Social Sciences." The Conference may decide that room could, or even should, be found for such subjects at the First M.B. stage, and this could be done if the student was less burdened with memorizing a large number of facts and formulae in order to protect himself against the unkind tricks the examiner may play on him. In the second section of the Conference surgeons and physicians will take a prominent part in the discussions on the teaching of anatomy and physiology, and the movement towards a new conception of this is shown in the title "The Integration of Physiology and Anatomy as a Single Subject in the Medical Curriculum." The title "Science is Measurement" in the premedical phase of the curriculum suggests that the Programme Committee would like to see some continuation of the teaching of mathematics so as to prepare the student for an introduction in the Second M.B. period to medical statistics.

Recent reports on undergraduate medical education stress that its aim is to produce an educated doctor and not any one particular type of doctor. Indeed, if we are to maintain and substantiate our claim to be a learned profession the teaching of medicine must be imbued with the university ideal. If the foundations are well and truly laid on the basis of principle and method, then the other things will be added with no great difficulty, whether the qualified doctor is to go into general practice, specialist practice, research work, teaching, or administration. Nevertheless, the majority of medical students will, after qualification, go into the most strenuous branch of medicine—that of general practice. The Programme Committee has therefore arranged for discussions on "The Undergraduate and General Practice," "Teaching in the Home," and "The Home Setting in Medical Education," these three subjects being dealt with in different sections. It is hoped general practitioners

will take an active part in the open discussion on these, as well as on other subjects. One morning will be given to a review of visual aids in medical education, and to supplement this the Film Committee of the B.M.A. expects to arrange a demonstration of visual aids in the intervals between the morning and afternoon sessions during the week.

August has its disadvantages as a month in which to hold a conference, but it is a month in which medical teachers can take a busman's holiday without leaving their students in the lurch. Many distinguished medical men are coming from various parts of the world to say their piece and to listen and perhaps learn from others. Apart from the work of the sections, they will welcome the opportunity of meeting their colleagues from other countries, and in particular from Britain. Time and money inevitably limit the number of persons who can be specially invited to speak, but time has been allowed for open discussion of each subject in each section. It is hoped that as many as possible of the teaching staffs in Britain will find it possible to attend at least part of the Conference so that they can meet and welcome their colleagues from abroad. The W.M.A. itself is anxious that the "practising physician," as, so to say, the consumer of medical education, will also seek to make his voice heard in the debates in the four main sections of the Conference.

RESPIRATORY FUNCTION

It has been said that science is measurement. But this is only partially true, for there is much that is merely qualitative description and reasoning in the content of science. Nevertheless, when a body of knowledge passes from the qualitative to the quantitative stage notable advances occur. Quantitative study of respiratory function is a case in point. The problem in this field is not only what to measure but also the assessment of the significance and relationship of the many measurements which can be made. In hardly any other branch of human physiology is it possible to amass so many figures in so short a time. Many investigators have tended to confine their observations more or less exclusively to one particular variable of respiratory activity. There have been those who have measured static volumes of the lungs, others have concentrated on rates of mixing, while the more sophisticated have realized the paramount importance of ventilation-perfusion relationships. Other workers have appreciated the indissoluble partnership between the circulatory and respiratory

¹ *British Medical Journal*, 1952, 2, 480.

systems and have brought to the study of pulmonary function the cardiac catheter and all its possibilities of pressure-flow measurements in the heart and lungs.

All this new knowledge is not exclusively a matter of academic science but of vital importance to patients. The obliteration of the tuberculous cavity and the removal of the neoplasm necessitate profound structural alterations of the respiratory system. Such questions as, "What is his respiratory function at present?" and, "How can we control this disease with a minimum loss of respiratory function?" arise continuously in thoracic medicine. It is only by the careful study of pulmonary function before and after various operations and other therapeutic procedures that the answers to the latter question will be obtained. An accurate answer is as important as a good histopathological report on the biopsy specimen. Dr. K. W. Donald in the two articles we have published in this and last week's *Journal* has given a most helpful, and much-needed, survey of respiratory function and reviewed the relative value of many different methods of investigation. All aspects of respiratory function are subservient to the efficient exchange of oxygen and carbon dioxide between blood and atmosphere. Spirometric studies alone have obvious limitations, and Donald recommends beginning with ventilatory studies, proceeding as experience is gained to arterial blood studies, and ultimately to consideration of ventilation-perfusion relationships. He also emphasizes that the effect of lung disease on the right heart is a relatively unexplored subject which would repay investigation with clinical rewards.

Donald's paper makes it plain that respiratory physiology is a matter which closely concerns the clinician. A sound knowledge of cardio-respiratory physiology adds greatly to clinical acumen and the correct interpretation of physical signs. As a result of recent physiological studies the physician is now able to recognize interference with oxygen diffusion in the lungs with tolerable certainty. The dangers of carbon-dioxide narcosis in oxygen tents have also been pointed out to the previously unsuspecting clinicians. The grave import of even slight cyanosis with a normal cardiac output and blood count is another urgent clinical matter: such patients may have an arterial blood saturation below 50% at a time when there is still doubt whether significant cyanosis is present. Many of these measurements require the presence of the patient in the laboratory, and it is now time to regard such investigations with something more than the usual good-tempered indul-

gence towards a few pioneering back-room boys. Clinicians investigating thoracic disease might well consider devoting as much personal attention to the assessment of respiratory function as they do to the discussions with the pathologist, to radiological screening, and to surgical operation. Physiological studies cannot be established and made useful in a short time. Practice and experience in their application, in constant association with clinical medicine, are required before rich dividends are likely. British workers in this field have no grounds for complacency. The main recent developments in both theory and practice have occurred in the United States. It is an illuminating experience to go from centre to centre there and see how extensive physiological studies are made on patients with respiratory disease and how such studies condition and improve the clinical work. For many years now radiology and morbid anatomy have been the predominant tools of clinical investigators in this country. Essential as these are, clinical physiology should now play its full and equal part in the practice of thoracic medicine and surgery.

A JOURNAL AND ITS READERS

Under this title the Editor of the *New England Journal of Medicine* recently observed¹ that "the most prominent feature of any journal is its original papers," and that, "obviously, few papers will be of universal interest to all the Journal's readers." He quotes with approval the comment of the Editor of *Science* that a journal is not so much what "its editors would like it to be, as what its contributors make it." And so it is with the *B.M.J.* In attempting to carry out the first object of the B.M.A.—"to promote the medical and allied sciences"—the *Journal* follows the sound tradition of putting first things first, and in an art and science practised by a learned profession the first things are contributions to knowledge, contributions, in the nature of things, varying in importance and interest to the generality.

Clifford Allbutt said in 1919 that medicine was becoming less of an art and more of an applied science. What would he have said to-day? Those of our readers who are at the peak or over of middle age must find the pace of medical research fast and furious, and the expression of it in the printed pages of medical literature tough going. What appears in the *B.M.J.*, and in other similar journals, is but a reflection of work in progress; it represents the results of investigations made by medical men into

¹ *New Engl. J. Med.*, 1952, 247, 577.

the causes and effects of disease and into the conditions of health. In these investigations there can scarcely be a science whose aid is not brought in to help to solve the problems of medicine; and so the language of medicine becomes scientifically ever more polyglot, and the tools it uses have to be applied with ever greater precision. It is more difficult than before for the "average" doctor (if there is such a person) to keep up to date, or even, on occasion, to understand the scientific ins and outs of a medical paper: indeed, it is probably easier for his medical student son or daughter. But that is the penalty of progress in medical science. As the Editor of the *New England Journal of Medicine* stresses, "a function of a journal such as this is to present the results of original investigations and observations in any field that pertains to medicine." The *B.M.J.* is a "journal such as this," and with its circulation in the region of 78,000 copies weekly goes to all kinds of doctors in all parts of the world. It is not a journal for general practitioners, or consultants, or public health officers, or laboratory workers. It is a journal which aims at representing the best of British medicine in order to "promote the medical and allied sciences." It tries to provide each week something for everybody, not everything for somebody.

The general practitioner, it is true, is specially catered for in the "Refresher Course" series and in "Any Questions?" But it may be questioned whether the multiplication of journals for general practitioners is a healthy tendency in medical journalism. It is a tendency which has behind it the assumption that the general practitioner is intellectually inferior to his colleagues, that for him medicine is somehow a different kind of profession than it is for others, that medical science in the making is something from which he should avert his eyes as being beyond his understanding. This tendency, carried to its limit, would make medical science and research esoteric mysteries into which the G.P. would not be initiated. We can think of nothing that would in the long run be more detrimental to the prestige and welfare of the G.P., or more harmful to medicine.

A journal such as the *B.M.J.* tries to put before its readers the whole of medicine, not just parts of it. It can do this because all medical men have had the same basic training and intellectual discipline; all are members of a learned profession. No reader should, we suggest, expect to find something of special interest to him on every page or, indeed, in every section of the *Journal*; any more than he

should expect to find something of special interest to him in every section, say, of *The Times*. To those who find the substance of some original articles hard to digest we can but offer apologies on behalf of modern medicine, the hard taskmaster of us all and in the last resort provider of the matter which fills these pages.

THROMBO-ANGIITIS OBLITERANS

Buerger regarded thrombo-angiitis obliterans as a specific inflammatory disease of unknown cause leading to progressive obliteration from the periphery of the vessels of the leg, occurring before the age of 40, affecting mainly Jews, and sometimes causing also a migrating thrombo-phlebitis. Subsequent recognition of other causes of vascular occlusion in the same age group has led to difficulties in diagnosis which are outlined by Dr. R. L. Richards elsewhere in this issue. As he points out, it is now agreed that Buerger's disease has no special predilection for the Jewish race. Nor is venous thrombosis a pathognomonic sign, for Lisa, Magiday, and Hart¹ found it in 19 of 53 limbs amputated for arteriosclerosis. Even the specificity of the pathological findings has been questioned by Boyd and his colleagues,² though most authorities do regard the histological changes as distinct from those seen in other forms of occlusive vascular disease.

Remarkably few cases with histological proof have been recorded, and analysis of the clinical features of large series of cases, whose true pathological basis is often in doubt, has done little to clear up the difficulties in diagnosis. Of Richards's 85 cases, 22 had the diagnosis proved pathologically, but unfortunately he has not analysed these separately. The diagnosis has been disproved in two of the other cases, and Luke's experience³ suggests that many more may not in fact be examples of Buerger's disease. Luke made histological examinations of leg arteries from 19 patients in whom a diagnosis of thrombo-angiitis obliterans had been made on clinical criteria similar to those adopted by Richards, and was able to confirm the diagnosis in only four cases.

Richards states that one of the two criteria which remain reliable indications for a diagnosis of thrombo-angiitis obliterans is the constant association with tobacco smoking. Telford,⁴ however, refers to undoubted cases in men who had never smoked. The traditional view that heavy smoking predisposes to the development of the disease is based almost entirely on clinical impressions. Harkavy, Hebal, and Silbert⁵ found positive skin tests to extracts of tobacco smoke in 83% of 68 patients with Buerger's disease and in only 10% of 107 controls. Sulzberger⁶ found positive skin

tests to tobacco extract in 78% of 24 patients with Buerger's disease; of his controls, 36% of 95 smokers and 16% of 58 non-smokers gave positive tests. However, almost as high a percentage of the patients with Buerger's disease gave positive tests to other allergens, and the results of the skin tests cannot be regarded as strong evidence of a special association between the disease and smoking. Shepherd⁷ appears to have established that cigarette smoking leads to constriction of peripheral vessels, so that patients with all forms of arterial insufficiency should certainly try the effect of giving up smoking. But a properly devised statistical investigation is needed before a history of heavy smoking from a patient with occlusive vascular disease can be regarded confidently as a point in favour of the diagnosis of thrombo-angiitis obliterans.

INTRINSIC FACTOR

Ever since the pioneer experiments of Castle¹ research workers have striven to purify and identify the "intrinsic" and "extrinsic" factors. Within recent years extrinsic factor has been identified as vitamin B₁₂,² but the exact nature of intrinsic factor is still undetermined. Nevertheless much is known about the properties of intrinsic factor, and recent work in the U.S.A. has led Glass and his co-workers^{3,4} to suggest that one of the components of gastric mucin, "glandular mucoprotein,"⁵ might be identical with it, or at least be the main carrier of intrinsic factor in human gastric juice. Certainly the similarities in behaviour from the laboratory point of view between glandular mucoprotein and intrinsic-factor-containing material are close. Moreover, glandular mucoprotein has been shown to be absent from, or present only in traces in, gastric juice from patients with pernicious anaemia.⁴ The American workers found that daily oral doses of 50-75 mg. of glandular mucoprotein given with 30 µg. of vitamin B₁₂ usually sufficed to produce optimal haematological responses in patients with pernicious anaemia.

In the opening pages of this issue Drs. A. L. Latner and C. C. Ungley, with their associates, describe work which has been proceeding in Britain on rather similar lines. Normal gastric juice was ultrafiltrated, freeze-dried, and finally reconstituted in a concentration 150-200 times stronger than the original. The concentrates were submitted to filter-paper-strip electrophoresis. Liquid from segments of the filter-paper strips was then tested for B₁₂-binding activity by microbiological assay and also for haemopoietic activity when given to patients with pernicious anaemia as a single oral dose, together with 50 µg. of vitamin B₁₂. Two peaks of B₁₂-binding and haemopoietic activity were demonstrated as a result of electrophoresis of the gastric-juice concentrates; one was on the cathode side and the other on the anode side of the starting point. The material from the anode

peak was more active haemopoietically, and Latner and Ungley state that this material contained either a mucoprotein or a mucopolysaccharide. They claim also that the material at the cathode peak, although containing more mucoprotein, had less intrinsic-factor activity.

