

a new way to maintain acidity within controlled limits

In the treatment of GASTRIC HYPERACIDITY
and the control of PEPTIC ULCER,
this new product acts as an antacid buffer
giving prompt action and prolonged effect
within a definite and safe pH range.

Each tablet contains:—
Aluminium glycinat (Dihydroxy aluminium
aminoacetate): 0.9 gramme
Magnesium carbonate : 0.1 gramme

PRODEXIN

DIHYDROXY ALUMINIUM AMINOACETATE

- ⊕ Gives prompt relief from pain.
- ⊕ Has a prolonged and stable antacid action.
- ⊕ Raises and keeps gastric pH in the 'safe zone' of 3.5 to 4.5.
- ⊕ Facilitates healing of peptic ulcer.
- ⊕ Is free from such side-effects as acid rebound and constipation.
- ⊕ Pleasant to take: convenient: economical.

tablets

PRODEXIN tablets, each in protective wrapping, are available in cartons of 30, at 5/3d. Retail price includes Purchase Tax and is subject to professional discounts.

CARDIFF, JULY 13-17
STAND 36

Manufactured in the Laboratories of
C. L. BENCARD LTD.
PARK ROYAL, LONDON, N.W.10

longer allergy protection

... 8 to 24 hours from
a single dose

WHEN a chemically different antihistaminic combines the convenience and economy of fewer doses with proven effectiveness and minimal side-effects, why not give it a full, fair trial this season?

Your hay-fever patients will really appreciate the 8 to 24 hours of relief they can receive from a single dose of DI-PARALENE. Note the results in the accompanying table reprinted from our literature.

benefit reported from use of Di-Paralene in 184 cases

Allergic State	Number of Cases	Cases in which Moderate to Complete Relief was Reported	Per cent Relief
HAY-FEVER	43	41	95
Urticaria	41	37	90
Allergic Rhinitis Non-seasonal	46	35	76
Asthmatic Bronchitis	19	13	68
Miscellaneous Dermatoses	35	23	66

Start your allergy patients with 50 mg. doses of DI-PARALENE three times daily. If the response is satisfactory, try reducing the dosage to twice daily, then once. The single daily dose should be administered about two hours before the time of day when peak symptoms occur.

DI-PARALENE is supplied in 50 mg. tablets, bottles of 25, 100, and 500. Ask our representative for literature, or write to Abbott Laboratories Ltd., Perivale, Greenford, Middx.

A MECHANICAL HEART-LUNG FOR USE IN MAN

BY

D. G. MELROSE, B.M., B.Ch.

*Assistant Lecturer, Department of Surgery, Postgraduate Medical School of London**

With a Foreword by IAN AIRD, Ch.M., F.R.C.S.

Professor of Surgery, Postgraduate Medical School of London

Foreword

Some years ago the department of surgery in the Postgraduate Medical School of London was concerned with research in the perfusion of isolated human organs. The perfusion of isolated organs by blood artificially oxygenated and propelled by a mechanical pump cannot be continued for more than a few hours. After some hours the perfused organ swells visibly and the outflow of blood from it progressively and rapidly diminishes. After a short and not very successful examination of the problem of prolongation of the survival time of isolated organs in these conditions attention was turned to the extracorporeal heart-lung circulation for the maintenance of the circulation of the experimental animal by a total replacement of its own heart and lungs, comparable to that which would be required in the application of an apparatus of this kind to intracardiac surgery. It seemed to us, after some experience in this field, that a machine to undertake the whole function of heart and lungs in a patient subjected to intracardiac surgery was not yet an immediately attainable aim.

Animals maintained entirely on an extracorporeal heart-lung circulation sometimes survive for indefinite periods, but a high proportion fail to survive, perhaps for reasons not dissimilar to those which make prolonged perfusion of the isolated organ impossible. The natural lung may have other functions than oxygenation. In any case, there are immediate practical difficulties in employing a heart-lung machine to replace the heart and lungs of a patient subjected to cardiac surgery. Heparinization must be complete, and the difficulty of obtaining a bloodless field even in a heart to which blood is not returned by the venae cavae has already been demonstrated at least once in man. Our attention accordingly passed to the use of a heart-lung machine as a form of "assisted circulation."

Our aim in this field became the ultimate use of an artificial heart-lung machine for the treatment of certain acute forms of cardiac or pulmonary failure. The value of artificial oxygenation of the blood for even a short period in acute pulmonary oedema or status asthmaticus seemed obvious enough, for, provided the patient can be kept oxygenated for a time, these pathological circumstances are often self-limiting. In coronary thrombosis there are patients in whom it might be expected that the

temporary provision of a high aortic pressure might tide the patient over a fatal low-pressure period, and might improve such coronary circulation as was still open. In congestive heart failure, when failure has been due to a relatively small fall in a previously low cardiac output, to withdraw blood from the congested veins and to perfuse it oxygenated into an arterial tree would seem to combine the advantages of venesection and adequate oxygenation. The mechanism would have a particular advantage in preparing grossly cyanotic sufferers from mitral stenosis for a valvulotomy which they could not otherwise sustain. Dr. Melrose proceeded to devise an apparatus which might ultimately be applied to these and similar purposes and to test that apparatus in the form of an assisted circulation in parallel with the natural circulation of an experimental animal. The results of his whole-time activity in this field over a period of four years are recorded in the two papers which follow. His data indicate that his machine might now be justifiably and humanely applied to certain varieties of anoxia and circulatory failure in man.

Artificial Maintenance of Life

The possibility of maintaining life artificially in animals or parts of animals has excited the interest of many over the last century. Numerous attempts have been made to create an apparatus capable of this, but until the last decade these efforts have been sporadic and isolated in character. The publication by J. H. Gibbon, jun., in 1937 of a paper on artificial maintenance of the circulation during experimental occlusion of the pulmonary artery heralded the beginning of a new approach to the problem. His object was to short-circuit the heart and lungs of animals to allow intracardiac surgery in a bloodless field. Coinciding as it did with the emergence of a new era in surgery—that of replacement rather than ablation—his work stimulated a great new interest and challenge which was taken up in many surgical centres. This challenging problem was, and still remains, to produce an extracorporeal apparatus capable of maintaining temporarily the entire circulation of the human body.

Contributions in this field from Crafoord and Björk in Sweden, Kolff and Jongbloed in Holland, André Thomas in France, Dennis and Leland Clark in America, and many others have resulted in continuous progress, and now the stage is almost set for clinical use.

*Part of the work was done under the tenure of a Studentship in Research from the Medical Research Council.

Stimulated by these advances, it was decided in 1949 that a machine should be constructed to serve three purposes. First, to carry temporarily a part of the cardio-respiratory function when the function of either or both of these organs is impaired; secondly, to provide a complete diversion of the blood stream away from the chambers of the heart in order to permit intracardiac surgery; and, thirdly, to perfuse isolated organs.

FIG. 1.—The pump-oxygenator with controlling apparatus.

The Pump-oxygenator

Initially, considerable experience was gained with a pump-oxygenator essentially similar to that described by Björk (1948a) and Crafoord (1949). In this machine a number of disks dip into a trough of blood; when rotated they pick up on their surfaces thin films of blood, exposing them to an atmosphere of oxygen, and in this way create a large gas-liquid interface. After this method had been investigated and compared with other methods, particularly those involving the dispersal of oxygen as minute bubbles, it was decided to embody the principle of rotating disks in a machine of novel design capable of circulating adequately oxygenated blood at a rate of at least 3 litres a minute (Fig. 1).

Two factors are important in the utilization of this principle. The first is that the optimum period for which each red blood cell should be exposed to oxygen is in the region of half a second. The second factor is that the exposure time must be achieved without increasing above a definite maximum the speed of rotation of the disks. Rotational speeds in excess of 80 r.p.m., corresponding to a velocity at the periphery of the disks of 52 cm. a second, frequently lead to foaming of the blood.

These two factors are of major importance, since they limit the effective area for oxygenation of each plate, but there are others which also affect the efficiency of such machines. These are: (1) The area of interface between blood and gas should not vary with changes in the volume of blood in the machine. (2) Mixing of blood should be very complete, for no provision can be made to replace completely each saturated film, after exposure to oxygen, with one as yet unsaturated. (3) The measures to ensure mixing should not impede smooth and rapid flow through the machine. (4) Foaming if it occurs should not greatly interfere with the efficient operation of the artificial lung. (5) The

apparatus should be capable of being completely dismantled for effective cleaning. (6) Adequate surface area should be obtained without the use of a very large volume of blood to charge the machine. (7) For ease in maintaining sterility, a system as nearly closed as possible is desirable.

From these considerations it is seen that enlarging the diameter of the disks makes a longer exposure of time inevitable if a safe rotational speed is to be maintained, while increasing the number of disks greatly increases the blood volume required for charging. Neither of these measures, nor a combination of them, confers any improvement in the mixing, or in ensuring the maintenance of an optimum blood film size.

The Oxygenator

The new oxygenator (Fig. 2) is essentially a rotating cylinder set at a slight angle to the horizontal. Within it blood travels under the influence of gravity from one end to the other, and is spread over a multitude of surfaces formed by blades projecting into the lumen of the cylinder. These blades are arranged within the cylinder somewhat in the form of an Archimedean helix. This analogy is not strictly accurate, but may clarify the method of construction, which is in fact carried out in the following manner. A cylinder of "perspex" 30 in. (76 cm.) in length and of internal diameter of 8 in. (20.3 cm.) is free to rotate in its long axis while supported on rollers at 20 degrees to the horizontal. It is closed at each end by an end-plate of "tufnol" 10 in. (25.4 cm.) in diameter. In this cylinder

FIG. 2.—The oxygenator.

annular plates of 1/24 in. (1 mm.) perspex, with an overall diameter of 7 1/4 in. (20 cm.) and an internal diameter of 4 1/4 in. (11 cm.), are separated one from the other by annular washers. These washers have the same external diameter as the plates but an internal diameter of 5 1/4 in. (13.6 cm.).

FIG. 3.—Sectional drawing of the oxygenator, indicating form of construction.

They are constructed from perspex 5/16 in. (0.8 cm.) thick. The holes in the plates are concentric, but the holes in the washers are cut eccentrically, the centres of the hole being 1 in. (2.54 cm.) from the true centre of the washers.

These plates and washers are mounted in the cylinder on chromium-plated rods and are freely detachable for cleaning. A maximum of 76 plates and their separating washers may be used to provide a surface area of approximately 1 square metre.

The plates (Fig. 3) are fitted so that their central holes form a cylindrical cavity, coaxial with the enclosing cylinder.

FIG. 4.—A portion of the oxygenator in sagittal section.

der, but the arrangement of the washers between each plate varies with each group of five. Each group of five washers are mounted so that the holes in them form a cylinder eccentric to the cylinder formed by the holes in the plates, and, as the internal diameter of the washers is larger by 1 in. (2.54 cm.) than that of the plates, these plates project as crescents within the cavity formed by the holes in the washers. Each group of five washers and plates is arranged relative to the next group so that crescentic protrusions of the plates are at opposite poles. In sagittal section, therefore, the cylinder presents a series of alternating platforms and troughs, these troughs being subdivided into five compartments by the five plates (Fig. 4).

Passage of the Blood

In describing the path of the blood passing by gravity along the tilted oxygenator, it is helpful to consider first the hypothetical case in which both washers and plates are fitted so that the holes in them are concentric. A pool of blood would lie along the base of the cylinder formed by the holes in the washers to the depth of the level of the holes in the plates. Rotation of the oxygenator would not affect the position of the pool in space. Where the holes in the washers are eccentric to the holes in the plates and the circumferences of these holes touch at one point in any group of five, a different action is apparent. When the point of touching is at top centre a pool of blood will be formed as in the previous case. During any revolution, as the point of touching approaches bottom centre this pool will be emptied by the action of the washers, which in effect rise to the level of the holes in the plates. The alternation of phase between adjacent groups ensures that as a pool in one group empties so it is re-created in the next group.

Further, during any revolution the crescentic projections of the plates are alternately fully covered by the pool of blood, and also, together with adherent films of blood, fully exposed to the gas contained in the oxygenator.

The stream of blood passing down the oxygenator is alternately raised and lowered by the action of the washers. This action avoids the necessity of the edges of the plates cutting across the streamline in order that they may become

covered with blood. In fact, blood is poured over the plates and into the pool formed between them, then raised up and carried down the oxygenator before being poured over the succeeding group of plates.

This arrangement permits a thorough mixing of the blood with a smooth and rapid passage along the machine. It also ensures that all the available surface area is utilized without reference to the volume of blood contained in the machine. Furthermore, it enables the machine to work with a relatively small charge of blood.

The cylinder is rotated by a friction wheel, driven by an electric motor. Adjustment of the position of the driving wheel in relation to the diameter of the end-plate allows cylinder speeds between 24 and 120 revolutions a minute to be obtained. At maximum speed the surface area exposed per minute is in the region of 120 square metres, though it is preferable to use only as great a rotational speed as is necessary to obtain efficient oxygenation.

The inlet and outlet tubes for the blood, together with the inlet for oxygen and a fourth tube used to estimate the level of the blood in the collecting chamber, enter at one end. These tubes are carried by a perspex rod which passes through a simple felt seal in one end-plate down the centre line of the oxygenator to a chromium-plated bearing on the other end-plate. No attempt has been made to make a gas-tight seal, though this is undoubtedly possible.

Experience has shown that the distance between the plates can be reduced from 5/16 to 3/16 in. (0.8 to 0.48 cm.) without increasing the danger of foaming. It is expected that a moulding in nylon or teflon (polytetrafluorethylene) will be produced combining both washer and plate, and this will enable the number of parts to be halved. It will also enable autoclaving to be used for sterilization. This latter point is undoubtedly of great importance, and might be considered essential in a machine for use in human beings. Further, during the moulding process a large number of corrugations can be pressed into the surface of the plates and the surface area of each greatly increased.

The Pumping Circuit

Since the oxygenator is not part of a closed circuit, it is essential that two pumps be used; one to act as the right side of the heart to supply the artificial lung and the other as the left side of the heart to return oxygenated blood to the recipient.

The pumping circuit must not only be capable of circulating blood at physiological rates and pressures without destroying its constituents, but must also be capable of exact regulation. For this purpose the most satisfactory pump is a rotary type without valves in which an elastic tube, through which the blood passes, is squeezed within the pump by the action of a roller. The decision to employ this type of pump was made after comparison with many forms of the Dale-Schuster pump. It has obvious advantages over the latter in simplicity and ease of sterilization, but had a disadvantage in that the action of the roller in squeezing the tube sometimes caused greater haemolysis. Investigation revealed that this was largely due to the scrubbing of one wall of the tube on the other, an effect produced by the severe shearing forces set up by the roller in squeezing the tube. Re-design of the pump tested, a model based on the design of Henry and Jouvet, resulted in a considerable reduction of this effect, which in turn reduced the rate of haemolysis by as much as 70% in some comparisons.

The pump (Figs. 5, 6, 7, and 8) now used consists of a circular housing in which there is clamped a loop of tube. Within this loop is a large single roller free to rotate on ball-bearings which are mounted on a compound driving shaft. This shaft is made up in the following way. A central driving spindle has fixed to it a cam, the centre of which is 1/4 in. (0.6 cm.) from the true centre. On this cam is carried an outer cam the centre of which is also 1/4 in.

from the true centre. This outer cam is free to rotate about the inner one, but may be locked in any position. Adjustment of the outer cam on the inner one provides any degree of throw from 0 to $\frac{1}{4}$ in. (1.3 cm.). In operation the outer cam is adjusted so that the roller carried on the shaft just closes the lumen of the tube in the pump. Then rotation of the driving spindle carries the roller around the

arterial pump is working, and one measures the pressure at which the venous pump is working. The signals from the three manometers are used to form a pattern of servo-loops which result in automatic adjustment of the pumping speed.

The most important function of the control is to ensure that the volume of blood in the machine is constant within narrow limits under varying conditions. As no two pumps of the type employed can be relied upon to deliver constantly matched outputs, it is essential that the rates should be controlled from the blood volume within the artificial circulation, as this will give a true indication of any imbalance between the two. For this reason the signal from the volume indicator manometer is used to induce the two pumps to work at such speeds that they will deliver the same blood flow.

The signal derived from the arterial pressure manometer can be used either to adjust automatically the rate of circulation to such a value that it maintains the blood pressure at a fixed level or as a limiting device to slow down or stop the circulation in the event of the pressure rising above a limit. Since the rate of circulation ultimately depends on the venous return available and as any excessive suction from the venous pump merely collapses the veins, it is clear that the suction pressure must play an important part in the controlling system. The signal from the venous suction manometer performs the same function in the control of the venous pump as the arterial pressure signal does for the arterial pump—that is, it tends to reduce the speed of pumping as the suction pressure rises, and will bring the circulation to a stop when a limit is reached. Hence a compromise is established

—the two pumps working to maintain the blood volume and the arterial pressure, and to prevent the venous suction becoming too great.

This control gear, with its indicating instruments, warning lights, and switches, is housed in a separate trolley. On the control panel of this trolley are arranged the manual and automatic speed-control selectors with meters indicating the rate and pressure at which each pump is working. Another meter indicates the volume of fluid in the oxygenator. Warning lights are placed above the pressure gauges and the fluid volume meter to draw attention to any variations that exceed chosen limits.

Working of the Pump-oxygenator

On the main trolley the pumps and oxygenator are arranged so that easy access to them is possible. The oxygenator lies on rollers in a recess in the top of the trolley and is covered by a transparent hood. Within this recess a constant temperature can be maintained by warm air, heated by infra-red lamps and circulated by a fan under thermostatic control. Oxygen and carbon dioxide are delivered to the oxygenator through rotameters which allow adjustments of flow rate to maintain the appropriate carbon dioxide tension. The gases pass through a warming, filtering, and humidifying system and then traverse the oxygenator in the opposite direction to that of the blood. A device

FIG. 7.—A loop of tubing in position between the pump housing and the roller, which is in the concentric position. FIG. 8.—The pump fully assembled. The tube is clamped within the pump housing and is compressed by the roller, which has been adjusted to a degree of eccentricity sufficient to close the lumen of the tube.

inner wall of the pump housing, causing it to squeeze the tube in such a manner that a pumping action is obtained. Adjustment is simple and rapid, no blood comes into direct contact with any moving parts, and a pulsatile flow is obtained.

Control Mechanism

The stroke volume depends only on the bore of the tube, and in the pump used this may be varied from $\frac{1}{4}$ to $\frac{1}{2}$ in. (0.3 to 1.3 cm.). Both pumps are driven by fractional horsepower D.C. shunt wound motors through reduction gearing and belt drive. These motors are of special type and are so designed that their speed may be controlled over a 10:1 range by magnetic amplifiers (English Electric $\frac{1}{2}$ h.p. "magamp"). These amplifiers have no thermionic valves in them and are almost mechanical in operation, gaining thereby in reliability and stability. They can be controlled by hand, and such adjustment will enable the circulation to be operated under direct control. However, a rather more sensitive control is achieved by an electronic apparatus designed to replace the delicate balancing mechanism of the animal. This control gear takes as its guide three quantities measured continuously by electrical manometers. These are of the differential-transformer type and are particularly stable. One measures the volume of blood in the artificial circuit from the depth of blood in the collecting chamber of the oxygenator, one measures the pressure at which the

for automatically controlling the gas mixture from the pH of the blood in the machine is under construction, but is not at present fitted to the machine.

All the tubes enter and leave the oxygenator at one end of the trolley in close proximity to the two pumps (Fig. 9). Connecting blocks at this end of the trolley facilitate the various junctions in the tubing. The arterial block acts both as a coarse filter and as a bubble trap from which bubbles may be returned to the oxygenator through a by-pass tube, which passes through a clamp controlled by a solenoid operated from the control panel. This clamp also acts as a relief valve in the event of a sudden blockage in the arterial line. Connexion to the arterial manometer is also made from the arterial connecting-block.

FIG. 9.—The general arrangement of the oxygenator, pumps, manometers, and tubing connections. 1, Gas entry. 2, Oxygenator level manometer. 3, Oxygenator. 4, Venous pump. 5, Solenoid clamps. 6, Venous manometer. 7, By-pass tube. 8, Arterial filter block and manometer. 9, Arterial pump. 10, "Artery." 11, "Vein."

From the venous connecting-block a tube goes to a reservoir from which the machine is charged and from which transfusions may be made. The tube passes through another electrically operated clamp controlled from the control panel. A second tube connects the venous line to the venous suction manometer.

The tubing in the circuit is of "portex" P.V.C. (polyvinyl-chloride), and is used but once. Before use it is treated with Dow Corning "dimethyl-dichlorosilane" to ensure that the surface is completely non-water-wettable. The arterial catheters are fashioned from this tubing, which is softened by immersion in boiling glycerin and drawn out into a convenient taper, after which rapid cooling fixes the tube in this shape. It can then be hardened by immersion in ethyl ether for 24 hours.

"Polythene" or portex is equally suitable for the venous catheter. Numerous side holes punched in this tube provide efficient collection of blood from the thin-walled veins by gentle suction.

Results of Tests

The machine is efficient, reliable, and comparatively easy to operate. *In vitro* tests confirm that it adequately fulfils the design criteria.

The volume of blood required to charge the machine has been varied between a minimum of 0.5 litre and a maximum of 2 litres without affecting the efficiency of operation.

When stored blood was used it was possible to introduce approximately 100 volumes of oxygen into each litre of blood flowing through it. At 2 litres a minute an average figure is 205 c.cm. of oxygen uptake into stored blood. With

fresh blood circulating at 900 ml. a minute, the difference in oxygen saturation between blood entering and leaving the oxygenator was 174 volumes per litre, indicating an uptake of 156 c.cm. of oxygen a minute. At this time the oxygenator was rotating at 60 revolutions a minute.

The average amount of haemolysis in 500 ml. of stored blood circulated for two hours at rates of up to 2 litres a minute was 0.1 g. Hb per 100 ml. When fresh blood was circulated at a rate of approximately 1 litre a minute the haemolysis was rarely detectable to the naked eye and did not exceed 0.05 g. Hb per 100 ml. an hour.

Foaming is not a serious problem, though it will occur if many air bubbles are carried into the oxygenator in the ingoing blood. This foam does not affect the rate of oxygenation, but may increase the rate of haemolysis. It can be prevented by ensuring that the tubes on the suction side are air-tight. If a film of Dow Corning "antifoam A" is deposited over the interior of the machine no foaming occurs whatsoever in spite of injecting foam into the oxygenator.

The servo mechanism controlling the operation of the pump will maintain the blood volume within 50 ml. over a speed range between 300 ml. and 3 litres a minute. It will adjust the pumping rate in response to the pressure manometers, and when one pump is suddenly stopped will bring the other to a standstill within a volume change of 150 ml. The electronic mechanism possesses remarkable stability, and during trials extending over several days, when the apparatus was called upon to repeat frequently, without adjustment, an elaborate series of tests, it proved faultless. The method of construction allows various forms of servo control to be employed by altering the interconnections between the various units.

Cleaning is effectively carried out after dismantling the apparatus, including all the washers and plates within the oxygenator. It has been found more economic to replace the tubing after each perfusion, though this is not absolutely necessary. As the entire surface with which the blood is in contact is of inert plastic material and the "intima" non-water-wettable, very little deposition of fibrin and other proteins occurs. This property also reduces the amount of anticoagulant required to maintain the fluidity of the blood. At present the oxygenator must be sterilized with chemical agents, for perspex deforms at 100° C. However, this material is being replaced by nylon or teflon, when it will be possible to autoclave in one unit everything in contact with blood.

An extensive series of animal experiments has amply confirmed that the performance under these conditions is in no wise different from that *in vitro*, and justifies the further development of this prototype heart-lung machine.

I am indebted to Professor C. Crafoord and Dr. V. O. Björk for their kindness during my visit to Stockholm in 1949, when I greatly benefited from their experiences in this field. Also I wish to acknowledge the important contributions of the many who have helped in the design and construction of this machine, particularly Mr. R. L. G. Rainbow, Mr. C. Lordon, and Mr. J. Neal, of the Postgraduate Medical School, Mr. Schranz, of the Genito-Urinary Co., Ltd., and Mr. Kellerman and Mr. Brown, of New Electronic Products Ltd. The design of the control gear was carried out by Mr. Brown, who will describe the mechanism in detail elsewhere. Patent applications have been filed and assigned to the National Research Development Corporation.

EXPERIMENTAL PHYSIOLOGY OF A HEART-LUNG MACHINE IN PARALLEL WITH NORMAL CIRCULATION*

BY

D. G. MELROSE, B.M., B.Ch.

J. W. BASSETT, M.D.

P. BEACONSFIELD, M.D.

I. G. GRABER, M.D., F.R.C.S.Ed.

AND

RALPH SHACKMAN, M.B., F.R.C.S.

(From the Department of Surgery, Postgraduate Medical School of London)

Recognizing the magnitude of the task involved in the mechanical maintenance of the entire circulation in humans, we turned our attention to the lesser problem of assisting the natural circulation by shunting part of it from vein to artery through the heart-lung machine. To assess the value of the heart-lung machine in resuscitation and in the treatment of a failing circulation, and to acquire information to be applied later to the problem of complete artificial maintenance of the circulation in man, a series of experiments was carried out in dogs.

In the planning and execution of these experiments we were helped by experience gained from a large number of studies carried out with earlier machines. These studies included the perfusion of isolated organs, which proved particularly valuable in providing the basis of the present technique, and enabled controlled conditions to be established.

The Experiments

Thirty greyhound dogs, each weighing between 20 and 30 kg. and apparently healthy, were used. They were dewormed and given intramuscular penicillin (300,000 units 8-hourly) for two days prior to the day of an experiment, when each dog was anaesthetized with intra-

peritoneal pentobarbitone sodium (30 mg. per kg. body weight). A cuffed tube was introduced into the trachea and inflated, and was then connected to a Benedict-Roth spirometer containing oxygen. Electrocardiograph leads were fixed to the two fore-limbs and to the right hind-limb.

A small incision was made in the neck, and an external jugular vein and a carotid artery were exposed. A radio-opaque catheter was then introduced into each of these vessels and was guided under fluoroscopic control into the right auricle and the ascending aorta or left ventricle respectively. The catheters were connected to continuously recording manometers and arranged so that blood samples could be obtained from them. The patency of each was maintained by flushing with saline which contained heparin (2 mg. per 100 ml.).

One or other deep femoral artery was exposed together with one of the major branches of a femoral vein. A tapered plastic catheter was then introduced into the deep femoral artery and connected to the "arterial" tube of the heart-lung machine. A plastic catheter 25 cm. in length, with numerous side openings, was passed into the femoral vein and advanced until its tip was judged to rest within the thoracic portion of the inferior vena cava. Connexion was made between this catheter and the "venous" tube of the heart-lung machine.

Concurrently with the preparation of the animal the machine was being assembled and made ready for perfusion (see Appendix I). In the first five experiments it was charged with approximately 750 ml. of donor dog's blood, but subsequently, because facilities for sterile blood collection proved inadequate and no definitive method could be achieved for cross-matching mongrel and greyhound blood, a solution of 6% dextran in normal saline was used.

The animals were now given heparin or dextran sulphate (Walton, 1951), 1-2 mg. per kg. being used. Primary readings were then made of the arterial and central venous pressures, the oxygen consumption, and the electrocardiograph, which were then recorded con-

FIG. 1.—Red-cell count, haematocrit, and plasma haemoglobin in 10 dogs before, during, and immediately after one hour's

FIG. 2.—White-cell count in 10 dogs before, during, and for five days after one hour's perfusion.

tinuously. Arterial and venous blood samples were also obtained. On these samples were made the following determinations, using standard techniques (Appendix II): (1) arterial and venous blood oxygen content; (2) counts of red cells, platelets, and leucocytes, including the differential and Arneith counts; (3) haematocrit and plasma haemoglobin; (4) plasma sodium, potassium, and chloride, sugar, urea, and carbon-dioxide combining power; and (5) pH.

The heart-lung machine was now started and adjusted to circulate at 50-100 ml. a minute, and then increased in rate gradually to between 750 and 1,000 ml. a minute. In most experiments the perfusion was continued for a standard time of one hour, blood samples being taken at intervals during this time and again ten minutes after it had ended.

RATIO OF GROUP I GRANULOCYTES TO GROUP IV GRANULOCYTES

FIG. 3.—Ratio of Group I to Group IV granulocytes in six dogs and the ratio of lymphocytes to granulocytes in 10 dogs before, during, and for two hours after perfusion.

When the final measurements had been made the cannulae were removed, the carotid artery and external jugular vein ligated, and the femoral artery and the vein repaired or ligated. Protamine sulphate was given to neutralize the heparin effect and the dog was allowed to recover consciousness. Subcutaneous vein blood samples were subsequently taken hourly for two hours and then daily for five days, and on these samples a full leucocyte count was carried out.

Effect of the Machine on the Blood

The most notable effect of the machine on blood circulating through it was on the cellular elements. After one hour's perfusion in 10 dogs the average red-cell count fell from 5,150,000 to 4,500,000 per c.mm., the average haematocrit fell from 51 to 46%, and the average plasma haemoglobin concentration rose to 43 mg. per 100 ml. (Fig. 1).

A dramatic fall occurred in the number of circulating white

The results of the experiments are considered under four headings: (1) clinical assessment of the effect of the procedure and analysis of morbidity and mortality; (2) the changes in the blood itself while circulating through the machine; (3) the general circulatory effects produced by the artificial circulation; and (4) evidence of the efficiency of the machine as an extrapulmonary oxygenator.

Clinical Assessment of the Procedure

No death directly attributable to the extracorporeal circulation occurred in the 30 dogs studied. Four dogs did not survive the procedure. Two died on the operating table as a result of misjudgments, one from an uncontrollable haemorrhage, and another from a period of asphyxia purposely induced to initiate anoxic collapse of the circulation. One died after prolonged hypotension which began immediately after the perfusion had started and which was probably the effect of donor blood, and one died of peritonitis following intraperitoneal pentobarbitone sodium anaesthesia.

Assessment of recovery from the procedure was complicated by the fact that in 18 cases the femoral artery was ligated and the leg in question temporarily immobilized.

CELLS /C.MM. PLATELETS x100,000

FIG. 4.—Platelet count in 10 dogs before, during, and immediately after perfusion.

FIG. 5.—Plasma chloride, plasma potassium, and plasma sodium in 10 dogs, before, during, and immediately after perfusion.

*This work was carried out at the Buckston Browne Research Farm, Kent, by permission of the President and Council of the Royal College of Surgeons of England.

cells during the same time (Fig. 2)—from an average primary value of 8,200 per c.mm. to an average value of 4,800. The greatest fall recorded was from 8,800 to 2,100 per c.mm. One hour after cessation of perfusion the average value had risen again to 6,000, and one hour later it had become 8,800 per c.mm. A leucocytosis persisted for five days in all animals.

Fig. 6.—Blood sugar, blood urea, pH, and plasma carbon-dioxide combining power in 10 dogs before, during, and immediately after perfusion.

The differential count, expressed as the ratio of lymphocytes to granulocytes, and the Arneth count, expressed as the ratio of Group I granulocytes to those of Group IV granulocytes (Fig. 3), showed, after 60 minutes' perfusion, a rise in the average lymphocyte:granulocyte ratio from 0.39 to 0.6, and a marked rise from 1.3 to 7.8 in the average ratio of Group I granulocytes to Group IV granulocytes. This indicated that the fall in white cells particularly affected the granulocytes, and that the more elderly are more greatly affected than the less-developed ones. Two hours after perfusion the ratio of lymphocytes to granulocytes had fallen again to 0.36, but the ratio of Group I to Group IV granulocytes had remained elevated at 6.2.

The platelet count fell from an average value of 463,000 per c.mm. in one hour to an average value of 378,000 (Fig. 4).

In contrast to the cellular elements the plasma electrolytes were relatively unaffected. After one hour's perfusion the average plasma sodium had increased from 149 to 156 mEq per litre, the average plasma chloride from 116 to 120 mEq per litre, and the average plasma potassium from 3.6 to 4.0 mEq per litre (Fig. 5). During the same time the average plasma carbon-dioxide combining power had fallen from 18.0 to 16.0 mEq per litre, while the pH had risen from an average of 7.5 to an average of 7.6 (Fig. 6). No significant change was recorded in the measurements of blood sugar and blood urea, the former falling from an average value of 86 to 82 mg. per 100 ml. and the latter falling from an average value of 36 to 30 mg. per 100 ml. (Fig. 6).