Thus important progress in the identification of intrinsic factor has been made both in the United States and in this country. Neither group of workers claim, however, that they have isolated intrinsic factor in a pure form. Have these advances a practical bearing on the treatment of pernicious anaemia? Enough human gastric juice will never be available for human intrinsic factor to be prepared on a commercial basis, but if intrinsic factor could be extracted economically from animal stomachs in a sufficient degree of purity, then the taking of perhaps a few milligrams of the material with a still smaller amount of vitamin B₁₂ in the form of a small capsule would be a way of treating pernicious anaemia which would be most convenient from the patient's point of view. On the other hand, crystalline vitamin B₁₂ is now readily available at a low price, and if given intramuscularly in sufficient dosage at two- or four-weekly intervals it provides a highly effective method of treatment. It has, too, the advantage over oral therapy that the patient necessarily remains under the doctor's personal supervision.

CHLOROFORM IN OBSTETRICS

In November, 1847, Professor James Young Simpson first used chloroform to relieve the pains of childbirth. Three months later the first death due to it was reported. Later the scientific papers, conferences, and commissions of the mid-Victorians clearly showed their concern at the death rate associated with so promising a drug. In the twentieth century we are still trying to find safer substitutes. But at least the causes of death have been clarified: they fall into three groups.

The first comprises cases of sudden cardiac arrest during light anaesthesia. The condition may be due to either ventricular fibrillation or ventricular arrest. Despite ideal conditions, there were four cases of ventricular arrest in Waters's series¹ of 1,000. His patients would have died had not all the facilities for resuscitation been available. Many will think these figures are enough to condemn the use of chloroform outside highly organized operating-theatres, and especially in the patient's own home. The second group of fatal cases comprises those of gradual cardiac and peripheral circulatory failure in the deeper planes of anaesthesia. This complication is easily recognized nowadays and can be treated promptly with oxygen and lowering of the head. The third group is of cases where liver failure occurs two to three days after the administration. Elsewhere in this issue Mr. R. L. Lunt describes three cases of jaundice in the puerperium following the use of chloroform for the delivery. Waters concluded that

chloroform caused only slightly more liver dysfunction than other anaesthetic agents. It is probable that the combination of the factors described by Mr. Lunt with the metabolic derangement resulting from any anaesthetic is more important in the causation of liver failure than any specific anaesthetic drug.

No single agent has been found with all the advantages of chloroform, although there are many which, when combined, give better results with greater safety. Chloroform has therefore lost its place in the anaesthetic room and operating-theatre to linger in its original domain—the home of the woman in labour. Here a single drug which is portable, non-inflammable, potent, and reliable is ideal, but if the risk of using chloroform in domiciliary obstetrics is not justified then safe and convenient substitutes must be provided. For intermittent analgesia the combination of pethidine and nitrous oxide and air supervised by the midwife is fairly satisfactory. The adoption of a safe automatic trichlorethylene inhaler for use by the midwife would improve the service she could give her patient.² For forceps delivery and other manoeuvres, when there are no fires or naked flames, ethyl chloride followed by ether on an open mask is a good and safe anaesthetic. Fires can sometimes be extinguished, but when this is not possible, or when lighting is dependent on gas or oil, or in great urgency, intravenous thiopentone in small dosage can be given and anaesthesia maintained with trichlorethylene and air. This technique should be used only if the administrator is confident that he can maintain a good airway and treat apnoea by controlling the respiration with a simple inflator.

GREASE ON THE SKIN

The skin is a self-sterilizing surface. *Streptococcus pyogenes* does not survive very long on it, and some other pathogenic bacteria are apt to die out. Ringworm has been known to clear spontaneously at puberty when the secretion of fungicidal fatty acids increases, while adult hair is protected against infection by its covering of such fatty compounds. It is the semi-fluid surface grease or sebum from the sebaceous glands which gives this protection, and the body produces 1-2 g. daily, half of it on the scalp.¹ This is enough to give a layer 0.7 µ thick, which would be visible in histological sections of skin if the usual preparative methods did not dissolve it off. The layer is not evenly spread over the whole body surface, being most noticeable on nose and forehead and over the shoulders, while in the ear and on the glans penis it is modified as cerumen and smegma respectively. Although attempts to study it have been going on for over 40 years, recent biochemical techniques, in particular new methods for microanalysis, are now making possible the study of the sebum from a single individual, or even from a single patch of his skin. It is hoped that differences or changes will be noted not only in various skin diseases but in general metabolic disorders, throwing fresh light on the

obscurities of fat metabolism. In the meanwhile results are already affecting the treatment of skin infections.

Sebum from the skin of the forearms has been chiefly investigated so far. It is dissolved off by plunging the arm into a jar of acetone and holding it there for three minutes. Each arm yields about 50 mg. of sebum; the skin so exposed secretes a new layer of normal thickness in about two hours.² Analysis of the dissolved material³ shows it to be a fatty mixture: 50% is neutral fat (triglyceride or other ester), 5% cholesterol, 30% free fatty acid, and the rest hydrocarbon, including 5% squalene (C₃₀H₅₀), a substance previously found in shark liver oil and yeast and also in the lipid of ovarian dermoid cysts. What function this and the other hydrocarbons serve on the skin surface is a physiological mystery. Squalene with its six double bonds has a slight resemblance to carotene and part of vitamin A. Applied pure to the skin of rabbits and guinea-pigs, it causes a reversible baldness, but whether it plays any part in human alopecia is unknown.⁴ It is noteworthy that sebum contains no vitamin A or D, in spite of their associations with skin physiology, and vitamin E is probably also absent.⁵

About one-third of normal sebum is free fatty acid, and that is the fraction responsible for repelling bacterial or fungal attack. There are two types of acid involved. One-third of the total consists in saturated fatty acids like the stearic acid of ordinary body fat but about half the molecular size. Whereas stearic acid has seventeen carbon atoms in a chain, the sebum saturated acids have only seven, nine, eleven, or thirteen. They are antagonistic to *Microsporon audouini*, a ringworm fungus, and are now sold for therapeutic use. The other two-thirds of the fatty acids are unsaturated, and are bactericidal, particularly oleic acid. Squire and his co-workers² have shown that the self-sterilizing power of the skin depends on these acids and on the maintenance of dryness. Streptococci and micrococci disappear from the skin in a few minutes under these conditions; *Staph. aureus* goes slowly, while *Bact. coli* and *Ps. pyocyanea* are resistant and remain unharmed. Corynebacteria, mycobacteria, and *H. pertussis* are also fatty-acid sensitive. On the other hand Dr. F. A. Whitlock concludes in an article on another page that *Pityrosporum ovale* is a harmless organism on the scalp and thrives in a heavy flow of sebum. Burtenshaw,⁶ in a review of the earlier work on this subject, pointed out that individuals differ in the bactericidal power of their skins. Another factor influencing individual variations in skin pathology is the presence of moisture, which impairs the bactericidal efficiency of the fatty acids; and stagnant damp in interdigital clefts and skin folds helps to explain their vulnerability to infection.

Two practical conclusions result. One is that skin dressings should be non-absorbent but permeable for evaporation. Nylon, which is unwettable, is much to be preferred² to the ordinary cotton gauze, which becomes damp and wets the skin under it. The other is that cleaning of the skin for vaccination and the like is best done with soap and water, which never removes more than a quarter of the protective sebum,³ while ether and acetone on the contrary wash it all off and leave the skin bare for over an hour afterwards.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

TACHYCARDIA

BY

CRIGHTON BRAMWELL, M.D., F.R.C.P.

Professor of Cardiology, Manchester University

Palpitation is a very common symptom, and, since it is often due to tachycardia, the various causes of this disorder merit careful consideration. It is convenient to classify cases of tachycardia in two main groups—those in which the tachycardia is due to simple acceleration of the normal sinus rhythm and those in which it results from the incidence of some abnormal rhythm.

I. ACCELERATION OF THE NORMAL SINUS RHYTHM

Before enumerating various conditions responsible for this type of tachycardia brief reference must be made to certain physiological principles bearing on the subject.

The cardiac reserve is a measure of the extent to which the heart is capable of raising its output to meet the oxygen requirements of the body during physical exertion, and, since the output per minute is the product of the output per beat and the heart rate, the smaller the increase in stroke volume the greater must be the increase in heart rate to achieve an equivalent increase in output. Comparative physiology provides an interesting illustration of the relation of heart rate to stroke volume. Animals capable of prolonged and severe exertion have slower pulses than sedentary animals. For example, the resting pulse rate of the hare, an exceedingly athletic animal, is under 70, while that of its cousin, the rabbit, a sedentary creature, which seldom strays far from its burrow, is over 200. To compensate for this difference in pulse rate, the hare's heart, relative to its body weight, is three times as big as the rabbit's. It seems to be a general law throughout all warm-blooded animals, both birds and mammals, that those with big hearts have slow pulses and vice versa.

The increase in pulse rate produced by exercise and the time taken to return to the resting rate following exercise have been widely employed in attempting to assess cardiac efficiency. The test employed by National Service medical boards in the examination of recruits was to place one foot on a stool about 18 in. (45 cm.) in height and to raise the body 20 times in 60 seconds. In healthy subjects in good physical training the pulse should return to the resting rate within one minute of the cessation of exercise.

We may now consider certain conditions in which physical exertion causes excessive tachycardia.

In many types of heart disease the stroke volume of the heart is reduced and, consequently, to increase output the heart has to beat faster than in health. But, short of actual disease, tachycardia on exertion may be due simply to physical unfitness resulting from obesity, excessive smoking, lack of exercise, and other causes; in patients with organic heart disease physical unfitness will add to their disability.

The term "effort syndrome" was coined by Lewis in the first world war to describe a condition in which the response of the circulatory and respiratory mechanisms to exertion was excessive in subjects without disease of either heart or lungs. In these patients the ability to perform muscular work is decreased and mild exertion causes breathlessness, palpitation, and other symptoms; the increase in the heart rate after exercise is greater than in health, and it takes longer for the pulse to return to its resting rate. It is now recognized that purely psychogenic factors are responsible

for many of these cases, but a similar clinical picture is seen in patients convalescent from an acute illness such as influenza.

In addition to exertion, emotion may induce tachycardia, in fact clinically it would probably be true to say that nervousness is the most common cause of tachycardia. Many perfectly healthy people are scared at the mere thought of a medical examination, especially when their fate may be determined thereby, while others become unpleasantly heart-conscious when called upon to get up and make a speech. One of my patients, a keen bridge player, told me that this lack of control proved most disconcerting, for whenever she picked up a particularly good hand her heart always started to race and consequently her murmur became audible to her opponents and gave the show away.

During the war National Service medical boards referred many recruits for a second opinion on account of persistent tachycardia. Was the tachycardia physiological or was it pathological? In point of fact it was generally due to fear of being rejected. When, in addition to tachycardia, the recruit had a systolic murmur, as was often the case, for overaction of the heart may produce such a murmur, an especially careful search for other signs of heart disease was indicated. In these recruits the possibility of thyrotoxicosis had to be considered, but even in the absence of thyroid enlargement or exophthalmos the diagnosis rarely presented much difficulty.

Acceleration of the normal sinus rhythm may be due to many other causes, but those mentioned above—namely, heart disease, physical unfitness, the effort syndrome, thyrotoxicosis, and nervousness—are clinically the most important when the patient's principal complaint is palpitation.

II. TACHYCARDIA CAUSED BY AN ABNORMAL RHYTHM

This type of tachycardia may occur either in paroxysms or as an established disorder. In paroxysmal tachycardia the heart rhythm is regular and the rate generally between 140 and 240 per minute. The paroxysm is, in fact, nothing more or less than a long series of premature beats with no intervening normal cycles, and, as in the case of premature beats, the ectopic focus from which the paroxysm arises may be either supraventricular or ventricular.

Supraventricular Paroxysmal Tachycardia

This type of paroxysm often occurs in people in whom there is no evidence of organic heart disease. Provided the paroxysm is not prolonged, it is not dangerous, but it may be very distressing and even alarming to the patient. Unlike tachycardia due to simple acceleration of the normal sinus rhythm, which arises in response to some obvious physical or nervous stimulus and abates when that stimulus is removed, these sudden bouts of tachycardia start abruptly at any time and for no apparent reason; not infrequently the attacks seem to be associated with a digestive disturbance, but whether this is a causal factor or not it is difficult to say.

Since we rarely have the opportunity of actually observing an attack, the diagnosis has generally to be based on the patient's description of his symptoms. The most characteristic feature is the abrupt transition from the normal to the rapid rate of beating, but not infrequently the paroxysm

is preceded by a short bout of irregular heart action due to extrasystoles (Fig. 1). Patients sometimes say that the attack terminates equally suddenly with a "thump." This is due to the forcible beat following the long compensatory pause which precedes the re-establishment of normal rhythm. In other cases the heart slows down gradually and imperceptibly. Unlike nervous tachycardia, the rate is unaffected by change of posture. The duration of paroxysms varies from a few minutes to a few days, or occasionally longer, but in most cases it lasts from two to twelve hours. When the attack is of long duration acute cardiac dilatation and congestive heart failure may supervene.

The disability experienced during an attack varies greatly in different individuals. In addition to palpitation, some

FIG. 1.—Sphygmogram showing short paroxysm of tachycardia, preceded by a period of irregular heart action, due to extrasystoles, and followed by normal rhythm. Note forcible beat following end of paroxysm.

patients complain of anginal pain due to coronary ischaemia, others suffer from manifestations of cerebral anaemia, such as dizziness or even actual syncope. I have, however, occasionally met with patients in whom the disorder of rhythm produced so little subjective disturbance that they were able, admittedly with difficulty, to carry on their normal occupations.

Attacks may terminate in vomiting, and can sometimes be aborted by inducing vomiting by tickling the back of the throat; pressure on the carotid sinus or on the eyeball will sometimes stop an attack; but, although these various tricks are worth trying, none of them is infallible. Fortunately most attacks stop spontaneously. In prolonged attacks, quinidine sulphate by mouth is the most useful remedy: 6 gr. (0.4 g.) should be given two-hourly for five doses, and a similar amount on two successive days if the attack persists. Intravenous quinidine should be used only in cases of exceptional urgency. Full digitalization (1 mg. of digoxin intravenously, followed by 0.5 mg. six-hourly) is sometimes successful in cases which fail to respond to quinidine. Of the cholinergic drugs, which have been used in prolonged attacks, methacholine ("amechol," "mecholyt"), 10–20 mg. subcutaneously, is the most reliable, but is apt to cause unpleasant side-effects. Recently procaine amide has been employed as an alternative to quinidine, but a difference of opinion still exists regarding the relative merits of these two drugs. Oral administration is apt to produce nausea and vomiting, and ventricular fibrillation has been reported when procaine amide was given intravenously. Some workers have reported favourably on intramuscular injection. It is said to be more effective in the ventricular than in the supraventricular type of paroxysm.

Ventricular Paroxysmal Tachycardia

Ventricular can be distinguished with certainty from supraventricular paroxysmal tachycardia only by the electrocardiogram, but its presence may be suspected clinically from the fact that, whereas the latter commonly occurs in an otherwise healthy subject, the former is generally asso-

ciated with serious heart disease. It may occur as a complication of acute coronary occlusion or may be initiated by mechanical stimulation in the course of surgical operations on the heart or cardiac catheterization, so that when performing such manipulations it is customary to give the patient quinidine or procaine amide as a prophylactic measure. In view of its seriousness, this complication should be regarded as a medical emergency requiring immediate admission to hospital, and its treatment hardly comes within the scope of the present article.

Auricular Fibrillation

This arrhythmia may be either permanent or paroxysmal. Paroxysmal auricular fibrillation is a not infrequent precursor of the established condition in patients with rheumatic or degenerative heart disease. Less commonly the paroxysms recur at more or less regular intervals over periods of years in apparently healthy subjects. The gross irregularity of the heart's action during the attack is generally obvious to the patient and will suffice to distinguish the condition from paroxysmal tachycardia.

In paroxysmal fibrillation the change from normal rhythm to fibrillation may prove most distressing to the patient, and one of my medical colleagues who suffered from such attacks, though otherwise his heart seemed to be perfectly normal, tells me that the sense of increased well-being when, after many years, he became a permanent fibrillator was quite remarkable. When attacks recur frequently continuous digitalization is indicated, in order to control the ventricular rate during the paroxysms. Quinidine, 3 gr. (0.2 g.) twice a day, may reduce the frequency of attacks, but often it has little beneficial effect.

Established auricular fibrillation is generally associated either with advanced rheumatic or degenerative heart disease or with thyrotoxicosis, but it has in rare instances been reported to follow an electric shock or other forms of trauma.

Uncontrolled fibrillation is easily recognized by the fact that it is the only type of tachycardia associated with grossly irregular heart action. From time to time two or more beats follow each other in very rapid succession. When this happens the ventricle contracts before it has had time to fill with blood. Such beats are ineffective on account of the small output of the heart, and only a very feeble pulse wave (Fig. 2), or it may be no pulse wave at all,

FIG. 2.—Sphygmogram from a case of auricular fibrillation. Upper record, before treatment, showing complete irregularity and a large number of very small pulse waves (marked with arrows). Lower record, after treatment with digitalis, showing greater uniformity in rhythm and form of pulse, all but one of the small ineffective beats having been eliminated. (Reproduced from *The Approach to Cardiology* by permission of Oxford University Press.)

reaches the periphery. Thus the heart rate, as counted with the stethoscope at the apex, is greater than the pulse rate at the wrist, the difference between the two counts being known as the "pulse deficit." The larger the number of ineffective beats the greater is the pulse deficit and the more unproductive work is the heart called upon to perform. It is merely tiring itself out to no purpose. Thus in untreated fibrillation tachycardia is largely responsible for the development of heart failure, the benefit derived from treatment with digitalis being due chiefly to control of the ventricular rate.

L m56, m32 N35-1

Failure to control the tachycardia is usually explained by inadequate dosage. Practitioners are apt to be unduly frightened of digitalis intoxication, which, in my experience, more often results from an excessive maintenance dose given over a prolonged period than from overdosage during the initial stage of digitalization. Patients vary greatly in their tolerance for digitalis, and it is therefore undesirable to use massive doses except in emergency: 3 gr. (0.2 g.) of the powdered leaf given eight-hourly will usually suffice to control the ventricular rate within 24 hours, and thereafter a maintenance dose of 1 to 2 gr. (0.065 to 0.13 g.) generally proves adequate; sometimes even smaller doses suffice. In an emergency 1 mg. of digoxin may be given intravenously.

The most obvious signs of digitalis intoxication are excessive slowing of the heart, nausea, vomiting, and bigeminal heart action, in which every normal beat is followed by an extrasystole. It is important to distinguish between the nausea due to overdosage with digitalis and that due to congestion of the gastric mucous membrane resulting from circulatory stasis in cases of heart failure, since the latter condition is attributable to inadequate control of the tachycardia, which can be relieved only by increasing the dose of digitalis. Likewise, bigeminal heart action is by no means always due to digitalis intoxication, and is not an indication for withdrawing the drug unless it is associated with bradycardia or other toxic manifestations.

When fibrillation is of recent origin, or persists after subtotal thyroidectomy, an attempt should be made to restore normal rhythm with quinidine, 6 gr. (0.4 g.) two-hourly for five doses, repeated if necessary. It is, however, only in those cases in which the disability is attributable to the abnormal rhythm rather than to the associated myocardial or valvular disease that quinidine therapy is indicated. In cases of old-standing heart disease there is a risk of embolism, and the patient is likely to derive more benefit from control of the tachycardia with digitalis.

Auricular Flutter

Flutter is closely related to fibrillation and, like fibrillation, may occur either in paroxysms or as an established condition. It is most often associated with either rheumatic or degenerative heart disease. In this disorder the auricle beats regularly at a rate of about 300 per minute and the ventricle usually responds at half that rate.

Clinically, therefore, auricular flutter may be suspected in cases of regular tachycardia when the pulse rate is in the neighbourhood of 150 per minute, and confirmation may be obtained by noting venous pulsation in the neck at double this rate or slowing of the pulse when pressure is applied to the carotid sinus; but the diagnosis can be established with certainty only by the electrocardiogram, which is distinctive.

Under the influence of digitalis the ventricular rate may be reduced to a quarter of the auricular rate or the heart's action may become irregular, the ventricle responding to every second, third, or fourth auricular impulse. Provided 4:1 heart block is maintained auricular flutter will *per se* cause no appreciable disability, but occasionally a 1:1 ventricular response develops, either spontaneously in untreated cases or in the course of treatment with quinidine, and unless promptly controlled may lead to acute cardiac dilatation.

If a patient with auricular flutter is fully digitalized the flutter will often be converted to fibrillation, and subsequently normal rhythm may supervene. Similarly a transient stage of auricular flutter may be observed before normal rhythm is restored when a patient with auricular fibrillation is treated with quinidine.

Next Refresher Course Article.—"Medical Aspects of Air Travel," by Sir Harold E. Whittingham.

COLLEGE OF GENERAL PRACTITIONERS

Eleven additional general practitioners from different parts of the British Isles have been elected to the Foundation Council of the College. Until the first annual general meeting, to be held in the autumn, the Foundation Council will consist of:

G. F. Abercrombie (London).	R. M. S. McConaghey (Devon).
<i>Chairman.</i>	J. G. Ollerenshaw (Yorkshire).
G. O. Barber (Essex).	R. J. F. H. Pinsent (Birmingham).
J. Cottrell (Lincolnshire).	F. M. Rose (Lancashire).
D. G. French (Staffordshire).	<i>Deputy Chairman.</i>
Annis C. Gillie (London).	Richard Scott (Edinburgh).
H. K. Glyn Hughes (London).	I. D. Grant (Glasgow).
J. M. Henderson (Perthshire).	G. Simpson (Cambridge).
W. V. Howells (Glamorgan).	G. Swift (Hampshire).
D. M. Hughes (Carmarthen).	A. Talbot Rogers (Kent).
J. H. Hunt (London), <i>Honorary Secretary.</i>	G. I. Watson (Surrey).
	J. C. Young (Belfast).

Foundation Membership.—By February 12 1,600 general practitioners had joined the College.

Reprints of Steering Committee's Report.—These will be sent to anyone on request.

Plans of Surgeries.—The College is collecting plans and photographs of up-to-date surgeries, consulting-rooms, dispensaries, waiting-rooms, etc. During the past few years many doctors have spent much time and thought in adapting, or building anew, such premises for single or group practices. It is hoped to provide a centre where plans, and perhaps scale-models, of these projects can be collected and studied, so that young doctors may benefit from the experience of others. As this collection grows it will be freely available to any doctors, architects, or builders who may wish to consult it. Will general practitioners who have recently adapted old houses to their practice needs, or who have built new premises, please send to the Secretary (at 14, Black Friars Lane, London, E.C.4) plans and photographs, with a note to indicate the special features of the buildings and of the practices concerned?

CANCER EDUCATION IN CHELSEA

The Borough of Chelsea's Cancer Education Committee held a public meeting on February 17 at Chelsea Town Hall. The meeting was attended by the Mayor of Chelsea, representatives of various interested bodies, and some 200 members of the public. Alderman G. L. TUNBRIDGE presided. He said that the Chelsea Cancer Education Committee had been formed in 1949 when the Borough Council was asked what it was doing about cancer education. Since then the Committee had produced 12 informative leaflets for lay people.

Mr. R. W. RAVEN, F.R.C.S., then gave a brief address in which he described an investigation carried out by the Chelsea Committee with the aid of a questionnaire. Of the people questioned, 17% believed that cancer is infectious, 27% that it is incurable, and another 20% that it is of doubtful curability; nearly all thought that a careful programme of education would be useful. The object of cancer education, said Mr. Raven, was to substitute knowledge and confidence for ignorance and fear. There were already about 15 cancer education committees at work in Britain, and these should be increased. The population would have to be covered in stages: special attention should be given to teaching district nurses and health visitors—their combined number being nearly 20,000—student nurses, welfare and social workers, who could then disseminate information among lay people. Later a more direct approach by leaflets, lectures, films, and carefully written newspaper articles would be possible. Mr. Raven ended his address by outlining a five-point programme for cancer control.

There then followed a film entitled "Time is Life," and a period for questions. Dr. J. BROWNING ALEXANDER moved the vote of thanks.

FIRST WORLD CONFERENCE ON MEDICAL EDUCATION

LONDON, AUGUST 24-29, 1953

The First World Conference on Medical Education will be held in London at B.M.A. House this year from August 24 to August 29, under the auspices of the World Medical Association. The President is Sir Lionel Whitby and the Deputy President Professor W. Melville Arnott. The first day of the Conference, Friday afternoon, and Saturday morning will be in Plenary Session. Details of the programme are printed below. (A leading article on the Conference appears on page 494.)