Determinations of the plasma proteins were invalidated by the use of dextran.

Effect of the Machine on the Circulation

In the first five experiments, when donor blood was used, the initial delivery from the machine produced a fall in arterial blood pressure which persisted throughout the per-

fusion. In the remainder, when a solution of dextran in sodium chloride was used, the introduction, maintenance, and termination of the perfusion was accomplished without untoward events, the blood pressure, pulse, and respiratory rates remaining virtually constant.

Electrocardiograph tracings revealed no changes other than an occasional alteration in cardiac rate. No arrhythmias were induced even when the perfusion was started or stopped suddenly.

The cardiac-output changes deduced by application of the Fick principle to the measurements of oxygen consumption and arteriovenous oxygen differences are well exemplified in the detailed consideration of Dog No. 20. This dog remained evenly narcotized throughout two and a half hours. Respiration was deep and regular, and before the beginning of the perfusion the oxygen consumption was 140 c.cm. a minute, the cardiac output 3.2 litres a minute, the mean arterial pressure 115 mm. Hg, and the central venous pressure +2 cm. H₂O. Three minutes after perfusion at 750 ml. a minute the oxygen consumption had fallen to 115 c.cm. a minute and the central venous pressure had fallen to -1 cm. H₂O. The mean arterial pressure had not altered. After 30 minutes the oxygen consumption had fallen to 85 c.cm. a minute and the cardiac output to 2 litres a minute. The mean arterial pressure was then 118 mm. Hg and the central venous pressure +1 cm. H₂O. Just after perfusion stopped the oxygen consumption rose to 160 c.cm. a minute for four minutes and then fell to 95 c.cm. a minute during the succeeding five minutes. At this time the cardiac output was 2.3 litres a minute, the mean arterial pressure 115 mm. Hg, and the central venous pressure +2 cm. H₂O.

Similar determinations of cardiac output were carried out in 12 dogs (Fig. 7). In nine the cardiac output fell during perfusion, in one it remained unaltered, and in two it rose. In seven of the nine dogs in which the cardiac output fell the extent of the fall approximated the rate of perfusion, averaging 850 ml. a minute.

Evidence of Efficiency of the Machine as an Extrapulmonary Oxygenator

Oxygen can undoubtedly be introduced into a recipient's blood stream by means of the heart-lung machine. In a single dog, for example, there was an oxygen difference of 15 vols.% between the venous blood entering the machine and the arterialized blood leaving it. And, since the rate of blood-flow through the machine was 1 litre a minute, approximately 150 c.cm. of oxygen a minute was introduced.

In order to determine if benefit followed from the extrapulmonary addition of oxygen six dogs were made anoxic by reducing the concentration of oxygen in the inspired air, replacing it with nitrogen. Venous blood, removed from the distal inferior vena cava, was returned after arterialization into the femoral artery in two dogs, into the thoracic aorta in two dogs, and into the superior vena cava in two dogs. The rate of perfusion did not exceed 1 litre a minute.

Fig. 7.—Cardiac output in 12 dogs before, during, and immediately after perfusion.

In each case oxygen was introduced into the circulation, but striking differences were revealed in the three pairs of dogs (Fig. 8). In the first two dogs, when the perfusion was returned into the femoral artery, there was little apparent effect on the oxygen content of the carotid artery blood, and the cephalic end of the dogs remained anoxic. After the animals had been breathing pure nitrogen for ten minutes the oxygen content of this blood had fallen to 23%. At the same time, however, the caudal end received an abundance of oxygen from the artificial lung, blood returning to the machine from the distal inferior vena cava being 65% saturated.

The perfusion was stopped at this point and complete anoxia maintained until cardiac arrhythmia and respiratory arrest had occurred. Resumption of the perfusion then restored respiration in both dogs and induced a normal heart-beat in one. The oxygen content of the carotid-artery blood was at this time identical with that of blood leaving the machine. In the second animal the heart ceased to beat after a short period of ventricular fibrillation, but perfusion was continued for two and a half hours, during which time natural respiration continued and the tongue and pupillary reflexes remained active.

In the second two dogs, in which the artificial circulation was returned into the aorta proximal to the splanchnic and renal arteries, a good perfusion of the cranial vessels was obtained, and the carotid-artery blood content did not fall below 50% even when pure nitrogen had been inspired for ten minutes.

In the last two dogs, in which arterialized blood was returned into the superior vena cava, the carotid-artery blood content was 52% ten minutes after exclusion of oxygen from the inspired air.

Discussion

The use of 6% dextran in sodium chloride to charge the heart-lung machine greatly contributes to its effective application to animal experimentation. The collection of blood from donor dogs, and its accurate cross-matching, is a difficult problem. In the five experiments in which donor blood was used, hypotension occurred when the contents of the machine were introduced into the circulation. We were not able to account for this, and it was concluded that an unknown factor in the donor's blood was responsible. The barbiturate used to anaesthetize the donor, the presence of products associated with exsanguination, bacterial contamination, and serological and cellular incompatibility were all possibly implicated.

No effects other than haemodilution and a resulting anaemia followed the use of dextran solution. The fall in the number of red cells is undoubtedly due to this deliberate haemodilution, for were the sole cause haemolysis the fall would not have exceeded 0.3%, and would not have been measurable. Of course it may be argued that no account is taken in the calculation of the fact that haemolysed blood may be fixed in the tissues. However, even if a figure of 200 mg. per 100 ml. is taken as the level of haemolysis, a figure considerably larger than any found in *in vitro* experiments, the fall in the red-cell count would only be in the order of 1%.

The amount of haemolysis is of no real consequence. No deleterious effects are to be expected from the liberation during perfusion of relatively minor quantities of haemoglobin. Much greater amounts have been administered to human beings without harm (O'Shaughnessy, Mansell, and Slome, 1939).

Deliberate haemodilution also accounts for much of the fall in the number of circulating platelets, which is too small to be of significance, but it cannot be responsible for the magnitude of the change in leucocyte values. Considerable destruction of circulating white cells does occur, and the resulting leucopenia may constitute a grave impediment to continuous perfusions over long periods. This problem is being studied at the present time, though it is evident

Fig. 8.—Percentage saturation of carotid artery blood in three dogs, A, B, and C, in which anoxia was induced by reduction of oxygen in the inspired air. Artificially arterialized blood was returned into the femoral artery in A, into the thoracic aorta in B, and into the superior vena cava in C.

that perfusions of short duration, such as are reported, need not be rejected on account of their effect on the leucocytes.

The alterations in the electrolyte balance are of a very small order, and in the main are caused by the addition of unbalanced fluids to the circulation, and by the absence of an accurate means of adjustment of the carbon dioxide tension in the oxygenator. The first is easily rectified, the second awaits the development of a device capable of regulating the carbon dioxide tension from the pH of the circulating blood. A device of this nature has been successfully exploited by Miller, Gibbon, and Gibbon (1951).

No untoward physiological effects accompany the shunting of a part of the natural circulation through the heart-lung machine. Changes in arterial pressure, pulse, and respiration rate are slight, and animals appear clinically unaffected by the procedure. Cardiac output determinations seem to indicate that a fall occurs when the perfusion is running, though it would not be wise to claim too much from these results, which are not statistically significant. In carrying out these determinations much difficulty was encountered in establishing a satisfactory baseline, particularly when pentobarbitone sodium was used as an anaesthetic. The smallest variation in the depth of narcosis altered the cardiac output, and we rarely achieved a uniform depth throughout the procedure. Even though the doses of pentobarbitone sodium were adjusted according to the weights of the animals the dogs did not all react in the same fashion. In some the dose was more than enough and produced deep anaesthesia, while in others it did no more than produce light narcosis. Even when anaesthesia was produced by cyclopropane, administered by a skilled anaesthetist, three hours of carefully regulated anaesthesia was required before two consecutive cardiac outputs proved to be identical.

Oxygen can be introduced into the blood stream by this method, and the extrapulmonary addition is of benefit to dogs made anoxic by a reduction of oxygen in the inspired air. The site of return of artificially arterialized blood is of great importance, and should be either into a central vein or into an artery close to the heart.

For these reasons it is felt that the heart-lung machine is now ready for clinical trials in selected cases of extreme cardio-respiratory dysfunction. In those patients in whom derangement of pulmonary function is the chief symptom, it may be advantageous to return the arterialized blood into a central vein, thus greatly simplifying the cannulation and making the surgical intervention a relatively minor one. Though no shunting of blood around the heart would occur in this technique, it is possible that the improved oxygenation would reduce the demands on the heart, and secondarily reduce its work.

Where the myocardium is primarily involved it is suggested that continuous venesection with return of arterialized blood into the arterial circulation will relieve the heart of part of its burden.

APPENDIX I

The oxygenator and connecting-blocks were chemically sterilized with "roccal" detergent and 3% formalin, being steeped in the solution for twelve hours. The tubing and cannulae, which we used only once, were autoclaved. After assembly the apparatus was washed with at least 40 litres of sterile distilled water to which had been added enough sodium chloride to provide approximate isotonicity. Frequent checks for the presence of formalin provided an indication of the efficiency of the washing process. When two checks were negative the wash-outs were discontinued and the apparatus was charged with donor blood or dextran solution. After circulation through the by-pass tube to ensure that no air bubbles remained in the arterial line, the machine was ready for use.

APPENDIX II

1. The arterial and venous blood oxygen were measured by the method of Van Slyke and Neill (1924).
2. The red-cell, platelet, leucocyte, differential, and Arneht counts were made, and haematocrit values found by standard methods (Dacie, 1950).
3. The plasma haemoglobin was estimated as oxyhaemoglobin on a Spekker absorptiometer modified to accept 1 by 6 in. (2.5 by 15 cm.) test-tube cuvettes. A standard oxyhaemoglobin curve was prepared for each estimation in the following manner: 3-ml. aliquots of plasma were placed in each of five cuvettes; to the first was added 8 ml. of dilute ammonia reagent (5 ml. concentrated NH_3 per litre), and this served as a plasma blank; to the remainder was added 0.02, 0.04, 0.06, and 0.08 ml. of whole blood diluted 1 in 2 with normal saline; these were then diluted with 8 ml. of ammonia reagent and read against the plasma blank. 3 ml. of plasma obtained from samples taken during the experiment was similarly treated and compared with the standard curve.
4. The plasma sodium and plasma potassium were determined by means of an internal standard flame photometer similar to that described by Berry, Chappell, and Barnes (1946).
5. The plasma chloride, plasma CO_2 combining power, blood sugar, and blood urea were estimated by standard methods (King, 1951).
6. The pH was measured by a Muirhead pH meter type D-303-b.

We would like to express our gratitude to the President and Council of the Royal College of Surgeons of England for their kind permission to work at the Buckston Browne Research Farm, Downe, Kent, and to Sir Arthur Keith and Professor David Slome for their many kindnesses to us while working there. We are indebted to the directors of Messrs. A. C. Cossor Ltd. for their generosity in placing a direct-writing electrocardiograph at our disposal.

POST-INOCULATION POLIOMYELITIS

BY

JAMES GRANT, M.D., D.P.H.

Medical Officer of Health, Gateshead, and Medical Superintendent, Sheriff Hill Hospital

The successful prophylaxis of diphtheria through the mass immunization of very young children with diphtheria toxoid was associated with few mishaps of importance. When given subcutaneously, the alum-precipitated toxoid commonly gave rise to a painless nodule which was gradually absorbed, but occasionally there was an inflammatory swelling and very rarely a sterile abscess. These rare reactions to the toxoid were minimized by intramuscular administration, a route which was necessary for the injection of the pertussis vaccine introduced in 1946 and of combined diphtheria toxoid and pertussis vaccine made available in 1947. Since then the latter product has been increasingly used to immunize children simultaneously against diphtheria and whooping-cough by one series of injections.

In 1948 Martin (1950) observed flaccid paralysis of the arm in two children, each of whom had received an inoculation of a prophylactic in the paralysed limb within the preceding three weeks. Having traced and studied 15 other patients who had developed limb paralysis following injections of antigens in 1944-9, he concluded that all of these had really suffered from poliomyelitis. Gale (1950) was able to add 56 cases of limb paralysis following the inoculation of prophylactics, and then, independently and simultaneously, McCloskey (1950) and Geffen (1950) published their findings during two epidemics of poliomyelitis in 1949. In Melbourne, McCloskey found that 35 out of 340 patients with poliomyelitis had been inoculated against diphtheria or whooping-cough within three months before the onset of the illness, and that the paralysis affected the inoculated limb in 24 out of 31 patients about whom full information was obtained. Geffen reported that out of 182 poliomyelitis patients under 5 years of age in London, 37 had been recently inoculated and about 30 of these suffered from paralysis, affecting particularly the limb recently injected. Investigating a small group of the London children, MacCallum (1950) was able to isolate the poliomyelitis virus from the stools of two children with paralysis of a recently inoculated limb and from three other inoculated children suffering from poliomyelitis without paralysis. Hill and Knowelden (1950) carried out a statistical inquiry, covering 33 areas, into the incidence of paralysis as a sequel to recent inoculation in 1949, and concluded that this misfortune occurred more frequently within a period of one month after the inoculation than could be attributed to chance.

On the other hand, Culley (1951) could find only nine recently inoculated persons among the 380 Welsh

patients with poliomyelitis in 1950 and only four of the nine with paralysis in the inoculated limb. In Scotland, Sutherland (1952), studying 43 cases of poliomyelitis following inoculation in 1950, could not show that inoculation increased the risk of a child developing poliomyelitis, although he found that the paralysis was suggestively but not significantly associated with the limb most recently injected. From both the academic and the practical point of view, the present position is best summarized in the advice of the Chief Medical Officer of the Ministry of Health (1952), that in any area in which poliomyelitis is exceptionally prevalent inoculation of diphtheria and pertussis antigens should be suspended for a time.

Poliomyelitis on South Tyneside

In the spring of 1952 a local epidemic of poliomyelitis began on Tyneside, centred mainly on the south side of the river. This outbreak witnessed the resumption of the classical age distribution of the disease, for two-thirds of the patients were under the age of 5 years. The districts chiefly involved were Gateshead (population 115,000), and the

contiguous districts of Felling (population 25,286) and Whickham (population 23,116). Poliomyelitis was confirmed in 91 patients from Gateshead, 28 from Felling, and 13 from Whickham. All these districts are normally served by Sheriff Hill Isolation Hospital, in which 112 of the patients were treated along with six cases from other areas.

In the last week of March and during April, four children were admitted to hospital at intervals for investigation of an illness which was at first diagnosed as "viral encephalitis" but later revised to polio-encephalitis in the light of further developments. The first patient with unmistakable poliomyelitis became ill with a sore throat on May 2, 1952, and was admitted to hospital on May 6 with flaccid paralysis of both legs. During May, 8 non-paralytic and 2 paralytic cases of poliomyelitis were later admitted from the three districts, to make a total of 15, of whom three were paralysed. Two of the three paralytic children had recently been inoculated. Intramuscular inoculations were therefore stopped in the Gateshead clinics, and local practitioners were advised on June 3 to restrict immunization to the subcutaneous use of A.P.T. and P.T.A.P. Confirmed cases of poliomyelitis in June numbered 38, and it was evident that the infection was widespread throughout the area. In July,

Poliomyelitis Following Inoculations—South Tyneside, 1948-52

August, and September confirmed cases numbered 50, 19, and 14 respectively, and thereafter only sporadic cases occurred.

In spite of the precautions, eight of the South Tyneside patients with poliomyelitis had previously been injected intramuscularly with an immunizing antigen not more than two months before the onset of the illness. All these were admitted before July 17, when the number of cases was 94.

The relevant details of the inoculated children are summarized in the Table on the previous page along with similar data relating to five examples of post-inoculation poliomyelitis in 1950 and 1948. Four were recorded among the 27 confirmed poliomyelitis cases on South Tyneside in 1950, while the fifth was a solitary patient who came to hospital two months after the notification of the last case in 1948.

After the end of May, 1952, 101 children were inoculated subcutaneously with A.P.T. and P.T.A.P., but none of these suffered an attack of poliomyelitis.

Comparative Incidence of Poliomyelitis in Recently Inoculated and Other Children in Gateshead in 1952

The total number of children aged 6 months to 2 years in the borough in mid-year, 1952, has been calculated from the births less deaths to be 3,097, among whom there were 17 cases of poliomyelitis, a ratio of 1 in 182. Of the 17 children, 13 presented some degree of muscular paralysis.

In April and May, 1952, 249 children, aged between 6 months and 2 years, received intramuscular arm injections in the Gateshead local authority clinics, and 105 others within the same ages received intramuscular inoculations from local practitioners in April, May, and early June—that is, a total of 354. Of this number, three aged from 11 to 22 months developed poliomyelitis in the paralytic form before the end of June.

Deducting the 354 inoculated children from the total, children of the same age not recently inoculated number 2,743, of whom 9 developed poliomyelitis in May and June, 6 being affected by muscular paralysis. The attack rate in recently inoculated children was therefore 1 in 118, as compared with 1 in 305 in non-inoculated children. During July another case of paralytic poliomyelitis occurred in a recently inoculated child and 3 cases in the control group, of whom two were paralysed. The comparative incidence in May, June, and July was therefore 1 in 88 for the recently inoculated and 1 in 228 for the control group. As an additional paralytic case occurred in the control group in August, the respective attack rate over the four months May to August remained 1 in 87 among the recently inoculated and increased to 1 in 211 in the controls.

Two of the children, E.S. and N.S., who developed a limb paralysis following an injection of antigen in April were previously inoculated in March, both in the left arm. Although these March injections were given one week before the first case of poliomyelitis in 1952, and E.S. was paralysed in the right arm, it seems advisable to recalculate the incidence of the disease in children inoculated in the months March to June.

In March, 53 children of the age group under study received intramuscular inoculations at the clinics and 43 others received similar injections from the general practitioners. Out of 450 children inoculated in the months of March, April, May, and June, 3 developed poliomyelitis in May and June, giving a ratio of 1 in 150. Of 2,647 children of the same age who had not been recently inoculated 9 developed poliomyelitis in these months, a ratio of 1 in 294. When this comparison is extended to include July there were 4 cases in the inoculated, or 1 in 112, and 12 cases among the others, or 1 in 221. Including the August case among the controls, the respective incidence rates for May to August were 1 in 112 for the inoculated and 1 in 204 for the others. As no other child of these ages contracted poliomyelitis, the last-mentioned attack rates cover the whole epidemic. The 13 children in the control group who contracted poliomyelitis were aged from 6 months to 1 year and 10 months. Only two of them had in fact ever been inoculated, the prophylactic injections having been given

in the autumn of 1951. In spite of the smallness of these numbers, I feel that they are reasonable in assessing the risk of a child developing poliomyelitis as being at least doubled as a result of intramuscular immunization during an epidemic.

In the 4 recently inoculated Gateshead children the paralysis was limited to the injected arm in three instances and the injected leg in one. In contrast, the 9 patients with paralytic poliomyelitis among the control group of Gateshead children suffered paralysis affecting the trunk and all the limbs in two cases (one of whom died), the right arm, leg, and facial muscles in the third, the left face, eye, and leg in a fourth, one leg only in four instances, and the left external rectus muscle of the eyeball in the ninth.

Poliomyelitis in Recently Inoculated Persons

Analysis of the form of the disease in the 138 South Tyneside cases, so as to compare the recently inoculated patients with the remainder, gives this result:

Form of disease	Recently Inoculated	Others
Non-paralytic	1	70
Paralytic:		
Cranial nerves only	1	15
One arm only	2	3
One leg only	2	17
Both legs	1	7
Arms and legs	1	3
Trunk and limbs	—	6 (2 died)
Cranial nerves and limbs	—	5
Cranial nerves, trunk, and limbs	—	4 (1 died)
	8	130

Among the recently inoculated patients, paralysis affected solely the inoculated arm in 3 patients, the inoculated leg in one, and extended from the inoculated arm of a fifth patient so as to involve the opposite arm and a leg. In two patients paralysis was localized to the ocular muscles and to the right leg respectively, although the injection had been given in the left arm. Only 60 of the 130 patients not recently inoculated suffered a paralysis, and this much more often affected the legs than the arms.

Health of Contacts

As it is well known that poliomyelitis becomes manifest in only a small proportion of the individuals who have been infected, it is common to find that familial contacts of patients suffer from illnesses which are presumably abortive attacks of poliomyelitis. It is rare, however, in urban areas to find two cases of undoubted poliomyelitis from the same family.

Among the 8 families of children with post-inoculation poliomyelitis two, those of E.S. and P.H., are notable for associated illnesses.

Family of E.S.—E.S., aged 1 year, was inoculated in the left arm on February 12 and March 11, 1952, and in the right arm on May 20, with combined antigen. She became ill on July 17 with paralysis of the right shoulder and upper arm. She was admitted to hospital on July 18 along with a brother Eric S., aged 6 years, who complained of headache and vomiting on July 17. On admission he presented an inflammatory exudate on the tonsils, a temperature of 100.6° F. (38.1° C.), but the cerebrospinal fluid was normal. He was considered to be a possible atypical case of poliomyelitis. Two weeks before, an older brother, H.S., aged 11 years, was ill with a high temperature lasting for 24 hours.

Family of P.H.—P.H., aged 5 years, inoculated in the left deltoid on May 5, 1952, with a "booster" dose of A.P.T., became ill on May 23 and was admitted to hospital on the 25th with pyrexia, marked signs of meningeal irritation, and an abnormal cerebrospinal fluid. She developed paresis of both arms and the left leg on May 28, the left arm being the more severely affected. Her sister, M.H., aged 2 years, became ill on May 22, with pyrexia, neck stiffness, and irritability, which persisted until the 28th, when she also was admitted to hospital, making a very rapid recovery in the following three days. In her case the cerebrospinal fluid showed a raised protein content only. Still another child in this house, aged 6 years, complained of pyrexia, headache, and neck stiffness, beginning on May 22, but she was convalescent when her sisters were removed to hospital.

On examining the family histories of the remaining 129 poliomyelitis patients who had not been inoculated recently

there was only one example of two siblings with frank poliomyelitis and one family with a possible double infection.

Family of Sw.—T. Sw., aged 2 years, became ill on July 9, 1952, with drowsiness and irritability accompanied by vomiting. On admission to hospital on July 16 he presented neck and spinal rigidity and loss of the tendon reflexes of the left leg, but he was able to move all his limbs. The cerebrospinal fluid showed an increased cell count and a raised protein content. On July 20 the patient showed a definite weakness of the muscles of the left ankle joint. A sister, G. Sw., aged 4 years, became ill on July 11, with vomiting, fever, and fretfulness, and complained of headache and backache. When admitted to hospital on July 19 there were signs of meningeal irritation but no paralysis. The cerebrospinal fluid showed a pleocytosis of polymorphs and lymphocytes and a raised protein content. This child was fully convalescent on July 27.

Family of M.—The patient D.M., aged 1 year, became fretful and off-colour on August 2, 1952, and was admitted to hospital on August 6, when he presented neck stiffness, minimal pyrexia, and weakness of the right hip muscles, together with a slight increase of cells in the cerebrospinal fluid. This child was not definitely paralysed, but the muscles governing the movement of the joint were all weak. Two weeks previously a sister, aged 3 years, was very restless and had a bout of vomiting, and was thought to have been an abortive case.

Among the 8 households of the recently inoculated patients one can find two with multiple illnesses in the family. In these, the two recently inoculated children suffered paralysis of the injected arm. To find two other instances of multiple illness one has to review the background of the other 129 patients. In these the paralysis affected the lower limb in two children and was slight. It seems probable that all three of the children in each of the households of E.S. and P.H. had been infected with the poliomyelitis virus, and that it was the recent inoculation which determined the appearance and the site of the paralysis.

Intervals between Inoculation and Onset of Poliomyelitis

In 5 of the 8 recently inoculated patients of 1952, paralysis was definitely related to the site of the preceding injection, whereas there was no paralysis in one, and paralysis remote from the inoculation in two. The intervals between the injection and the onset of symptoms in the former patients were 15, 16, 16, 18, and 58 days respectively. In contrast, the respective intervals were 3, 5, and 46 days in the latter three cases. Turning to the 5 patients of 1948 and 1950, the relevant intervals were 10, 13, 13, and 18 days in the cases with paralysis involving an inoculated limb, and in the exceptional case the onset of polio-encephalitis coincided with the inoculation. This divergent finding raises a strong probability that the relationship between the preceding inoculation and the subsequent localized paralysis was one of cause and effect in the group of 8 patients showing intervals of 10 to 18 days between the inoculation and the onset of symptoms, whereas the association was purely a coincidence in the 3 patients in whom the respective intervals between the inoculation and the onset of illness were 5 days or less.

There remain two patients with lengthy intervals between inoculation and illness. In one of these the relationship between inoculation and paralysis may also have been causal.

Site of Injection

In the 1952 group of 8 recently inoculated patients, the upper-arm paralysis following injection tended to be fairly severe and lasting, whereas the paresis of the leg following previous injection of antigen in the buttock was very transient. Studying all the 13 cases of poliomyelitis following recent inoculation, it is notable that antigen given intramuscularly in the arm on 10 occasions was followed by severe paralysis limited to the arm in 5 patients and by more extensive paralysis involving both arms in 3 others. All these 8 patients have or are likely to have some degree of permanent disability. On the other hand, in 3 patients inoculated in the buttock or thigh only one showed paralysis of the injected limb, which was transient. All the 5 post-inoculation cases of paralysis limited to the injected arm

were of a severity and permanence not observed in the three single-arm palsies among the 129 patients not recently inoculated, in whom the affected muscles showed a transient loss of power without any residual disability. In the 3 cases of more extensive paralysis following the injection of an arm, paralysis started and was most severe in the injected limb, whence it spread to the opposite arm and thence to other muscles. Although the issue here is clouded by the time relation between inoculation and subsequent illness, the relative severity and persistence of the damage to muscles of the arms in post-inoculation poliomyelitis were impressive.

Prophylactics Used

In the 13 cases of post-inoculation poliomyelitis, paralysis followed the use of diphtheria alum-precipitated toxoid, pertussis alum-precipitated vaccine, and combined diphtheria toxoid and pertussis vaccine.

The dose injected was taken from multiple-dose containers of 5 ml. and 10 ml. Two patients, E.S. and M.J., probably received antigen from the same container, but otherwise each patient was the sole poliomyelitis case associated with a multiple-dose container. The worst case was K.M., to whom the largest dose of antigen, 1 ml., had been given, with a severe local reaction.

During the summer of 1952 many intramuscular injections of penicillin, streptomycin, and other medicaments must have been given to Gateshead patients, both children and adults, in hospital wards and departments and at home, for the treatment of various conditions. In only one instance was there a suspicion that intramuscular injection of a substance other than a prophylactic antigen might have precipitated paralytic poliomyelitis. In this instance, a child of 6 months admitted to hospital with pneumonia on May 30, 1952, was given penicillin by injection into the buttocks alternately before June 5. In convalescence a flaccid paralysis of the right leg was first noticed on June 14, and the cerebrospinal fluid taken on July 21 showed an increase of cells and a slightly raised protein.

Discussion

The Gateshead experience must be added to the London and Melbourne evidence against intramuscular inoculation with diphtheria and whooping-cough antigen as a causal factor in the development of paralytic poliomyelitis affecting particularly the limb previously injected. In Gateshead as in London, the upper limbs were much more frequently affected in the recently inoculated than the legs, and the left arm more often than the right—features quite contrary to the usual distribution of paralysis of poliomyelitis. This can be accounted for only by the traditional use of the left arm for all the immunization procedures.

That the patients with whom we are concerned in Gateshead were in fact cases of poliomyelitis cannot be doubted. They were all diagnosed as such on clinical grounds, for they showed an involvement of the motor neurones and a complete absence of sensory disturbance, together with the changes of the cerebrospinal fluid and many of the common symptoms and signs of this disease. They occurred at a time when poliomyelitis was prevalent, and their numbers were proportionate to the intensity of prevalence. I have, too, been able to cite the simultaneous occurrence of non-paralytic and post-inoculation paralytic poliomyelitis in the same household.

Although mass immunization against diphtheria started in Gateshead in 1941, there were no recorded cases of post-inoculation paralysis among the thousands of children inoculated. This seems to be largely true of the millions of children in the country who were immunized before and after 1941.

The indications are that these mishaps became so numerous as to attract general attention in 1949, a year when poliomyelitis was prevalent in England. Yet in 1947, also a year of high prevalence of this disease, cases of post-inoculation paralysis were very few, if in fact they occurred. It seems that the change in frequency of the misfortune of

post-inoculation paralysis may have been associated with the increasingly popular use of the pertussis vaccine, alone or combined with diphtheria toxoid. It is worthy of note that these antigens were given by the intramuscular route.

Although there is ample room for speculation and research regarding the pathology of post-inoculation paralytic poliomyelitis, the convenient explanation is that muscle trauma due to inoculation enables the virus already present in a patient to attack the motor cells in the spinal cord which innervate the muscles that have been damaged. This would mean that, as a sequel to previous inoculation during the outbreak of poliomyelitis, a number of non-paralytic, atypical, or symptomless cases of infection with the virus would be transformed into frank cases of paralytic poliomyelitis. There would then be an actual increase of the number of cases of paralytic poliomyelitis as a result of the common inoculation procedures. Statistical proof of this increased incidence has not been forthcoming in two national surveys, but this is understandable when one recalls that poliomyelitis seldom shows a national prevalence, and information has to be gathered second- or third-hand about a disease notorious for errors of diagnosis. In a local epidemic it is difficult to get adequate numbers to offset the vagaries of chance.

Difficulties will also arise as a result of the recommended advice to suspend intramuscular inoculation during an epidemic, and there is, too, the further consideration that children who have been recently inoculated may acquire poliomyelitis during an epidemic without this being related at all to previous immunizing procedures. If one could disregard the element of chance in the Gateshead experience of poliomyelitis in 1952, the risk of contracting the disease was doubled, if not trebled, for a child in the age group usually selected for primary immunization. If so, one-third to one-half of all the recorded cases of poliomyelitis following recent inoculation would present the disease as it might have occurred naturally, and the remainder would present the special feature of the localized paralysis in the limb injected. This, in fact, is what did happen to something like the proportions expected, a point which seems to justify the statistical comparison.

In Gateshead, patients developing poliomyelitis less than six days after inoculation were clinically similar to those with the naturally occurring disease, but in those who were inoculated more than 10 days and less than 18 days before the onset of symptoms the inoculated limbs showed the paralysis of the disease. This is in accord with the findings of McCloskey. In two patients with respective intervals of six and eight weeks, the findings were equivocal, but it seems that the effect of the muscle trauma may extend much longer than a period of three weeks.

The practical aspects of this problem require some attention. The advice of the Ministry of Health to suspend intramuscular immunization was acted upon fairly early in the Gateshead epidemic, but it could have been given three weeks before. Then 6 of the 8 cases of post-inoculation poliomyelitis would not have been recorded as such, and at least three cases of post-inoculation paralysis would not have occurred. Now that poliomyelitis has become the most important acute infectious disease, intramuscular immunization should normally be suspended at once on the appearance of the first case of paralytic poliomyelitis in any year, in order to allow an assessment of the trend of prevalence of the disease. The earlier in the year the first case occurs, the more important it is to follow this course, for poliomyelitis in the spring presages a severe visitation.

Manufacturers of prophylactics differ in their advice regarding intramuscular injection. One firm recommends deep intramuscular injection above the insertion of the deltoid; another recommends that this should be given on the outer side of the thigh; and a third leaves it to the physician to choose the site. Certain considerations suggest that all intramuscular inoculations of prophylactic antigens should be given in the buttock or thigh, as is the custom in hospital. It seems that the amount of trauma in the muscle may exer-

cise an effect on the severity and extent of post-inoculation paralysis. The smaller the muscle the greater the proportion of the whole muscle damaged by the injection of an irritant antigen. Local trauma will probably be more severe when an irritant antigen is injected into the deltoid muscle of an infant than when the same amount is injected into the gluteal or vastus muscles.