Section A: Requirements for Entry into Medical School

Vice-President: Dr. VICTOR JOHNSON, of the Mayo Foundation

Time	Tuesday, August 25	Wednesday, August 26	Thursday, August 27	Friday, August 28
9.45 a.m. to 1 p.m.	General Education in an Age of Science	History of Science Teaching Scientific Method Science is Measurement	Biology Fundamental to Study of Medicine How Much Chemistry and Physics? Introduction to the Social Sciences	Use and Value of Intelligence and Aptitude Tests Method and Value of Interview Examination and Discussion Group
3 to 6 p.m.	Requirements for Entry into Medical Schools	Excursion	Selection of Students	Plenary Session

Section B: Aims and Content of the Medical Curriculum

Vice-President: Sir ARCOT MUDALIAR, of the University of Madras

9.45 a.m. to 1 p.m.	Anatomy for the Doctor Physiology for the Doctor Integration of Physiology and Anatomy as a Single Subject in the Curriculum	The Aim of the Medical Curriculum Introductory Clinical Course Teaching Psychological Medicine	Teaching Medicine and Surgery as One Discipline Teaching Minor Surgery The Doctor, the Midwife, and Obstetrics	The Undergraduate and General Practice The Balanced Curriculum
3 to 6 p.m.	Pathology—the Basic Clinical Science Pharmacology and the New Therapeutics Medical Statistics and the Design of Experiment	Excursion	Paediatrics a Branch of Medicine The Place of the Specialties in the Curriculum Is an Intern Year Necessary?	Plenary Session

Section C: Techniques and Methods of Medical Education

Vice-President: Dr. A. HURTADO, of the University of San Marcos, Lima

9.45 a.m. to 1 p.m.	The Hospital - bedside Teaching of Medicine Teaching Surgery at the Bedside and in the Theatre Teaching in the Out-patient Department or Polyclinic	Visual Aids in Education One-way Observation Screen The Moving Picture in Medical Education The Still Picture	The Lecture and Group Discussion Medical Education and the Full-time System The Place of the Text-book in Teaching	Methods of Testing Knowledge
3 to 6 p.m.	Teaching in the Home The Clinico-pathological Conference The Laboratory in Teaching Experimental Medicine	Excursion	Library and Reference Services The Museum in Teaching The Students' Clinical Society	Plenary Session

Section D: Preventive and Social Medicine

Vice-President: Professor RENÉ SAND, of Brussels

9.45 a.m. to 1 p.m.	Present Status of the Teaching of Preventive and Social Medicine	The Teaching of Epidemiology Demography and Vital Statistics The Teaching of Medical Genetics	The Teaching of Social Psychology Social Environment and Individual Illness The Home Setting in Medical Education	The Teaching of Nutrition Housing Integration of the Teaching of Social Medicine in the Medical Curriculum
3 to 6 p.m.	Social Medicine as an Academic Discipline Teaching Social Medicine in the Pre-clinical Period Social Medicine in the Clinical Period The Need for Reorientation of Teaching	Excursion	The Teaching of Occupational Health The Use of Student Health Services in the Education of the Student Infant and Child Care as a Medico-social Problem	Plenary Session

Reports of Societies

HYPOTENSION IN ANAESTHESIA

On February 4 the Sections of Anaesthesia and Surgery of the Royal Society of Medicine discussed "Low Pressure Anaesthesia in Surgery." Professor F. A. R. STAMMERS (Birmingham) was in the chair.

Methonium Compounds

Dr. J. B. WYMAN (London) said that in addition to lowering blood pressure methonium compounds might also protect the patient from shock and prevent established shock from becoming irreversible. At the Westminster Hospital methonium drugs had been used at first only in cases subject to excessive blood loss, or in those in which blood loss impeded the surgeon. Later their use had been extended, and the technique had now been applied in 1,037 operations. He stressed the excellence of the working conditions for the surgeon, the steadiness of the patient's general condition during operation, and the remarkably good recovery afterwards. The patient was protected from trauma as well as from blood loss. The main theoretical objections to hypotension were the risk of dangerously reducing the blood supply to the vital organs and the possibility of vascular accidents. Thrombosis was probably no more liable to occur, and this might be because the linear rate of blood flow was not altered. Cerebral thrombosis had occurred in only one patient, a man with advanced hypertension. There had been two cases of cardiac arrest precipitated by some asphyxia during the operation. However, despite these fatalities, he thought that patients with a cardiac lesion did better than they would with ordinary anaesthesia, and that, once under control, the blood pressure and pulse rate remained remarkably steady. Possibly the damaged heart worked better against decreased peripheral resistance. A patient who had had a previous coronary thrombosis was liable to have another whether or not a methonium compound was used.

Post-operative haematoma was rarely troublesome once the surgeon was accustomed to the technique and tied off all slightly bleeding vessels. Renal complications were few, and the only example of renal failure had been in a patient with Ellis type 1 kidneys, who died two weeks after the operation. Oliguria had occasionally occurred. No major disturbance of liver function had been seen.

Of the five deaths, two were due to the underlying disease and three to faulty technique. A high standard was essential, and the penalties of failure were heavy. Despite his earlier remarks about patients with cardiac lesions doing better, Dr. Wyman mentioned that there might be a depression of the S-T interval in some of the E.C.G. leads for a few days after operation, and that this indicated a certain amount of cardiac ischaemia.

After the operation a head-down position was used for a few hours. He did not recommend the use of methylamphetamine, and he thought that phenylephrine (U.S.P.) was in some respects better. Slow recovery of the blood pressure was sometimes due to dehydration and delayed excretion of the hypotensive drug. The difficulties due to prolonged action of methonium compounds might be overcome by the use of "Arfonad (Ro2-222)," which had a very short-lived effect. From his own experience Dr. Wyman suggested that the future of these drugs might lie as much in the prevention of shock during major surgery as in the provision of an ischaemic field.

Mr. ROBERT COX (London) spoke as a surgeon who had worked with Dr. Wyman and who had no experience of other methods of producing hypotension. The diminished blood loss was sometimes most striking: as examples of blood loss in different operations performed with and with-

out this technique he cited: thyroidectomy 30 and 260 ml., radical mastectomy 32 and 690 ml., prostatectomy 30 and 560 ml., and pelvic evisceration 160 and 1,150 ml. With proper care in general surgery there did not seem to be an increased incidence of reactionary haemorrhage or haematoma formation, and there had been no evidence of an increase in embolism or in renal or hepatic complications. On return to the ward regular blood-pressure readings were taken. Morphine should be given if the patient was restless, otherwise the restoration of blood pressure might be delayed. The extra post-operative attention was compensated for by the lesser need for transfusions. The ward sisters thought that the patients were unusually well after operation, and this opinion was shared by everyone who dealt with the cases.

High Spinal Block

Dr. J. GILLIES (Edinburgh) spoke of high spinal block in which postural adjustment was the main factor in determining the fall in blood pressure and the primary means of restoring it in an emergency. Briefly reviewing the mechanisms involved in the various methods of inducing hypotension, he said that in arteriotomy blood flow and bleeding were reduced more by virtue of the vasoconstrictive response than by the drop in blood pressure. However well controlled, this state came very near to being pathological. Total sympathetic paralysis, by either extradural or subarachnoid block, caused generalized vasodilatation. By appropriate positioning, pooling of blood in dependent parts and a marked degree of hypotension could be achieved. Loss of fluid from the skin ceased during the sympathetic paralysis, and as the motor block did not affect the upper intercostal and phrenic nerves respiration remained spontaneous and a reliable guide to the state of the medulla. In autonomic blockade by methonium compounds the effects were complex, and this might explain why the results were less predictable. Spinal block was a more certain method of producing hypotension for a definite period of time. While all three methods had been used in Edinburgh, he would deal only with a series of 802 operations in which high spinal block had been applied. The patients were poor risks undergoing surgery for vascular diseases. This provided a severe test for a method which in 1946 was considered a reckless procedure. In abdominal surgery high spinal block was chosen as much for its other advantages of muscle relaxation and sensory blockade as for its hypotensive effect, although the latter could be of help in cases where, owing to the nature of the lesion, much bleeding might be expected.

Most of the avoidable mortality had occurred in the first half of the series. Two patients died during operation, one owing to mechanical limitation of pulmonary ventilation and anoxia, the other following a small dose of thiopentone which abolished spontaneous respiration and lowered arterial pressure still further. The few patients who died of cerebral vascular accidents had all had similar trouble in the past, and the technique was now contraindicated in such cases. One patient died of reactionary haemorrhage. There had been three non-fatal reactionary haemorrhages. Seven patients had cerebral vascular accidents (six of these were hypertensives, five of whom had a previous history of such trouble). There was only one case of coronary thrombosis with cardiac arrest in a patient with previous angina. Cardiac arrest occurred in one other patient as a result of asphyxia. Immediate cardiac massage was successful in both cases. Oliguria was noted in three patients, a figure which was in no way significant. A low head of pressure to the kidney did not seem to matter so long as there was vasodilatation and an undiminished volume flow. Post-operative ischaemia of the limbs occurred in 7 of 222 lumbar sympathectomies, and one limb was lost.

In 782 patients with no severe pre-operative cerebral vascular episode only two had developed such troubles

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Smoking and Lung Cancer

SIR,—It would seem, according to some of the critics of our conclusion that "tobacco smoking is a factor in the production of carcinoma of the lung" (for example, Professor R. D. Passey, February 14, p. 399), that we ourselves based that conclusion in part—and even largely—upon the observation that over the last 50 years cigarette smoking and the recorded mortality from lung cancer have risen together. In fact our conclusion is based upon evidence that is *entirely* independent of that time correlation. The time correlation was, of course, our starting point—it suggested that smoking was a factor worth investigating. But having applied that stimulus it ceased to have any interest whatever for us until our epidemiological inquiry was over and had *alone* led us to the conclusion we have quoted above.

That epidemiological approach and the results it gave are also, perhaps, being underestimated by Professor Passey and others. In drawing our conclusions we were not dealing with a handful of uncontrolled patients, nor making light-hearted suggestions, such as those he quotes about breast cancer and Edwardian corsets, based upon a few clinical impressions and a vivid imagination. We set about a most carefully designed survey, a survey that took in, all told, nearly 5,000 patients, was carried out in Greater London and four provincial cities, and occupied nearly five years. Evidence based on 1,465 lung cancer patients and 1,465 carefully matched controls does, we submit, carry some weight. In view, however, of the emphasis that has been placed, quite wrongly in our view, upon the correlation in time we might perhaps remind the reader briefly of the salient features of that survey. We have endeavoured to bring all its important results together in one single table, given below (for details of the absolute numbers, which vary according to the items, and for technical tests of significance, etc., the reader must see Doll and Hill (*British Medical Journal*, December 13, 1952, p. 1271).

The Proportion of Patients Interviewed who were Noted to have Given Characteristics

Section A. Equalities

	Characteristic	Carcinoma of the Lung Patients	Control Patients
1	Sex		
2	Age		
3	Places of interview (5 areas)		
4	Occupations		
5	Social class (males) number falling in classes I and II	15%	17%
6	Social class (males) number falling in class V	17%	16%
7	Number with previous residence near a gas works	23%	22%
8	Number with different forms of heating in living room for 30+ years:		
	Coal fire	86%	85%
	Gas fire	14%	15%
9	Number with previous history of asthma, chronic nasal catarrh, pleural effusion, or pulmonary tuberculosis	17%	15%
10	Regular users of petrol lighters	43%	41%
11	Number of smokers who said they inhaled	65%	67%
12	Smokers of mainly hand-rolled cigarettes	21%	19%
	Users of one of 4 main named brands of cigarettes	57%	57%
	Users of mixed brands	34%	32%
	Regular users at some period of Turkish cigarettes	4%	5%
13	Number of male snuff-takers, occasionally or regularly	3%	4%
14	Number of non-smokers amongst women in the provinces	57%	57%

* In two occupational groups—miners and policemen—there was a relative deficiency of cancer cases.

later, whereas in 20 with a history of severe cerebral accident before operation 9 developed them later. Similarly in 784 patients without severe myocardial disease there was no subsequent coronary thrombosis, whereas in 18 patients with severe myocardial damage there was one post-operative coronary thrombosis. Spinal cord damage occurred in two others, and this was a serious matter. In expert hands, however, this complication should reach a low irreducible minimum.

Contraindications to inducing hypotension were (1) myocardial disease; (2) arteriosclerosis, whether local or generalized; (3) a history of previous cerebral vascular accident; (4) anaemia, chronic pulmonary disease, congestive heart failure, and other conditions affecting oxygen transport; and (5) malignant hypertension. The *only* indication for hypotension was when its advantages to the patient and the surgeon were definite and were likely to outweigh the accepted risks.

Discussion

Mr. GEOFFREY PARKER (London) said he had been prejudiced against the use of methonium compounds at first, but was now 'happier about them. The bloodless field made it wonderfully easy to demonstrate all the steps in an operation such as prostatectomy. Dr. C. T. BARRY (Edinburgh) said that with methonium compounds he had had 8 deaths in 212 cases. He thought a high spinal was more reliable. Four of his eight fatalities had been due to severe paralytic ileus. Dr. R. F. WOOLMER (Bristol) said that vasoconstriction was Nature's way of combating shock, and yet the opening speaker had advocated methonium in the treatment of established shock. He thought that the exponents of this method were confusing "shock-shielding" with "shock-hiding." Dr. M. H. A. DAVISON (Newcastle), after considerable experience, had abandoned the methonium drugs. He pointed out that the opening speakers had recorded three deaths on the table in less than 2,000 cases, whereas there had been only one such death in the last 60,000 cases at his hospital. He emphasized, too, the very real risk of cerebral damage in many cases. Dr. A. R. HUNTER (Manchester) described the limited use of hexamethonium in neurosurgery, chiefly to make the impossible possible. The method was mainly of value with angiomas, aneurysms, and vascular meningiomas. Some patients had prolonged hypotension, and a few had shown intolerance by developing venous congestion in the operative field. There was also a significant increase in post-operative vomiting. Dr. P. R. BROMAGE (Chichester) said that in the presence of complete afferent blockade from the operation site eosinophil counts suggested that the adrenocortical response was delayed until the effects of the block had worn off. In the arteriosclerotic subject the electroencephalogram showed delayed return of normal alpha rhythm after profound hypotension.

Dr. GILLIES, in reply to a question by Mr. N. E. Tanner on whether the induction of hypotension was indicated in the surgery of portal hypertension, said that he did not consider the method suitable. The hazards of bleeding in such patients were great. With reference to Dr. Barry's remarks on paralytic ileus he quoted a personal communication from Dr. F. Holmes, at Edinburgh, reporting 19 non-fatal cases of paralytic ileus in 155 orthopaedic operations (mostly on the hip) in which hexamethonium had been used. Dr. Davison's emphasis on possible cerebral damage was important, although Nilsson's observations were on few cases and all effects were transient. With spinal block anything above 10 degrees head-up must be considered dangerous. The head-down position should never be much below horizontal, otherwise a dangerous congestion might ensue.

Dr. WYMAN congratulated Dr. Davison on his long series of cases without a death on the table. He felt, however, that such events were largely unpredictable and that such a satisfactory experience could be purely due to chance. Contrary to Dr. Bromage, he thought that there was a normal eosinophil response to operation.

Observed Proportions of Patients with Given Characteristics
Section B. Inequalities

	Characteristic	Carcinoma of the Lung Patients	Control Patients
1	Number of men who were non-smokers: Greater London, 1948-9 Greater London, 1950-1 Bristol, Cambridge, Leeds Newcastle	0.3% 1.0% 1.3% 0.0%	4.2% 4.2% 4.4% 5.3%
2	Number of women who were non-smokers: Greater London	30% 54%	
3	Number of men smoking 25 cigarettes or more daily (or the equivalent in pipe tobacco): Greater London, 1948-9 Greater London, 1950-1 Bristol, Cambridge, Leeds Newcastle	26% 26% 24% 21%	13% 16% 11% 12%
4	Number of women smoking 25 cigarettes or more daily: All areas	11% 1%	
5	Number who started smoking before the age of 20: Men Women	80% 29%	77% 24%
6	Number who had given up smoking for more than 10 years: Men Women	1% 1%	4% 4%
7	Number of male smokers who, as a rule, smoked cigarettes only Number of male smokers who, as a rule, smoked pipes only	74% 4%	69% 7%
8	Number of male cigarette smokers who had used cigarette holders occasionally or regularly	5%	12%
9	Number of males who had chewed tobacco occasionally or regularly	3%	5%
10	Number of men aged 45-74 smoking 25 ciga- rettes or more daily (standardized rate): Patients with carcinoma of the lung Patients wrongly diagnosed as lung cancer Patients with other respiratory diseases Patients with other forms of cancer Patients with other diseases	24% 11% 11% 13% 14%	
11	Number with previous history of: Chronic bronchitis Pneumonia	17% 17%	11% 10%

In the upper part of the table, Section A, we set out the principal characteristics in which our carcinoma of the lung group did *not* differ appreciably from the control patients—that is, those patients whom we took into the inquiry as a standard of comparison. To limit the possible variables, the design of our survey deliberately made them equal in sex, age, place of interview, and, largely, in hospital of admission. It will be seen that they have also revealed themselves to be remarkably alike in other characteristics—their social class and their occupations, their residence near a gas works, their heating in the home, their previous history of certain respiratory diseases. In relation to smoking they do not differ in their use of petrol lighters, of hand-rolled cigarettes, of different brands of cigarettes; they do not differ in the habit of inhaling. With these striking equalities—particularly in some aspects of smoking—it would seem to us to be unreasonable to argue that either our controls or our cases are biased, and therefore not comparable, or that the information given by the two groups is not equally reliable.

How, then, can we explain the picture given by Section B of our table? Here we have brought together the various ways in which the carcinoma of the lung patients *do*, as a group, differ from the control patients. They include significantly fewer non-smokers and a marked excess of relatively heavy smokers in both sexes, with, in men, a consistency in time and space that is striking; they include more persons who started smoking earlier in life and fewer who have given up; they include relatively more cigarette smokers and fewer pipe smokers; they include fewer users of cigarette-holders and fewer chewers of tobacco. In short, broadly speaking, they differ radically in the *amount* of tobacco they have smoked, and they differ, it seems probable, in the *way* they have smoked. Other groups of patients do not reveal this difference in the amount smoked—including, be it noted, a group originally, but wrongly, diagnosed as carcinoma of the lung. It is the privilege of the lung cancer group to be so marked. The only exception lies in the equality of non-smokers amongst the few

women we observed in the provinces (as shown in Section A).

The two groups are also different, Section B shows, in their previous history of chronic bronchitis and pneumonia. We give reasons in our paper for supposing that this comparison may be fallacious, though we do not wholly dismiss it. Chronic bronchitis is held by many to be related to smoking. There is also some evidence (not included in the Table) that the carcinoma patients had passed more of their lives in urban areas, which is consistent with Stocks's work on the urban/rural incidence rates. Basically, then, it is the contrast between Section A and Section B of our Table that leads us to the belief that tobacco smoking is of aetiological importance in lung cancer.

This evidence, we repeat, is quite independent of the time correlation. No critic has offered any alternative explanation of it that carries conviction—and indeed the only one that has been put forward at all is that subjects with a particular constitution may be prone both to smoking heavily and to carcinoma of the lung. We have put forward our own interpretation and belief—that the figures simply mean what they show.

Professor Passey and Dr. Gallop ask, If the reported increase in lung cancer is due to tobacco smoke, how does it come about that there is no increase in the incidence of cancer in other parts of the respiratory tract, such as mouth, tongue, and pharynx, which suffer a greater exposure to the smoke and for a longer time? There are, however, analogies for such events, however curious they may appear to be. For instance, in nickel refining in South Wales it is well known that some undetermined carcinogenic agent, acting in the first quarter of the present century, produced a gross excess of cancer in two sites, and two sites only—the ethmoid and the lung. Why not the mouth, the tongue, and the pharynx? Similarly, no excess in any site but the lung has followed the exposure of the Schneeberg miners. A declining cancer rate in the buccal cavity is, in fact, consistent with the hypothesis put forward by some that cancer in these sites is related to the prevalence of pipe-smoking.

We made perfectly clear in our paper that we did not believe that *all* cases of lung cancer were due to smoking—indeed, we called that a most unlikely event and pointed out that we had observed certain cases who had never smoked. One of us (R. D.) has, indeed, elsewhere attempted to calculate from our data the death rates of men and women non-smokers, and on the assumptions made those death rates did not differ materially (Milroy lectures, in the press). We need hardly point out that with *far* more women than men non-smokers in the population a relatively greater proportion of deaths in women must be of non-smokers—though their death rate among them might still be negligible. The difference in past tobacco consumption between the sexes is, it appears to us, quite capable of providing the main explanation of the present sex ratio of mortality. Trade statistics show that of the total tobacco consumption of the country 25 years ago only 2.5% was smoked by women. We do not believe that Dr. Shera need invoke sex hormones as a factor.

Professor Passey suggests that the only "satisfactory solution of the problem would be the study of a large group of smokers in comparison with an equally large group of non-smokers." This we are endeavouring to make in our observations of the mortality amongst those doctors who told us their smoking habits some 15 months ago—but we hardly like to appear impatient.

Finally, he asserts that "when doctors disagree it is bad for the patient." We might remind him that in the past they often have disagreed. They disagreed when Lord Lister endeavoured to introduce antiseptic measures. It was bad for the patient. Quite often he died.—We are, etc.,

RICHARD DOLL.
A. BRADFORD HILL.

London, W.C.1.

SIR,—There are certain points in the letter of Professor R. D. Passey (February 14, p. 399) which I feel require some comment. Professor Passey suggests that the "immeasurably greater degree" of ability to diagnose cancer of the lung is as closely related to the increase in lung cancer as between cigarette smoking and the increase of lung cancer. Surely Professor Passey cannot seriously suggest that in the past 10 years the ability of medical practitioners to diagnose cancer of the lung as a cause of death has markedly changed. If there was some social reason for the increase in the number of certifications—that is, reluctance of doctors to certify cancer as a cause of death—then this should be reflected in the certifications of death of all other forms of cancer. Deaths from cancer of the trachea and bronchus have risen from 4,815 in 1940 to 11,241 in 1950, an increase of 133%. Certified deaths from cancer of the large intestine have risen only from 9,809 in 1940 to 10,153 in 1950. This trifling increase of 3.5% would seem to dispose of the idea that there has been any marked increase in the x-ray diagnostic facilities. The second point was that no carcinogen had yet been found in tobacco smoke, but it was stated in Professor Bradford Hill's article that carcinogen has been demonstrated in tobacco tar.

A mere correlation in time between the increase of tobacco smoke and cancer of the lung would indeed be a highly fallacious premise on which to base any argument as to the aetiology of the one against the other, but what the survey shows is that a much larger number of persons who suffer with cancer of the lung smoke cigarettes than would be accounted for by chance. It is certainly true that in the past many theories as to the causation of carcinoma have been proved false by later experiment, but a statistical survey of this type is one of the most potent methods of distinguishing facts from fancy—that is, in the demonstration that residence near a gas works is of no import and the non-carcinogenic properties of the cigarette lighter.

Finally, Professor Passey states that we do not know how many of the 68 women smokers who suffer with carcinoma would, in fact, have suffered from this disease had they not smoked, but, applying the figures of relative risk in table XII, it would appear that this figure would have been under 10. Professor Bradford Hill's article may not have proved that carcinoma of the lung is caused by tobacco smoking, but it has put the matter in so grave a doubt that any reasonable person would need to receive very strong weight of evidence before dismissing the matter as of no account. No single survey, even one so carefully planned and carried out, could be said to prove so important a subject, but it certainly does make it of the utmost importance that further research be pressed forward with the greatest celerity.—I am, etc.,

London, W.8.

H. BINYSH.

SIR,—Your publication of "A Study of the Aetiology of Carcinoma of the Lung," by Dr. R. Doll and Professor Bradford Hill (December 13, 1952, p. 1271), which was followed by a television programme on smoking, and much Press publicity, including front-page banner headlines in at least one daily paper, have resulted in great and justifiable public alarm about the ill-effects of smoking. A conference has been hurriedly called for the purpose of planning further and more extensive research on this subject. Let us have this, by all means. Let us make assurance doubly sure. But extensive research, well planned and carried out, is extremely time-consuming, and must not be made an excuse for our neglecting to take immediate steps to safeguard the public from this grave and rapidly increasing malady.

Your leading article (December 13, 1952, p. 1299) implied that the association between smoking and cancer of the lung was virtually proved, in so far as statistics can prove anything. The second limb of Doll and Hill's investigation

confirmed the conclusions of their first, and the whole confirmed those of Wynder and Graham,¹ and of other investigators. A long-nurtured suspicion, born of extensive clinical observation, has thus been subjected to repeated large-scale investigations by independent investigators of high standing, and has been shown to be well founded. Its validity is therefore proved beyond all reasonable doubt, although I appreciate that many smokers are, understandably, not reasonable when there is a threat to their supplies of tobacco, and are certain to cast doubts, including "phony" ones, on the validity of such utterly unacceptable findings. But this should not be allowed to deter or delay us in the performance of our duty, which is clearly to call on the nation to stop smoking now, voluntarily in the first instance. I realize that the psychological and financial repercussions would be enormous. But even more enormous, in my view, would be the upsurge in the national health and morale. Tobacco smoking is a disease in its own right—a drug addiction—and well worth curing even if it did not predispose to any other affection.—I am, etc.,

Wallasey.

"A Thorough Overhaul"

SIR,—We in this partnership are concerned over the increasing number of requests we have from National Health Service patients for a "thorough overhaul," or, as they frequently put it, a "medical." While we agree with the desirability of this and have not as yet turned any such requests down, we are getting a little apprehensive at the increasing frequency of these requests, due, we have no doubt, to the many health articles in the popular magazines and the sometimes horrifying programmes on the radio and television. This is certainly going to become an acute problem, because, if such examinations are not done as thoroughly as those for life assurance purposes, they are not only useless but may be dangerous.

We should like to ventilate this question and ask how our colleagues elsewhere deal with it.—We are, etc.,

RONALD COLDREY.
D. R. W. BURBURY.

G. A. F. QUINNELL.
G. E. P. KELLY.

The College of General Practitioners

SIR,—It is evident from the letter of Drs. J. P. Denny, C. H. Highfield, D. L. Isaac, and A. Murphy (February 7, p. 333) that my previous communication (January 24, p. 219) has been misunderstood. In order to eradicate any false impressions, I would be grateful for the opportunity to answer a few of the points which they make.

First, it is not quite fair to speak of a *fait accompli* being presented to the profession. The steering committee has considered the views offered to it by members of the profession, and Dr. Denny and his co-writers had every opportunity to submit theirs. The committee has now gone a stage further and made some *provisional* arrangements for the establishment of the College and has given it a *provisional* constitution. In its report it makes it quite clear that a general meeting will be held in 1953, at which a new council will be elected by the full body of members, the provisional constitution will be reviewed, and the by-laws will be submitted for amendment and confirmation. A second general meeting will be held in 1954, when the same procedure will be followed. Such an arrangement can hardly be called undemocratic.

The fact that more than 1,500 general practitioners have joined the new college in its first five weeks has shown indisputably that there is a real need for it. Those who have not yet enrolled are not necessarily opposed, and many, I am informed, are still joining daily. This degree of support from practitioners immediately after the birth

of their college, with its enthusiastic reception from many other quarters, has been far more encouraging than even its most ardent supporters had expected.

The steering committee clearly states in its report that the new college is for *all* general practitioners who care to join it. None are excluded, and it is quite untrue to state, as Dr. Denny and his colleagues have done, that the college is only for a few enthusiasts and not for all. Furthermore, it is not one of the aims of the college to "dispense distinctions" under its present constitution. If eventually it is decided to institute a diploma, it will be for the profession as a whole to accord it the value which it deserves.

The B.M.A. has, I believe, welcomed this venture and recognizes the college as a body complementary, and not antagonistic, to itself. This should allay any fears that a new negotiating body has arisen to interfere with existing work in this field.

After three years the Royal College of Obstetricians and Gynaecologists had 276 members; after five years the American Academy of General Practice, a highly successful and useful organization, had enrolled 15% of the general practitioners of the United States; in its first five weeks our new College of General Practitioners has made a truly remarkable start, and its future success is assured.—I am, etc.,

Sheffield.