A further point concerns the observed tendency of the damage in the cord to spread locally so as to affect other muscles in the vicinity, to cross the mid-line so as to affect muscles innervated by the same segment of the cord and even to spread further. Now the fifth and sixth cervical segments of the spinal cord innervating the arms are continuous above with the segments supplying the diaphragm and below with those innervating the intercostal muscles. Thus respiratory paralysis in poliomyelitis is usually coupled with an arm paralysis. There is therefore at least a theoretical possibility that the possible spread of post-inoculation paralysis of the arm may involve the muscles of respiration, and that this has actually occurred seems to be demonstrated by three if not four of the cases reported by Geffen. Thirdly, it seems that the disability inflicted by an arm paralysis must be compared with that produced by paralysis of a corresponding degree and extent in the leg. Although there is room for controversy, it is felt that in modern conditions a paralysis of leg muscles which can be neutralized by modern orthopaedic appliances is to be preferred to a corresponding paralysis in the arm which cannot at present be compensated by appliances. These arguments indicate the election of the lower limb as the site for intramuscular injections.

It would, of course, be better still if all the prophylactic antigens were issued for use only after they had proved acceptable to the subcutaneous tissues, for proper subcutaneous administration would seem to avoid all the risk of inducing a subsequent paralysis. In the prophylactics incriminated in the matter under discussion, the presence of alum seems to emerge as the common factor. If immunizing antigens cannot be made suitable for subcutaneous administration, manufacturers would also be well advised to try to reduce the quantity of material to be injected, in order to minimize the amount of muscle trauma.

There is an obvious medico-legal aspect of the problem of post-inoculation poliomyelitis which concerns all who administer prophylactic antigens. In the interest of both patients and practitioners, it is particularly important that confirmed cases of poliomyelitis should be promptly notified in order that the medical officer of health may at once apprise and advise the practitioners of his area.

Summary

A number of cases of post-inoculation poliomyelitis personally encountered in Gateshead and district have been studied. It is concluded that there was no doubt of the increased risk to a child of developing a paralytic attack of poliomyelitis as a result of intramuscular immunizing injections at a time when poliomyelitis was prevalent.

A close look-out must now be maintained in every area for the appearance of poliomyelitis. Immediately the first confirmed case has been detected intramuscular immunization procedures should be halted for a short period so as to take stock of the situation.

Manufacturers of prophylactics should aim at the production of antigens which will be satisfactory in every way when given by subcutaneous injection.

ACUTE APPENDICITIS IN INFANCY AND EARLY CHILDHOOD

BY

G. L. BUNTON, F.R.C.S.

Senior Surgical Registrar, University College Hospital, London

Bailey and Love (1949) begin their section on appendicitis with these words: "Over 3,000 persons die annually from acute appendicitis in England and Wales alone. Many of them are in youth or the prime of life. Practically all these lives could be saved if an early diagnosis were made, and, at this stage, the comparatively simple operation of appendicectomy carried out. The importance of the subject cannot be overstated." Recent years have seen an improvement in the saving of lives, though not necessarily in early diagnosis.

In this paper are reviewed 115 consecutive unselected children whose appendices were removed. They were admitted to the wards of the Westminster Children's Hospital during 1950-2. Thirty-two suffered from "recurrent" appendicitis. The remainder had appendices which were unequivocally demonstrated to be the seat of acute inflammation. All were under 12 years old.

It is not proposed to deal in detail with those in the "recurrent" group or with those over 5, but to make special reference to the 28 cases under 5. It should be noted that in those cases which have been called "recurrent" there was evidence, either macroscopically or microscopically, of past inflammation in the appendix. Cases in which a normal appendix was removed, either through erroneous diagnosis or during the course of some other operative procedure, are not included.

Fig. 1 shows the incidence by age of all cases. Fig. 2 does not include "recurrent" cases. It is seen that quite a high proportion of cases occur under 5, and that "recurrent" appendicitis was not observed at all in this group, which will be subjected to further scrutiny; and the Table sets out those at each age who had complicated appendicitis and in whom there was an

Age	No.	Complicated	Recent Upper Respiratory Infection	Presenting with D. or D. and V.
0-1 year	2	—	1	1
1	4	2	2	2
2	7	4	5	3
3	9	4	6	3
4	6	2	4	2
	28	12	18	11

antecedent upper respiratory infection, and the main presenting symptoms. Complicated appendicitis is taken to mean the presence of general or local peritonitis, including abscess formation, on admission.

Several facts now emerge. First, 28 (24%) cases occurred in children under 5, and among these the incidence of complicated appendicitis is high, being 43%; whereas in the older children the figure is only 18%. Secondly, a large number of children had diarrhoea, with or without vomiting as a presenting symptom, and in these there was a recent history of an upper respiratory infection. Such a history is often misleading, and judging from these cases it would seem that in the young child acute appendicitis is often missed.

The average duration of symptoms before admission to hospital was four days. Two typical case histories are given.

Case 1

A little girl aged 4 was seen one evening in the casualty department. Four days previously she had gone off her food, appeared listless, and complained of abdominal pain. She had recently recovered from a "sore throat," for which a course of penicillin injections was given, and was still having penicillin when her general symptoms appeared. Her temperature, which had fallen to normal limits, rose to 100-101° F. (37.8-38.3° C.) and the penicillin was therefore continued. She seemed to improve somewhat during the next four days but still complained of abdominal pain, and her bowels were opened several times, the motions being very loose. This state of affairs continued until she was brought to hospital.

On admission her temperature was 101° F. (38.3° C.), pulse 120, and she looked flushed and ill. On examination the abdomen was a little distended and did not move well with respiration. She was tender to palpation in the right iliac fossa and in the midline below the umbilicus, but owing to guarding nothing definite could be felt. On rectal examination, however, a tender mass could be felt high up on the right, and the finger of the glove was covered with mucus.

She was put to bed and kept under observation. By the next day her abdominal pain seemed less, and on careful examination the mass could also be felt through the abdominal wall. It was decided to treat her conservatively, and over the next three weeks the abscess gradually resolved. She was finally sent to convalescence and readmitted four months later, when a fibrotic and still slightly adherent appendix was removed.

Case 2

A boy aged 3 was admitted with a three-day history of abdominal pain, vomiting, and diarrhoea. At the onset he had started vomiting one evening after his meal. He was put to bed and later complained of abdominal pain, which woke him up. Early next morning he passed two very loose motions. On examination at that time he apparently had few physical signs beyond some tenderness across the lower abdomen. His temperature was 100° F. (37.8° C.). It was thought that he might have an enteritis, so a course of chloramphenicol was begun. His symptoms temporarily improved, but his temperature remained between 100 and 101° F. (37.8 and 38.3° C.). He had no further diarrhoea, but vomited twice the next day. His pain got no worse. The following day, however, he appeared much worse, the vomiting recurred, and his pulse rose to 130. The abdomen was by now distended and tense, and showed tenderness all over, especially below the umbilicus. He was immediately sent to hospital.

On admission his temperature was 102.4° F. (39.1° C.) and pulse 146. He appeared extremely ill with obvious peritonitis, the abdomen being tense, tender, and silent. At operation a spreading peritonitis was found with little or no attempt at localization, the cause being a gangrenous

appendix, which was removed. He was given aureomycin intravenously.

His convalescence was stormy and he had a further operation for the relief of small-bowel obstruction due to kinking from an adhesion. However, he was finally fit to go home nine weeks after his operation.

Treatment

Treatment has in no way differed from that now generally advised by all authorities. Immediate operation is carried out in all early acute cases. Those in whom an abscess has formed are treated conservatively unless spread demands drainage. The appendix is removed four to six months later. Those with peritonitis have had the remains of the appendix removed and the peritoneal cavity drained if the amount and character of the exudate warranted it. Drainage was needed in 9% of all the cases.

In one respect I find we differ from most other surgeons who have published series of similar cases—that is, in our use of Graham's incision, instead of McBurney's, as advocated by Mr. David Levi. We find it gives an extremely good exposure, is quick to make and close, and is easily extended if more room is required; also it does not imperil any nerves even if suppuration occurs.

In every recent series published the ultimate credit is given to the antibiotics. Certainly among our own patients there were several who would have undoubtedly died had it not been for these drugs—in particular aureomycin, which was given by intravenous drip. Doses of 100 mg. were given six-hourly, dissolved in 10 ml. of 1.95% leucine as supplied by the makers. Five to ten minutes were taken to inject the solution into the drip tubing to avoid undue pain and to minimize the danger of thrombosing the vein. Rapid injections, apart from quickly setting up an irritant thrombosis, cause such intense pain that even a comatose patient is aroused.

Wright *et al.* (1949) reported six cases of general peritonitis following ruptured appendicitis, all of which recovered with aureomycin. Olshaker *et al.* (1950), using the same drug, reported six similar successful cases aged between 4 and 8.

There were no deaths in this series, which, though the numbers are comparatively small, is encouraging.

A "spectacular" drop in mortality in the United States was observed by Slattery *et al.* (1950) even for the years during the war—from 14,113 in 1939 to 5,285 in 1946. This they attribute, amongst other factors, to the use of antibiotics and the principle of non-intervention in abscesses. Weiss (1950) reckoned that the total mortality in and around New Orleans had fallen from 15.2 to 2.9 per 100,000 in the last decade.

Pathology

We found that most cases of acute appendicitis in younger children were catarrhal in origin rather than obstructive. I have no records of some of the earlier cases, but in all those which were examined obstruction by faecalith or stricture was the exception. In the older children faecaliths were common.

The initial site of inflammation is in the lymphoid tissue of the wall—tissue which is far more abundant in youth, and which, like the mesenteric glands, often takes part in infection elsewhere. As already mentioned, over 60% of these young children give a history of recent tonsillitis, otitis, or a "cold." Babcock (1944) stated that "infections that produce general lymphoid hyperplasia often precede appendicitis." Scott and Ware (1945) denied this, but it seems common experience, in this country at any rate, that upper respiratory tract infections are frequently forerunners of appendicitis.

In addition, it must be realized that the margin of safety in the young is small. A thin-walled appendix containing a mass of lymphoid tissue through which infection spreads easily, and a small ineffective omentum, contribute to early perforation and wide dissemination of infection.

Discussion

Most authorities seem generally agreed in several points concerning this condition in childhood. First, acute appendicitis is not common in children under 5. Under 3 it is "rare" or "very uncommon." Reyes and Pascual (1950), reporting a series of 50 cases, found the youngest to be 6. Secondly, the diagnosis in early childhood is difficult. Thirdly, the mortality is high. The second of these points is undoubtedly true, but for the others there seems less justification at the present time.

Of our 82 patients, 28 (34%) were under 5, an incidence which cannot be regarded as uncommon. Abel and Allen (1950) reviewed 1,165 cases treated at the Bellevue Hospital, New York, and found that 165 were under 5. Morton and Kilby (1950) found an incidence of 20% in 100 cases at Newark, N.J.

Packard and McLauthlin (1951), reviewing 280 cases at the Denver Children's Hospital during the five-year period 1945-50, found that the average age of patients with peritonitis was 4.8 years. For those with simple appendicitis it was 8.6. Of their patients, 25% were 4 or under, and of this group 60% had local or diffuse peritonitis on admission. The only death among these was in a 3-year-old child with a ten-days history.

In searching for some explanation there would appear to be three main causes. First, the difficulties in diagnosis already referred to; secondly, the practitioner is often loath to diagnose acute appendicitis at this age, or thinks of some other condition first because he has been taught that it is uncommon. Such phrases as, "This child seems rather young for an appendix," or, "Could this be appendicitis at this age?" are often encountered in letters accompanying the patient to hospital. They betray the diagnosis as being late, and even an afterthought. Lastly, I believe the picture of appendicitis at this age to be changing: not because of any alteration in the disease itself but because of the widespread, and in some cases indiscriminate, use of antibiotics.

Difficulties in Diagnosis.—The four earliest signs are pyrexia, abdominal pain, vomiting, and local tenderness. Any of these may predominate, any may be absent, and any may be associated with one other symptom which is uncommon in the older patients—namely, diarrhoea.

Temperature and Pulse.—In a young child very little constitutional upset is enough to produce a considerable rise in temperature and pulse. It is often said that a high temperature associated with abdominal pain is rather against appendicitis and in favour of pyelitis. This is dangerously untrue, especially if a thorough examination of the urine is neglected. Half our patients had temperatures of over 101° F. (38.3° C.) and a quarter over 102° F. (38.9° C.). The pulse is proportionately raised—a ratio of 12 to each 1° F. (0.55° C.) rather than 10. The rate is not of such importance as a steady rise.

Pain.—This is notoriously difficult to assess in the very young. It is usually colicky or cramp-like and initially comes in waves, causing crying and screaming attacks with the knees drawn up. After a time it becomes continuous and the child lies characteristically curled up. Localization is also poor, and if the patient is of an age to understand the question he usually puts a hand on the umbilicus. Tenderness, on the other hand, is confined to the right iliac fossa, unless perforation has already occurred. In the early case a difference in "tension" of the two sides of the abdominal wall is more easily appreciated by very light palpation with the tips of the fingers. Strang (1950) recommends examination of the abdomen from behind with both hands while the child is held in the mother's arms in the natural nursing position. In this way we avoid a crying, frightened child in whom abdominal palpation is impossible. In other cases the bedclothes may be better. The disappearance of "abdominal" breathing and its replacement by "thoracic" respiration also occurs surprisingly early on, and must be

carefully looked for. The most dangerous aspect of pain is its disappearance when perforation occurs. The child, after what may have seemed a trivial abdominal disturbance, appears well for several hours. He may even show a desire for food or fall quietly asleep. The sinister sequence of a steadily increasing pulse and abdominal distension is all too early missed after the parents' and one's own conscience has been reassured. The following morning may be already too late. It is surprising not only how well many such patients appear at this stage but also how rapidly and alarmingly their condition may suddenly deteriorate.

Vomiting and Nausea.—These, with pain, form possibly the commonest manner in which the condition presents. But again a note of warning should be sounded. Reliance on the old axiom "Pain precedes vomiting" can easily mislead; for in many cases the sequence is reversed. Both may be absent.

Diarrhoea.—This may be a cardinal sign, and much more often than is generally supposed it is so. It may occur with or without vomiting. A diagnosis of enteritis or food-poisoning is fatally easy. How many of us have not had the humiliation of referring an unsuspected acute appendicitis to a fever hospital? Diarrhoea is often the first presenting sign in infants; the stool is very loose, often containing mucus, but never blood. It is due to the proximity of the appendix to the sigmoid or upper rectum. The child's pelvis is very small compared with the length and size of the appendix, and such contiguity may be demonstrated at operation. The caecum may be similarly irritated. Spurious diarrhoea coming on two or three days after the onset of pain, and consisting of small amounts of faeces-stained mucus, is pathognomonic of an appendix abscess. Rectal examination will reveal the mass. Auscultation, while it may show normal or near normal amounts of peristalsis, will not disclose the excited hubbub of the enteritic. Silence means ileus and peritonitis.

The High Appendix.—It is often loosely stated that in children the appendix lies high in the abdomen; sometimes under the liver. This may well be true, and every surgeon at one time or another has experienced confusion in diagnosis and difficulty at operation in removing such an abnormally placed organ. But the condition is a true abnormality. It is a defect in the last stage of the rotation of the gut. It is not common. Only two children in this series showed it, and in only one was it of a degree to cause trouble at operation.

It has been said that the surest sign of appendicitis is tenderness over the appendix, and the proper and usual place for the appendix is just above the brim of the pelvis in the right iliac fossa.

Finally, a point which I believe to be often responsible for the diagnosis being missed. If a child has sought medical aid because of inflammation remote from the peritoneal cavity the almost invariable treatment now afforded is an antibiotic, usually a sulphonamide or penicillin, although chloramphenicol is beginning to gain ground in popularity. The most dangerous complication of these chemicals is the masking of any extension of such inflammation and especially of abscess formation.

Should a metastatic lesion now develop, the classical signs are absent. There is little if any increase in constitutional signs. The appendix can perforate in comparative quietude and large quantities of pus collect without notice. This becomes doubly dangerous in the inarticulate young. As a result the picture of appendicitis is very different from that which used to be taught and expected in practice.

In conclusion it may be said that the only real safeguard is unceasing vigilance—a thorough examination if, and when, any abdominal symptoms develop, which may mean repeated visits even though this is onerous to a busy man.

Professor Aird (1949) has said that the old saying "Never wake a child at night to have an operation" is not dependable, and by the same token should be mentioned Mr.

Levi's maxim that "if abdominal pain in a child, associated with vomiting, lasts continuously for more than six hours and is unrelieved by an enema, he should be seen by a surgeon." Some may dismiss these as "rules of thumb." They may be—but they can be most helpful in times of doubt.

This renewed anxiety concerning the late diagnosis of these little children is not parochial. Packard and McLauthlin (1951) stated that "slower recognition of the diagnosis seems the most important factor in the markedly increased incidence of abscess and peritonitis in the infant and young child," and that "the high incidence of appendicitis with peritonitis in the very young child because of delay in diagnosis presents a challenge."

Riker (1950) out of 136 cases found 56 with rupture on admission: two died. He gives no figure for those in infancy, but states that there was "a high incidence of perforation in early childhood." Hawk *et al.* (1950) had 139 cases under 10. The youngest was 5 months old, and six out of eight children under 2 had peritonitis. There were no deaths in this series. In Reyes and Pascual's (1950) series 68% of cases under 10 had local or diffuse peritonitis. In Abel and Allen's (1950) 1,165 cases there was a 10% mortality in 165 cases under 5, as opposed to 2.9% in the remaining thousand. The majority of deaths occurred in the years before the war. Howard Williams (1947), of Melbourne, said of this condition, "Early diagnosis . . . will be established only by better clinical training of the student, family physician, and paediatrician." It would seem that the lesson has not yet been learnt.

Summary

A review of 115 cases of appendicitis is given; 82 had acute appendicitis. Special reference is made to those aged under 5. The high incidence (43%) of complicated appendicitis in this age group gives cause for concern.

Some difficulties in diagnosis are discussed and a plea is made for earlier diagnosis. It is suggested that the widespread use of antibiotics is changing the picture of appendicitis in the young.

I wish to thank Mr. David Levi and Mr. G. H. Macnab, of the Westminster Children's Hospital, for their helpful advice and criticism.

Accident Prevention and First Aid in the Home, a 24-page illustrated booklet published by Messrs. E. & S. Livingstone, Edinburgh (price 1s. 6d.), indicates the commoner precautions that should be taken to prevent accidents in the home, and advises on the measures to be taken and those to be avoided if accidents should occur. Each point is driven home with a suitable illustration. The booklet is intended for mothers and those having the care of small children. It has been compiled by the surgical staff of the Royal Hospital for Sick Children, Edinburgh, and profits from its sale are to be devoted to the treatment of children brought to that hospital as a result of home accidents.

THE PRINCIPLES AND PRACTICE OF YAWS CONTROL

BY

C. J. HACKETT, M.D., F.R.C.P.

The Wellcome Museum of Medical Science, London

With the use of such a powerful and satisfactory drug as procaine penicillin in aluminium monostearate (P.A.M.) in the mass treatment of yaws, it may be useful to consider the principles and practice of yaws control based upon present knowledge. The realization of these possibilities is largely due to the work of the national and international staffs carrying out the W.H.O./U.N.I.C.E.F. Treponemal-disease Control Programmes.

The Principles of Yaws Control

I. Decision to Undertake the Anti-Yaws Campaign

This indicates that those in executive positions realize or have been convinced of the necessity for such a campaign. The purpose of the campaign will be the eradication of yaws from the community, not merely its reduction to some ill-defined low endemic level. The technique of the campaign must be adequate, scientifically sound, and economical. The campaign is a public health measure applied to the community and not a curative measure applied to the individual.

II. Decision to Undertake Activities After the Campaign Itself has Subsided

Experience in many parts of the world (Harding, 1949) has shown that this is, in practice, as important as the planning of the campaign itself if lasting benefit is to result. Failure to undertake post-campaign measures has often led to a return of the yaws incidence to the level preceding the control measures.

III. Planning and Execution of the Campaign Itself

These have become matters of skilful organization and careful supervision.

(i) A complete census of the whole population is made by the civil administrative authorities.

(ii) A medical survey of the whole population is then carried out so that all patients with infectious yaws and all persons likely to develop infectious yaws, especially during the next year, are recognized. This last group includes (1) all who have not yet had yaws but who have been in contact with infectious patients either in the household, village, school, or more remotely—the importance of these regions of contact varies with age (Soetopo and Wasito, 1953); and (2) all those in the latent secondary stage. The latent secondary stage is that in which a patient, who has had yaws, has no clinical manifestations at the time, has a positive Wassermann, Kahn, and other similar serological reaction in his serum, and has had no tertiary destructive lesions. At present this stage can be defined but not directly recognized.

(iii) Adequate treatment is given at the time of recognition on the survey to all patients in the above categories. A single intramuscular injection that will result in serological reversal is ideal.

If it once be recognized that it is a public health measure that is being carried out, there is no reason why, as a separate but concurrent measure, patients with other lesions due to yaws, or even other diseases, should not be treated. Such action must not jeopardize the success of the preventive measure that is planned to treat all

infectious and potentially infectious patients so that the source of infection will be eradicated and thus transmission stopped. A wider range of treatment, especially in areas where other treatment facilities are not readily available, may help to gain the co-operation of the people and thus facilitate the work of the campaign. In all large campaigns there might be certain areas where investigations are carried out with the purpose of improving the effectiveness of the campaign itself.

IV. Post-campaign Activities

These comprise: (i) At the very start of the campaign the establishment of rural dispensaries or small treatment centres to be staffed by trained medical auxiliaries under medical supervision. At these centres free treatment would be available for all yaws patients and perhaps some other diseases. Members of the staff, after the mass treatment, would make tours of inspection of the related villages to recognize and treat infectious yaws; cases of other diseases would probably be referred to the treatment centre. As the breadth of the work expands and more diseases are brought under control the therapeutic activities of these centres would become less important and the preventive ones more important, so that they may more appropriately be called "prevention centres." "Health centres" may be preferred by some, but a rather special meaning has become attached to these larger, more urban, and more complicated establishments, while "rural centres" may be suggested by others, but no non-urban population likes to be called "rural."

(ii) Measures to recognize and treat, and thus prevent, the reintroduction of the infection into the population from other areas, and also recognize and treat any patients who have developed infectious lesions since the mass treatment. These measures may involve some form of rapid survey of the whole population and treatment at three- to six-monthly or longer intervals and especially itinerant medical auxiliaries. There might well come a time when contacts of the few cases of yaws that are found would be sought.

(iii) The undertaking of further control measures against the next most important disease for which there is effective treatment available which can be given by the staff of the prevention centre. The high incidence of an endemic disease before a campaign may make its effective treatment numerically impossible at a small rural treatment centre. However, after effective mass treatment it should be easily dealt with at a prevention centre.

The need for post-campaign activities was first realized and demonstrated by Harding (1949) in Sierra Leone, but these were not fully described in his paper as published.

In his few reprints he added a typescript insertion. With the permission of his widow, who worked with him in the field, this is being published here. The addition by the late Dr. R. D. Harding follows the "Conclusion" on page 365 of his article:

"Though not strictly connected with yaws, the possibilities of carrying out other medical activities in rural areas in conjunction with a yaws campaign may be briefly outlined by indicating ancillary work actually done during 1946. By the end of that year seven dispensaries had been designed and their attendants trained to treat most ailments and the diseases endemic in their localities as well as sleeping sickness and yaws, while seven less ambitious dispensaries were designed to treat only sleeping sickness, yaws, wounds, ulcers, scabies, malaria, bilharzia, ankylostomiasis, ascariasis, and amoebic dysentery. Two maternity centres were built in areas where the chiefs and people were favourably disposed to this innovation and suitable girls were available for training as midwives. (The lady doctor and sisters of Segbwema Methodist Mission Hospital, situated in the vicinity, very kindly undertook their training.) On the health side, the nuclei of two new chiefdom headquarters villages were laid out and their construction supervised, to replace the old villages consisting of dirty and crowded huddles of huts. Wells were dug and springs impounded to provide an alternative water supply to the foul puddles previously used. Citrus, guava, pawpaw, and other fruit trees provided by the Agricultural De-

partment were planted round the dispensaries in the hope that in course of time the villagers would learn to appreciate these fruits and cultivate them themselves.

"During the year 40,250 cases of all kinds were treated at the yaws dispensaries. Of these 10,400 were yaws, 1,530 sleeping sickness, 700 bilharzia, 580 hookworm, 1,760 ascariis, and 660 amoebic dysentery. There were 260 confinements in the wards of the maternity centres (one of which only opened in October), and there were 3,300 antenatal and 4,700 baby clinic attendances. 74,000 people were examined by touring teams. The entire European staff comprised three medical officers for half the year and two for the remainder, but one of these was engaged for nearly the whole year on a special trypanosomiasis investigation. The overall cost, including salaries, equipment, buildings, transport, etc., but possibly excluding drugs and dressings for diseases other than sleeping sickness and yaws, was under £10,000. These activities would not have been possible without the confidence which the successful treatment of sleeping sickness and yaws had engendered, and the close contact between populace and staff arising from the mobile character of the campaign.

"The possibility of mass treatment or control of other endemic diseases by mobile teams was carefully considered, particularly gonorrhoea and bilharzia. Gonorrhoea is extremely prevalent, but apart from difficulties of accurate diagnosis, the prohibitive cost of penicillin on the one hand and the inadvisability of handing out sulphonamide tablets for patients to take home on the other made the project of mass attack on this disease quite impracticable; the end-result of an attempt at mass treatment would almost certainly have been a local trade in sulphonamides, demoralization of attendants, and the development of resistant strains of gonococci, without any marked or lasting lowering of the incidence of the disease. A study of the local epidemiology of bilharzia, which in one locality affected 75% of the population, would have been undertaken if the staff position had allowed, but it would no doubt have taken several years to evolve suitable methods of control over a wide region, and the money and personnel required would greatly exceed that necessary for controlling sleeping sickness or yaws over the same area. It therefore seemed better to concentrate available resources on those improvements in general sanitation and midwifery which were possible in the immediate vicinity of the dispensaries, together with the treatment there of those endemic diseases readily diagnosable and curable by attendants trained for the purpose and proficient in the use of the microscope and the syringe."

This principle, that an anti-yaws campaign must be made the means of improving rural health services, was more recently stressed at the First International Symposium on Yaws Control in Bangkok in March, 1952, by Troupin *et al.* (1953).

The Practice of Yaws Control

The application of the above principles may be briefly discussed under the same headings.

I. Decision to Undertake the Anti-Yaws Campaign

In many countries in the past, it is possible that the numerical, medical, or economic importance of yaws may not have been fully realized at executive headquarters, since it is a disease of the more remote rural areas. It may also have been realized that, although a few injections or arsenical or bismuth preparations might work temporary wonders, their effect as a rapid public health measure was poor. However, in some areas in the past relatively casual but widespread treatment with bismuth has, after some years, apparently resulted in a very considerable numerical decrease in yaws. Again, the populations of yaws endemic areas are usually undeveloped and have often not understood the importance of the disease to themselves and the need for more continued treatment than might appear obvious to them. It will be generally agreed that in all countries in which yaws is endemic there also occur several other diseases more important as causes of sickness and death. These may include malnutrition, tuberculosis, malaria, and schistosomiasis. All these factors militate against the initiation of anti-yaws campaigns. With the realization of the immediate effects and ultimate possibilities of successful yaws control by mass treatment with P.A.M., there is much greater encouragement to undertake these measures.

II. Decision to Undertake Post-campaign Activities

Unless the vital importance of these activities is realized at the start of the anti-yaws campaign they will not be included in the planning. Thus the purpose of the campaign will be lowered, with loss of inspiration to those engaged in it. Even if these post-campaign activities are later undertaken continuity may be lost. The interest and confidence of workers and populations may be weakened and ultimate success gravely jeopardized. Although the immediate purpose of the anti-yaws campaign is the eradication of yaws the ultimate purpose of the campaign must be the gradual but steady and secure improvement of the rural health services. When one step is approaching successful completion the next in importance that is within the financial resources of the community is started; thus each improvement gained is maintained with certainty.

III. Planning and Execution of the Campaign Itself

(i) *Preparation of the Census.*—This has now become a routine civil administrative process of well-established practice.

(ii) *Survey.*—Unless a survey is carried out there is no way of assessing either the need for the campaign or its success. It is, of course, upon the findings of the survey that the mass treatment is based; all the population must be examined so that all infectious and potentially infectious yaws patients can be treated. Research may reveal some technique, such as an intradermal test with specific antigens, which will make possible the recognition of the latent secondary stage. As anti-yaws mass therapy becomes better established it may be practicable to search for other diseases in the same survey.

In countries where the rural population lives mostly in large villages or small villages close together, surveys can best be made by arranging for the authorities concerned to have the inhabitants gather at a suitable place at a certain time. In Indonesia, where this is done, it has been shown that one simply trained local medical auxiliary can examine over 750 persons each week. Those suffering from yaws are directed to a near-by established clinic (Soetopo and Wasito, 1953).

Where, however, the villages are small and scattered or where the population live in widely dispersed houses this method is impracticable and house-to-house visits must be made. Guimarães (1953), of the Instituto Oswaldo Cruz, when working in the Baixade Fluminense, near Rio de Janeiro, used local persons, chosen for their intelligence and initiative, to make the house-to-house survey and to refer patients to the yaws treatment centre. This employment was part-time, and payment was made according to the number of patients found. However, the payment per patient was raised as the campaign progressed in an area and the number of patients greatly decreased. Since these persons relied largely upon their usual occupations for their living they naturally made their house-to-house inspections "after hours," which is the time most country folk are at home. Only local people could have found the houses. Perhaps in village communities in which the incidence of yaws is low house-to-house surveys would be the method of choice. The co-operation of the population and their leaders is essential throughout the campaign. This is possible only if the purpose of the campaign is understood and the campaign desired. This has been shown in combating African trypanosomiasis in places where the population has learnt its deadly nature. It is equally important that those engaged in the campaign itself should understand the outlook of the population and that there should be mutual sympathy.

(iii) *Treatment.*—This, ideally, would be a single intramuscular injection of a cheap, effective, and non-toxic drug. This would go far to win the co-operation of the population. There must be as little trespass upon the time of the population as possible. Their occupations may be mainly agricultural, but at many seasons of the year they will have

little time to spare to attend survey-treatment gatherings. In Yugoslavia mass treatment against epidemic syphilis is available in villages at any reasonable time throughout the day, so that the patients' activities are interfered with as little as possible.

The Committee on Venereal Diseases and Treponematoses, at the 4th session in London, July/August, 1952, recommended that "in mass campaigns against non-venereal treponematoses the minimal dosage for early infectious lesions in adults be no less than 1.2 mega units of P.A.M. [of approved standard] and proportionally less for children; that this dose be given in one injection and that the preventive (or 'abortive') dose for contacts be no less than one-half of that used in the early infectious stages of the established disease."

The staff of the prevention centre should be carefully selected from the local people and suitably trained under the same conditions of buildings, equipment, and supplies as they will have in the final appointment. This employment of local people—under, of course, some medical supervision—has in many countries been completely satisfactory. It is economical, and as nearly as possible ensures a contented staff. Their influence for good health can far exceed that due to their official duties.

Until some means of detecting the latent secondary stage has been evolved, one of three expedients might be used. Treatment might be given to: (a) all who have had active secondary lesions during the previous five years (Saunders, 1937); (b) all of the population under 18–20 years of age, which will include 80–90% of persons likely to suffer infectious relapses; (c) all children at schools and in the 2–6-year age group who have yaws or have a history of having had yaws (these may comprise 80% of the scholars in some endemic areas). This action would cover many "contacts" of the disease. Contacts outside these ranges would not be very important.

IV. Post-campaign Activities

(i) The establishment of rural dispensaries suitably located to serve the population—the prevention centres already referred to—may well be regarded as the most important achievement of the anti-yaws campaign. Perhaps it would not be extravagant to say that their establishment during the campaign is the first step, to which the campaign itself was only the way. The importance of these rural dispensaries with itinerant staff, which was clearly demonstrated by Harding (1949), cannot be overemphasized, and until their importance is realized much money and effort in anti-yaws work may still be wasted. Of course, if other established static units are already present they would become the centre of the development.

(ii) Prevention of the reintroduction of the disease into an area in which yaws had been controlled could best be achieved by extending the range of anti-yaws campaigns as widely as necessary. It should be regarded as absolutely essential to the success of any mass-treatment campaign that effective case searching and treatment facilities remain in the field, so that the few cases which are certain to occur during the following year may be dealt with. There is not, and probably will never be, any drug which in mass use will produce cure in all patients.