H. H. PILLING.

SIR,—I much appreciate the kind reference of Dr. J. P. Denny and others (February 7, p. 333) to my letter (January 24, p. 218) and want to dispel some doubts expressed about my meaning. Regarding the increasing deterioration of the status of general practice in the past decade, the profession will welcome from the College of General Practitioners any help in our attempts to "stop the slide." I did not venture the opinion that the college was necessary in addition to existing efforts; but the exigency presents a great opportunity for the new college to show its mettle.

Is the doctor's prestige, *vis à vis* his specialist confrères, synonymous with worth, as my correspondents assume? Prestige means influential status judged by worldly standards, and it is the fall of this that we lament. Whereas the sustained concurrent efforts of doctors to serve their patients' vital needs despite degrading conditions enhance our esteem for their worth—moral or academic. But, "trying to cope," they are losing touch seriously with the specialists. Consultations are fewer; at those in the patient's home the absence of the general practitioner is often accepted; patients are commonly introduced to the out-patient clinic with but scrappy notes. Scamped procedure is foreign to healing. It also impresses the public unfavourably. A cold formality is supplanting the good fellowship that made a consultation an event in pre-war practice. *Spiritus intus alit*. Not only was discussion stimulating but, writing from personal experience, the young consultant gained much from the shrewd dicta of the family doctor and his way of handling the patient. Incidentally, the quiet decorum of the occasion inculcated respect among patient and relatives.

When the consultant-general-practitioner bond weakens, the doctor's prestige—within his profession, too—diminishes. I tried to emphasize in my letter how indispensable the directive influence of the general practitioner has become for the patient to derive full benefit from the cluster of specialists now available in the N.H.S. The family doctor should not only invoke but also co-ordinate their services and play the nuclear role in the clinical cell. It is our duty among our clientele to acclaim him *primus inter pares*. The warning words of Dr. F. H. Young in his address on pulmonary tuberculosis (February 7, p. 287) illustrate how needful this function is. Unless the general practitioner is in charge, the patient is apt to fall between two stools—medicine and surgery—and "the best laid schemes o' mice and men gang aft a-gley."

Let the profession give due prominence to this major responsibility of the general practitioner. Such a signal from the "technicians" is due to convince both the public and the Ministry of Health that the bad conditions in general practice are converting the patient's "guide, philosopher, and friend" into a health "official."—I am, etc.,

Bristol.

A. WILFRID ADAMS.

Acute Labyrinthitis

SIR,—In reference to the article by Dr. W. L. Burrowes on "Acute Labyrinthitis" (November 29, 1952, p. 1182), we have during the last year seen many cases of labyrinthitis, although most have not been as severe as those reported. The attacks were frequently associated with other symptoms of influenza, and we feel that, when it occurs alone, the labyrinthitis is possibly caused by an influenza virus of low virulence.

With respect to treatment, we added potassium iodide 3 gr. (0.2 g.) to a simple sedative mixture such as the following: ammon. brom. 3 gr. (0.2 g.), sodii brom. 3 gr. (0.2 g.), tinct. nux vom. 4 min. (0.24 ml.), sp. chloroform. 10 min. (0.6 ml.), inf. gent. co. ad $\frac{1}{2}$ oz. (15 g.). Patients will often be improved within 24 hours even in quite severe cases.—We are, etc.,

Burwood, Australia.

JOHN MALCOLM.
SYDNEY L. CHURCHWARD.

Malignancy in Undescended Testis

SIR,—Mr. Eric Coldrey's case of malignant tumour in an undescended testis (February 7, p. 335) is remarkable not only for the extraordinary size of the growth but also for the association with a marked degree of hypospadias. Since the earliest times of cancer research the frequency of association between developmental disturbances and malignancy has been observed and has given rise to various theories on cancer origin. I myself investigated a case of evolutionary anomaly connected with carcinoma which may be worth recording, particularly, as Mr. Coldrey says, as malignant changes with imperfect migration of the testis are very uncommon.

A woman aged 30 was admitted to a gynaecological clinic in a state of complete unconsciousness. A prominent malignant tumour was located in the right inguinal area, spreading considerably. It was inoperable. The patient had always been in good health, but had never had a period. Her body was well proportioned and completely female, with excellently formed breasts and female hair distribution. Only the axillary region was hairless. On examination, however, I found complete absence of a uterus, the vagina ending blindly. From this syndrome I made a diagnosis of error of sex and cancer of a cryptorchid testis in a case of male pseudohermaphroditism. The patient died four days later, and the findings at necropsy confirmed the diagnosis. The patient had never had a doubt of being a woman. The anomaly must have started at an extraordinarily early stage of embryonic life, resulting in such a complete form of pseudohermaphroditism accompanied by the secretion of oestrogen quite excessive in a male.—I am, etc.,

London, N.W.3.

HANS BAB.

The General Practitioner and Mass Radiography

SIR,—Dr. F. A. Nash, Mr. B. Benjamin, and Dr. T. J. Lee describe (February 7, p. 304) the facilities offered to general practitioners by the South-west London Mass X-ray Service. This was the subject of favourable comments in your annotation (p. 322). I would like to add my appreciation of the above article and say how experience in Newcastle-upon-Tyne has shown that rapid x-ray facilities of this kind are greatly appreciated. Such a scheme has been in operation in Newcastle-upon-Tyne since 1944. The following Table gives some particulars of this. It will be seen that the numbers of doctors' patients attending have risen considerably since the scheme started.

Dr. W. H. Dickinson, the first medical director of this mass x-ray unit, was responsible for the inception of the scheme; I have only continued the work since his retirement in April, 1952. At first practitioners were requested to send a note with the patient, and a printed letter form

Year	Total Attending	Recalled for 2nd Examination	Requiring Investigation or Observation
1944	754	196	45 or 6%
1946	457	25	65 " 14.5%
1947	348	54	25 " 7%
1948	2,625	570	238 " 9%
1949	1,985	385	119 " 6%
1950	3,486	601	236 " 6.5%
1951	4,503	793	313 " 7%
1952	6,959	842	516 " 7.5%

was sent back to the general practitioner. Now they are supplied with cards and envelopes, and the report upon the miniature film is typed or stamped upon the card, which goes back to the general practitioner. No elaborate analysis of the patients' symptoms has been kept. In 1949, 44 cases referred by general practitioners were found to have active pulmonary tuberculosis, in 1950 81, and in 1951 86, giving an average of 2% compared with 0.2% from routine x rays done in the unit. With the consent and approval of the general practitioner concerned, patients with other abnormal shadows, including probable cardiac lesions or conditions other than tuberculous, were referred to the cardiovascular department or the thoracic unit in the Newcastle General Hospital, where the mass radiography unit is based.

As the mass radiography unit is mobile, the amount of general-practitioner work is affected by the amount of time that it is away from its base, but when it is not away special sessions are arranged on one afternoon and evening per week for general practitioners' cases.—I am, etc.,

Newcastle-upon-Tyne.

GEORGE HURRELL.

SIR,—Your annotation on "The G.P. and Mass Radiography" (February 7, p. 322) seemed to attribute to us the suggestion that all mass x-ray units should concentrate entirely on the examination of minor symptom cases sent by doctors. We did not express any views about the uses to which existing mass x-ray units should be put. We did estimate that a comprehensive general-practitioner x-ray service could be provided if the units in large towns concentrated entirely on such cases. In fact, we are in agreement with your annotator's views on the importance of the other duties of the mass x-ray teams. The question of the relative values of different methods of using these units is an important and separate issue, but we did not deal with it in our paper (February 7, p. 304).

Since our paper was written the South-west London Mass X-ray Centre has been opened to provide for the needs of general practitioners. This centre now serves 400 doctors, who are sending 200–300 patients a day for examination. This increase in referrals by general practitioners at a time when they are immensely busy indicates that they value the service.—We are, etc.,

F. A. NASH.
B. BENJAMIN.
T. J. LEE.

Measurement of Tissue Components Radiologically

SIR,—We are pleased to learn from the letters of Dr. E. A. Miskin and Dr. Frank Falkner and Miss Sylvia Wisdom (January 31, p. 275) that some consideration had been given to the geometry of their tube-shift technique, although withheld from the original publication. We wonder, however, if Dr. Miskin, Dr. Falkner, and Miss Wisdom are agreed as to the scope and limitation of the method, for whilst Dr. Falkner and Miss Wisdom write: "Our method is intended for measurement of tissues in such parts of limbs as the upper arm, calf, thigh, etc., in both infant and adult," Dr. Miskin writes: "In the method as applied, and as recommended for *child* study . . ." We have never denied that the shift method may be mathematically accurate for children's calves, but with limbs of diameters up to, say, 6 cm. an anode film distance of only 120 cm. may be regarded as teleradiography with an error of less than 3%.

We were misquoted as recommending an exposure of 1 second at 15 mA in radiographing infants. This was not our intention. However, should we be asked for a practical solution, an exposure of $\frac{1}{4}$ second at 15 mA with an anode film distance of 120 cm. would be a suitable starting point for the smaller patients with whom short exposures are necessary. This compromise (which has been tested in our departments) is put forward as but one of many alternatives, as it is not possible to discuss this subject at length in these columns. The advantages of this method are: (1) only one 15 mA apparatus is required; (2) the exposure time is the minimum these sets will allow; (3) errors due to focal spot size, photographic quality, motion blurring, measurement of tube-shift and anode film distance, subjective errors and calliper errors are far less important; and (4) tissue proportions can be read directly from a normal film rather than calculated indirectly from a film which looks like Clapham Junction in a fog.—We are, etc.,

B. C. H. WARD.
G. N. WEBER.

London, S.E.3.

Effect of Isoniazid on Glucose Tolerance Tests

SIR,—In view of the figures published by Dr. G. R. W. N. Luntz and Mr. S. G. Smith (February 7, p. 296) of the effect of isoniazid on glucose tolerance tests, the attached small series may be of interest.

Between April and June, 1952, six non-diabetic patients suffering from active bilateral pulmonary tuberculosis—Case 3 also had a gastro-enterostomy—received isoniazid in doses of 200–250 mg. daily. At first this was given in 50-mg. doses distributed throughout the 24 hours, but later in doses of 100–150 mg. twice daily. Plasma levels of isoniazid were not determined. Blood sugar estimations (Folin and Wu) were carried out in the fasting condition and one hour after the ingestion of 50 g. of glucose before isoniazid therapy was started, and thereafter at weekly intervals. The series is thus comparable with Dr. Luntz's controls.

Case		Blood Sugar in mg./100 ml.					
		Before Isoniazid	Weeks after Isoniazid				
			1	2	3	4	5
1	Fasting	86	96	77	88	88	64
	1 hr. after glucose	148	124	91	112	104	76
2	Fasting	82	104	108	73	92	
	1 hr. after glucose	136	120	145	86	96	
3	Fasting	116	108	108	96	84	
	1 hr. after glucose	192	128	144	224	136	
4	Fasting	96	92	105	77	84	
	1 hr. after glucose	104	120	140	69	112	
5	Fasting	64	68	60	88	64	
	1 hr. after glucose	96	88	84	96	80	
6	Fasting	80	68				
	1 hr. after glucose	120	132				

We draw no conclusions from this small series, but the results do not appear to confirm Dr. Luntz's findings of raised blood sugar levels in non-diabetics receiving isoniazid.—We are, etc.,

J. A. KEEPING.
M. W. HUTCHINGS.

London, W.10.

School Dental Service

SIR,—Dr. F. G. Hardman (February 14, p. 401) cannot see why dental nurses should be considered a menace. The dental profession is happy to employ auxiliaries in the shape of technicians, receptionists, secretaries, surgery assistants, and oral hygienists. It objects to a new type of auxiliary who will perform surgical operations on living tissues. The analogy with nurses and the medical profession is false. Nurses do not normally administer anaesthetics, perform minor surgery, or use local analgesia, with or without supervision.

The dental profession still has "Dentists 1878" on the Register, and nearly 30% of its ranks are "Dentists 1921." It is liable to have "Dentists 1953" in service until A.D. 2028, even if the so-called "experiment" is judged a failure.—I am, etc.,

Birmingham.

C. N. JEFFRIES.

Kindness to Patients

SIR,—I read with great interest your leading article (January 31, p. 264) and the letter from Dr. Guy Roworth (p. 271) explaining his valuable idea of having a leaflet in the wards. I suggest, however, that, in addition, "conditioning" of the patients should start before they enter the hospital, and for this purpose I sent a leaflet some time ago to the King's Fund in the hope that hospitals would send it out with the card of admission. This leaflet sought to explain the domestic details and relationships which exist in the life of a hospital ward and to simplify the details of routine which sometimes cause anxiety at first to new patients. I understand it was turned down by the nursing committee.—I am, etc.,

York.

MALCOLM DONALDSON.

Surgery of the Heart

SIR,—You gave us a very kind and good leading article (February 14, p. 383) on our recent follow-up of 200 patients with morbus caeruleus (p. 349).

Your comment that we said nothing about similar patients with direct operations might be interpreted as disapproval of Mr. Brock's operation. We should, perhaps, have concluded our paper by saying that we are hoping to produce a similar follow-up in the very near future of the patients who have had valvotomy and infundibular resection, but these operations started about a year later, and we wanted the follow-ups to be as comparable as possible.—We are, etc.,

MAURICE CAMPBELL.