(iii) The carrying out of further control measures against other diseases that can be diagnosed and treated by the staff is the logical sequence of the stabilization of the campaign results and the rural dispensaries. All through these progressive achievements the education of the population in preventive matters would be taking place, even without the intentional efforts that would be made at every opportunity. There is an urgent need for the discovery of some educational technique which could be applied to health and other problems among undeveloped people. It is probable that the purpose of such a technique would be to create in the people a strong desire for the improvement that is intended. The late Dr. Harding's notes, published above, show what can be done and what should be planned for.

Summary

For a long time yet the sequence of census, survey, and treatment of yaws will be required. Procaine penicillin or some other depot preparation will, with difficulty, be improved upon. The importance of recognizing cases in the latent secondary stage of the infection must be emphasized; some way to doing this is urgently needed.

An anti-yaws campaign is only a means to an end, and that end is the gradual and stable development of improved rural health services. This alone can justify the efforts required to carry out an effective anti-yaws campaign. Such a campaign, in areas where yaws is endemic, is probably the best first step in the improvement of rural health services.

The work of the World Health Organization and the United Nations International Children's Emergency Fund in assisting treponematoses control work in various countries is of great importance, and is an encouragement for the future. Reynolds *et al.* (1951) discuss the ways this help can be most effectively applied.

Professor G. Macdonald, of the London School of Hygiene and Tropical Medicine, saw this article before publication and has made the following pertinent comments:

"I am convinced that the general principle is sound. The extension of such work depends on what is wanted. If what is wanted is to start a rural public health service, there is no doubt that the best way of doing so is through measures which are immediately obvious to the population as beneficial, and of course yaws is one of the more prominent examples. Credit earned by this such work could be used to persuade people not to accept other obviously less useful work. If I were starting such a scheme I would want a curative measure, such as yaws treatment of this nature, and also an environmental measure. Quite the best example of the latter is the application of residual insecticides in houses, which is appreciated at once for the effect on fleas and flies and later for that on malaria. I would therefore start with a yaws campaign and a residual insecticide campaign as initial steps towards a rural health centre service which undertook environmental and curative work. The approach, in the paper, to the curative side of it seems ideal."

This combined attack is being carried out by W.H.O. in Liberia.

I am deeply indebted to Dr. Kodijat and his staff in Indonesia, to Dr. F. Nery Guimarães, and to those whom I met of the Division of Sanitary Organization of the National Department of Health concerned with yaws control in Brazil, for information about their work.

According to a report of the Committee on Child Health of the Scottish Health Services Council, only about 50% of mothers attend with their infants where child welfare clinics are provided. This is a matter of concern, although the report records a great improvement in child health in recent years. The importance of instruction in breast feeding and mothercraft is stressed. Every effort should be made to underline the value of immunization against certain infectious diseases. Recommendations are made regarding the management of premature infants: the report considers that breast-milk should be available to all infants in hospital, and that milk banks should be established where necessary. The report (*Child Health*) is published by the Department of Health for Scotland and is available at H.M. Stationery Office, price 2d.

EFFECT OF LARGE DOSES OF HISTAMINE ON GASTRIC SECRETION OF HCl

AN AUGMENTED HISTAMINE TEST

BY

ANDREW W. KAY, M.D., Ch.M.

(From the Peptic Ulcer Clinic, Western Infirmary, Glasgow)

In the routine histamine test of gastric secretion the dose of histamine advised has been determined arbitrarily as being generally sufficient to provoke an acid response and generally free from liability to cause untoward symptoms. It is thus a compromise, and fails to take account of individual variations in susceptibility. This defect can be overcome by utilizing the group of synthetic drugs known as the antihistaminics.

These compounds have been shown to antagonize all histamine effects save that on gastric secretion. This interesting anomaly has been well demonstrated by the work of Halpern (1948). He has shown that, although guinea-pigs could be protected against the systemic effects of as much as 1,500 lethal doses of histamine, many animals died within a day or two as a result of gastric perforation.

The purpose of this paper is to describe the parietal cell response in man to large doses of histamine, the systemic effects of the drug being prevented by the use of an antihistamine. It will be shown that in this way it is possible to give a maximum stimulus to the parietal cells. An augmented histamine test of gastric secretion, based on this principle of maximum stimulation, is described and an analysis made of the results of 148 such tests performed on normal subjects and on patients with peptic ulcer.

Secretion of HCl after Increasing Doses of Histamine

Dosage.—Throughout this investigation histamine has been given subcutaneously as histamine acid phosphate in multiples of the usual body-weight (B.W.) dose of 0.1 mg. per 10 kg. body weight. Mepyramine hydrogen maleate ("anthisan") was chosen as the antihistamine. In a series of preliminary experiments it was found that, in order to protect the patient against the systemic effects of histamine, each body-weight dose of histamine had to be covered by 1 ml. of mepyramine (25 mg.). It was also found that the antihistamine should be given intramuscularly 30 minutes before giving the histamine injection. Thus, a patient about to be given four B.W. doses of histamine would have an intramuscular injection of 4 ml. of mepyramine 30 minutes previously.

Secretion Studies.—Secretion tests were begun at 9 a.m. following a 12-hour fast. A constant size of stomach-tube, having multiple perforations at its tip, was used throughout. The fasting juice was first aspirated by syringe, the position of the patient and the position of the tube being altered until the "residual pool" of gastric juice had been tapped. This achieved, the tube was fixed to the side of the face and the patient made comfortable in this position—usually reclining on the left side. Subsequent collection of gastric juice was made by continuous aspiration, using the suction provided by an electric pump. The spontaneous secretion was withdrawn for a control period of 45 minutes before giving mepyramine, and thereafter aspiration was continued for 30 minutes until the histamine injection was made. The volume of the gastric juice withdrawn in the 45-minute period after histamine was measured and the titratable free hydrochloric acid estimated. The

weight of HCl secreted in this time was then calculated and expressed in milligrams of HCl. All saliva was expectorated during these tests.

Effects of Increasing Dosage of Histamine.—With these standard conditions, one, two, three, or more B.W. doses of histamine covered by the requisite amount of antihistamine were given to each subject on successive days. The order in which the different doses was given was varied in each subject. This series of experiments was made on five "normal" males (hernia cases without history of dyspepsia) and on five male patients with clinical and radiological evidence of duodenal ulcer. In all, 77 separate secretion tests were made. The largest single injection of histamine given was the equivalent of 12 B.W. doses; thus one ulcer patient was given 6.8 mg. and one normal subject 7.1 mg. without untoward effects. Headache and flushing were not more severe after large doses of histamine than after the usual single B.W. dose uncovered by antihistamine. The latter often induced drowsiness, which enabled the subjects to endure more readily a trying succession of secretion tests.

Results.—The weights of HCl secreted in 45 minutes in response to various doses of histamine have been plotted as ordinates on a graph, with the dose of histamine along the abscissa: in both

FIG. 1.—Dose-response curves in five cases of duodenal ulcer.

FIG. 2.—Dose-response curves in five normal subjects.

Duration of Maximum HCl Secretion after Four Body-weight Doses of Histamine

The following observations were made to determine the duration of the secretory response to large doses of histamine with a view to standardizing an augmented histamine test.

Eight male patients with duodenal ulcer were selected for study. Each patient was given a single test in which the subcutaneous administration of four B.W. doses of histamine was preceded by an intramuscular injection of 4 ml. of mepyramine. The juice was again collected by continu-

FIG. 3.—Gastric output of HCl (mg.) in response to four B.W. doses of histamine. Continuous aspiration—five-minute specimens from eight patients.

FIG. 4.—Gastric HCl output after histamine (four B.W. doses). Repeated estimations in 12 patients.

FIG. 5.—Gastric output after histamine (four B.W. doses).

ous suction, but the collecting vessel was changed every five minutes for a period of one hour. The weight of HCl secreted in each five-minute period was expressed in milligrams of HCl.

In all cases maximum output was reached in about 10-15 minutes and persisted for the next 30-35 minutes (Fig. 3). The best measure of output, therefore, is based on the secretion during the half-hour period from 15 to 45 minutes after administration of histamine.

Adopting this half-hour period of continuous aspiration, each of 12 patients was given two or more tests on successive days. The consistency of consecutive estimations is shown in Fig. 4. The error occurring between separate tests was about 5%.

That it is essential to collect the gastric juice by continuous aspiration has been shown by a simple experiment in which the histamine test was repeated on three successive days on each of two patients. The method of aspiration was the only variable factor in the three tests: continuous aspiration was used on the first day, syringe removal at five-minute intervals on the second day, and syringe removal at 15-minute intervals on the third day. It will be seen that the "maximum" HCl output of the stomach appears to fall when interval aspiration is employed (Fig. 5). This fall is due to the reduction in the volume of juice aspirated from the stomach, a considerable amount having been lost through the pylorus in the intervals between aspiration.

The Augmented Histamine Test

The test to be described is based on the conclusions reached in the foregoing studies. It provides two single results expressed in milligrams of HCl. The first figure indicates the basal secretion, and the second gives an expression of maximum parietal cell activity. The test is made as follows:

(1) The test is preceded by a 12-hour fast.

(2) A No. 9 stomach tube is introduced into the stomach and the fasting juice aspirated by means of a 50-ml. syringe. It is essential to alter the position both of the tube and of the patient until the tip of the tube reaches the most dependent part of the stomach and permits aspiration of the residual pool of fluid. This position of the tube is now maintained by fixing it to the side of the face and by insisting that the patient does not alter his posture until completion of the test. This will usually mean that he will lie comfortably on his left side.

(3) The spontaneously secreted gastric juice is now collected for a period of 45 minutes and the basal secretion expressed in milligrams of HCl produced in this time interval.

(4) 4 ml. of mepyramine is now given by intramuscular injection.

(5) The gastric juice is aspirated for the next 30 minutes and is discarded.

(6) A subcutaneous injection of a 4 B.W. dose of histamine acid phosphate is now made.

(7) The histamine-provoked secretion is continuously aspirated and the volume secreted in the half-hour from 15 to 45 minutes after injection is measured and its titratable free HCl estimated. The weight of HCl produced in this 30-minute period is the figure expressing the maximum parietal cell response.

This test of gastric secretion has certain advantages over other gastric-function tests. It is simple to do and lasts only two hours. The systemic effects following the administration of a large dose of histamine are prevented and the main subjective sensation is the drowsiness due to the anti-histamine. More than 200 such tests have now been made in this unit without incident. It provides two figures—one expressing basal secretion and one maximum secretion of HCl.

Analysis of Results of 148 Augmented Histamine Tests

The histamine test described, unlike other tests of gastric secretory function, has been shown to impose a maximum load on the secretory cells whose function it is designed to test. Furthermore, the consistency of consecutive estimations has been demonstrated. In an attempt to establish standards of normality for the test and note deviations from these

standards in patients with peptic ulcer, 148 subjects have been examined. This group comprises 25 normal subjects, 103 duodenal ulcer cases, and 20 patients with gastric ulcer. All were males. The normal group consisted of patients awaiting operation for hernia; in none was there a history of dyspepsia and none were febrile. The diagnosis in the ulcer patients was confirmed at operation in every case.

Results.—In the normal group the average basal output of HCl was 70 mg. and the average maximum output 422 mg.; in patients with duodenal ulcer the basal output averaged 265 mg. and the maximum output 837 mg.; in patients with gastric ulcer the means were 113 mg. and 478 mg. respectively. The occurrence of a wide variation on either side of these mean volumes is shown in the frequency distribution charts (Figs. 6 and 7).

FIG. 6.—Frequency distribution of basal acid output (males).

FIG. 7.—Frequency distribution of maximum acid output (males).

Three normal subjects and three gastric ulcer patients were found to have basal anacidity. All showed an acid response after histamine. The presence of stenosis did not appreciably influence either the basal or the maximum acid output in the duodenal ulcer group; a reduction in concentration was compensated by an increase in the volume of juice secreted, so that the actual amount of HCl produced was similar to that in the uncomplicated cases.

Discussion

The gastric secretory response to the commonly employed stimuli of food, alcohol, or small doses of histamine is known to vary greatly from day to day in any one individual. Indeed, the stomach has come to be regarded as capricious in its behaviour. That this is not so has been demonstrated by administering increasing doses of histamine: Four or more B.W. doses of histamine will result in an output of HCl which is constant for an individual and which represents the maximum parietal cell output of acid.

The usual interpretation of an S-shaped curve such as is shown in Figs. 1 and 2 is that the dose-response relationship is of an all-or-none nature. Therefore, with regard to the gastric secretion of HCl, this means that there is no secretion by a parietal cell until an effective stimulus is applied to it; then the parietal cell secretes maximally. The entire population of acid-secreting cells can be stimulated by giving four or more B.W. doses of histamine. Several investigators have attempted to make actual counts of the parietal cells in the gastric mucosa. As accurate counting necessitates detailed examination of the entire stomach, this method can rarely be applicable to human material. Furthermore, the visualization of a parietal cell under the microscope does not necessarily mean that it had been a functioning parietal cell. It would seem reasonable, however, to regard the maximum acid output of a stomach as an index of its parietal cell population.

The routine use of test meals is futile; in selected cases it is of value to determine the presence or absence of HCl. The failure of the stomach to yield gastric juice which was acid to Töpfer's reagent in response to a gruel meal was formerly taken to imply achlorhydria. Until recently, absence of free acid in response to histamine acid phosphate (0.1 mg. per 10 kg.) was regarded as a satisfactory criterion. Palmer and others have shown, however, that, although acid may be absent in several histamine tests, subsequent tests may reveal its presence. In short, the available tests, though satisfactory in most cases, cannot be relied upon to decide the presence or absence of complete achlorhydria. In several of a series of cases believed to have achlorhydria, as indicated by the ordinary histamine test, reinvestigation by the test described here has revealed an appreciable acid response. It should be emphasized that pH measurements should be employed in addition to titration methods if small changes in acidity are expected. The application of this test to cases of proved pernicious anaemia has regularly shown a true achlorhydria to be present. The advantages claimed for this augmented histamine test are that it imposes a uniform stimulus which exerts a full load on the acid-secreting cells, and that the results of the test are capable of repetition.

Although the test provides accurate data, its application, like that of all gastric secretory tests, is limited. No narrow standards of normal can be established, and it is consequently difficult to interpret the findings in disease. The observation that duodenal ulcer is associated with a higher range of acid output than normal is in agreement with the accepted work of Bloomfield (1932-3) and Pollard (1933). Similarly, the results of the present analysis, which show that the acid output in patients with gastric ulcer varies but little from the output in normal subjects, are not at variance with present beliefs. There is clearly no place for "hypoacidity" and "hyperacidity" as aids to diagnosis. Pernicious anaemia is the only common pathological condition having a characteristic secretory response.

Vanzant *et al.* (1932) found a considerable incidence of "unexplained anacidity" in a study of normal subjects, but not all of these were tested with histamine. Pollard (1933) quoted a 9.3% incidence of anacidity to histamine in normals. There were no cases of anacidity to large doses of histamine in the present study. Although the group was a small one, it seems likely that extensive use of the augmented histamine test will reveal a much lower incidence of this "unexplained anacidity."

As no true correlation can be shown between variations in output and pathological states, the main fields of usefulness for the augmented histamine would seem to be in physiological study, in certain anaemias, and in those rare and controversial cases in which peptic ulcer is claimed to exist in the presence of achlorhydria.

Summary

The effects of increasing doses of histamine on the gastric secretion of hydrochloric acid have been studied

in normal subjects and in patients with duodenal ulcer. The dosage required to effect maximum acid output has been established and the duration of this response determined.

An augmented histamine test of gastric secretion, based on these findings, is described.

This test, which imposes a uniform and maximum stimulus on the acid-secreting cells, gives consistent results on repeated estimations in any one individual.

An analysis has been made of the results of the test in 25 normal subjects, 103 duodenal ulcer cases, and 20 patients with gastric ulcer.

I am indebted to Professor C. F. W. Illingworth for his direction and helpful criticism throughout this investigation, to Mr. Gabriel Donald for preparing the charts, and to May and Baker Ltd. for presenting generous supplies of anthisan.

AN ANTIHISTAMINE IN THE FENESTRATION OPERATION FOR OTOSCLEROSIS

BY

TERENCE CAWTHORNE, F.R.C.S.

AND

P. B. FOXWELL, M.B., B.S.

(From the Ear, Nose, and Throat Department, King's College Hospital, London)

As the window in a fenestration operation is made in the vestibular part of the bony labyrinth, signs of a vestibular disturbance are to be expected after the operation. Thus vertigo, with its associated nausea and vomiting, is a constant and sometimes troublesome early sequel, and plays an important part in determining the length of stay in hospital.

In a unit where the demand for beds is always greater than the number available, there is a constant stimulus to search for some means of increasing the rate of turnover of the beds. For some years now we have employed special head and balancing exercises to overcome the vertigo following operations on the labyrinth (Cawthorne, 1946; Cooksey, 1946), but even with these it was not possible to turn a fenestration bed over in less than two weeks.

Because of the immediate post-operative vestibular disturbance it was our practice to keep patients as comfortable and quiet as possible by means of twice-daily injections of soluble phenobarbitone. The disadvantage of this treatment was that the patients were made very drowsy; and vertigo was rarely sufficiently controlled for them to be fit to move to the gymnasium for exercises in under five days. We therefore started to search for a more effective means of controlling the vertigo without causing too much drowsiness, and this brings us to "avomine" (promethazine-8-chlorotheophyllinate). This contains one of the most active of the antihistaminic drugs, promethazine hydrochloride, combined with theophylline and in a form suitable for ambulant

patients. It was introduced primarily for the treatment of travel sickness, and its success in this condition suggested that it might help in our problem. Campbell (1949) has already reported on the value of another preparation, dimenhydrinate ("dramamine"), after the fenestration operation.

We first used avomine in our fenestration cases in July, 1951, and to date it has been given to nearly 300 patients. Treatment is started as soon as the patient is admitted to hospital, the day before operation. We have found that a dose of 50 mg. three times daily usually suffices, and this dosage is continued for two weeks after operation.

Results

The results of avomine therapy have been striking, and may be summarized as follows.

Post-operative Vomiting.—Formerly vomiting was often troublesome for two or three days after operation. Since the introduction of avomine vomiting is rare once the patient has recovered from the anaesthetic. With regard to the effect of the anaesthetic on the post-operative course, it has been found that the agents used rarely cause vomiting once the patient is fully conscious. The anaesthetics have been given by Dr. V. F. Hall and Dr. S. A. Mason; after pre-medication with "omnupon" and scopolamine, in half the cases intravenous thiopentone only was used, whilst in the other half this was supplemented with intravenous pethidine and gas-and-oxygen.

Diet.—Because of the vomiting patients rarely ate solid food for the first two or three days after operation. Now they welcome a light diet the day after operation and usually enjoy normal food the day after that.

Drowsiness.—Continued drowsiness caused by prolonged sedation with barbiturates no longer occurs.

Getting Up.—Formerly patients were reluctant to leave their beds within four days of operation, but now they get up on the second or third day.

Exercises.—The head and balancing exercises can now be started in bed the day after operation, and they go down to the gymnasium to join the class on the fourth day. Formerly they were reluctant to do this before the sixth or seventh day.

Walking.—Whereas patients were unable to walk steadily unaided for about ten days, they can do so now as a rule by the sixth day.

Discharge.—Patients are able to leave hospital on the seventh post-operative day, thus enabling a fenestration bed to be turned over each week.

Micturition.—It is not uncommon for patients to have difficulty with micturition following operations on the labyrinth. This complication has become much less frequent with avomine.

Since the introduction of avomine, and although four or five fenestrations are performed each week, not a single patient has had to be kept in hospital longer than seven days because vertigo was not sufficiently controlled. Perhaps the most convincing proof of its success is given by patients who have had a fenestration operation performed on each ear—one before and the other after we started using avomine. Almost without exception they have commented upon how much less disturbing they found the second compared with the first operation. So far we have not observed any unpleasant side-effects, and it has not been necessary to withdraw the drug in any case.

We would like to thank Messrs. May and Baker for providing the avomine used in some cases of this series.

A HUMAN BLOOD-GROUP CHIMERA

BY

I. DUNSFORD

C. C. BOWLEY, M.B., B.S., M.R.C.O.G.

ANN M. HUTCHISON, B.Sc.
National Blood Transfusion Service, Regional
Transfusion Laboratory, Northfield Road, Sheffield, 10

JOAN S. THOMPSON, B.Sc.

RUTH SANGER, Ph.D.

AND

R. R. RACE, Ph.D., M.R.C.S., F.R.S.

Medical Research Council, Blood Group Research Unit,
the Lister Institute, Chelsea Bridge Road, London, S.W.1

Mrs. McK., a donor aged 25, gave her first pint of blood in March of this year. When the blood came to be grouped it seemed to be a mixture of A and O cells, for anti-A serum caused large agglutinates to appear to the naked eye, but the microscope showed these agglutinates to be set in a background of unagglutinated cells. The appearance was such as might be seen for a time after a large transfusion of O blood into an A recipient: but Mrs. McK. had never been transfused. Further samples excluded the possibility of any accidental mixing of bloods.

The evident mixture of blood called to mind the work of Owen (1945) on "immunogenetic consequences of vascular anastomoses between bovine twins." Anastomoses are usually present between bovine twin embryos; primordial red cells belonging to one twin take root in the other twin and continue throughout the life of that animal, to produce red cells with genetically foreign antigens. Chorionic vascular anastomosis and transfer of endocrine secretions between bovine twins of different sex had been postulated as the cause of the freemartin condition by Lillie as early as 1916.

When asked if she were a twin, Mrs. McK., somewhat surprised, answered that her twin brother had died 25 years ago at the age of 3 months. The cause of death was said to be pneumonia complicating a strangulated inguinal hernia.

The O and A₁ cells in the blood of Mrs. McK. can be separated. The result of grouping the two components is shown in the pedigree; the O cells are kk, Jk (a+b+), the A₁ cells are Kk, Jk (a-b+): in their other groups they do not differ. There is no doubt that the true genetic blood of Mrs. McK. are those shown under her name in groups of Mrs. McK. This is established by the fact that she secretes O (H) antigen in her saliva but does not secrete A antigen. Since the red cells of her twin are A₁, Le(a-b+) antigen. It is strange that we should be able to group completely this twin 25 years after his death.

Miss Marie Cutbush, of the Medical Research Council Blood Transfusion Research Unit, has counted the relative numbers of the two kinds of red cells: 61% are Group O (σ=1.7%), which does not differ significantly from the count made by Miss Cutbush one month earlier.

Mrs. McK. is the first human being to be shown to have a double set of blood groups, and there can be little doubt that one set is the consequence of vascular communication with her twin. Though we have been prepared for this discovery by the work of Owen on bovine twins, such a mixture of blood cannot be common in human twins: the Blood Group Research Unit has tested the blood of 58 pairs of dissimilar twins and 82 pairs of apparently identical twins without finding any evidence of mixed blood groups.

Alternative explanations have been considered: somatic mutation is excluded because three separate genes are involved, and dispermia is highly improbable, for Mrs. McK. shows no obvious sign of asymmetry. None of the blood samples from the other surviving members of the family was in any way unusual.

The blood groups of Mrs. McK. and of her family. The groups shown under Mrs. McK. are those which she inherited and about 61% of her red cells are stamped with these groups. About 39% of her red cells are of the groups shown under her twin brother. The antisera used to group the family and the two components of Mrs. McK.'s blood were: anti-A-A₁-B₁-O₁-H, anti-M-N-S-s, anti-P, anti-C-c-Cw-D-E-e-f, anti-Lua, anti-K-k, anti-Le-a-Leb, anti-Fy^a, anti-Jka-Jkb.

Apart from its general interest the case of Mrs. McK. has particular implications:

(a) The early presence of A antigen has presumably inhibited the production of anti-A. Mrs. McK. is group O and her serum contains anti-B, but there is no detectable anti-A: it has been looked for by methods using saline, albumin, anti-human globulin, trypsin, and papain. If anti-A were being produced by Mrs. McK. and promptly adsorbed, the only tissue capable of such adsorption would be her A₁ cells, but these cannot be shown to be either sensitized or blocked.

(b) Secretion of A antigen in saliva clearly must depend on the presence in the genotype of the A gene as well as the secretor gene, for the secretor gene of Mrs. McK. cannot command the secretion of A present only in her circulation.

(c) Mrs. McK. is feminine in appearance and has had one child: she is clearly not a freemartin. Nevertheless, now that it is established that there can be prenatal communication between the circulations of dissimilar human twins, it may be worth recording the proportion of twins among people suffering from infertility and from abnormal sexual development.

In 1916 Lillie wrote: "In the case of the free-martin, nature has performed an experiment of surpassing interest." No doubt the same could be said of Nature's experiment on Mrs. McK. were we able to appreciate more of its implications.

The World Health Organization Area Representatives Conference held recently in Delhi approved a proposal that W.H.O. should assist the Ceylon Government to initiate a postgraduate course for nurses in administration and training at the Colombo Nurses Training School: at present, nurses from Ceylon are sent abroad for postgraduate training. The Area Representatives Conference also agreed to the provision of a principal and three nursing tutors for a nurses' training school to be established at Galle or Jaffna in Ceylon. W.H.O. will also give Ceylon help in controlling tuberculosis, venereal diseases, and leprosy.

Reviews

TREATMENT OF POISONING

The Symptoms and Treatment of Acute Poisoning. By Professor G. H. W. Lucas. (Pp. 320. £1 7s. 6d.) London: H. K. Lewis and Co. 1953.

The danger of accidental, suicidal, or homicidal poisoning by the older galenic drugs or by certain species of plants, which has been a perpetual source of interest for hundreds of years, has nowadays been increased by the introduction of numerous potent new remedies into therapeutics, by the widespread use of agents to destroy pests of all kinds, and by the use of toxic substances in industry. It is fortunate that the treatment of poisoning is now more effective than it used to be. This little book provides concise and up-to-date information on the symptoms and treatment of acute poisoning by most of the agents likely to be encountered in medical practice. It is entirely concerned with the results of overdosage and not with the side-effects of drugs given in therapeutic quantities or with reactions arising as the result of idiosyncrasy in the patient.

Children are particularly liable to accidental poisoning owing to their singular propensity to investigate with their mouths substances which excite their curiosity. This danger is increased by the modern tendency of pharmaceutical firms to market their tablets and capsules in attractive and vivid colours and to temper their elixirs with the most fascinating flavours. In consequence a chapter of the book is devoted to the management of poisoning in children. A table is provided giving domestic equivalents for solid and liquid antidotes which may have to be measured out quickly in an emergency, and another showing for many poisons the least fatal dose recorded in the literature and the largest dose from which patients have recovered—information which may prove valuable to a doctor under cross-examination in a court of law. A complete index with adequate cross-references enables the reader to locate quickly the desired information. The book tells the doctor in short, sharp sentences, mostly in the imperative mood, what to do in an emergency and does not cloud the issue by stopping to reason why. The advice is usually scientifically sound, and it is a comfort to read in a work on poisoning that the skilful use of the stomach tube has largely superseded emetics. The book can be confidently recommended to general practitioners.

D. M. DUNLOP.

CHILDREN'S DISEASES

Fanconi and Wallgren's Textbook of Paediatrics. Edited by W. R. F. Collis, M.D., F.R.C.P., F.R.C.P.I., D.P.H. Translator and Co-editor E. Kawerau, M.B., M.Sc., A.R.I.C. (Pp. 1,104; 440 figures. £7 7s. 2d.) London: William Heinemann. 1952.

This book first appeared as Fanconi and Wallgren's *Lehrbuch der Pädiatrie*, and Dr. W. R. F. Collis, with the assistance of Dr. Kawerau as translator and co-editor, has been responsible for the new edition in English. The opportunity has been taken of making revisions in the original text, and a new section on megacolon by Dr. M. Bodian has been added. The numerous authors are all highly distinguished paediatricians, and their book is a considerable volume of some 1,100 pages, with over 400 illustrations, most of which are of high standard; the coloured plates are wonderfully good.

The book is planned on the usual textbook lines, system by system. Separate chapters are devoted to certain diseases and to particular aspects of paediatrics—for instance, tuberculosis, juvenile rheumatism, syphilis, and nutrition. The authors have been allowed a good deal of latitude, and they have responded by giving their personal views; this always makes for interesting and stimulating reading. The book is likely to be more suited to the hospital paediatrician than to the general practitioner, who is helped by stronger

emphasis on the early symptoms and signs of disease and by fuller reference to the scope of prophylaxis. The chapter on the disorders of puberty and adolescence—a subject that often receives scanty notice in textbooks—is an exception to the above comment, and is to be warmly welcomed.

The reader who is accustomed to the English textbooks will find some charts and tables that present facts in a new and stimulating fashion. But he will also find many mistakes in spelling and punctuation, and some paragraphs that appear to have defeated the skill of an earnest and competent translator. Doubtless these errors will be corrected in the next edition, and the work should prove to be a valuable addition to paediatric libraries.

N. B. CAPON.

ACUTE RENAL FAILURE

Acute Renal Failure: Including the Use of the Artificial Kidney. By John T. MacLean, M.D., F.R.C.S.(C.), F.A.C.S. (Pp. 114; illustrated. £2 7s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

There is much useful information in this little book, though none of it is new. Modern views on the causes, pathology, and treatment of acute renal failure are adequately presented and evaluated, though so outstanding an example of the condition as cortical necrosis of the kidneys would seem to have been overlooked. Prognosis also could have been discussed more fully. The description of the uses, application, and limitations of the various forms of the artificial kidney and other methods of dialysis is excellent, and the author's warning of the inadequacy of rigidly standardized solutions for perfusion therapy is important and timely.

The book is well written, contains many informative case records, tables, graphs, and illustrations, including five coloured plates, and concludes with an adequate subject index. The production is admirable, and the book can be recommended as a useful introduction to the subject.

A. A. OSMAN.

PSYCHOSOMATIC MEDICINE

Psychosomatic Medicine: Its Principles and Applications. By Professor Franz Alexander, M.D. (Pp. 300. £1 1s.) London: George Allen and Unwin. 1952.

The author of this book is the director of the Chicago Institute for Psycho-analysis, the first such institute with funds adequate for the necessarily prolonged research combining psycho-analytic and physiological observations on patients presenting combined psychiatric and medical problems. He has written and collaborated in writing many other more specialized books, but this volume should make a general appeal to senior medical students and general practitioners as well as young psychiatrists and specialists in the fields covered. The basic postulate of the author's approach is "that the psychological factors influencing physiological processes must be subjected to the same detailed and careful scrutiny as is customary in the study of physiological processes. Reference to emotions in such general terms as anxiety, tension, emotional imbalance is outdated. . . . Only such studies are included in this book as are carried out in accordance with this principle." The bibliography of 260 references is mostly to recent publications.

The first third of the book is a concise, clear exposition of the present American marriage of the detailed psychopathological principles of the pupils of Freud and the multi-dimensional approach of the pupils of Adolf Meyer. The remainder of the work is on gastro-intestinal disturbances (anorexia, bulimia, vomiting, cardiospasm, peptic ulcer, chronic diarrhoea, spastic and mucous colitis, ulcerative colitis), respiratory, cardiovascular, skin, metabolic and endocrinal, and joint and skeletal muscular disturbances. In a final chapter Benedek discusses male and female disorders in accordance with the principles outlined above. Many excellent half-page histories of psycho-analytic treatment or of psychiatric treatment by psycho-analytically

trained psychiatrists are included. The reasons for and the difficulties of co-operation between psychiatrists and physicians are clearly stated.

This book reads easily and is brief when compared with the material psychiatrists usually write. The psychiatric concepts should be understood by all physicians as easily as the medical student will understand the physiological concepts. What is hidden perhaps is that, whereas both psychiatrists and physicians take for granted the judgment and experience necessary to make use of the physiological principles, physicians have more difficulty in recognizing the need for psycho-analytic training taken by the psychiatrists whose basic studies have made this book possible. One can only hope it will be read as much in preparation for medical examinations as it surely will be for psychiatric. The nearest comparable book is Stanley Cobb's popular *Foundations of Neuropsychiatry*, first published in 1936.

W. CLIFFORD M. SCOTT.

CARDIOGRAPHY IN GENERAL PRACTICE

Cardiography in General Practice: Electrocardiography, Vectorcardiography, and Ballistocardiography. By Abraham I. Schaffer, M.D. (Pp. 136; 55 illustrations. £1 4s.) London: Baillière, Tindall and Cox. 1952.

The author of this book seems to aim at giving general practitioners a modern account of electrocardiograms based on a simple exposition of the physiological facts, and he succeeds very well indeed. It is remarkable how much information is compressed into a small space. The expression throughout is clear and concise, and there is no taking refuge in pseudo-scientific jargon. The result is that as a rule it is easy to follow the reasoning. At times perhaps the author is didactic; at times the exposition is too brief for anyone starting to learn the subject. On page 66 it is not made clear how to distinguish the minor variations seen in the cardiogram on exercise and acceleration from those of pathological significance. The Q wave which appears over an infarct is said to be due to a vector pointing from the contact. The idea of a "window" in the wall of the ventricle is not mentioned. It is not easy to see how the vector can distinguish between infarcts on the posterior wall of the ventricle from those of the diaphragmatic surface (p. 109). But the chapter on vectorcardiography is made clear and simple and well worth reading. There is no doubt that the idea of interpretation by vectors would not deter the beginner, who will soon find that "new presbyter is but old priest writ large." The diagrams are simple. There is also a chapter on ballistocardiography. This is a good little book and one deserving, and needing, very careful study.

TERENCE EAST.

EARLY DIAGNOSIS OF CANCER

Fundamentals of Clinical Cancer: With Emphasis on Early Diagnosis and Treatment. By Leonard B. Goldman, M.D. (Pp. 312. 221 figures. \$8.75.) New York: Grune and Stratton. 1953.

This book is intended for all who diagnose and treat cancer. Its aim is to make practitioners cancer-conscious so that they suspect the disease in its early stages, and to show how the diagnosis may be confirmed and what treatment should be given.

Some of the author's views differ from those usually held in Britain. Facing page 1 are 10 commandments of cancer control. Many readers here will disagree with the first—"Circumcise at birth to prevent cancer of the penis, and to reduce the incidence of cancer of the cervix and cancer of the prostate"—and the last—"Do not operate on tumours which cause continuous pain except bone tumours." Some operable cancers cause continuous pain, and most non-malignant painful tumours require drainage or removal. The malignant painful tumours require drainage or removal. The author lays great stress on biopsy; the methods of localized removal by scissors and by punch illustrated in Figs. 1 and 2 would be anathema to most British surgeons and pathologists.

Other statements to which exception may be taken are that "early cancers may be removed by simple surgery, invasive cancers should be eradicated by radical surgery," that "squamous cell cancers on the skin of the face rarely metastasize," and "every enlargement of the testicle should be biopsied by removal of the testicle." The view that "70% of lung cancers can be seen through the bronchoscope" is unduly optimistic, but the assertion that "occasionally cancer of the lung can be removed by radical surgery" is quite unjustifiably gloomy. About 20% of lung cancers can be resected, and a quarter of the patients thus treated are alive five years later.

Apart from these minor criticisms, the book is excellent. It will not interest the specialist surgeon or the radiologist, for treatment is not discussed in any great detail, but it should be of considerable help to general practitioners. The common types of cancer in each region are described. Methods of diagnosis and differential diagnosis are given, as well as the different methods of treatment available, with advice on which is most suitable. The illustrations, which are numerous, well chosen, and well reproduced, are an admirable feature.

HENEAGE OGILVIE.

GYNAECOLOGICAL PATHOLOGY

Gynecological and Obstetrical Pathology. By Professor Peter A. Herbut, M.D. (Pp. 683; 428 illustrations on 246 figures and two coloured plates. £4 13s. 6d.) London: Henry Kimpton. 1953.

The size and title of this book raise hopes that it is the one for which all gynaecologists and pathologists have been waiting. Unfortunately its title is rather deceptive in that its size is explained not by an abundance of pathology but by an attempt to cover every condition from every approach—its incidence, cause, clinical features, complications, diagnosis, and even treatment and prognosis. The only real justification for including obstetrics in its title is a chapter on diseases of the placenta and membranes, a chapter notable for the statement that "infarcts of the placenta, even when massive, are of little clinical significance."

The discussion of clinical aspects by a laboratory worker must almost inevitably be based on reading and hearsay rather than on experience, and here the reader gets the same impression of the sections on morbid anatomy and histology. Instead of giving his own views and observations Dr. Herbut is content to treat most subjects by giving a précis of some article which has appeared in the medical press at some time during the last ten years. The review of the literature, confined almost entirely to journals published in the U.S.A., is incomplete and could be positively misleading. For example, the author states that he can find only two recorded cases of air embolism resulting from vaginal insufflation, whereas references to four such cases were given in the *British Medical Journal* as long ago as 1945, and there has been at least one other published since. Again, can we really believe that only 28 cases of female pseudohermaphroditism had been described by 1942?

In a wide coverage of the field some account is given of many rare and bizarre conditions whose description is not easy to find elsewhere, and this is the most useful feature of the book. Unfortunately, one's confidence in it as a work of reference to the rarities is shaken by the many errors and discrepancies which are to be found in regard to the conditions on which one has some prior knowledge. The statement that the cause of uterine fibroids is now known is as startling as it is untrue. Erosion of the cervix—a fascinating problem for pathologists—is mentioned only once, to be dismissed as synonymous with ectropion. Fig. 114 is upside down. Fig. 175 is alleged to show a serous cystadenoma of the ovary, whereas the arrangement of the blood vessels in its wall shows clearly that it is an extraperitoneal cyst—probably fimbrial or parovarian in type. Ovarian agenesis is said to represent a failure in the development of the part of Mullerian duct which gives rise to the ovary. The book is a queer mixture and, on the whole, disappointing.

THE ARTIFICIAL HEART

Research into the creation of an artificial circulation has been going on since 1937, when Gibbon¹ reported the use of a heart-lung apparatus to maintain the circulation during experimental occlusion of the pulmonary artery. Dr. D. G. Melrose and his colleagues have now brought such an apparatus to a high degree of perfection, and their results are published in our opening pages this week. The design of their machine is based on that of the pump-oxygenator described by Björk² and Crafoord.³ The oxygenator is a rotating cylinder set at an angle to the horizontal and containing annular perspex plates. The blood travels through it under the influence of gravity and is spread over the plates. These are arranged so that the greatest possible surface area of blood is exposed to the oxygen pumped into the cylinder. Two valveless rotary type pumps, driven by electric motors, are used: these are a venous pump to supply the oxygenator with blood, and an arterial pump to deliver the oxygenated blood to the subject. Three manometers measure, respectively, the volume of blood in the oxygenator, the pressure in the venous part of the artificial circuit, and the pressure in the arterial part of the artificial circuit. The speed of the pumps is controlled electrically by signals from the manometers, thus ensuring that they work in harmony to maintain blood volume and arterial pressure; excessive venous suction is thus prevented. This mechanism is capable of maintaining the blood volume within 50 ml. over a range of flow of between 300 ml. and 3 litres per minute. The oxygenator is kept at a constant temperature, and oxygen is delivered through an adjustable rotameter which permits of adjustments of rate of flow. The acid-base balance is controlled by altering the rate of flow of oxygen or by the addition of small amounts of carbon dioxide. The gases are passed through a warming, filtering, and humidifying system.

In the second paper published in this issue Melrose and his colleagues describe the results in thirty anaesthetized dogs of using the heart-lung machine in parallel with the normal circulation, blood being fed into the machine from the femoral vein and returned

to the animal via an artery. Careful studies have been made of cardiac output, central venous pressure, systemic blood pressure, and cardiac rate and rhythm, as well as investigations into the effect of the oxygenator on the cellular and chemical constituents of the blood. In order to prevent coagulation in the oxygenator the animals were heparinized initially, and then given protamine sulphate to neutralize the heparin at the end of the experiment. Most of the experiments lasted one hour, the rate of perfusion being 750-1,000 ml. per minute. No dog died as a direct result of the perfusion, although for other reasons four did not survive the procedure. Two to three days later the surviving dogs were normally active and apparently had suffered no ill effects. Post-mortem examination of 25 dogs, which were sacrificed three months later, did not show any abnormalities.

The results obtained are of great interest, and there can be no doubt of the efficiency of the machine as an oxygenator: for instance, in one dog 150 c.cm. of oxygen was introduced into the circulation per minute. When dogs were made anoxic by reducing the content of oxygen in the inspired air the arterial oxygen rose significantly in the region where the oxygenated blood was returned from the machine, but remained depressed in other areas. Thus, when the blood was returned to the femoral artery, the cephalic end of the animal remained anoxic, while the oxygen content of the arterial blood in the caudal end increased. Cardiac output determinations on twelve dogs showed that the output fell in nine and rose only in two. In some dogs the fall was of the order of 30%, although the authors point out that considerable difficulty attended the accurate estimation of the output under the conditions of the experiment. No arrhythmias occurred, and there were no significant alterations in heart rate, mean arterial pressure, or central venous pressure. The formed elements of the blood changed in several ways, the most striking being a fall in leucocytes of nearly 50%, mainly the granular series. The numbers of platelets and red blood cells fell also, but to a less extent. The plasma haemoglobin rose, and the haematocrit fell, indicating haemolysis and haemodilution, which were considered to be due in part to the dextran solution used to charge the oxygenator. Cleaning and sterilization of the apparatus was carried out chemically by detergents and 3% formalin, but sterilization by autoclaving should soon be possible.

ally by detergents and 3% formalin, but sterilization by autoclaving should soon be possible.

Melrose and his colleagues consider, and with justification, that their apparatus might now be applied to the treatment of certain forms of cardio-respiratory failure in man, the oxygenator being used in parallel with the normal circulation. Clearly the step from experiment on the animal to treatment of the human is a big one, and careful thought will have to be given to the type of patient likely to benefit from the artificial heart, and to the problems which may arise. The indications for its use would include any form of acute, potentially reversible anoxia which does not respond to the usual forms of treatment—for instance, acute cor pulmonale, severe congestive cardiac failure, or acute circulatory failure such as may follow cardiac infarction. The oxygenator would also be of great value to the cardiac surgeon to augment the function of the heart during long and difficult operations for the relief of cyanotic congenital heart disease, but heparinization of the patient, which is apparently essential for the working of the oxygenator, would present a formidable problem to the surgeon. Although the coagulation time can be rapidly restored to normal after operation by the injection of protamine sulphate, this may apparently result in acute arterial hypotension.⁴ Disadvantages of the oxygenator at present are the difficulties of complete sterilization (with the possibility of introducing pyrogenic or other toxic material into the recipient), the profound fall in circulating white blood cells, haemolysis, and a possible fall in cardiac output. The most important of these are likely to be the reduction in white blood cells and in cardiac output, though the former may prove to be less of a disadvantage than is at first apparent, since the number of white blood cells apparently rapidly returns to normal at the conclusion of the treatment, and may later exceed the original level. Moreover, there was no leucopenia after the use of a pump-oxygenator in man by Helmsworth and his colleagues.⁵ Cardiac output is unlikely to fall by more than the output of the machine, but any further reduction in output might be undesirable in an acutely anoxic patient, even though the arterial oxygen saturation was increased.

In heart failure due to chronic bronchitis and emphysema, the respiratory centre may respond only to a low arterial oxygen saturation. In some cases coma and neurological abnormalities have been induced by oxygen administration.⁶ If the oxygenator is applied to such patients, measures will have to be taken to ensure adequate pulmonary ventilation

and carbon dioxide elimination, and some form of assisted respiration should be at hand. The vein-to-vein, rather than the vein-to-artery, route would appear to be preferable for perfusion, in view of the difficulties and potential hazards of intra-arterial transfusion.⁹ Helmsworth and his colleagues⁵ used a similar machine to treat a patient with cor pulmonale, drawing blood from the inferior vena cava via a catheter in one saphenous vein and returning it to the other, the arterial oxygen saturation being raised from 43% to 58-65%. No ill effects resulted from the use of the machine, but improvement was not maintained after withdrawal of the artificial circulation.

Professor Ian Aird, in his foreword to Melrose's first paper, wisely suggests that the use of an oxygenator to replace the heart during cardiac surgery may not yet be immediately attainable. Certainly the most formidable difficulties have been encountered by other workers when the whole heart has been excluded from the circulation, such as air embolism or haemorrhage when the venous end of the pump is attached to the right auricle, and acute arterial hypotension and bradycardia when the right auricle is emptied.⁷ But Dodrill and colleagues⁷ have reported the absence of such hypotensive reflexes from the left auricle, and have succeeded in isolating the left side of the heart in animals by removing blood from a pulmonary vein and returning it to the aorta through a cannula in the subclavian artery. By this means they were able to expose the mitral valve for 20-30 minutes, with subsequent survival. They were also able successfully to by-pass the left ventricle in a patient with mitral-valve disease for 50 minutes, maintaining the artificial circulation at a rate of 4½ litres per minute.⁸ If this technique (which, incidentally, does not require the oxygenator) should prove generally applicable, the surgery of mitral incompetence and aortic valve disease would be greatly assisted.

Whatever the future applications of the artificial heart, Melrose and his colleagues are to be highly commended for their ingenuity and resource. The vital step of applying the machine in treatment has presumably still to be taken. The circumstances justifying a trial at the present time are few, but the potentialities of the machine may be considerable. A glimpse of the uses to which a similar machine has been put in the treatment of a desperately ill patient has already been given by Helmsworth *et al.*⁷ We can feel assured that this machine will be used wisely and humanely, and it is likely to be a valuable contribution to the advancement of cardiac surgery.

FLUORIDATION OF WATER

For many years it has been observed that the presence of fluorine in drinking water affects the structure of the teeth to a greater or less extent according to the quantity present. McKay reported¹ in the United States in 1929 that the incidence of dental caries was reduced in a district where there was a high concentration of fluorine in the water supply. In consequence a number of field surveys were carried out, and by 1942 it was established that dental caries is less in the groups of individuals who drink water containing fluorine during the period of tooth formation. This has since been confirmed by reports from many other countries, including Great Britain.

United States research workers decided to ascertain whether a similar beneficial effect followed the addition of enough fluorine-containing compound to a fluorine-deficient water supply. The concentration of 1 p.p.m. of fluorine was selected as giving considerable protection against dental caries without mottling of enamel. The first of six projects was started in 1945 at Grand Rapids, Michigan. But more recently fluoridation of drinking waters has been adopted in many communities in the United States purely as a public health measure.

In Britain the Medical Research Council, in a report to the Minister of Health, recommended that a small mission should study the fluoridation of water supplies, and one was therefore sent to the U.S.A. to study the schemes there at first hand. Its 100-page report has just been published.²

The mission considers the evidence is conclusive that a reduction in the incidence of dental caries is obtained comparable to that experienced when fluorine occurs naturally in the water. However, since the schemes have been in operation for only seven years, data relating to individuals over the age of 6 years are not yet available. But there is nothing to suggest that water containing naturally occurring fluorine has properties different from those of water to which fluorine has been added.

The possible hazards of adding fluorine have been carefully considered. The risk of producing mottled enamel at the level of 1 p.p.m. is extremely small. Only an occasional white fleck on the enamel occurs, which is so slight that it can be recognized only with experience. No sound evidence was found that there is danger to health from the continuous consumption of water containing fluorine in low concentration. Mortality statistics did not indicate any hazard, and according to local medical opinion there was no

increase in morbidity. The mission concludes that "the proving of a negative is extremely difficult. Meanwhile we are impressed by the fact that millions of people are living in ordinary good health on waters containing fluorine at levels of 1 p.p.m. or more."

It may give rise to some surprise that in the United States, "where by 1951 fluoridation of water supplies had become a fairly common practice," a Select Committee of the House of Representatives conducted a public inquiry into the safety and efficacy of fluoridation and concluded "that a sufficient number of unanswered questions concerning the safety of this program exists to warrant a conservative attitude." This conservative attitude is mirrored in the mission's recommendations. It advises in the first instance the addition of fluorides to water supplies of some selected communities which should be regarded as study centres to observe the effectiveness of the procedure under our own particular conditions of diet and caries experience. Research should also be carried out in areas where fluorine occurs naturally and in higher concentrations than that suggested for artificial addition, where the general health could be studied and investigations carried out into bone development and disease, and diseases of the kidney in particular, so that no question remains unanswered.

The amount of reduction in dental caries caused by the presence of fluorine in the drinking water should be viewed in perspective. Comparative studies show that much the greatest change in the incidence of dental caries is associated with alteration of diet. Even the reduction in dental caries experienced by many communities under wartime conditions was greater than could be expected from drinking fluorine-containing water. And the increase in dental caries observed since the war, an increase that seems to be continuing even now, would scarcely be reversed by the fluoridation of drinking water. Even so, such preventive measures as topical applications to the teeth are far less effective. Of the measures available, fluoridation of drinking water to a level that shows a decrease in caries without discoloration of the teeth would seem to be a most useful procedure. Although not every child would necessarily benefit from it, since the water intake might be below average, the greatest benefit to the greatest number of children would result, and its effect would last well into adult life. But in spite of this preventive measure dental caries will be a common disease and nearly everyone will need to have carious teeth treated annually.

Such a measure as fluoridation of public water supplies, entailing the treatment of a commodity consumed by almost everyone, is likely to be the centre of warm controversy.

emotions in which they have a vested interest, some politicians and publicists may try to divert public attention from the facts so far gathered. This report makes an informative and dispassionate contribution to the debate.

A HUMAN CHIMERA

The *chimaera* of classical tradition was a creature consisting of parts of several different vertebrate species. In the natural world individuals composed of two genetically distinct parts are rare. They are found in the plant kingdom and more rarely among insects. In their more obvious manifestations chimeras are unknown among mammals, but serology, more subtle than the unaided eye, has shown that they do exist in cattle. And now Mr. I. Dunsford and his colleagues, as they report in this week's *Journal* at p. 81, have demonstrated the existence of a composite human being.

It has long been known that when cattle twins are of unlike sex the female is usually sterile, and Lillie¹ showed that this was associated with an anastomosis between the chorionic circulations. In the freemartin or imperfect female twin the abnormal genitalia are cytologically female and are the consequence of a transfer of hormones, not of cellular material, from the blood stream of one individual to the other. Owen² was the first to show that a cellular transfer can indeed take place. He demonstrated that in non-identical cattle twins, whatever their sex, there is a double set of red blood cells, one set corresponding in its blood-group antigens to the genetical constitution of the individual carrying them, and the other set to the constitution of the twin. To account for this it must be assumed that viable erythroblasts traverse the chorionic anastomosis in each direction, and become implanted in the bone marrow of the opposite twin. Vascular anastomoses between dizygotic twins and abnormalities in the genitalia of twins of unlike sex do not appear to have been described in man, nor have mixed blood groups hitherto been observed in human twins.

The chimera described this week by Dunsford and his colleagues is a woman with a mixture of A and O red cells. She is the survivor of a twin pair. The two sets of cells are distinct genetically, differing in two other antigens as well as those of the ABO system. The authors consider a number of possible explanations and show that almost certainly the case is the result of an antenatal implantation of erythroblasts from the twin, as already described in cattle.

The research described opens up an interesting but limited field of investigation into the blood groups of twins, the anatomy of their foetal blood supply, and, though not present in this case, the possible occurrence in them of abnormalities of the genitalia. But there are some wider implications. The observations reveal a further example of the failure of the organism to become immunized to an antigen to which it has been exposed

in early foetal life. Another suspected example of this was recently discussed by Booth *et al.*³ But perhaps the most fundamental finding was that the genetical control of salivary secretion of the blood group substance does not operate through the red cell at any stage of the cell's existence. This may have a bearing on the recent discovery of a relation between blood groups and the incidence of carcinoma of the stomach⁴ and the suggested relation of this to secretion.⁵

UNIVERSITY GRANTS

Great changes have taken place in medical education since the war, according to the latest report of the University Grants Committee.¹ They were in response to the scientific revolution that is still in full spate in our profession and to the proposals of the Goodenough Committee made in 1944.² Since then fifty-five new full-time professorial chairs have been created, together with their staffs of readers and lecturers from whom future professors will be recruited. Postgraduate education has been greatly strengthened, notably in the British Postgraduate Medical Federation established by London University. And most of the teaching hospitals have greatly expanded their research programmes. Much the same story can be told of the other branches of science—though with one striking difference. Whereas the total student population rose from 50,000 to 83,000 between 1938-9 and 1951-2, the medical student population showed little change, being 12,000 in the earlier year and 14,000 in the later. So, with fifty-five new professorial chairs to contend with as well as an intern year, the students are likely to share the regret expressed in this report that "little appears to have been done to carry out the recommendations of the Goodenough Committee for a lightening of the medical curriculum." If teachers can ever bring themselves to lighten instead of to increase the load they think their charges ought to bear, some of them will have an opportunity of suggesting how it should best be done when they speak at the First World Conference on Medical Education to be held at B.M.A. House next month.³

If the methods and subjects taught have changed in the years reviewed, so too have the students. Though figures for financial assistance are not given separately for medical students, they probably do not differ much from those for all students, of whom 41% received assistance in 1938-9, 72% in 1951-2. But the quality of the students seems not to have altered much. The very clever have remained few, the really weak have not found places; consequently the proportion of good second-class students is higher than it used to be. Apart from that the report finds some evidence of a general improvement of student quality in medicine, attributing it to the fact that entrants come from a wider field than formerly. Inquiring into health services organized by the universities, the University Grants Committee found a strong demand for them from the students, who attached

much importance in particular to psychiatric advice being readily available. But, as the report points out, the coming of the N.H.S. must make universities think again about the expenditure of money on services of this kind lest they merely duplicate what is already provided.

The functions and powers of this committee, which make it unique in university administration, are discharged with such sagacity that not only is it the envy of universities in other countries but—a harder test—it continues to hold the respect of universities in Britain. Its members give abundant evidence of that love of learning whose advancement it is their task to help.

PLASMA EXPANDERS

The introduction of gum acacia solutions by Bayliss and other investigators for infusion into the wounded toward the end of the first world war saved many lives. During the second world war the Allies relied on blood and plasma infusions with notable success, but new plasma expanders were developed, mainly in Sweden and Germany, to help overcome difficulties in supplying sufficient quantities of blood and blood products. These difficulties are still present in many parts of the world, and in certain circumstances even Britain is apt to experience them in spite of the finest of transfusion services. The risks from plasma and blood transfusion have not all been overcome, notably that of plasma jaundice; others are probably still to be discovered. Progress in finding out the advantages and disadvantages of plasma expanders is therefore important.

Two modern plasma expanders are now available commercially—dextran and polyvinyl pyrrolidone. Their therapeutic value in retaining fluid within the circulatory system depends on their colloid osmotic pressure, which is a function of the number of their molecules not free to pass through the blood capillaries. These colloids are unfortunately not homogeneous in molecular size: they usually range from about 20,000 to 200,000 in molecular weight terms. These small and large molecules differ in their effects in the body, not only in degree but also in kind. Substances with molecular weights below about 25,000 are rapidly removed from the body by renal excretion through the glomeruli,¹ and they are virtually useless as plasma expanders,² since any effect obtained will be nearly as transient as if physiological saline had been administered. Material with high molecular weight has other disadvantages, especially evident because large concentrations are needed to produce colloid osmotic pressures equivalent to that of plasma (30–40 cm. of water). High molecular weight solutions are unduly viscous. They may form precipitates with plasma constituents, especially with fibrinogen³; they are deposited in the reticulo-endothelial system⁴; and they tend to aggregate red blood corpuscles, as shown by a raised erythrocyte sedimentation rate. These last two effects are probably more marked in solutions of equivalent molecular size with polyvinyl pyrrolidone than with dextran.

For use as plasma expanders, then, colloid solutions of intermediate molecular size are required—perhaps of the order of 70,000 to 100,000 for dextran, and somewhat smaller for polyvinyl pyrrolidone. Attention may also have to be directed to the molecular shape of the material. This varies in dextrans from different sources according to the nature of the linkages between its component glucose units. Medical men must choose the material to give their patients, and this implies manufacture to specification, as was adopted temporarily in the early clinical trials of dextran in Britain.⁵ Suitable specifications and legal control of the composition of plasma expanders are therefore required before they can be recommended unreservedly and full advantage taken of their sphere of usefulness. This does not (and cannot) include their substitution for blood in the treatment of severe haemorrhage or anaemia. More blood donors still are needed.

MEDICAL LIBRARIANS IN CONGRESS

London is unequalled for its wealth of medical libraries: some of the most important collections in the world are contained within a small area—the libraries of the Royal Colleges, of the Royal Society of Medicine, of the B.M.A., of the London School of Hygiene, and the Wellcome Foundation's famous historical collection. Appropriately, therefore, the First International Congress on Medical Librarianship is to be held in London, from July 20 to 25. Sir Cecil Wakeley, P.R.C.S., is the president of the Congress, and he will be supported by thirty-eight vice-presidents, representing the chief medical libraries of the world, universities, and other organizations. Exhibitions to be held in connexion with the Congress are of medical periodicals (in the Old Library of B.M.A. House), of medical books and equipment (in the Gymnasium of University College), of the U.S. Armed Forces Medical Library (in the auditorium of the Wellcome Research Institution), and of the history of medical libraries and of medical bibliography (in the Wellcome Historical Medical Museum).

Sir Cecil Wakeley, in a presidential message to the Congress, quotes Osler's warning that "to study the phenomena of disease without books is to sail an uncharted sea," and he aptly continues the simile by emphasizing the needs not only for charts but also for pilots, among which medical librarians can count themselves. Pilots, of course, should be carefully trained, and one of the subjects to be discussed at the Congress is the education and training for medical librarianship. At present Britain is the only country in which medical librarians qualify as such by special examinations. Two sessions of the Congress will be given up to a symposium on the role of the medical librarian in the world to-day.

Among the other subjects to be debated are international co-operation and aids to the current indexing of medical literature—a matter of topical importance, since the existing indexes are falling behindhand. By discussing their common problems at this Congress and by fostering the spirit of international co-operation, medical librarians will be increasing their already great contribution to the spread of scientific learning throughout the world.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

LEUCORRHOEA

BY

C. S. RUSSELL, M.D., F.R.C.S.Ed., M.R.C.O.G.

Professor of Obstetrics and Gynaecology, University of Sheffield

Whiteness is not a common feature of the abnormal discharges from the vagina, and so the word "leucorrhoea" is being used less and less: it is being replaced by the more widely applicable phrase "vaginal discharge," which covers all varieties of discharge regardless of colour, though usually excluding those that are blood-stained. The symptom is common; it occurs at all ages and is of widely differing significance.

Bacteriology

A distinction must be drawn between the flora of the vulva and vestibule and that of the vagina. At birth the vulva and vestibule are usually sterile, but this state of affairs does not last long: within a few hours organisms reach the area. Their type depends largely on those present in the immediate environment; provided this is clean, pathogenic bacteria in harmful concentration will be absent.

During the mother's pregnancy the foetal vagina is under the influence of the maternal oestrogens, and at birth therefore its epithelium is well stratified and the cells contain glycogen. Within 12 to 24 hours of birth Döderlein's bacillus makes its appearance and remains for about two weeks, until the effect of the maternal oestrogen has worn off. This bacillus, assisted by enzyme activity, is thought to break down the glycogen in the vaginal cells into lactic and other acids in lesser amounts, which together have a powerful bactericidal action. By the end of the second week of life the vagina is probably once again sterile, and it normally remains so in infancy and childhood. Another factor in keeping the vagina free of pathogenic bacteria during this period may be the anatomical arrangement: the walls of the vagina are in close apposition and the introitus is so nearly closed by the hymen that the passage of harmful organisms upwards from the vulva is unlikely.

During the reproductive years of life the bacterial flora is mixed, and pathogenic bacteria may be present, particularly in the lower one-third of the vagina. But they should not survive long, being inhibited in their growth by the vaginal acidity (pH 4–5.5). It has been estimated that a concentration of lactic acid of 1% may be present during these years. The vaginal acidity, which is so important in maintaining vaginal health, is temporarily neutralized by the menstrual flow, and this accounts for the tendency of infections of the vagina to return or relapse after each period.

Examination of the Patient

From all patients complaining of vaginal discharge a careful history must first be taken to obtain as much information as possible about the time and mode of onset; its quantity, colour, and consistency; whether it is irritating, offensive, or blood-stained; and any other special features. Then examination should be carried out in a good light. After preliminary examination of the abdomen and any general examination that seems necessary, the patient should be made to lie comfortably on her back with her thighs drawn up and separated; the labia are then parted, and the vaginal introitus is examined for the presence of discharge, signs of inflammation, ulceration, or oedema or other swellings. The urethral orifice should be swabbed clean with saline; if there is any suggestion of urethritis the urethra should be gently "milked" downwards with

the finger on the anterior vaginal wall; if it is possible to express pus from the urethra a swab must be sent for bacteriological examination: pus can never be expressed from the urethra in a simple case of vaginitis; it always means that there is some other condition present. The patient should then be turned on her side with her thighs drawn up, the upper one slightly more so than the lower one (see Fig.), and a lubricated Sims speculum gently inserted into the vagina.

If a discharge is seen a specimen diluted with saline should be inspected under the microscope for trichomonas or the spores and hyphae of vaginal thrush. The discharge is then removed with a swab on sponge-holding forceps, and the vaginal walls are carefully inspected for redness, signs of abrasion, ulceration, or other abnormality. The

Position for examination with a Sims speculum. A lower pillow or even no pillow might be better.

cervix is next inspected for erosion and evidence of cervicitis, and any excess of cervical mucus noted. Sometimes it is helpful to turn the patient into the knee-chest position, because, with the Sims speculum in the vagina and the patient in this position, the vagina balloons out, and a very clear view of the vaginal walls may be obtained. Finally, an ordinary bimanual examination should be performed to exclude disease of the pelvic organs.

In most cases this examination will give as much information as is required to find out the cause of a vaginal discharge. If the findings are equivocal specialist opinion should be sought, as special culture methods may be necessary.

Vaginal Discharge before Puberty

Vaginal discharge before puberty is most commonly a sign of infection, seldom localized to the vagina, more usually taking the form of a vulvo-vaginitis: any of the pathogenic bacteria may be responsible. The vulva and vaginal introitus are red, swollen, and oedematous, depending on the severity of the infection. There may be purulent discharge, in which case it should be possible to obtain some on a swab for immediate culture. Treatment with one of the sulphonamides or other appropriate antibiotics is usually quickly effective: daily baths with gentle washing and drying are also indicated. In resistant cases oestrogens (ethinyl oestradiol or stilboestrol) should be given by mouth, the dose being appropriate to age. For a child of 6 a daily dose of stilboestrol 0.5 mg. should be sufficient.

Another cause for discharge in childhood and infancy is a foreign body in the vagina. This may sometimes be

⁴ Bull, J. P. et al., *Lancet*, 1949, 1, 134.
⁵ Maycock, W. d'A., *ibid.*, 1952, 1, 1081.

seen sticking in the introitus, when it may be readily removed. If the foreign body is well in the vagina, recognition is much more difficult, though it may be possible to feel it with a little finger in the rectum. For removal, admission to hospital and examination under anaesthesia with tiny specula (Kelly's cystoscope may be useful) is usually required.

Vaginal Discharge During the Child-bearing Years

Discharge at this time is fairly common and generally results from infection of the vagina or cervix. The two common forms of vaginitis are those due to *Trichomonas vaginalis* and to the fungus *Candida albicans*. Cervicitis is usually the result of lacerations at childbirth, with infection and failure of involution leading to chronic hypertrophy of the cervix, and thus to blockage of the cervical mucus-secreting glands with the formation of visible cysts, known as Nabothian follicles.

Trichomonas Vaginitis.—*T. vaginalis* is an oval flagellate with axostyle and undulating membrane; it is found in great numbers in the vaginal secretion in certain forms of vaginitis. The discharge in these cases is offensive and may cause a burning sensation: dyspareunia, dysuria, and frequency of micturition are other symptoms. In appearance the discharge is yellowish, watery, and slightly frothy. The vagina may be very tender: it looks inflamed, and widespread discrete red spots may be seen, giving the surface a strawberry-like appearance. Because of the activity of its three or four flagellae the organism is easily seen under the microscope in a fresh hanging-drop preparation. The source of infection is not known: though the disease is seen in virgins, there are cases in which transmission during coitus cannot be excluded, because the organism has been found in the subpreputial and prostatic secretions and in the bladder of the male. The organism causing vaginitis differs from that found in the mouth and large bowel. One perplexing observation is that *T. vaginalis* may be present in the vagina without causing any inflammation or other inconvenience. Treatment of the vaginitis, in the first instance, is by pessaries, such as those containing acetarsol or silver picrate. The patient should be told to insert one or two pessaries each night between two periods, and thereafter daily for the week immediately following the next two periods. This will cure most cases. Alternatively, antiseptics may be injected as a thick cream into the vagina by means of special applicators. Douches are of little value in the treatment of vaginitis: they may, however, be prescribed two or three times a week as a method of cleansing the vagina between treatments. Salt solution, one teaspoonful of salt to the pint (570 ml.), should then be used. For the few cases which are not cured, vaginal cleansing, drying, and powdering twice a week is required, using acetarsol or silver picrate powder. Insufflation of the vagina with antiseptic powder must never be carried out in pregnancy, because of the risk of fatal air-embolism. In resistant cases the possibility of reinfection by the husband should be considered.