D. C. DEUCHAR.

London, S.E.1.

Intercourse after Syphilis

SIR,—Your expert, in his reply (February 7, p. 348) to the comments of Dr. P. A. Clements and Dr. T. E. Osmond on his original reply to a question (January 10, p. 115), does not seem to have been very fortunate in his choice of Pariser¹ for support of his contention that *S. pallida* is not found in the semen of an uncured syphilitic person. Study of Pariser's paper inclines one strongly to agree with the criticism of it by that very sane syphilologist, Dr. Joseph V. Klauder, who is reported at the end of Pariser's paper as having said in the discussion thereof:

"Unfortunately these studies do not offer a laboratory test to discover when the seminal fluid no longer harbors the organism. Fournier showed some years ago that the seminal fluid may transmit the disease before the appearance of the chancre. I recently observed a patient with an extra-genital chancre, there were no lesions on the genitalia. He infected his wife through the seminal fluid, since she presented a chancre of the cervix soon after the appearance of her husband's extra-genital chancre. If Dr. Pariser continues his studies I would suggest that he concentrate pooled specimens of seminal fluid from the same patient by partial evaporation in order to inject the entire residue into a rabbit's testicle."

But why does your expert rely, as apparently he does, on the alleged absence of *S. pallida* from the pure semen as secreted in the testicle? What does it matter whether the fluid emitted in sexual intercourse picked up *S. pallida* in the testicle or in the urogenital canal? Does your expert think that seminal fluid could infect only through the ovum? This question of the precautions that are necessary after treatment for early syphilis is highly important. It is all very well to be optimistic when the penalty of mistaken judgment is not borne by the expert, but for the

kind of people who matter to the country a syphilitic infection is psychologically, if not physically, a life sentence and I suggest one should be sure of one's facts before airily telling a syphilitic patient that he can do something which might pass the disease to his consort. Proof of a negative in this matter demands most scrupulous and exacting tests, and, until we have evidence that early syphilis is always eradicated by the usually prescribed course, the precautions and the after-treatment observation should be as severe as they ever were.—I am, etc.,

London, S.W.1.

L. W. HARRISON.

"Pilot" Tube for Bottles of Blood

SIR,—From time to time there is discussion in hospitals about the wastage of donor blood. It has been pointed out that the practice of cross-matching bottles of blood which are not subsequently needed can be made less wasteful if each bottle is accompanied by a "pilot" tube of the same blood, so that the main bottle need not be opened until it is actually needed. Two chief objections to this practice are made—that study of films to exclude the presence of organisms in the blood must be made with the bottle itself, and that a pilot tube may be detached from its parent bottle or wrongly labelled.

To the first of these objections there is, no answer, except that there are few laboratories where routine tests for infected blood are made. The second objection can be met by a method of incorporating the pilot tube in the bottle. I have devised a method which does not necessitate any alteration in the existing bottles. In place of the flat rubber disk covered by the aluminium cap at present used, a deep rubber stopper with an upper flange closes the neck of the bottle. Through an opening in this stopper a 10-ml. test tube fits tightly so that its top is flush with the top of the stopper. After the bottle has been filled a small quantity of blood is run through the tube of the taking set into this pilot tube, which is already in place in the stopper. Finally, the aluminium cap with its rubber disk is screwed firmly down to seal off the pilot tube. The accompanying diagram shows the stopper and tube in place and the cap closed. With this method the bottle and the tube are independently sealed, and there is no possibility of the pilot tube becoming separated from its parent bottle.—I am, etc.,

Northampton.

E. A. J. ALMENT.

Treatment of Threadworms

SIR,—Patients with hookworm disease often have an intense and persistent craving that compels them to eat earth and mud. Is it possible that the ancylostoma, in order to satisfy its own needs, influences the host in some subtle manner to supply the soil or mineral that it requires?

Children who harbour threadworms are reputedly always hungry, especially for sweets and sugar, and this is commonly taken by mothers and the laity as a diagnostic sign of the disease. Is this another example of a similar effect by a worm? This was the theory, admittedly erroneous, that suggested it may be possible to eradicate threadworms by altering the diet in such a way as to deny them the food they desired and thus starve them.

Obituary

HAROLD BALME, O.B.E., M.D., F.R.C.S.

Dr. Harold Balme, who died in London on February 13 at the age of 74, contrived, with conspicuous success, to live a life full of interest to himself and of great benefit to his fellow men. Towards the end of his professional life he became a leading authority on rehabilitation.

Harold Balme was born in London on May 28, 1878, the son of Mr. Paul Balme, and received his medical education at King's College and King's College Hospital. He won the Worsley scholarship in 1898, and in the course of his studies he won the Warneford, Leathes, and Todd prizes in medicine. As his aim was to become a medical missionary, he also studied divinity and won the Barry Prize. The outbreak of war in South Africa in 1899, however, upset his plans temporarily, for, like many others of his generation, he responded to the call for volunteers, and from 1900 he served with the Imperial Yeomanry Field Hospital, being awarded the war medal with three clasps. After the war he returned to London, and qualified by taking the M.R.C.S., L.R.C.P. in 1903. He then held the posts of resident medical officer at the London Medical Mission and clinical assistant at the Royal Eye Hospital and at King's College Hospital, and in 1905 he obtained the F.R.C.S. In the following year he went to China as a medical missionary at Taiyuanfu, in the Shansi province. In 1913 he was appointed professor of surgery in Cheeloo University (formerly known as the Shantung Christian University) at Tsinan and superintendent of the University Hospital, later becoming dean of the medical school. He became president of the University in 1921 and chairman of the first Council on Medical Education in China and president of the Council on Higher Education. His services to the profession in China were recognized by his election as an honorary member of the National Medical Association of China. He was elected also an Associate of King's College. A record of his experiences and his work is to be found in his book, *China and Modern Medicine: A Study in Medical Missionary Development*. Dr. Balme relinquished his appointment as president of the Cheeloo University in 1927 and returned to England to engage in consultant practice. In the following year he graduated M.D. at Durham University.

During the last war he worked in the Emergency Medical Service and became medical superintendent first of the Haymeads Hospital at Bishop's Stortford and later at Pinderfields Hospital, Wakefield. Before the war there was very little in the way of an organized service to help the disabled return to work, and of course as the war went on the need for such a scheme grew greater. Balme became one of the first to work in this field, and his services were recognized by his appointment as O.B.E. in 1942. Later on during the war he became the Ministry of Health's adviser on rehabilitation, and he brought to that task the same enthusiasm and energy he displayed in everything else he undertook. In 1944 he wrote a booklet for the British Council entitled *The Unfit Made Fit*. After the war he became consultant adviser on rehabilitation to the United Nations, the World Health Organization, and the United Nations International Children's Emergency Fund, work which took him to many European countries. Last September he was in Sweden directing the group training course

was noticed that the patients who suffered from threadworms were either children or pregnant women in both of whom the diet was a low-protein high-carbohydrate one as compared with that of the general population. These patients were therefore treated by altering the diet so as to decrease the carbohydrate and starch and increase the protein and fat. Sugar was eliminated as far as possible, starchy foods were reduced, and meat, fish, eggs, and butter were given in increased amounts. For example, the usual breakfast of cereal and sugar, bread and jam, was replaced by one of bacon and egg with bread fried in fat. The amount of milk was not changed. A mild laxative was used once or twice a week but was later given up as unnecessary. The results were consistently and entirely satisfactory, complete cure being achieved in about two weeks, and relapses did not occur while the patient was on this adult type of diet. During twenty years of busy general practice I treated a great number of patients with threadworms by this method with unvarying success, and I am convinced that dietary measures are simpler, more efficacious, and preferable to treatment by vermifuges and enemata.

Confirmatory evidence of the link between diet and threadworms will be provided by older obstetricians, who will remember the prevalence of this infection in those pregnant women who avoided protein because of its supposed injurious effect on their kidneys compared with its absence since the modern high-protein low-carbohydrate diet has been adopted. Some explanation is required to account for threadworms being predominantly a disease of childhood, for surely everyone is equally liable to infection. From my experience it would seem that the presence and persistence of threadworms in a patient depend on the chemistry of the bowel contents which makes the environment favourable for their growth, and that this is to a great extent dependent on the diet.

I should be interested to learn if threadworm infection is more prevalent in Great Britain since the reduction in the consumption of meat, or has this been replaced by adequate protein from other sources?—I am, etc.,

IVON HAYES.

Melbourne, Australia.

The British X-ray and Radium Protection Committee Valedictory

SIR,—A disturbing series of deaths amongst early workers with x rays led a small group of their surviving colleagues in 1921 to formulate some rules which would prevent a continuance of such casualties. Thus was born the British X-ray and Radium Protection Committee. The late Sir Humphry Rolleston consented to become its first chairman. Under him, and largely financed by him, the first memorandum was issued in July of that year and the first detailed report followed in 1923. The code was welcomed by all classes of radiological workers and formed the basis for similar recommendations in most countries of the world and for subsequent international recommendations.

Towards the end of the war the Medical Research Council set up a Committee on the Medical and Biological Applications of Nuclear Physics. Its subcommittees, and particularly the Tolerance Doses Panel, under the chairmanship of Professor Mayneord, produced a large series of papers dealing with the fundamental data upon which protection measures for all those dealing with sources of ionizing radiations could be formulated. With the passing of the Radioactive Substances Act, a statutory committee came into existence. Whilst the Medical Research Council groups are concerned with the research aspects, the statutory committee has a duty in respect of regulations and licences, and is concerned with codes of practice over the whole extensive field now to be covered. In these circumstances the British X-ray and Radium Protection Committee, which, despite its lack of any statutory authority, had attained international status, had lost its *raison d'être*. A final meeting was held in September, 1952.

The passing of a committee through which Great Britain set a pattern for the world would seem to be a landmark that deserves record. At the suggestion of its last chairman, this letter is signed by the two surviving members of the 1921 meeting.—We are, etc.,

CUTHBERT ANDREWS.
SIDNEY RUSS.

London.

on the rehabilitation of the adult disabled, and in the previous May he was present at the opening by the President of the Austrian Republic of the rehabilitation and training centre at Tobelbad, near Graz, a centre which Dr. Balme himself described in an article published in this *Journal* on November 15, 1952.

During his work in China Dr. Balme published many articles on a variety of medical subjects, including one with the intriguing title, "Intussusception Through the Neck of an Opium Lamp-glass Shade" (*China Medical Missionary Journal*, 1907). After his return to London he wrote a book on *The Relief of Pain* (1936), and another entitled *A Criticism of Nursing Education, with Suggestions for Constructive Reform*. In the writing of this book his experience as a member of the council of the Royal College of Nursing stood him in good stead.

Dr. Balme married Miss Hilda E. Carr, of Carlisle, in 1910, and she survives him, together with their only son, who is principal of the University College of the Gold Coast.

Dr. C. F. HADFIELD writes: Dr. Harold Balme's great administrative ability was put to a severe test when in 1939 he was appointed medical superintendent of the Haymeads E.M.S. Hospital at Bishop's Stortford. An initial difficulty was that this was an office which had never previously existed, and still apparently did not exist. Haymeads was an infirmary rather than a hospital and so had no medical superintendent, its medical needs being served from outside by a local practitioner. All real control was in the hands of the local and county council authorities. The buildings were old and inconvenient, there being only two wards in any way approaching modern standards. There was not even a dispensary of any kind. From such beginnings Dr. Balme succeeded in threading his way through a network of local customs and established routine, and so laying the foundations of what quickly developed into a really well-equipped and modern hospital of some 800 beds. One secret of his success was the manner in which he speedily obtained the loyal support of his medical staff. This staff had been collected from a variety of sources, and at the start most of its members were quite unknown personally to himself or to each other. By means of friendly contacts, and almost daily staff consultations, he quickly converted it into a homogeneous, friendly, co-operative, and, it may be claimed, efficient unit.

Professor JOHN KIRK writes: To remember Harold Balme is like contemplating a giant tree in the forest, a monarch supreme, and pre-eminent among its kind. Those of us who were privileged to know him in his China days will always count that experience as one of the gladdening and enriching episodes of our lives; here was a man endowed with intellectual gifts of the highest order, possessing outstanding medical skill, and having powers of administration and leadership which marked him out in any company. Yet, when one has recognized and said all that, one feels that one has completely failed to describe the true greatness of Harold Balme. As one seeks to account for the impression he made on his colleagues and friends, one realizes that springing up in him and overflowing from him was an exuberance of spiritual freshness and buoyancy which pervaded all his life and made even an occasional meeting with him a tonic of happiness. It was in China that I knew him best, and there the effect of his life upon his Chinese colleagues and students was just as sure and noticeable as upon those of his own race. One of my early impressions was of discovering his fluency in the Chinese language and his ability to give lectures on surgery in the Shantung medical school which were not only completely intelligible but eagerly appreciated by his students. As a medical missionary in planning and in action he was alike superb. He was not only a skilled clinician, but his compassion flowed continuously from his heart to his fingertips. He was an eloquent and convincing speaker and a

gifted writer. With statesmanlike vision he grasped the truth that for the West to extend the benefits of modern medical science to China without at the same time giving her a medical profession enlightened and inspired by the Christian faith was to discharge only half of the obligation. Thus medical education in an atmosphere like that of the Shantung Christian University won and held the utmost loyalty and energy of his mind and heart. The world does not often see men like Harold Balme, and though our sense of sorrow at his passing is inevitable our deep sense of thankfulness for his life overwhelms the sorrow.