Vaginal Thrush.—This form of vaginitis is particularly common during pregnancy and causes much local irritation. The findings are striking: the vaginal walls are covered with a thick white curd-like matter that adheres to the skin. Confirmation of the diagnosis is made by finding the characteristic spores and hyphae on microscopy. The urine in such cases should be particularly tested for sugar. Treatment comprises, first, vaginal cleansing under vision, with soap or detergent and water, until all the matter has been removed; and, secondly, antiseptic measures. The cleansing gives the patient immediate relief, and should be repeated twice a week. Thereafter the vagina, vestibule, and vulva are painted carefully and completely two or three times a week for two weeks with 1% gentian violet in water or 1% gentian violet in equal parts of spirit and water, care being taken that no vaginal folds are overlooked.

Alternatively, chlorophenesin ("mycil") pessaries may be advised. In resistant cases subclinical diabetes should be excluded by a sugar-tolerance curve.

Cervical Discharges

Cervical erosion is recognized by finding a circular area of velvety redness around the external os. This appearance results from the downgrowth of columnar epithelium from the cervical canal. If, in addition, there is overgrowth of the columnar epithelium the erosion is thrown into folds and may be called papillary. The condition is seen in virgin women and in women who have not borne children, and its cause is then unknown: in parous women infection at childbirth is probably the main factor, and the erosion is seldom seen without some cervicitis.

Chronic cervicitis produces a sticky discharge, not usually irritating or offensive unless there is some superadded vaginitis. It may also be associated with a number of other symptoms, particularly lower abdominal aching and backache, which probably originate from the tense, blocked cervical glands. The general health may be impaired. There may also be sterility, because the purulent cervical discharge is inimical to the spermatozoa.

The cervix in such cases is hypertrophied, lacerated, and often everted. The columnar epithelium of the canal may be exposed and may have replaced the squamous epithelium around the external os as in erosion. Mucoid material may be seen in the os, and when it is lifted away with forceps its stickiness is at once apparent. There may be an associated parametritis, when the woman may complain of pelvic pain, backache, and dyspareunia; then pain on moving the cervix is an important sign. Bacteriological examination of cervical discharges is necessary only if there is an associated urethritis or Bartholinitis, or if the condition does not respond to treatment; then specialist facilities are required because of the uncertainty in excluding gonococcal infection by smears and culture methods alone, and because of the advisability of blood tests.

Cervicitis may be materially improved by superficial linear cauterization of the cervix in the out-patient department, the anterior lip being treated one week and the posterior lip the next; but symptoms are unlikely to be completely relieved, at least in a severe case, until deep cauterization with electric hot-point, diathermy coagulation, or excision with knife or diathermy of a substantial part of the hypertrophied cervix has been carried out; for these latter procedures admission to hospital or nursing-home and anaesthesia are required. Treatment in this way is effective; there are few complications and little risk. The most troublesome complication is secondary haemorrhage occurring about the end of the second week. This is treated by morphine and rest if the bleeding is slight, and by a firm vaginal pack if bleeding is severe. Very occasionally a widespread pelvic infection flares up after cervical cauterization. In women over the age of 40 amputation of the cervix or even hysterectomy may be preferred.

The prevention of cervicitis is an aspect of intrapartum and post-partum care which tends to be neglected. During labour every care must be taken to prevent infection of the mother, by strict aseptic and antiseptic techniques and by keeping her away from the sources of infection. Should infection occur it must be treated adequately. When the woman is examined a month or so after delivery the examination should include a careful assessment of the state of the cervix and thorough speculum examination in a good light so that any cervical faults may be recognized and treated without delay.

Post-menopausal Discharges

After the menopause the lack of ovarian secretion leads to a partial atrophy of the vaginal epithelium, which together with lack of acidity at this time may allow infection to occur. A thin watery discharge results which may be blood-stained, and the vagina shows a widespread nuncate red

mottling. In such cases preliminary curettage, possibly cervix biopsy, and examination under anaesthesia are usually required to exclude genital cancer. Treatment of the vaginitis is first by oestrogen pessaries, one twice daily for two to three weeks, reserving stilboestrol 0.5 mg., or ethinyl oestradiol, 0.05 mg., daily by mouth, together with sulphonamides or antibiotics locally or parenterally, for resistant cases. Treatment with oestrogen by mouth should not be continued for more than 7 to 10 days at a time if the likelihood of oestrogen-withdrawal bleeding is to be kept to a minimum. Pessary treatment is less likely to cause such bleeding.

Also after the menopause are to be seen the discharges caused by retained and neglected pessaries and by other foreign bodies. After removal of the irritant the discharge usually clears up quickly unless some permanent damage has resulted.

After the menopause and after surgical procedures on the cervix there may be some cervical stenosis leading to accumulation of fluid or pus in the uterus, forming a hydro-metra or pyometra. This may discharge suddenly or intermittently. Examination under anaesthesia and dilatation and curettage are required in such cases to establish the diagnosis, to promote drainage, and to exclude associated cancer.

Miscellaneous Causes of Discharge

Every now and then a woman is seen with a severe vaginitis which is being maintained by treatment. Douching with antiseptics can cause a severe vaginitis either because the antiseptic remains on the skin in high concentration after the water has evaporated or, more likely, because of skin sensitivity; the daily wearing of a tampon can also cause much local irritation. To stop all local applications is the obvious first treatment in such cases; often no other therapy is required.

More troublesome is the occasional patient who has a vaginitis, often of unknown aetiology, in which the epithelium in some part of the vagina, perhaps at the vault, is seriously devitalized, being thin, atrophic, and often with great loss of mobility. The most that can be done in such cases is to search diligently for the cause, while trying by the judicious use of oestrogens locally and tonic measures generally to improve the patient's healing powers. Meantime temporary avoidance of coitus is desirable to encourage healing.

It is worth bearing in mind that watery discharges may be urinary in origin. If dating from a difficult confinement or operation, there may be a tiny vesico-vaginal fistula, perhaps with a sinuous tract and only discharging intermittently. Closely allied are the very rare cases in which a cyst of Wolffian duct origin has an external opening and discharges a small amount of fluid. Perineal sinuses, stitch abscesses, and tiny rectal fistulae can all cause vaginal discharge. The appropriate surgical treatment is required for all such cases.

A watery blood-stained discharge is an important sign of early carcinoma of the genital tract, especially carcinoma of the cervix and of the corpus uteri. If there is any suspicion of these diseases, careful examination under anaesthesia, biopsy of the cervix, and dilatation and curettage must be carried out without delay.

Refresher Course Book.—The first collection of articles of this series (fully revised) are available as a book containing 55 chapters, price 25s. Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

BRITISH EMPIRE CANCER CAMPAIGN

REPORT FOR 1952

The thirteenth annual report of the British Empire Cancer Campaign, covering the year 1952, is an impressive volume of over 400 pages. It records the results of work in many centres in Britain; deals briefly with cancer research in Canada, New Zealand, Australia, and South Africa; and describes the researches of individual investigators supported by the Campaign, of Campaign Fellows, and of Campaign Exchange Fellows. In 1952 income from donations, collection, and legacies was £318,773, the highest figure so far attained. The total is £59,000 above the previous year, mainly owing to a large increase from legacies, which amounted to £138,416. In addition £19,393 was received from investments. The Campaign spent £221,439 on cancer research, £36,623 on appeals and publicity, and £8,162 on administration. There was a balance of £88,910 of income over expenditure at the end of the year.

The Campaign is attacking cancer on a wide front. This is evident from the admirable summary, by Lord Horder and Sir Heneage Ogilvie, of the work supported. There are sections on experimental and clinical carcinogenesis, hormones, the biochemistry of growth, tumour viruses, experimental chemotherapy, radiation chemistry and radiobiology, radiotherapy, and clinical pathology.

Clinical Pointers

Technical advances in radiotherapy which make it more effective, yet at the same time less unpleasant for the patient, are a major contribution to cancer research. There is, for instance, the use of very high-powered radiotherapy units. As long as 15 years ago a million-volt machine was being used in Britain, and to-day there are several operating at 2 MeV. Now, apparently, with the installation of x-ray equipment operating at voltages up to 30 MeV, we are about to enter what is likely to be the last phase of this line of advance. To reach this stage a great deal of painstaking physical and biological research has been necessary. At the Middlesex Hospital the much less costly "rotational therapy" method of delivering a large radiation dose to deep-seated lesions is being investigated, and the results appear promising. Work at Cambridge suggests that the combination of a chemical radiosensitizer ("synkavit") with conventional x-ray therapy may prolong the lives of those with inoperable bronchial carcinoma. At many centres the possibilities of radioactive isotopes are being eagerly explored. In contrast with the success of physical methods in treating cancer, trials of new chemotherapeutic substances have been less fruitful; nor has the work on hormones yielded any new lines of treatment for immediate application.

What may be termed environmental cancers have received their full measure of study. A suggestion that coal smoke and tobacco smoking may act together after the manner of a carcinogen and a co-carcinogen in causing lung cancer is being checked by studying the amount of carbon in the lungs and bronchial glands. Questions such as, Why is lung cancer rare in coal-miners? Why is it common in London, in both sexes? are being examined by statistical methods. Other experiments aim at isolating their carcinogenic activity in animals. Bladder cancer in dye-workers has been the subject of a four-year field study and of a report to the Association of British Chemical Manufacturers. Some interesting findings have emerged: each individual carcinogen has a characteristic induction time, and the age at which tumours appear depends on when exposure began; and, although incidence may depend on severity of exposure, the induction time is not affected by this. In parallel with the field work, the carcinogenic properties of the aromatic amines have been studied in the laboratory. Among other things, this may help in deciding which of them are too dangerous for industrial use. With a similar object, the carcinogenic activity of crude oils and their fractions has

been assessed. Several Kuwait and Lagunillas sub-fractions are strongly carcinogenic in rabbits.

Among other observations of direct clinical use is the recognition of the value of serial biopsies during radio-logical treatment of carcinoma of the cervix (this permits the rapid recognition of radio-resistant cases which can then be treated surgically), and of restricting salt intake after uretero-colic anastomosis for bladder tumours (this reduces the mortality from disordered metabolism). Another study defines the place of local *versus* widespread excision in the treatment of malignant rectal polyps.

Radioactive cobalt dust was found to have been leaking from the radio-cobalt units in Leeds and Sheffield, and radioactivity was detected in their operators. However, the amounts absorbed were well within the safety range, and the faults in the machines have been dealt with.

Fundamental Research

It is a truism that, when dealing with a really stubborn problem, the quickest solution is not always the most direct. This is certainly so in medical research, and much of the report of the British Empire Cancer Campaign is concerned with fundamental research. From a host of such studies it is possible to pick out only a few for remark. Some of the most interesting work is on the way in which chromosomal aberrations take place. By applying a chemical mutagen to the root-tip cells of beans it has been possible to observe what happens. This has led to an entirely new interpretation of chromosomal aberrations; namely, that chromosome breakage and reunion are simultaneous, the event being similar in nature to chiasma formation in meiosis. In the words of the report, "There is no need to emphasize the importance which would attach to any correlation between mutagenesis, carcinogenesis, and something akin to the physiological process of meiosis, rather than through a more random mechanism of damage and repair by chance."

Anything that adds to our knowledge of the processes of normal growth may throw light on the disordered growth of cancer: hence the interest of the observation that in the chick embryo ascorbic acid synthesis is related to the rate of growth. The next step, which is being taken, is to see whether this applies to tumour tissue also.

Lastly, from this mine of material, one experiment may be selected for its technical virtuosity. It has proved possible to take the nucleus from one amoeba and exchange it with that of another. This remarkable feat has been used to study the effects of nitrogen mustard and x rays on nucleus and cytoplasm separately. The results show that direct damage is done to both nucleus and cytoplasm, although the nucleus is the rather more vulnerable of the two.

Pedestrians over 60 are involved in a high proportion of road accidents, and, as the ratio of people in the higher age groups is increasing, their safety on the roads is becoming a greater problem. In March the Pedestrians' Association held a conference on this subject, and the report of this meeting has now been published by the association. Road accidents are often due to the inability of the elderly to adapt themselves to the speed and volume of modern traffic. The report recommends that local authorities and road safety committees should, where necessary, provide special facilities for old persons to cross the road. Propaganda should be directed to drivers, many of whom make insufficient allowance for the limitations of the elderly. Conductors of public vehicles should show special consideration for elderly passengers. The old people themselves should be given advice about road usage, and clergy and social workers among old people should use their opportunities to do this. Lame and infirm persons should, if possible, be accompanied on the roads; risks of accidents to them could be minimized by the organization of a rota of neighbours, social workers, etc., to do their shopping. The report costs 1s. (by post 1s. 2d.), and is obtainable from Mitre House, 44-45, Fleet Street, London, E.C.4.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Male Pseudohermaphroditism

SIR,—I have read with the greatest interest the account by Drs. D. C. Beatty, C. J. Champ, and G. I. M. Swyer of "A Case of Male Pseudohermaphroditism" (*Journal*, June 20, p. 1369), since a case which conforms fairly closely to the clinical picture which they describe has come under my own observation, and forms the subject of a chapter ("Features in the Analysis of a Patient with a Physical Genital Abnormality") in my recent book.¹ My interest in the case was primarily psychiatric, the individual in question having been referred to me by "her" family doctor for psychotherapy on account of symptoms of anxiety and periodic depression. Accordingly, my reference to the physical aspects of the case is only incidental—which is perhaps unfortunate from the standpoint of general medicine, since I understand that only a few such cases have been described in the literature. It is also unfortunate from this standpoint that I found it necessary to withhold certain interesting data from my account and to leave others intentionally vague for reasons of discretion. My account is subject to further limitations in consequence of the fact that, although it was not published until 1952, it was written in 1930 for a meeting of the British Psycho-Analytical Society on January 21, 1931; for at that time knowledge regarding the sex hormones was less advanced than it is to-day, and laboratory facilities for their investigation were comparatively undeveloped. Also, I did not feel it justifiable to seek confirmation of the nature of the gonads by subjecting the patient to exploratory surgical intervention solely in the interests of scientific curiosity, especially since the effect of such intervention and of discovery of the data thereby revealed might well have inflicted a psychological trauma upon the patient, whose mental equilibrium was already precarious. The interested reader will perhaps desire to refer to my published account; but I take the opportunity to draw attention to certain of the data which it contains.

The patient to whom I refer had always been regarded as female, even after the discovery of her abnormality by her family doctor, whose introductory letter included the following statement: "She appeared to be a perfectly normal child until she reached the age of puberty. She began then to grow unduly tall, but did not menstruate, but kept perfectly well. When she was about 20 I was consulted, and made an examination. I found . . . only a pin-head opening as a vagina which led nowhere. As she felt perfectly well, nothing further was done."

Accepting the doctor's account, I took no steps to initiate a more detailed physical investigation before proceeding with psychotherapeutic treatment. As treatment proceeded, however, I began to entertain doubts not only regarding the adequacy of his account, but also regarding the sex to which "she" properly belonged. Accordingly, I arranged for the patient to be examined by a distinguished gynecologist, who reported it as his impression that the case was one of male pseudohermaphroditism, and who described his findings in the following terms: "The general development is strongly masculine; the chest is very broad, but the mammary development is, if anything, more suggestive of the female type in that the tissue is soft and slightly dependent. The pubic hair is normal in its distribution for the female, and the more superficial organs are quite definitely female—namely, labia, mons, clitoris, vestibule, and urethra. The hymen is completely closed, and is represented by a series of small bands crossing the site of the normal depression. Rectal examination was not easy, but . . . no cervix or uterine body was made out. These, under ordinary circumstances, are usually made out with perfect ease by this route. At the same time the examination was not sufficiently complete to exclude the presence of an imperfectly developed organ. The general impression which I have formed is that we are dealing with a condition of essential masculinity with the presence of male gonads accompanied by secondary characters of a female type."

It may be added that, in spite of his diagnosis, the gynaecologist agreed with my opinion that it would be inadvisable to acquaint the patient with the nature of his findings. Doubts were, however, subsequently cast upon the diagnosis when a specimen of the patient's urine was examined for oestrin and gonadotropic content, and reported upon as follows: "Oestrin—at least 20 mouse units per 24 hours. Gonadotropic content—less than 100 mouse units of follicular maturation hormone per 24 hours. These excretion results are similar to those usually obtained in a female subject, and the oestrin excretion is higher than would be expected in a male. The results suggest the presence of female secretory gonads."

In the light of this report I considered it all the more desirable to continue, for practical purposes at any rate, to regard the patient as a female.

The case in question differs interestingly from that described by Beatty, Champ, and Swyer in the facts that pubic hair was present and that the patient was abnormally tall (about 6 ft. 4 in. (1.93 m.)). Another interesting feature was that during adolescence she was subject to recurrent rectal haemorrhages which lent themselves to interpretation in terms of vicarious menstruation, and which were actually mistaken for proper menstrual periods. These were followed *later in life* by periodical bouts of epistaxis, which lent themselves to a similar interpretation. It is also a striking fact that, while under my observation, she always spoke quite spontaneously of her periodic attacks of depression as "being unwell," and would also speak of "missing a turn" when an attack was deferred for longer than usual. The case conformed to the description of Beatty, Champ, and Swyer in that she had a definitely female mentality and displayed no evidence of Lesbian characteristics; and it may be added that her libido was highly developed towards men, and that men seemed to find her singularly attractive.

In conclusion it is of interest to record that an identical abnormality was present in several of her numerous sisters, the remainder of whom were normal women, married, and the mothers of children.—I am, etc.,

W. RONALD D. FAIRBAIRN.

Mean Body Weight, Food Intake, and Temperature

SIR,—Although Alice's consumption of cake and mushroom was undoubtedly responsible for some of the variations in her size, and hence presumably weight, it was, significantly, the White Rabbit's fan that she dropped hastily to avoid shrinking away altogether. The fact that the fan was overlooked when its owner discovered Alice is no excuse for it to be forgotten in preoccupation with other matters this side of the rabbit hole. In the discussion of the valuable paper by Mr. J. M. Harries and Miss D. F. Hollingsworth (*Journal*, January 10, p. 75) little reference was made to non-dietary factors, other than activity, affecting body weight: the suggestion therefore that weight data can be used as an "index of inadequacy in food supplies" deserves some comment.

The closeness of the demonstrated weight-calorie relationship is paralleled by that between weight and mean temperature of the month in which it was recorded. The correlation coefficients for the whole series are respectively $r_{cw} = +0.612$, $r_{tw} = -0.730$, both highly significant; these may be obtained from the analysis, given in the table, of variance and co-variance, calculations permissible since serial correlations in the weight series used were not significant and since there was no reason to assume serial correlations in the independent variates. That these correlations were independent of each other is shown by the partial correlation coefficients ($r_{cw.t} = +0.586$, $r_{tw.c} = -0.714$). The temperature factor therefore should also be considered in assessment of the adequacy of food supplies from body weight.

Several points of interest emerge from the figures in this table. Limitations of the data may well account for the insignificant contributions by temperature and calories to the small residual sum of squares for weight. The caloric effect predominates in the longer term weight fluctuations and contributes little to the seasonal variations, while it is in the latter that the temperature effect is most marked. Thus it might appear that the state of food supply in Britain is indicated by mean body weight if this is observed over a long period—long enough, that is, for temperature fluctuations to be cancelled out. However, caution is still necessary, since differences in weight from year to year remain

highly significant after allowance is made for calorie intake, both alone and in combination with temperature. Some further influence thus appears to operate on long-period variations in weight, and hence not all such can be used to diagnose dietary adequacy or inadequacy. Not all of Alice's metamorphoses were occasioned by what she ate and by the White Rabbit's fan.

The writer wishes to acknowledge his indebtedness to Mr. M. H. Quenouille, of the Institute of Statistics, Oxford, who advised upon statistical procedures, and to Mr. Harries and Miss Hollingsworth, of the Ministry of Food, who made available their data for further examination, which was prompted not by any spirit of unappreciative criticism but rather by the wider implications of their work.—I am, etc.,

Oxford.

D. F. ROBERTS.

Peptic Ulcer in Women

SIR,—Mr. D. H. Clark's article on peptic ulcer in women (*Journal*, June 6, p. 1254) essentially confirms the findings of previous authors and establishes the absence or disappearance of peptic ulcer symptoms during pregnancy as the most impressively unequivocal coefficient in the natural history of this much studied and as yet incompletely understood condition.

In Mr. Clark's series of 400 women over the age of 21 with histories of peptic ulceration, 204 of whom had reached the menopause, only 118 had pregnancies, and it would be interesting to know how this proportion compares with a similar but unselected group of women in the same town. Should the incidence of pregnancies in Mr. Clark's series be significantly lower than in the unselected sample, this would enhance the importance of his observations on the reverse aspect of the correlation—namely, the frequency of pregnancy toxicoses in sufferers from peptic ulceration in whom the ulcer symptoms persisted or recurred during pregnancy. The possibility then arises of an abnormality of the endocrine secretions being the common factor underlying peptic ulceration, some cases of pregnancy toxicosis, and at least one circumscribed type of sterility in women. The data suggest strongly a correlation between the secretion of some of the sex hormones and the inhibition of the periodicity of peptic ulceration and emphasize *inter alia* the need to study the curious and often dramatic action of gonadotrophic hormones of placental origin on the symptoms of peptic ulcer patients. This does not imply that gonadotrophic hormone produced during pregnancy has a specific effect or even any direct effect upon ulceration, but only indicates that it is involved in some manner, a subject which I have recently discussed elsewhere (*Lancet*, 1953, 1, 1000).—I am, etc.,

T. CSATO.

Intravenous Barbiturates for Drunkenness

SIR.—Dr. Peter Nobes's comments (*Journal*, April 11, p. 836) to my letter on this subject (*Journal*, January 17, p. 163) call for a reply in defence of my procedure in dealing with such cases.

Dr. Nobes theorizes on what might happen if my procedure was adopted for "obstreperous drunks," but surely such complications as "silent regurgitation" and "glottic spasm" are no more a danger here than in any of the emergency cases that receive a similar dose of any intravenous barbiturate. Moreover, I think I am right in saying that when the stage of obstreperous behaviour is reached

such cases have an empty stomach, either from an earlier stage of vomiting or from having digested what was already there. However, I wonder if Dr. Nobes has ever tried to wash out the stomach of an obstreperous drunk.

I do not think that the fact of my series of cases coming through without a mishap was just pure luck on my part. None of them developed a venous thrombosis with the 10% solution either.—I am, etc.,

Tumatumari, British Guiana.

A. M. BARTLEY.

Amphetamine

SIR.—The element of historical interest introduced in your leading article "Mr. Macleod on the Drug Bill" (*Journal*, June 20, p. 1380) is somewhat misleading. The volatile amine— β -phenylisopropylamine (amphetamine)—was first prepared from phenylmethylacrylic acid by Edleano in 1887.¹ In 1910 Barger and Dale,² during a pharmacological examination of aromatic amines, described this drug as a member of a group of similar substances to which they gave the name "sympathomimetic." For 20 years thereafter no attention was paid to this compound, the interest of investigators being centred on ephedrine.

Amphetamine sulphate ("benzedrine") was first prepared and investigated by G. A. Alles in 1927³ also in the course of a search for a compound better than ephedrine. He discovered its stimulating effect on the central nervous system and suggested that this might have therapeutic value. At that time attention was focused on the peripheral effects of the amine, and through the pioneer work of Messrs. Smith, Kline, and French Laboratories, of Philadelphia, the base was introduced to the medical world in 1932 as the first volatile nasal vasoconstrictor. However, they also started an extensive pharmacological investigation to follow up the observations made by Alles on the systemic action of the drug, and in 1935 Prinzmetal and Bloomberg⁴ were able to report on the value of amphetamine sulphate in narcolepsy—a condition in which it is now regarded as diagnostic and specific. Since that date the value of this drug has been confirmed in a wide range of clinical conditions.

The anorexigenic properties of the amphetamines were first reported as a side reaction when the drug was used for its psychic effects⁵ and amphetamine sulphate found some use as an aid in the treatment of overweight. However, as a result of further work the dextro-isomer—dexamphetamine sulphate ("dexedrine")—was isolated and made available some 10 years later, and was found to be preferable in this and a number of other conditions. It thus appears that this valuable drug, although known since 1887, was ignored until its potentialities were explored and developed by a pharmaceutical house.

This is an example of the special contribution made by pharmaceutical manufacturers to medical practice—the way in which they are able to develop and extend a new discovery and greatly reduce the time interval between laboratory work and its clinical application.—I am, etc.,

Medical Auxiliaries

SIR.—I do not think that those who advocate freedom for study and work for all will agree with the opinion expressed in your leading article on medical auxiliaries (*Journal*, June 6, p. 1267).

The decision of the Minister of Health to give equal rights to the three associations of physiotherapists and not to accept monopoly in favour of the Chartered Society, far from being a "meagre conclusion," is, in fact, an act of justice and statesmanship. I am the first to recognize the good work done by the Chartered Society, but it is common knowledge that the Physiotherapists Association and the Faculty of Physiotherapists include at least equally well trained and skilled physiotherapists who are doing excellent work. To refuse these keen workers hospital facilities to study, and to bar them from hospital employment, would be an arbitrary and

unjustified measure. As the monopoly in favour of the Chartered Society has been proposed by a committee composed, apart from the president and two Government officials, by six other members all connected with the Chartered Society, it is not astonishing that the Government demanded a wider inquiry which resulted in the declaration of the Minister of Health: "Fairness to all societies concerned."

I cannot understand why this decision of the Minister has been considered as a criticism of the Cope report. This report represents a painstaking work in which general directions are proposed for medical auxiliaries. It is unfortunate that this question of monopoly has cropped up, but surely an amicable settlement of this vexed problem can be reached.

We are in great need of good physiotherapists, but for that we must avoid monopolies and exclusiveness. We must open wide the portals of the hospitals to all those wishing to devote themselves to that branch of the healing art, demanding from them not a label of any particular association but keenness, hard work, and skill.—I am, etc.,

London, W.1.

A. P. CAWADIAS.

Children in Hospital

SIR.—It is believed that the Ministry is encouraging an increase of visiting at children's hospitals. It would seem that this is related to the annotation (*Journal*, March 14, p. 609) in which daily visiting at Great Ormond Street Hospital for Sick Children was favourably reported. I have nothing to say on the medical or administrative angle of this matter with regard to a short-term hospital, but with regard to the long-stay orthopaedic hospital I think frequent visiting is distinctly detrimental to the children. It should be realized that in long-stay hospitals the child has to make an entirely new adjustment to a life which is likely to continue for two or more years. Frequent visiting delays or utterly prevents this adjustment by reminding the child constantly of home life. It is very noticeable that new arrivals are upset by the first few visiting days which they experience, and there is little doubt that the quickest, and possibly the kindest, way of bringing about adjustment would be the prohibiting of visiting altogether, or at least during the first six weeks of admission—as is done at most boarding schools.

At this hospital we have endeavoured to achieve a compromise by fortnightly visiting, and we find that after the first six weeks the children look forward to visiting day with good cheer and manage to keep in touch with their parents in this way without being gravely upset when the visit closes. The opinion has been expressed elsewhere that infections are not introduced to children's hospitals on visiting days. It has been noticeable nevertheless that the majority of new infections and dietetic upsets are referable to the past visiting day.

A further consideration which should not be neglected with regard to visiting at long-stay hospitals is the hardship inflicted on parents who naturally feel they must visit their children as often as possible. The majority can and do manage a long journey every alternate week-end for months or years, at very considerable sacrifice. Many beggar themselves by bringing a multitude of toys on each occasion—toys which are usually broken within two or three days of the visit. There remains, however, a proportion of parents who absolutely cannot manage to visit as frequently as the rest and therefore their little one finds itself isolated on visiting days. Visiting permitted more frequently than fortnightly would enhance the hardship to the parents and increase the discrimination between visited and neglected children which the unfortunate children are incapable of understanding and therefore of tolerating.

This problem is a delicate one, and no effort should be made by the administrators to interfere with what is primarily a medical decision, which must be governed by individual hospital circumstances. It is also worth remembering that it is foolish to abandon a tried and reasonably satisfactory position in favour of an untried theoretical improvement if it is probably impossible to return to it should the theory prove false (cf., among other things, nationalization).—I am, etc.,

Burton-on-Trent.

RANDLE LUNT.

Electro-convulsive Therapy

SIR.—The following method is used for giving electro-convulsive therapy at Cork Mental Hospital. The patient receives 1/100 gr. (0.65 mg.) atropine sulphate ten minutes before stimulus, followed by thiopentone sodium, 0.15–0.25 g. intravenously. The syringe is disconnected, but the needle remains intact, and through it is injected succinylcholine, 50 mg. As soon as fibrillation ceases the patient's lungs are inflated 3–4 times with oxygen, using a mask and rebreathing bag. The headpiece is then applied and the electrical stimulus is given.

We would like to record the following observation which may be of interest. If the pupil contracts immediately after the stimulus we have noticed that a convulsion very rarely occurs. Owing to the short time factor involved before the succinylcholine wears away, we now feel it safe to give another stimulus straight away, as there seems to be little danger of a delayed convulsion. We have found this sign very useful and wondered if other readers have had any similar experience.—We are, etc.,

Christmas Disease

SIR.—The correspondence which has followed publication of the article by Dr. Rosemary Biggs and colleagues on "Christmas Disease" (*Journal*, December 27, 1952, p. 1378) has raised several important questions, including that of nomenclature. Dr. A. S. Wiener's suggestion that this disease be called haemophilia II or B (*Journal*, March 7, p. 559) has merit because it focuses attention on the genetic similarity to classical haemophilia. His proposal, however, is based on the assumption that the mutant genes for classical haemophilia and Christmas disease occupy the same locus on the X chromosome—that is, they are alleles. We believe this assumption to be incorrect. There are well-defined differences, biological and chemical, between the normal plasma components which prevent haemophilia and Christmas disease. For example, the factor preventing haemophilia (AHF) is not absorbed by BaSO₄, and its activity diminishes during clotting. On the other hand, the "Christmas factor" is absorbed on to BaSO₄, and its activity increases during clotting.

It was suggested that the same allelic relationship exists between Christmas disease and classical haemophilia as exists between mild and classical haemophilia. This analogy, we believe, is unsound. The two forms of haemophilia, resulting from different degrees of reduction of the identical plasma protein, AHF, are due to the mutant genes *h* and *h^m*; Christmas disease, resulting from diminution of an entirely different protein, is probably due to a mutant at a different locus on the X chromosome. The facts that normal plasmas, even in males with the single X chromosome, possess both AHF and Christmas factor, that haemophilic plasma contains "Christmas factor," and that AHF is present in Christmas disease can hardly be interpreted in any other fashion. Linkage studies would be most valuable.

As for the problem of nomenclature, we suggest that haemophilia and Christmas disease be grouped with the other haemorrhagic diatheses which are characterized by absence or malfunction of a specific plasma protein required for normal clotting, and a resultant clotting defect due to impaired conversion of prothrombin to thrombin. Haemophilia is the archetype of this group of diseases. The name "haemophilia" is hallowed by tradition and deeply ingrained in the literature; we suggest that its use be limited to those haemorrhagic states due to inadequate AHF. For the other diseases meeting the above criteria we suggest the term "haemophiloid states."

The following table indicates the presently described members of this group of haemorrhagic diseases. The proposed classification has the merits of simplicity and elasticity. When the exact chemical impairment in each disease is

known, more meaningful terms, neither eponymic nor arbitrary, can be applied. An elaboration of this classification, along with diagnostic criteria, will be published soon.

Disease State	Synonyms
Haemophilia	
Haemophiloid state A	Parahaemophilia, accelerin, or AcG deficiency
Haemophiloid state B	Hypoproconvertinaemia, spca-deficiency
Haemophiloid state C	"Christmas disease," PTC-deficiency
Haemophiloid state D	PTA-deficiency.

Controlled Respiration and Apnoea in Anaesthesia

SIR.—Dr. Gordon M. Wyant (*Journal*, June 13, p. 1334) recommends anaesthetists not to lose sight of the fact that apnoea "is essentially an unphysiological state of affairs." Now what does Dr. Wyant mean by "unphysiological"? How, for example, would he achieve, in his sense, "physiological anaesthesia"? Surely it must be admitted that anaesthesia essentially is unphysiological, in that it involves interference with the normal mechanisms of maintaining the internal environment. It is, for example, true to say that under general anaesthesia it is impossible to produce relaxation of the abdominal muscles without some involvement of the respiration. It is under these conditions that "the lesser of the two evils" is to have ventilation of the lungs which is artificial but efficient, rather than that which is natural and impaired.

Professor E. A. Pask (*Journal*, May 9, 1948), writing on the same subject, believes that "many physiologists will be surprised to learn that positive pressure ventilations can be carried out at all without causing some disturbance in the cardiovascular system." It is not clear in this context whether he necessarily implies by the term "disturbance" a resultant reduced efficiency. We are sure he would join us in wishing to refer these physiologists to the all-important work on human subjects carried out by Courmand and his colleagues.¹ These workers showed that, given the correct intrapulmonary pressure curve, artificial inflation of the lungs did not, in fact, impair cardiac function.

We would conclude with two points: (1) It appears that the term "unphysiological" is being too loosely used. In artificial circumstances, for example, during anaesthesia, the maintenance of the internal environment to comply with cellular requirements—that is, normal physiology in Claude Bernard's sense—may imply the use of artificial methods. (2) Many in the vanguard of modern anaesthetic progress still maintain a regard amounting almost to a superstition for the authority of the—to quote Professor Pask—"old-fashioned" anaesthetist. We are not, however, prepared to believe that the virtue of being old-fashioned gives any doctrinal authority in respect to the matters under discussion.—We are, etc.,

The Post-operative Chest

SIR.—Mr. V. J. Downie's remarks regarding the treatment of the "post-operative chest" (*Journal*, June 20, p. 1388) cannot be allowed to pass without comment.

During the past 25 years or so, many workers have investigated this problem very carefully; if would be a great pity if their work were to be wasted because it came to be accepted that prevention and treatment based on a proper understanding of the pathology of this condition was of little or no importance. Mr. Downie suggests that a good anaesthetic technique will prevent these complications. This is certainly not the case. A bad anaesthetic technique may certainly increase the incidence of post-operative chest com-

plications, but the best technique cannot reduce it below a certain minimum level. This is because anaesthesia, if any reasonable technique is used, is not an important factor in the causation of the condition. The cause of nearly all post-operative chest complications is the gross interference with respiratory mechanics and in particular with the cough mechanism which results from certain operative procedures—notably upper abdominal incisions, hernia repair, thoracotomy, and thyroidectomy. When the operation does not involve one of these incisions post-operative chest complications (apart from hypostatic pneumonia in the old, enfeebled patient) are practically non-existent. I recently anaesthetized a patient suffering from chronic bronchitis for repair of a ventral hernia using a ventral sheath block combined with a small dose of thiopentone. Post-operatively he developed a well-marked basal segmental collapse with pyrexia and mucopurulent sputum. It is difficult to see how the anaesthetic could have caused this, but one had only to watch the patient for a few minutes to appreciate the very real difficulty he had in coughing up his sputum.

I quite agree that it is very doubtful if post-operative segmental collapse commonly results in bronchiectasis, but I do not think that this is any reason for failing to treat a condition which is usually easily diagnosed and which often responds to relatively simple measures. It is true that these cases "respond" to antibiotics in that the temperature returns to normal, and I agree that they have an important part to play in prevention and treatment. Nevertheless they often fail to have any effect on the underlying pathological condition, which is the blocked bronchus. Several years ago, as a junior resident anaesthetist, I saw a patient discharged from hospital with definite radiological signs of segmental collapse, the result of an operation about two weeks earlier, still present. She had been on routine penicillin, and there was little in the way of symptoms or general upset. I do not think that either the patient herself or the surgeon in charge realized that there had been any pulmonary complication. Quite probably her atelectasis later expanded without leaving any permanent pulmonary damage, but I think it would have been better if she could have left hospital with her lungs in the same condition as when she entered.

Prevention and treatment need not be either elaborate or expensive, and certainly should not be aggressive. Routine breathing exercises by themselves are useless and a waste of time (I do not, of course, deny that they have an important part to play in the preparation of the patient for certain operations). There is no substitute for the careful pre- and post-operative examination and individual treatment of each patient undergoing the type of operation I have mentioned. When atelectasis is diagnosed or suspected the patient must be encouraged and assisted to clear the blocked-bronchus in whatever way seems best for him. If simpler methods fail bronchoscopic suction should probably be used, although it is rarely necessary.

The last word on this problem has probably not been said. The value of the routine use of bronchial anti-spasmodics has not, I feel, been proved. Nevertheless, using the relatively simple methods so clearly set out by Brock¹ many years ago, we can do much towards the prevention and satisfactory treatment of post-operative chest complications to the probable benefit of the patient.—I am, etc.,

W. S. DAVIS.

Omagh, Co. Tyrone.

Possible Sequel of Treating Infants in Erect Posture

SIR,—At the follow-up clinic last week I saw two infants, both aged nearly 7 months, who had been treated for hiatus hernia by being placed in the erect posture day and night for the last four months. Both of them now have skulls somewhat flat on the top, and the circumference of one is 17½ in. (45 cm.) and of the other 18½ in. (46.7 cm.). The skulls appear to have altered in shape, and have not the characteristics of those of other members of the families.

It is possible, I believe, that such a shape of skull may be a sequel of treatment in the erect posture. The condition is being further investigated, but I write now to ask if any other observers have found flattening of the skull resulting from such treatment.—I am, etc.,

Aberdeen.

JOHN CRAIG.

Intravenous Pituitary Extract in the Control of Haemoptysis

SIR,—I feel that a word of caution should be added to the letter by Dr. N. D. J. de S. Wijesekera (*Journal*, June 20, p. 1389) on the use of intravenous pituitary extract in the control of haemoptysis. In the course of clinical investigations on the action of pituitary extract—admittedly for reasons far removed from the control of haemoptysis—I have given scores of injections by various routes and have come to regard the single-dose, intravenous injection with a respect bordering on trepidation. Dr. Wijesekera was fortunate that after the administration of 10 units no more ill effect was seen than that "the patient's face assumed a cadaverous hue except for a faint malar flush." I strongly urge that if this very potent substance is to be given intravenously by a single injection a dose of one unit (or certainly not more than two units) should be used, and this small volume of solution well diluted in saline and given very slowly, as Dr. Wijesekera in fact advises. If intramuscular injection is employed a somewhat larger dose may be permissible.

To compare the doses employed by workers 40 years ago with those in use to-day is meaningless, for standardization of pituitary extract did not become established until the late nineteen-twenties.—I am, etc.,

Oxford.

J. CHASSAR MOIR.

Television Glaucoma

SIR,—Since the advent of television to Northern Ireland I believe the following is the first case of acute glaucoma which commenced while the patient was viewing television.

A lady of 80 years of age, seeing television for the first time, watched with enthusiasm the Coronation service and processions. During the late afternoon her right eye became red and painful. When seen by me the following day the eyeball was hard and congested, the cornea was hazy, and the pupil was dilated—typical acute congestive glaucoma. She was unaware of any previous eye trouble.

It is well known that when instability of intra-ocular tension exists an abnormal rise of tension may take place on remaining in a dark room or when accommodating, as on close reading for about an hour. It would thus appear that prolonged periods of television viewing, especially in a darkened room, are not without risk to the aged and to those with certain recognized eye defects.—I am, etc.,

Belfast.

V. A. F. MARTIN.

Mammary Abscess

SIR,—The limitations of the antibiotics in curing mammary abscess are referred to in Mr. C. P. Mills's paper (*Journal*, June 27, p. 1427), as also are the difficulties encountered later in dealing surgically with encapsulated pus.

Early drainage would appear to be indicated by Mr. Mills except in those cases which were effectively treated with an appropriate antibiotic in the initial acute stage. Even assuming that most, if not all, the infections are staphylococcal, it must be extremely difficult to isolate the causal organism in the early inflammatory stages. Many inflammatory symptoms of mastitis disappear entirely without treatment, and pus formation is a late present themselves after they have been discharged from the maternity hospital.

My experience as a medical officer of health and former superintendent of hospitals has been that mastitis is primarily a readily either to faulty technique or to individual members of the staff. Empirical measures, based on the assumption that the causal organism builds up in the dust and air of the wards from time to time, have been successful in reducing dramatically any outbreak. The tragedy lies in the fact that much suffering and disability occurs before these measures—which temporarily disorganize the hospital—can be taken.

It has always appeared to me as an epidemiologist that maternity hospital infections should be preventable and that

the staphylococcus—the enemy No. 1 of such hospitals—warrants urgent attention with all the resources at our command. The direct approach is undoubtedly to identify the presence and establish the source of any pathogenic strain of the organism. This, alas, is fraught with technical difficulties these days when it is no longer possible to direct operations under a unified command. In promoting the first local health authority scheme (staphylococcal investigation) for research to be approved under the National Health Service Act I had hoped to get the necessary typing done, but it appears that no laboratory in Scotland can do this. I can only suggest therefore that the work be carried out by the Medical Research Council laboratory services in conjunction with a maternity hospital where accurate control can be exercised over the investigation. I know that there is any amount of clinical material, and the resulting recommendations may well abolish a most distressing condition which is admittedly difficult to treat.—I am, etc.,

Kirkcaldy.

J. W. R. HAY.

Hypnosis in Modern Medicine

SIR,—Professor Alexander Kennedy (*Journal*, June 20, p. 1377) takes me to task for stating, in *Hypnosis in Modern Medicine*, that we should "detensionize the child with hypnosis and the anxiety will fall to pieces." This statement is, of course, taken from its context. What I actually say is: "I have tried to show that tension is the root of most childish ills and I have coined the word *detensionize* to explain this reaction to hypnotic suggestion. Seemingly conflict, repression, and frustration, given the right soil, grow anxiety, which produces tension and finally a neurosis. . . . Detensionize the child with hypnosis and the anxiety will fall to pieces, allowing the physician to re-educate both child and parents. . . ."

Professor Kennedy is upset that "two articles by British contributors . . . do not fairly represent British medicine." May I remind Professor Kennedy that hypnosis has been viewed with suspicion, incredulity, aggression, and emotional bigotry for nearly 200 years by those very physicians who should have led the profession to a knowledge of the subject?—I am, etc.,

Carshalton Beeches, Surrey.

GORDON AMBROSE.

Spiritual Healing

SIR,—I would be grateful for space in which to invite information from medical colleagues with knowledge of patients treated by spiritual healers. By "knowledge" I mean adequate medical case-histories with radiographs and other records before and after treatment.

My search on behalf of the Society for Psychical Research is for documented cases likely to stand up to investigation of the organic state following such "healing." The experience of others in this field would be most helpful in widening the scope of investigation and the reliability of conclusions.—I am, etc.,

45, Wimpole St., London, W.1.

LOUIS ROSE.

POINTS FROM LETTERS

Dental Sepsis

Dr. T. STORDY (Surrey) writes: I should like to make a plea for the patient whom we treat according to modern methods, and would beg the dentist, with the utmost urgency, to remember that there is a patient attached to the tooth, and most grievous general conditions are produced by anything septic in the mouth. X-ray films of teeth cannot be relied upon absolutely. I have carefully observed thousands of dead teeth, teeth filled in all parts of the world, teeth which have had apicectomy performed on them, or have been splinted for periodontitis and passed as being free from infection, but which on extraction showed signs of long-standing subacute inflammation. . . . We have all carried out this treatment and seen the results of our own and others' efforts, in the vast majority of cases to the patient's detriment. In this connexion I very strongly urge the teaching of more general medicine to the dental student, so that he may be able to recognize the signs of sepsis and low resistance to toxins.

Obituary

VICTOR BONNEY, M.D., M.S.,
F.R.C.S., F.R.C.O.G.

We record with regret the death on July 4 of Mr. Victor Bonney at the age of 80. With the late Sir Comyns Berkeley, also of the Middlesex Hospital, he did much to raise the reputation of British gynaecological surgery to its present high position.

Victor Bonney was born in Chelsea on December 17, 1872, the son of Dr. W. A. Bonney, a well-known physician and surgeon. He studied medicine at the Middlesex Hospital, graduating M.B., B.S. in 1896 and proceeding to the degrees of M.D. in 1898 and M.S. in 1899, the year in which he also became a Fellow of the Royal College of Surgeons. To complete this impressive list of degrees and diplomas he became a Member of the Royal College of Physicians in 1900 and took the B.Sc. (anatomy) of London University with first-class honours in 1904. After resident appointments Bonney won the Emden research scholarship in the Cancer Investigation Laboratories of the Middlesex Hospital. His interest in obstetrics and gynaecology was not slow to develop and as early as 1905 he was appointed obstetric tutor, becoming assistant gynaecological surgeon in 1908. When Sir Comyns Berkeley retired in 1930 he succeeded him as senior gynaecological surgeon. Bonney and Berkeley, who were both great teachers, worked together to extend and perfect Wertheim's operation for cancer of the cervix and they were the joint authors of the well-known *Textbook of Gynaecological Surgery*. When the fourth edition of this work was reviewed in this *Journal* in 1943, the author of the review wrote:

"Scattered throughout the British Commonwealth of Nations there is a band of younger men whose privilege it has been to serve an apprenticeship at the Chelsea Hospital for Women, London, where they have become imbued with the Berkeley-Bonney tradition. They are the disciples of the Bonney technique and the Bonney conservatism, and to them, as to many others, Bonney is the greatest living exponent of gynaecological surgery. They remember him as an exquisite surgeon, a stimulating thinker and leader, and a rare and generous teacher."

Bonney's other contributions to the practice and literature of gynaecology were numerous and important, and he devised a number of ingenious instruments. During the first world war he worked as a surgeon at the military branch of the Middlesex Hospital at Clacton-on-Sea. For many years he was on the staff of the Chelsea Hospital for Women, and at one time or another he held appointments at the Royal Masonic Hospital, the Miller General Hospital, Putney Hospital, and Queen Alexandra's Military Hospital. He was also visiting gynaecologist to the Postgraduate Medical School in London. On the council of the Royal College of Sur-

[Lafayette, London]

geons Bonney played a noteworthy part and rose to be a vice-president of the College. He was Hunterian lecturer in 1908, 1930, and 1931, Bradshaw lecturer in 1934, and Hunterian Orator in 1943. The Royal College of Obstetricians and Gynaecologists conferred on him the Honorary Fellowship of the College in 1946. During a visit to Australia he was made Honorary Fellow of the Royal Australasian College of Surgeons, and the Association of Surgeons of Great Britain and Ireland and the American Gynaecological Society in the U.S.A. paid him similar honour. For many years he was a member of the council of the Central Midwives Board, and he examined for the Conjoint Board and several universities. In 1923 he was president of the Section of Obstetrics and Gynaecology at the Annual Meeting of the B.M.A.

Victor Bonney painted and drew with great skill. Not only did he regularly exhibit his paintings at exhibitions of work by medical artists but he illustrated his own books with admirably clear drawings. When he retired he went to live on the banks of the Wye, where he could indulge in another favourite hobby, fishing.

In 1905 he married Annie, daughter of the late Dr. James Appleyard, of Longford, Tasmania.

We are indebted to Sir GORDON GORDON-TAYLOR for the following appreciation:

A friendship of exactly fifty years compels a tribute from a colleague and perhaps condones the venture of a general surgeon to appraise the work of a specialist. In 1903 Victor Bonney returned as gynaecological tutor to the medical school that cradled him, full of enthusiasm, his lectures brimful of references to Teacher's ovum and the views of Targett, Schlagenhauser, and Bland-Sutton on ovarian tumours. It was Bland-Sutton who had directed his footsteps to the Chelsea Hospital for Women, who had turned his gaze towards pelvic surgery, and to whom he always expressed his indebtedness for anything which he himself had achieved. By 1903 he was already on the staff of "Chelsea" and forging ahead as a skilful and intrepid operator. He had already accumulated a plethora of academic degrees and diplomas, but despite the fullness of his days the attraction of a recently created B.Sc. degree in anatomy of the London University made him ready and eager to sacrifice his nights also to attain his ends. I had the immense privilege of working with Bonney for a whole year in the dead of night, when four times a week the two companions toiled through the livelong night, only ceasing at 12.45 a.m. on the other three evenings in the week. Friendships forged in such an environment last as long as life endures. Not only did this year of prodigious toil secure its academic reward, but it also revealed to Bonney that he could draw, and it would be superfluous to refer to the self-drawn illustrations with which he has always adorned his books and scientific communications. The discipline of that year also introduced him to histological methods, which he at once turned to account in his work as Emden Research Scholar in the Middlesex Cancer Laboratories and also in the elucidation of the phenomenon of the implantation of the ovum in cases of tubal gestation, which was engaging his attention. Bonney was quick to recognize that gynaecology and the maieutic art constituted a branch of surgery, and first at "Middlesex" and subsequently in most institutions those who practised the specialty were destined no longer to be "men-midwives" but surgeons with the proud prefix of "Mr." to their name. If Lawson Tait and Bland-Sutton first rescued womankind with their pelvic tumours from the inert, inept "men-midwives" who had previously "treated" their ailments, it was Victor Bonney who became the scintillating ornament of gynaecological surgery.

Bonney was made of such stuff and fibre that he would have excelled in any branch of surgery that his fancy selected. I would not dare to compare the perineal surgery

of one operator with that of another, but I have seen the Wertheim operation performed by gynaecological surgeons throughout the whole world, and among these Bonney stood supreme. He knew every trick of the tool's true play, and had an inventive turn where instruments were concerned: many of the surgical gadgets in use in gynaecological and other operating theatres owe their origin to him. Victor was not content to limit his sphere of surgical activity to the pelvis and had his own views about the treatment of gall-bladder disease, and one of the last operations which he performed only a few months ago was a radical operation for cancer of the breast.

He was the first gynaecologist to secure a seat on the council of the Royal College of Surgeons of England, and served the council for twenty years, and the first of his specialty to become an Honorary Fellow of the Association of Surgeons. The lack of emphasis on surgical training in the requirements for the diplomas of the recently created College of Obstetricians and Gynaecologists aroused his strongest disapproval, and only when years later this defect was remedied would he accept the Honorary Fellowship of that College. He was the first Honorary Fellow of the Royal Australasian College of Surgeons, being admitted to the Fellowship at the same time as Lieutenant-General Sir John Goodwin, then Governor of Queensland (1928).

Victor was a man of intense kindness, and his quaint address of endearment, though perhaps not advancing his promotion in the councils of men, nevertheless revealed the heart of gold that beat within his breast. His loyalty to colleagues was one that "passeth all understanding," and the memory still remains with me of an enthusiast who half a century ago prepared the specimens, the paraffin blocks, employed the histological stains, wrote most of the paper or book, made the drawings, while the contribution of his co-author was confined to turning the handle of the microtome. Yet he went his smiling way, nor did any rancour impair the lightness of his step. His married life, which lasted nigh on fifty years, was one of great happiness, and to the end of his life he remained the same devoted lover as he was fifty years ago in his courting days, when every morning he wrote a note to his fiancée and scampered across the hospital quadrangle from our dissecting room to catch the 3 a.m. post which existed in that far-distant period. To the writer of this tribute he was a great master surgeon and a loyal friend.

EWEN A. JACK, O.B.E., Ch.M., F.R.C.S.Ed.

Mr. Ewen A. Jack, lecturer in orthopaedic surgery at Edinburgh University and consultant orthopaedic surgeon for the South-Eastern Region of Scotland, died at his home in Edinburgh on June 28 at the early age of 44.

Ewen Alistair Jack was born on January 31, 1909, at Hartlepool, where his father was in general practice, and was educated at Fettes College. On leaving school he studied medicine at the University of Edinburgh, where he distinguished himself as an athlete, being captain of the University Rugby fifteen. While at the University he lived in Ramsay Lodge, and there must be many Ramsay men the world over who will mourn the loss of their old friend, cut off at the peak of his career.

Ewen Jack graduated M.B., Ch.B. in 1932, and after a series of house appointments in Edinburgh and Leicester became a Fellow of the Royal College of Surgeons of Edinburgh in 1935. A period of post-graduate training in London followed, and he then returned to Edinburgh as clinical tutor in surgery at the Royal Infirmary, an appointment he continued to hold till the outbreak of war in 1939, when he entered the R.A.M.C. Up till then Jack's aim had been to secure a sound general training in surgery, and it was on this that he rapidly built up experience in his chosen specialty of orthopaedics.

He had a distinguished career in the Army, serving with the British Expeditionary, Middle East, and Central Mediterranean Forces, both as an orthopaedic specialist in charge of a large orthopaedic centre in Cairo and as the officer in charge of a field surgical unit in Sicily and Italy. He was then promoted lieutenant-colonel with charge of the surgical division of a general hospital in north-west Europe, where he served till demobilization. He was appointed O.B.E. in 1944 in recognition of gallant and distinguished services in Sicily, and in the following year he was mentioned in dispatches for his services in north-west Europe. It was while serving with No. 9 General Hospital in France in 1940 that he met his wife, formerly Miss Vivien Weekes, and they were married in Cairo early in the following year.

Edinburgh was indeed fortunate that he chose to settle down in his old school after the war. He played a notable part in the formation of an orthopaedic scheme for the area and was instrumental in its success. It was typical of his drive and determination that in the midst of this exceptionally busy time he obtained the higher degree of Ch.M. in 1948. His skill and ability as a teacher and as a surgeon were known not only to the students in Edinburgh but to a far wider circle, as was evident at the joint meeting of the Orthopaedic Associations of the English-speaking World in London last year. It was characteristic of him that his interests were not confined to a limited sphere but to the advancement of orthopaedic surgery in general. He was an indefatigable worker and had an uncanny ability to strip a problem of its non-essentials, having a keen eye for the basic facts. He made several important contributions to the literature of his specialty, and his many friends will not be surprised to learn that when even his stout heart could not drive his broken body to the physical effort of attending to his patients he was still actively engaged in the preparation of another paper, which, alas, he was not to be allowed to finish.

Ewen Jack was a big man, physically and in every other way. Those who knew him well and worked with him entertained a tremendous respect for his judgment and a high regard for him as a companion. Any of his gifts would have brought a man honour, respect, and admiration, but he had an even greater gift, and that was personal courage. A few months ago he knew that his end was near, but there was never any suggestion of limiting his activities. Indeed, he worked under a terrific physical burden till three weeks before his death. Those who knew of Ewen Jack's end realized that here was a man who set a fine example of how to die nobly. He died at home within sight of the beautiful garden of which he was so proud and which he had been allowed to enjoy for such a short time. No man could have been better nursed than he was by his wife. Her courage and devotion were an inspiration to all who were privileged to be with him during his last illness. To her and to his two young children goes our deepest sympathy.—J. H. C. and W. M.

OSWALD MARRIOTT, M.D., M.R.C.P.

Dr. Oswald Marriott, well known in Hong Kong and in London, died on June 17 at the age of 79.

Oswald Marriott was born on December 30, 1873. From Dulwich College he went to Guy's Hospital to study medicine, qualifying in 1900. After resident appointments at Guy's and the Dreadnought Hospital, Greenwich, he continued his medical education in Vienna and Brussels and at the London School of

Tropical Medicine. He took the M.D. of Brussels University and then graduated M.B., B.S. at London University in 1908, proceeding M.D. (tropical medicine) in the same year. Shortly before this he had gone out to Hong Kong as a member of the firm of medical practitioners which had included among its members Dr. (later Sir) Patrick Manson and Dr. (later Sir) James Cantlie. From 1905 to 1923 he served as a surgeon to the Chinese Maritime Customs. A keen member of the council and senate of Hong Kong University, he lectured there on materia medica and therapeutics. His practice was a large and busy one, for he put his work and his patients in front of everything else. All his work was run on strictly business-like lines, and every minute was accounted for. He took a great interest in the local Branch of the B.M.A. and was for a time its indefatigable secretary. He was in the R.A.M.C. for a short time towards the end of the first world war.

After Marriott returned to England in the early nineteen-twenties he built up a consulting practice in the City of London, specializing in tropical diseases. In 1923 he took the M.R.C.P. He maintained his early interest in the affairs of the B.M.A. and was a member of Council for many years, besides serving on a number of committees and as a Representative at Annual Meetings.

We are indebted to Mr. W. SAMPSON HANDLEY for the following appreciation: The passing of Oswald Marriott severs a link of friendship which dates unclouded from the dim past of 1895. At that time he was one of the ward clerks on the firm of the late Mr. Clement Lucas, to whom Sir Arbuthnot Lane was assistant surgeon and I was house-surgeon. I recall delightful visits to Marriott's home at Forest Hill, an old manor house with gardens and orchards even then embedded in a mass of small villas.

After house-surgeons at Guy's and the Seamen's Hospital, Greenwich, Marriott went to Hong Kong as a member of the distinguished firm to which the late Sir Patrick Manson belonged, and henceforth his interests were mainly in tropical medicine. After a long and successful career in Hong Kong he returned to England, and until a few months before his death practised as a tropical and insurance consultant in the City, the trusted adviser of many important firms with tropical interests. He leaves a widow, two sons, and a grandson to mourn his loss, and his friends the world over will share their feelings. In him modesty was allied with high competence, unswerving loyalty to his ideals and his friends, and lifelong devotion to the demands of his profession.

ARTHUR MARTIN-LEAKE, V.C. and Clasp, F.R.C.S.

Dr. ERNEST JONES writes: The following recollection illustrates one of Martin-Leake's most prominent attributes—his modesty. He was not the first University College Hospital doctor to win a V.C. in the South African war, but when we desired to honour him in the same fashion as we had his predecessor, who was given a banquet with Dr. G. V. Poore in the chair, he firmly declined. He had "only done his duty," and he abhorred any fuss being made about it. How high his conception of "only doing his duty" was he showed in the first world war by winning a V.C. again in heroic circumstances.

We record with regret the death of Mr. J. R. LEE on March 29 at the age of 79. Before his retirement he was senior honorary surgeon at the Battersea General Hospital. John Robert Lee was born in Australia on July 17, 1873, and was educated at Grenville College, Ballarat, and Melbourne University, where he graduated M.B., B.S. in 1898. During the next few years he engaged in surgical experience, obtaining the F.R.C.S. of Edinburgh in 1906 and proceeding to the degree of M.D. in 1908. Among the appointments he held was that of surgeon to out-patients in the

98877

Alfred Hospital, Melbourne. Lee was a captain in the Royal Australian Army Medical Corps from 1901 to 1915, and during the first world war he served in the R.A.M.C., attaining the rank of major, and being appointed O.B.E. for his services. After the war he settled in London, taking the F.R.C.S. of England in 1923. During the last war he served as a surgical specialist in the E.M.S. A paper in which he described his experiences in the reception and treatment of air-raid casualties was published in this *Journal* in 1941.

We are indebted to Mr. JOHN SOPHIAN for the following appreciation: The recent death of John Robert Lee has brought to a close a life that was lived unselfishly. He had been spared to a ripe old age, and even in his later years his zeal in his task remained largely unabated. There are several among the ranks of consultants who will remember him with deep gratitude. Not only did he help to provide them with professional opportunity, but he fostered and guided them with kindness, wisdom, and encouragement while their maturity was being attained. Particularly will he be remembered by the poor of Battersea. For he came to the rescue and identified himself with the then Anti-Vivisection Hospital (now the Battersea General Hospital) when at the lowest ebb of its fortunes. Those who had witnessed its rapid rise to prominence thereafter equally well knew that such success was due to his devoted exertions. On many an occasion have I heard the warm appreciation of the local sick for his efforts in having established a medical sanctuary in what had been an area bereft of such aid. The poverty of the locality had restricted professional help, and the hopelessness of families faced with illness was by his wisdom and planning greatly relieved. The last decade and a half, because of the intervention of the war and a reorientation of the social system, has tended to obliterate from memory these signal services of rescue and of help.

Lee was highly qualified and was an excellent surgeon in every sense of the word. When carrying the burden of the hospital on his own shoulders, obstetrics and gynaecology had to be included in his efforts—a task in which he manfully acquitted himself. But it was as a general surgeon that he chiefly showed his skill. His was no narrow specialization, and his intrepidity carried him successfully into every anatomical region. Even towards the end of his career his approach was characterized by sound judgment and his execution by good technique. However, it was as a good man that he will long be remembered by those privileged to have known him. He was always guided by high Christian principles, and he lived his life by these ideals. In one very human moment, which I vividly recall, he confided to me how he used to undertake the long and arduous journey by car from home to hospital during the heaviest blitz singing hymns all the way. Though his career may not have been exceptional, his memory will long be cherished, and the good he effected will ever be a monument in the hearts of the many he so unselfishly assisted. His wife predeceased him by a few years. Our sympathy goes out to his only daughter.

The sudden and unexpected death from coronary thrombosis of Dr. D. H. McDOWELL at the early age of 41 is a tragic loss to his family, his friends, and to the Three Counties Hospital at Arlesey, Bedfordshire, which he served so well. Daniel Henry McDowell was born on July 7, 1911, and received his medical education at Dublin, where he took the diplomas of L.R.C.P. & S.I. in 1935. After holding an appointment at the County Infirmary, Armagh, he was medical superintendent of a mission hospital at Kirin, in Manchuria, from 1937 to 1941, when he went to Australia. After practising in various places in the State of Victoria, he returned to Northern Ireland in 1945, and two years later he was appointed to the staff of the Three Counties Hospital. In 1948 he obtained the D.P.M. of the British Royal College.

N. McD. writes: Dan McDowell will be remembered with real affection by all who knew him, and by none more so than the patients and staff of the Three Counties

Hospital. Equipped with high ideals and a pleasant personality and with a quiet sense of humour, no one could wish for a more reliable or more agreeable colleague. He was more than fortunate in his married life, and our sympathy goes out to his widow and three children.

Medical Notes in Parliament

TRUTH IN ADVERTISING

Mr. PETER THORNEYCROFT on June 26 moved the second reading of the Merchandise Marks Bill, which had already passed the House of Lords. He said the effect of existing legislation was that if a trader elected to describe his goods he must not describe them falsely. The Bill widened the definition of trade descriptions to include misleading descriptions.

Dr. BARNET STROSS seconded an amendment for the rejection of the Bill. He said that in the "plugging" of things like deodorants and chlorophyll toothpaste the technique used was to make the young people and women frightened that they would become social outcasts and believe that their armpits and mouths were objectionable. Everyone associated with medicine knew that chlorophyll did not take away bad smells at all. He looked forward to seeing these people change the quality of their advertisements. The least critical of the people were subjected to advertisements of a most misleading type. One knew of advertisements of rejuvenation cures which no reputable newspaper would accept to-day and of so-called cures for incurable diseases. Such advertisers always selected psoriasis as a subject for advertising because they knew that it was not curable by any available means, but was always likely to appear to get better for a while.

Miss ELAINE BURTON said that in 1950 she had asked a Parliamentary Secretary if he was aware that the American public had the choice of 65 different kinds of aspirin which were advertised as various qualities. Some were pure, some were certified, some dissolved fast. One was advertised as giving quicker relief because it dissolved more speedily in water. It was found upon testing that the speed with which an aspirin dissolved in water was no indication of the speed with which it was absorbed into the system. It was also found that there was no relationship between the speed with which it was absorbed into the system and the speed with which it cured headache. If in this country we had advertisements of aspirins like those in America she presumed that the manufacturers or advertisers would be obliged to prove their case or they would be guilty under this Bill.

Mr. JAMES HUDSON drew attention to medicated wines. These things were sold to poor women on the assumption that what they needed was medicine. The quantity of nutritive matter contained in many of these beverages was negligible.

Mr. HENRY STRAUSS, replying for the Government, said that many of the matters that had been quoted by Dr. STROSS were not trade descriptions and could not, in his opinion, be proved to be false.

The Bill was read a second time without a division.

MERGING OF MINISTRIES

On June 30 Mr. HARRY CROOKSHANK moved for the approval of a Draft Order to merge the Ministry of Pensions and the Ministry of National Insurance. He said that in 1921 there were 67 Ministry of Pensions hospitals. To-day there were only eight. There had been a marked decline in the use by war pensioners of the special hospital and treatment services of the Ministry of Pensions, which had been replaced by the National Health Service. The National Health Service had come into being for all classes of medical treatment, and the Ministry of National Insurance

did work for the industrially disabled similar to that done for the war disabled by the Ministry of Pensions. There was already a considerable link in case-work between the two departments.