RANSOM PICKARD, C.B., C.M.G., M.D., M.S.
F.R.C.S.

We record with regret the death of Colonel Ransom Pickard, the well-known ophthalmic surgeon, at his home at Exeter on February 9 at the age of 85.

Ransom Pickard, who was born on May 18, 1867, received his medical education at St. Bartholomew's Hospital, qualifying in 1889 and graduating M.B. in the same year. He won the gold medal in medicine and gained first-class honours in forensic medicine and honours in obstetrics. After qualifying, he held appointments as ophthalmic house-surgeon at St. Bartholomew's Hospital and clinical assistant at Moorfields Hospital. Between 1891 and 1893 he obtained the B.S. with first-class honours, the F.R.C.S., the M.D., and the Cambridge D.P.H. Having acquired all these distinctions, Pickard elected to live at Exeter, where after a few years in general practice he established himself as a consultant ophthalmologist, being elected to the staff of the West of England Eye Infirmary. He acquired a great reputation, both locally and nationally, as an ophthalmic surgeon, and from 1934 to 1936 he was president of the Section of Ophthalmology of the Royal Society of Medicine. One of his special interests was glaucoma, and he published several papers on this and other eye diseases. His hospital work was all-important to him, but it was inevitable that one who took such pains with his patients should build up a large consulting practice, and his reputation spread far and wide. His character and ability soon brought him into prominence in civic affairs, and he was sheriff of Exeter in 1906-7 and mayor in 1926-7. He took a great interest in the University College of the South-west, of which he became a vice-president.

In the first world war he served in the R.A.M.C., and was placed in command of the 1st Wessex Field Ambulance, which he had helped to raise. He went to France immediately war broke out, and later was promoted to colonel and appointed A.D.M.S. of the 48th Division, with which he served in Northern Italy. He was five times mentioned in dispatches, and for his services he was appointed C.M.G. in 1916 and C.B.E. in 1919. He also received the Italian Croce della Guerra. During the last war he served as chairman of the local medical war committee.

A member of the British Medical Association for 58 years, Pickard served as one of the honorary secretaries of the Section of Ophthalmology when the Association held its Annual Meeting at Exeter in 1907, and he was a vice-president of the same Section at Portsmouth in 1923. He was president of the South-western Branch of the Association in 1927-8, and was also on the Ophthalmic Committee for some years.

Pickard developed a great love for the West England, and for Devon in particular. At one time he was a keen mountaineer, but as the years went by he took his exercise in the form of long country

on which his wife usually accompanied him. He was a past president of the Devon Archaeological Exploration Society, and in 1947 he published a monograph on *The Population and Epidemics of Exeter in Pre-Census Times*. A lifelong Methodist, he was a non-smoker and teetotaler, but was never one to thrust his personal views upon others. In 1912 he married Miss Mabel Lucy Childe, and the sympathy of all his many friends will go to his widow. By Colonel Ransom Pickard's death Exeter has lost a fine citizen and the medical profession a worthy and distinguished member.

Sir HOLBURT WARING, Bt., C.B.E., M.S., F.R.C.S.
We are indebted to Mr. R. W. RAVEN for the following appreciation:

The death of Sir Holburt Waring, whose obituary notice was published in last week's *Journal* (p. 456), diminishes further the number of those outstanding men who played such an important part in guiding and developing British surgery during the first half of this century. Each in his particular way made an important contribution. Few have possessed like him such ability in so many fields, or the clear vision which penetrates so far into the future and the deep convictions providing the motive force for action. He was a dominant figure for many years, and time was granted him after retirement to see many of the results of his labours. As one of those privileged to receive his early surgical training from Sir Holburt, may I offer my tribute to his memory? His old house-surgeons cannot fail to look back with gratitude upon the time we worked for him, when the fundamental principles of surgery were instilled into us and our habits of thought and reactions were consolidated. He set a high standard without leniency and his methods were a ritual. How much we admired his wonderful hands as we watched him examine a patient or assisted him at operations. What a depth of surgical knowledge and experience there was to draw from. In his home we also probed beneath the surface and found a deeper feeling and a friend. He was always greatly interested in the problems of cancer, and his book *The Surgical Treatment of Malignant Disease* is full of his mature surgical wisdom.

Sir WILLIAM DOUGLAS, G.C.B., K.B.E.

The many friends of Sir William Douglas, Permanent Secretary to the Ministry of Health from 1945 to 1951, will have heard with great regret of his death on February 17. He was 62 years of age. We are indebted to Sir WILSON JAMESON for the following appreciation:

When Sir John Maude retired from the office of Permanent Secretary to the Ministry of Health in 1945, most of the preparatory work for the proposed National Health Service had been done. A Bill had been drafted and might well have been presented to Parliament had not the war in Europe come to an end and a Labour Government taken the place of the wartime Coalition. Who was to be the new Parliamentary Secretary? The appointment was nearly as important as that of the new Minister. The choice fell upon Sir William Douglas (Willie Douglas to all his Civil Service contemporaries), and he rather unwillingly left the Ministry of Supply for what he knew would be something of a political storm centre for the next few years. Douglas was a born negotiator. He was attractive in appearance and persuasive in speech. He was in his element as chairman of a conference. No matter how awkward the question put to him or how unpleasant the decision he had to impart, he would give his tie a twist and his head a shake, and the situation would be dealt with in such a way as to cause the least possible ill-feeling. Though he was at times sorely tried by the protracted arguments and discussions with the various sections of the medical profession prior to the appointed

day, he always retained his good humour and his debonair manner. He was a good friend to the doctors, as members of the B.M.A. know very well. I myself could not have wished for a kinder or more helpful colleague. Unlike his predecessor, he rarely put pen to paper. His business was to see people and to talk to them, not to draft letters or memoranda. All his drafting was done for him, and he was fortunate in having such able assistants.

As one would expect, Douglas had lots of friends. He was a good golfer, and no Civil Service golf meeting was complete without him. It was strange, too, how often official business took him north when an international was staged at Murrayfield. He had made all his plans for a happy and useful retirement and had just got well into his stride when his fatal illness overtook him. The Ministry of Health and the medical profession were fortunate in having his help during those critical five years.

Dr. A. ESMEE RUCK was brutally murdered at her home in Kenya on the night of January 24, together with her husband, Mr. Roger Ruck, and their only child, Michael, aged 6 years. Adeline Esmee Ruck, better known to her colleagues by her maiden name of Esmee de Smidt, was born at Cambridge in July, 1920, the only child of Captain F. P. G. de Smidt, a member of the medical profession who had a distinguished career as a bacteriologist, and who served in the Colonial Medical Service in Kenya from 1926 to 1936, when ill-health caused his retirement. Esmee de Smidt was educated at the Limuru Girls' School and at the Kenya High School, and graduated M.B., Ch.B. from the University of Capetown in 1943, thus becoming the first woman pupil of a school in Kenya to graduate in medicine. In 1945 she was appointed a temporary medical officer in Kenya, serving in the Native Civil Hospital, Nairobi, and working chiefly among the children of the Kikuyu tribe. The children, for whom she had a real affection, made up the majority of the patients in the overcrowded ward in which she laboured. A year later she had to give up the work when she became herself a mother. In 1947 she took the D.P.H. at Capetown and returned to Kenya, where in recent years she had conducted a dispensary for Africans in the farming area in which she and her husband had settled. Dr. Ruck had a winning way which tended superficially to cloak her fine intellect. Though never robust in health, she accepted the reverses of life with fortitude and devoted herself to her profession, to her husband, and to their only child. While fully conscious of the danger which surrounded her home, she felt it her duty to remain there and was looking forward to restarting the dispensary for Africans in a few months' time, when her son was due to leave for a boarding-school. That the three should be deliberately and savagely killed in one night is a tragedy indeed for Kenya. Dr. Ruck is mourned by her professional colleagues of all races. She is survived by her invalid widowed mother, to whom our deepest sympathy is extended. —F. J. W.

With the death of Dr. W. W. HORTON on February 4, within a few days of his 95th birthday, one of the few remaining links with the Edinburgh of the 'seventies has been severed. Born on February 10, 1858, Wilfred Winnall Horton was educated at Shrewsbury and at the University of Edinburgh, which he entered in 1875. He graduated M.B., C.M. in 1880, and proceeded M.D. four years later. After holding appointments at a number of mental hospitals, Dr. Horton was in general practice, first in the U.S.A. and then for 20 years at Malvern. In 1915 he entered the R.A.M.C. and was attached to the Gloucestershire Regiment. On being invalided out of the service in 1917 he became medical superintendent of Wye House, a private mental hospital at Buxton, and remained there for 22 years, retiring at the age of 81. On the rare occasions he talked about his early days, Dr. Horton would describe his student years as being a time of transition, especially in surgery.

His reminiscences were full of interest. He had seen operations performed in a carbolic spray produced by a steam kettle; he knew Cunningham as an able demonstrator in anatomy and Huxley as a temporary lecturer—"interesting, but far above the heads of the students most of the time." He remembered James Spence operating in an old frock-coat kept for the purpose and scorning Lister's newfangled antiseptic methods; Lister himself, lecturer in clinical surgery, a revered figure; and finally Joseph Bell, extramural lecturer in surgery, who entertained the students by displaying his remarkable powers of observation and was afterwards immortalized by Conan Doyle in the person of Sherlock Holmes. Dr. Horton was much loved by his patients, both in general practice and in mental hospital work, and he stood for all that is best in the profession to which he belonged for over 70 years.

Dr. E. A. BARTON, a well-known general practitioner in Kensington before his retirement, died at University College Hospital on February 10 at the age of 89. Born on July 12, 1863, the son of the late Dr. A. B. Barton and a nephew of Mr. Berkeley Hill, a surgeon at University College Hospital, Edwin Alfred Barton, who was educated at Harrow, was originally intended for the Army, but he decided to follow in his father's footsteps and studied medicine at University College Hospital, where he qualified in 1887. While holding an appointment as house-physician he had under him as clerks such men as Leonard Hill, George Murray, of Newcastle-upon-Tyne, who became notable for his work on the thyroid, and Herbert Tilley, later well known as a throat specialist. Subsequently he obtained the coveted post of outdoor obstetric assistant. In his book *A Doctor Remembers* he described the dirt, squalor, and drunkenness which were then rife in the districts around University College Hospital. After further hospital work he went into partnership with an elderly doctor in Kensington Square in 1890, and remained in practice in Kensington for 40 years, retiring in 1930. On the outbreak of war in 1914 he offered his services to University College Hospital, where he became anaesthetist to out-patients. Later he became medical officer to the hospital's child welfare department. Dr. Barton had many outside interests, being a keen photographer and fisherman, and a vice-president of the Flyfishers' Club. In addition to the book mentioned above, he wrote *Essentials of Infant Feeding* (1925), *Chalk Streams and Water Meadows* (1933), *Running Water* (1944), and *An Album of the Chalk Streams* (1946). Some years ago he contributed a sincere and impressive article entitled "Death and Euthanasia" to the *University College Hospital Magazine*. He married Margaret E. Pittis in 1895, and she, with their daughter, survives him.

Medical Notes in Parliament

Medical Research in Scotland

The Hospital Endowments (Scotland) Bill was given a second reading in the House of Lords on February 18.

The EARL OF SELKIRK explained that it was based on the recommendations of the Hospital Endowments Commission, which was established to prepare schemes for the regulation of endowments transferred to hospital boards of management under the National Health Service (Scotland) Act. The Commission had recommended that part of these funds should be devoted to research, under an independent trust, and it was estimated that about £120,000 a year would be available for the purpose. There was a wide measure of support for the scheme in Scotland. The Chairman of the Commission, Sir Sydney Smith, had borne in mind that adequate funds must be available to provide reasonable amenities at individual hospitals, and had said that even when a research fund had been provided the hospitals would be reasonably catered for.

The Bill set up the trust, and empowered the Endowments Commissioners to transfer funds to it. The Chairman and members of the trust would be appointed by the Secretary of State, and would probably number about seven. The trust would be able to receive also legacies and gifts. They were to consult an advisory committee, which in the first instance would be the Advisory Committee on Medical Research under the chairmanship of Sir Edward Appleton, Principal of Edinburgh University. This body had links with the Medical Research Council, so that as far as possible there would be no overlapping or difficulty, and information would be circulated as widely as possible.

LORD INMAN attached particular importance to money given for definite purposes being used for those purposes if at all possible, and to the importance of consultation with other research bodies to avoid overlapping.

LORD KINNAIRD asked if the trustees would be able to consider applications for grants for research work in hospitals outside the National Health scheme, and instanced the research work on tuberculosis at two hospitals near Aberdeen run by the Scottish branch of the British Red Cross.

The EARL OF SELKIRK said that it was implicit in the Bill that funds given for specific purposes should not be diverted to uses antagonistic to the donors' intentions. It was clear from the report of the Endowments Commission that there would be adequate funds available for the hospital management boards. The total capital of the funds was about £13m. The purpose of the Bill was to enable the trustees to assist any medical purpose that might be brought to their attention if they thought it worthy of assistance. It mattered not whether the establishment concerned was connected with the National Health Service or was a private hospital, a university, or any other organization, if they considered it most useful to promote a particular type of research.

Proprietary Medicines

Mrs. JEAN MANN asked on February 17 about the amount spent in prescriptions in 1950, 1951, and 1952 on slimming tablets, and what researches the Scottish Office had made to satisfy itself as to the value of these tablets in reducing obesity.