Mr. GEORGE ISAACS hoped that the new Ministry, if it was established, would carry on the specialized services of Roehampton or Queen Mary's Hospital. There was another specialist centre at Stoke Mandeville which had been developed by the Ministry of Pensions and now was at the service of civilians. Miracles could be seen there. He asked for an assurance about continuation of the welfare services.

After further debate the proposed merger was approved by 226 to 212.

Priority for War Pensioners

A motion approving the Transfer of Functions (Ministry of Pensions) Order was moved in the House of Lords on July 2 by LORD SELKIRK. He said the organizational changes would take place gradually. The preferential position of war pensioners and existing priorities in regard to medical treatment would be preserved. War disabled would receive priority in the existing pensions hospitals and in all National Health Service hospitals. Treatment at clinics would be discussed with ex-Service organizations. Ex-Service interests would be represented in the management of pensions hospitals. There would be no changes in Queen Mary's Hospital, Roehampton, without full consultation with its governors.

After debate the House agreed to the motion.

Providing for Old Age

Mr. R. A. BUTLER on July 2 told the House of Commons that the Government had decided to set up an independent committee to review the economic and financial problems involved in providing for old age, having regard to the prospective increase in the number of the aged. He said the number of men and women over the ages of 65 and 60 was expected to rise from nearly 7 million in 1952 to nearly 10 million in 1977, a rise of more than 40%. In the same period the number between the age of 15 and these pensionable ages was expected to decline. Sir Thomas W. Phillips had agreed to serve as chairman of this committee. A first report was expected shortly from the Ministry of Labour Advisory Committee on the Employment of Older Workers.

Sewage in Rivers—While it is true that some tidal river estuaries are polluted by the discharge of sewage, Mr. Macmillan has no evidence of any danger to public health.

Extensions at Mental Hospitals.—Mr. Macleod hopes to make a special allocation available next year for extensions at suitable mental deficiency and mental hospitals. He has circulated to boards sketch plans to assist them in framing proposals.

Calcium.—One pint of milk (0.57 l.) supplies 680 mg. calcium; 1 lb. (0.45 kg.) of bread, containing added calcium carbonate, 649 mg.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

On July 2 Professor Lambert C. Rogers was re-elected and Professor Ian Aird, Professor R. Milnes Walker, and Professor C. A. Wells were elected members of the Council of the College. The result of the poll was as follows:

	Elected					Votes				
Lambert Charles Rogers, V.R.D. (Royal Infirmary, Cardiff)										1,206
Ian Aird (Postgraduate Medical School of London)										788
Robert Milnes Walker (Royal Infirmary, Bristol)										684
Charles Alexander Wells (Royal Infirmary, Liverpool)										640

In all 1,993 Fellows voted; in addition 22 votes were found to be invalid.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending June 20 (No. 24) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ———. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The incidence of infectious diseases in England and Wales during the week ending June 20 increased slightly. The largest rises in notifications were 559 for whooping-cough, from 3,545 to 4,104; 168 for scarlet fever, from 1,055 to 1,223; 71 for dysentery, from 486 to 557; and 48 for measles, from 7,532 to 7,580.

The largest rises for whooping-cough were Essex 79, from 249 to 328, and Warwickshire 65, from 207 to 272. Only small fluctuations occurred in the local trends of scarlet fever. 25 cases of diphtheria were notified during the week, 8 more than in the preceding week. The rise in diphtheria was due to cases scattered throughout the country. The largest increases in the incidence of measles were Yorkshire East Riding 118, from 178 to 296; Lancashire 113, from 1,438 to 1,551; and London 84, from 207 to 291; while the largest declines were Yorkshire West Riding 139, from 843 to 704; Gloucestershire 70, from 386 to 316; and Cornwall 68, from 209 to 141.

23 cases of paratyphoid fever were notified, 18 more than in the preceding week, and this was the largest total for 36 weeks. The rise was due to sporadic cases over a wide area.

The 65 cases of acute poliomyelitis were 7 fewer for paralytic and 1 fewer for non-paralytic cases than in the preceding week. The largest returns were Kent 6, Essex 6 (West Ham C.B. 2), London 4, Middlesex 4, and Somerset 4.

The largest returns for dysentery were Lancashire 93 (Preston C.B. 27, Liverpool C.B. 21), London 79 (Islington 12), Bedfordshire 66 (Luton M.B. 59), Middlesex 50 (Edmonton M.B. 16, Willesden M.B. 12), Yorkshire West Riding 43 (Barnsley C.B. 16), Surrey 37 (Dorking and Horley R.D. 10), Leicestershire 28 (Leicester C.B. 24), and Essex 21.

Of the 998 cases of food-poisoning, 860 were notified in Lancashire. Food-poisoning was notified from 37 administrative areas of Lancashire.

Quarterly Return for Scotland

The birth rate during the first quarter of 1953 was 18.1 per 1,000 of the population and was 0.1 above the rate for the first quarter of 1952 but 0.7 below the average of the five preceding first quarters. The infant mortality rate was 34 per 1,000 registered live births; this was the lowest rate ever recorded in a first quarter, being 4 below the rate for the March quarter of 1952.

The general death rate was 13.7 per 1,000 of the population and was 0.8 below the rate for the corresponding quarter of 1952 and 1.3 below the five-years average. 219 deaths were registered from the principal epidemic diseases. These included 186 from influenza, 13 from measles, 12 from meningococcal infections, and 4 from whooping-cough. The death rate from all forms of tuberculosis was 32 per 100,000 (27 from respiratory tuberculosis); these rates were 15 and 14 respectively below those for the first quarter of 1952, and were 33 and 30 below the five-years average. Deaths from violence numbered 737, including 130 attributed to road transport, as compared with 643 and 86 in the first quarter of 1952.

Week Ending June 27

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,333, whooping-cough 4,116, diphtheria 18, measles 6,871, acute poliomyelitis 60, dysentery 676, paratyphoid fever 5, typhoid fever 4.

The Services

Major-General C. W. Greenway, C.B.E., late R.A.M.C., has been appointed Honorary Surgeon to the Queen, in succession to Major-General F. R. H. Mollan, C.B., O.B.E., M.C., late R.A.M.C., retired.

Brigadier A. E. Campbell, late R.A.M.C., has been appointed Honorary Physician to the Queen, in succession to Major-General T. Young, C.B., O.B.E., late R.A.M.C., who has retired.

Medical News

Queen's Honorary Physicians.—The following were gazetted as Honorary Physicians to the Queen for three years from July 1: Dr. G. E. Godber, deputy chief medical officer, Ministry of Health; Sir Harold Himsworth, secretary, Medical Research Council; Dr. H. L. Glyn Hughes, senior administrative medical officer, South-East Metropolitan Regional Hospital Board; Dr. J. M. Hunter, medical adviser to the General Health Services Board for Northern Ireland; Dr. E. K. Macdonald, medical officer of health and school medical officer, City of Leicester; and Dr. R. J. Peters, deputy chief medical officer, Department of Health for Scotland.

Fifth Birthday of the Health Service.—The Minister of Health and the Secretary of State for Scotland have each marked the fifth anniversary of the start of the National Health Service on July 5, 1948, by sending grateful messages to those who administer the Service. Mr. Iain Macleod speaks of the "great and remarkable tradition of this country to rely for local administration on the selfless voluntary work of thousands of men and women": "on the continuance of this work," he declares, "the National Health Service must inevitably depend." Mr. James Stuart pays a similar tribute to the "unpaid voluntary workers" who carry so much of the burden of planning and running the Service. Looking back, Mr. Stuart is able to say that the "essential services of medicine have been brought more fully within the reach of the whole population of Scotland than ever before." What do the figures tell us? In England and Wales there are now 470,000 staffed hospital beds in the N.H.S., an increase of 35,000 since the appointed day; there are 142,000 whole-time nurses and 27,000 part-time, increases respectively of 27,000 and 10,000; over 10 million dentures and 27 million pairs of spectacles have been supplied. In Scotland, the establishment of staffed beds is now 61,400; whole-time nurses number 19,000, part-time 3,400; nearly 2 million dentures and nearly 3 million pairs of spectacles have been provided.

Rockefeller Institute for Medical Research.—A New York report states that Dr. Detlev W. Bronk, the distinguished American neurophysiologist, has been nominated as director of the Rockefeller Institute for Medical Research, in succession to Dr. Herbert S. Gasser. Dr. Bronk, who was born in New York in 1897, is both an able research worker and an experienced administrator: for ten years he directed the Institute of Neurology at Pennsylvania University; during the war he was co-ordinator of research at the Air Surgeon's Office of the U.S. Army Air Forces; and after the war he was appointed chairman of the National Research Council. In 1949 Dr. Bronk was elected president of Johns Hopkins University. This experience is likely to be specially valuable, as there are to be changes in the direction of the Rockefeller Institute which will mean greater administrative responsibility for the new director.

Benefits for Occupational Diseases.—The Minister of National Insurance has appointed a committee under the chairmanship of Mr. F. W. Beney, Q.C., to review the present provisions of the Industrial Injuries Act under which benefit is paid for diseases and for personal injuries not caused by accident. The medical members of the committee are Sir Ernest Rock Carling, Dr. L. G. Norman, and Dr. Alice Stewart. The inquiry is concerned with the extent to which persons who claim they are suffering from diseases due to their employment should be eligible for the special benefits of the industrial injuries scheme. At the moment, apart from the "injury by accident" provisions, cover is given only for certain specified occupational diseases, at present numbering 40. The committee invites written evidence, which should be sent to the committee's secretary, Mr. H. B. Lewin, Ministry of National Insurance, 10, John Adam Street, London, W.C.2.

Royal Patronage for Chartered Society of Physiotherapy.—The Queen has granted her patronage to the Chartered Society of Physiotherapy. The society has been under royal patronage since the grant of its charter in 1920, when the late Queen Mary became its patron.

Professor Wilder G. Penfield, O.M., was one of the five former Rhodes Scholars to be given the honorary degree of D.C.L. at the Rhodes Centenary Celebrations at Oxford last week. Dr. Penfield is director of the Montreal Neurological Institute and professor of neurosurgery at McGill University.

Honorary Degrees at Edinburgh.—On July 3 the honorary degree of LL.D. was conferred on Dr. S. L. A. Manuwa, Inspector-General of Medical Services, Nigeria, and on Professor Charles McNeil, professor emeritus of child life and health in the University of Edinburgh.

William Marsden Travelling Professorship.—The Board of Governors of the Royal Free Hospital has awarded the 1953 William Marsden Travelling Professorship to Dr. Ernest T. D. Fletcher. He will attend the eighth International Congress for Rheumatic Diseases at Geneva, and then visit various rheumatism research centres in Italy and Spain, returning via Paris, Copenhagen, Stockholm, Malmo, and Lund. After this he will go to America, where he will visit hospitals in Canada and the United States.

Dr. H. C. Maurice Williams, medical officer of health to the county borough and port of Southampton, has been elected chairman of council of the Royal Sanitary Institute from October 1, 1953. Dr. Williams is a past president of the Society of Medical Officers of Health, and the honorary secretary of the Association of Sea and Air Port Health Authorities.

Dr. Louis Findlay, who graduated from Aberdeen University in 1936, has been appointed chief of the Health Division of the United Nations Relief and Works Agency for Palestine Refugees. Dr. Findlay's last post was that of medical consultant to the United Nations Korean Reconstruction Agency.

Dr. N. E. Waterfield has been gazetted as a Deputy Lieutenant of Surrey.

Thoracic Surgery.—Georg Thieme Verlag, Stuttgart, have commenced publication of *Thoraxchirurgie*, which will appear every two to three months and will publish papers on the pathology and surgery of pulmonary and cardiac disease. Subscription per volume of six parts is DM.60.

COMING EVENTS

British Diabetic Association.—The Annual Scientific Meeting of the British Diabetic Association will be held in the Littlewood Hall of Leeds General Infirmary on July 17 and 18. The meeting will commence with the 1953 Banting Memorial Lecture, to be given by Professor R. E. Tunbridge, whose subject will be "Socio-medical Aspects of Diabetes Mellitus." There will also be discussions on clinical experiences with new forms of insulin, and on various other topics. Accommodation may be obtained on request to the Warden of Lyddon, Virginia Road, Leeds, 2.

Postgraduate Paediatrics Symposium.—Paediatrics is the subject of the next of the monthly symposia for postgraduate students organized by the Cambridge University Medical School. The symposium will be held at Addenbrooke's Hospital, Cambridge, at 10.30 a.m. on July 18, and will comprise lecture-discussions and clinical demonstrations. Those wishing to attend the symposium are asked to notify the secretary, Cambridge University Medical School, Tennis Court Road, Cambridge, as soon as possible.

Norfolk Branch Dance.—The Norfolk Branch of the British Medical Association will hold a dinner-dance at the Samson and Hercules Ballroom, Norwich, on September 30. Invitation cards will be sent out later.

British Social Biology Council.—The Summer School of the British Social Biology Council is being held at Aix-en-Provence from August 6 to 20. The theme of the school is "Nature and Nurture." The principal speakers will be Mr. Alec Rodger and Dr. C. O. Carter. The cost of the school is £34, which includes registration, tuition, accommodation, and second-class travel. Those requiring further information should communicate as early as possible with the secretary, British Social Biology Council, Tavistock House South, Tavistock Square, London, W.C.1.

Davidson Clinic Summer School.—The Summer School of the Davidson Clinic for medical psychotherapy will be held in Edinburgh from July 29 to August 4. Further details may be obtained from the secretary of the Clinic, 58, Dalkeith Road, Edinburgh, 9.

Oesophageal Speech.—An institute on teaching and improving oesophageal speech will be held in Cleveland, Ohio, from August 10 to 16. This institute, the second to be held on voice pathology, is being sponsored by the American Cancer Society and other bodies. Surgeons and speech therapists will lecture and demonstrate the teaching of oesophageal speech, and non-speaking laryngectomized persons may attend the institute without charge. Anyone wishing for further details should write to Dr. Warren H. Gardner, 11,206, Euclid Avenue, Cleveland, 6, Ohio.

The Eighth International Congress of Rheumatic Diseases will be held in Geneva from August 24 to 28, 1953. The president is Professor E. Jarlov, of Copenhagen. Those wishing for further information are asked to communicate with Professor K. M. Walthard, Institut de Physiatrie, Hôpital Cantonal, Geneva.

The Second International Congress of Cardiology will be held in Washington, D.C., U.S.A., from September 12 to 15, 1954. Further details will be available later, but all correspondence should be sent to the secretary-general, Dr. L. W. Gorham, 44, East 23rd Street, New York 10.

NEW ISSUES

British Journal of Ophthalmology.—The next issue (Vol. 37, No. 7) will be available in a week's time. The contents include:

DEGENERATION OF THE DOG RETINA. I: STRUCTURE AND DEVELOPMENT OF THE RETINA OF THE NORMAL DOG. H. B. Parry.
AN EYE SANATORIUM: SURVEY OF ONE YEAR'S WORK. D. P. Choyce and A. G. Cross.
MODIFICATION AND DEFENCE OF THE SCLERAL IMPLANT. W. Hedley Summerskill.
THE RIDLEY INTRA-OCULAR ACRYLIC LENS. A SIMPLIFIED OPERATIVE TECHNIQUE. V. P. Patel.
FLICKER STIMULATION IN AMBLYOPIA. G. Parsons-Smith.
SECONDARY GLAUCOMA DUE TO SPONTANEOUS RUPTURE OF THE LENS CAPSULE. F. S. Hubbertsey and J. S. Gourlay.
THE MEASUREMENT OF CORNEAL THICKNESS AND ITS APPLICATION TO KERATOPLASTY. A. Lister, A. S. Philips, and M. Langham.
A SPEED-OF-PERCEPTION MEASUREMENT APPARATUS. J. C. Neely.
VENOUS PRESSURE AND OCULAR TENSION. DATA CONCERNING THE DIURNAL VARIATION OF OCULAR TENSION. P. Weinstein and J. Forgacs.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Tuesday, July 14

INSTITUTE OF NEUROLOGY.—5 p.m., Dr. L. Cox (Melbourne): Disorders of Consciousness from Basal Lesions of the Brain.

Thursday, July 16

LEEDS UNIVERSITY.—At General Infirmary at Leeds, 4.15 p.m., Dr. L. B. Cox (Melbourne): Torulosis.

Friday, July 17

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, Bute Medical Buildings, St. Andrews, Fife, 11 a.m., 320th meeting. Scientific papers will be read.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Charles Tomes Lecture by Mr. G. T. Hankey: Temporo-mandibular Arthritis.

APPOINTMENTS

DAVIES, ILID META LEWIS, M.B., B.Ch., D.Obst.R.C.O.G., Assistant Medical Officer, South-east Glamorgan Health Division.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—A. H. Millard, F.R.C.S., Surgical Registrar; M. R. Williams, F.R.C.S., Part-time Surgical Registrar; K. Till, M.B., B.Ch., Clinical Assistant to the Neurosurgical Department; N. T. Jacob, B.M., B.Ch., M.R.C.P., D.C.H., Assistant Medical Registrar; Elizabeth A. Martin, M.B., B.S., and T. J. Haywood, M.D., House-physicians; H. B. Eckstein, M.B., B.Ch., and J. A. Wilkinson, M.B., B.Ch., House-surgeons.

JENKINS, DAVID HUGHES, M.S., F.R.C.S., Consultant Surgeon, United Cardiff Hospitals and Welsh Regional Hospital Board.

RICHARDS, R. D., M.B., B.Ch., F.R.C.S., Consultant Surgeon, Royal Gwent Hospital, Newport, Mon.

SLEIGH, J., M.B., Ch.B., D.P.H., Divisional Medical Health Officer, Nova Scotia Provincial Government.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—D. Finn, M.B., B.Ch., Assistant Psychiatrist at Horton Road and Coney Hill Hospitals, Gloucester; R. M. M. Hunter, M.B., Ch.B., M.R.C.P.Ed., D.P.H., D.P.M., Consultant Psychiatrist to North Gloucestershire Clinical Area; C. D. Linton, M.B., Ch.B., D.Obst.R.C.O.G., Anaesthetic Registrar, Southmead Hospital, Bristol; W. L. Walker, M.B., Ch.B., D.P.H., D.P.M., Senior Registrar in Mental Deficiency and Child Psychiatry to Bristol Clinical Area; S. Schwartz, M.B., Ch.B., F.R.C.S.Ed., Orthopaedic Registrar, Winford Orthopaedic Hospital, near Bristol; T. Galla, M.B., Ch.B., Registrar in Psychiatry to South-western Region; R. H. Ellis, M.D., M.R.C.P., Consultant Chest Physician to North Gloucestershire Clinical Area; J. M. Whelchan, L.R.C.P.&S.I., Assistant Psychiatrist, Roundway Hospital, Devizes.

UNIVERSITY COLLEGE HOSPITAL OF THE WEST INDIES.—J. B. Self, M.B., Ch.B., F.R.C.S., Surgical Registrar; J. H. M. Pinkerton, M.D., M.R.C.O.G., Senior Lecturer in Obstetrics and Gynaecology; Joyce Ford-Smith, M.B., Ch.B., D.Obst.R.C.O.G., Lecturer in Obstetrics and Gynaecology; R. A. St. C. Hoyte, M.D., C.M., D.Obst.R.C.O.G., Registrar in Obstetrics and Gynaecology.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Flucker.—On June 25, 1953, at Plymouth, to Christine, wife of Dr. J. L. Flucker, a daughter—Christine Louise.

Robinson.—On June 24, 1953, at Old Court Clinic, Ealing, London, W., to Gay (formerly Selig), wife of Dr. Keith J. Robinson, of 12, Presto Hill, Kenton, Middlesex, a son—Martin Clifford.

Shotts.—On June 28, 1953, at the West Middlesex Hospital, Isleworth, to Barbara (formerly Layman), wife of Alan Shotts, M.R.C.S., L.R.C.P., L.D.S., a son—Paul David.

Stock.—On June 27, 1953, at St. Mary's Hospital, Portsmouth, to Freda (formerly Lunt), M.B., D.C.H., wife of Dr. S. D. Stock, of 20, Magdala Road, Cosham, Hants, a daughter—Lexley Freda.

Thomas.—On June 30, 1953, at the Radcliffe Infirmary, Oxford, to Katie (formerly Walker), wife of F. Brian Thomas, F.R.C.S., Putson Manor, Hereford, a daughter.

MARRIAGES

Shirlaw—Davidson.—On July 1, 1953, at St. Andrew's Church, Waterloo, Liverpool, Herbert Anthony Douglas Shirlaw, M.B., Ch.B., Flight-Lieutenant, R.A.F., of Upholland, Lancs, to Patricia Magdalen Davidson, of Great Crosby, Lancs.

DEATHS

Cox.—On June 14, 1953, at his home, 24, Offington Drive, Worthing, Sussex, William Alfred Spencer Cox, M.D., late of Church Street, Kensington, London, W., aged 89.

Evans.—On June 20, 1953, Albert Edward Evans, C.B.E., M.B., B.S., D.P.H., Lieutenant-Colonel, R.A.M.C., retired, of 11, Weymouth Avenue, Mill Hill, London, N.W.

Feilden.—On June 13, 1953, at the Royal Surrey County Hospital, Frederick Ernest Feilden, L.M.S.S.A., late of Guernsey, Channel Islands, aged 88.

Hamond.—On June 22, 1953, at 133, Tonbridge Road, Maidstone, Kent, Philip William Hamond, M.D., aged 73.

Hayden.—On June 12, 1953, Roger Keith Hayden, M.R.C.S., L.R.C.P., of London, W. and N.W.

Holroyd.—On June 14, 1953, at Nynhead, Somerset, Gilbert Holroyd, M.B., B.Ch., Lieutenant-Colonel, I.M.S., retired, formerly of Budleigh Salterton, Devon, aged 72.

Hynes.—On June 18, 1953, Mortimer Hynes, M.B., B.Ch., of 35, Southwood Lawn Road, London, N.

Ince.—On June 21, 1953, at Woking, Surrey, Joan Katherine Somerville Ince (formerly Cave), M.B.E., M.R.C.S., L.R.C.P., of Kenot Lodge, Lechlade, Glos.

Kilner.—On June 15, 1953, at 1, Lismore, Hollington Park, St. Leonards-on-Sea, Sussex, John Newport Kilner, M.B., D.P.H., aged 79.

MacMahon.—On June 22, 1953, at 63, Milton Road, Harpenden, Herts, Charles Grant MacMahon, M.B., Ch.B.

Newell.—On June 22, 1953, Alfred George Newell, M.D., D.P.H., of 14, Dane Road, St. Leonards, Sussex, aged 80.

Sharp.—On June 19, 1953, at the Kent and Sussex Hospital, Tunbridge Wells, Kent, Leonard Whitaker Sharp, M.B., of Woodlands, Wadhurst, Sussex, aged 70.

Shireore.—On June 23, 1953, at Zomba, Nyasaland, John Owen Shireore, C.M.G., M.B., Ch.B., M.R.C.P.Ed., aged 71.

Sturdy.—On June 17, 1953, Joseph Cornelius Sturdy, L.R.C.P.&S.Ed., L.R.F.P.S., of 13, Carr Lane, Acomb, York.

Taylor.—On June 22, 1953, at Gubblicote Cross, Tring, Herts, James George Taylor, M.D., formerly of Chester, aged 78.

Tuohy.—On June 15, 1953, Joyce Tuohy (formerly Stirling), M.B., Ch.B., of Street, Somerset, late of Dunelm, Lasswade, Midlothian.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Child-bearing in the Tropics

Q.—Are there any special dangers attending pregnancy and childbirth in a tropical climate? Would a European woman be well advised to come home, or go to a hill resort, for the birth of her baby?

A.—A tropical climate *per se* does not create any special dangers in pregnancy, though it may be difficult to obtain proper medical attention in the Tropics. In this respect facilities vary from country to country, and it is impossible to generalize. Provided satisfactory medical attention is obtainable locally, it is not essential for the pregnant woman to return to this country for the birth of the baby. The advisability or otherwise of going to a hill resort should be decided on the relative merits of the facilities available. Other things being equal, it may be more comfortable to go to the hills if term should fall during the hot season.

Premedication for Thiopentone

Q.—What is the safest and best premedication before thiopentone anaesthesia?

A.—Thiopentone, like any other barbiturate, is not really an anaesthetic at all, since, so long as breathing is spontaneous and adequate, it does not abolish to any extent reflex motor responses to pain. Thiopentone is primarily a hypnotic, and it should really be used only for this purpose. In that case it provides a pleasant and rapid means of inducing sleep by intravenous injection, and when given in proper dosage interferes but little with the subsequent anaesthetic. Any premedication should have reference to the latter rather than to the small "sleep dose" of thiopentone.

Thiopentone is, however, still being used by itself as an anaesthetic—usually for short and minor procedures. In these circumstances premedication is best avoided altogether, since even the smallest additional sedative may prolong the period of recovery greatly. In general, respiratory depressants and hypnotics should be avoided before such use of thiopentone, unless the anaesthetist is prepared to manage respiratory depression and delayed recovery. If the patient is to be ambulant within a short time after thiopentone, additional sedatives, such as opiates and other barbiturates, are particularly contraindicated. The only form of premedication which is at all helpful when thiopentone alone is being used is atropine. This should never be omitted if there is any likelihood that an inhalation anaesthetic will follow the administration of thiopentone.

Pneumoconiosis without Radiological Changes

Q.—Is a diagnosis of pneumoconiosis ever tenable in the absence of radiological changes? If so, what diagnostic criteria must be satisfied?

A.—This question raises the difficult problem of the definition of pneumoconiosis. Pneumoconiosis is an abnormal process in the lung caused by the inhalation of dust. Theoretically it must start as soon as dust is retained in the lung and histological changes attributable to its presence develop. Such microscopic changes may be found in cases without radiological change during life. In such cases the diagnostic criteria are purely histological, and the diagnosis cannot be made during life. If the questioner implies by "pneumoconiosis" a disabling disease, then there will be radiological changes in the vast majority of cases. Occasionally coal-miners with gross respiratory disability but without radiological evidence of pneumoconiosis are found, at

necropsy, to have severe focal emphysema associated with considerable fibrosis due to dust, which must have played an important part in producing the disability. Presumably the translucency of the emphysema had obscured the radiological opacities which the dust deposits might have caused in its absence. This obscuration by emphysema may be more frequent than we realize. In byssinosis there may be gross disability attributable to cotton-dust inhalation, but there are no characteristic radiological abnormalities.

A diagnosis of disabling pneumoconiosis in the absence of radiological changes must always be presumptive unless recourse is to be had to lung biopsy. It may be that in the future a specific pattern of disturbance of respiratory function characteristic of pneumoconiosis may be defined and may assist in the diagnosis, but this has not yet been done, and one can do no more than recognize the possibility that a man with respiratory disability who has had significant dust exposure may be suffering from pneumoconiosis even though there are no radiological changes.

Inheritance of Amaurotic Idiocy

Q.—I have a patient, a first-born child aged 20 months, with amaurotic family idiocy. There is no Jewish strain on either side of the family nor any evidence of in-breeding. I should be grateful for information regarding the probable incidence of the condition in any future offspring, as the textbooks suggest the risk is considerable. Have any figures been published on actual cases?

A.—Infantile amaurotic idiocy (Tay-Sachs disease) is due to a recessive gene. The condition is considerably commoner in Jews than in others; nevertheless it does occur with a smaller frequency amongst those who are not Jews. In this instance the parents are unfortunate in that both happen to carry the gene, and the chance that any subsequent child will be similarly affected is one in four. An excellent paper on the genetics of infantile amaurotic idiocy has been published by D. J. Home.¹

Asthma and Deep X-ray Therapy

Q.—A woman of 60, who has suffered fairly frequent asthmatic attacks for the last 20 years, has been completely relieved of them since starting deep x-ray therapy a year ago for cancer of the breast with metastases in the lungs. What is the explanation of this?

A.—The possibility of coincidence can certainly be dismissed, for there is quite a literature on the results of deep x-ray therapy of the chest and spleen in the treatment of asthma. It is generally accepted that this therapy is often beneficial in asthma—occasionally dramatically so, as in this case—but more often improvement rather than complete relief occurs, and such improvement is usually temporary. Success is commonest in the chronic long-standing or infective type of asthma, the type of asthma which responds so well to cortisone and A.C.T.H. In this connexion it is interesting that Jiménez Díaz² has obtained marked improvement in asthmatics from nitrogen mustard injections; in these cases there was an increased excretion of urinary ketosteroids.³ How deep x-ray therapy works we do not know. Previously it was suggested that the psychological effect played a large part, but this cannot be the whole story. It may be because of its action on the reticulo-endothelial system.

Phenoxyethanol

Q.—What are the actions and clinical uses of phenoxyethanol? Are there any special contraindications to its use?

A.—Phenoxyethanol ("phenoxetol") is a bacteriostatic and bactericidal substance which is effective against the

pyocyanus bacillus. It also acts on other Gram-negative organisms including *Proteus vulgaris*, although to a less extent. It has little action on the pyogenic cocci. Laboratory evidence¹ and the results of clinical trials² suggest that it is of considerable value. It has been used for superficial wounds, burns, and abscesses infected with *Ps. pyocyanus*, and should be applied along with an antiseptic active against Gram-positive bacteria—for example, penicillin or cetrinide.

After absorption phenoxyethanol causes drowsiness in rats, mice, and rabbits. In high doses (about 5 ml. intraperitoneally in the rat, and 16 ml. intravenously in the rabbit) it kills the animal, presumably by paralyzing the respiratory centre. No ill effects have been seen in man after the application of 40 ml. of a 2.2% solution daily to a large granulating wound, and this should be regarded as the maximum safe amount. There would seem to be no other special contraindication to the use of this substance, although if it were more widely used examples of hypersensitivity reactions would probably be reported.

Use of the Title "Doctor"

Q.—Is the use of the title "doctor" by medical practitioners not possessing the M.D. degree governed by any legislation? The minute book of an old medical club from 1826–71 designates some members as "Mr.," some as "Esq.," and some as "Dr." In 1890 it uses the term "Dr." for all members, some of whom had previously been addressed as "Mr." or "Esq."

A.—This subject has been discussed in the medical journals on more than one occasion during the past century. In 1859 a correspondent to the *Lancet*¹ asked: "Non-graduated licentiates of the London College of Physicians being by courtesy styled 'Doctor,' may not the recently-elected licentiates of the Edinburgh College of Physicians so style themselves?"

The *British Medical Journal*² reported that under legal authority the College of Physicians of Ireland had assumed the right of giving the title of doctor to their fellows and licentiates (the legal authority being the Attorney-General for Ireland and the Solicitor-General for England). Again in 1862 the *Journal*³ gave its opinion that, "as regards the prefixing of Dr. before his name, we believe that any individual can do so with impunity." Correspondence on the subject, both in the *Journal* and the *Lancet*, continued to appear sporadically until 1874, when it was summarized in a leading article in the *Journal*.⁴ The difficulties of obtaining the M.D. degree by those who were otherwise qualified to practise were pointed out, and suggestions were made to remedy them. It further pointed out that "if the public choose to style every gentleman legally qualified to practise medicine or surgery by the title of Doctor, that is the public's own affair. Those only who hold the degree of M.D., obtained by examination, and not by purchase, are really entitled to it." The fact remains that the use of the title "doctor" is not controlled by any of the Medical Acts or by other legislation. It has by common practice become generally used by those duly qualified to practise medicine, whether or not in possession of a university doctorate.

The use of the title M.D. is another matter. Section 40 of the Medical Act, 1858, while not forbidding practice by the unqualified, attempts to enable the public to distinguish between qualified and unqualified practitioners. It prescribes penalties for the unlawful use of certain well-recognized titles, of which doctor of medicine is one, or any description implying that the user is registered under the Act. Even those entitled to use such a qualification may be prosecuted if they are not in the *British Medical Register*, and if such use is intended to represent that they are.⁵ The Medical Act, 1950, raised from £20 to £500 the

fine that may be imposed on a person wilfully and falsely holding himself out to be a registered medical practitioner.

Comedones in Infants

Q.—I have recently seen a breast-fed infant of 5 months who had numerous minute comedones on both cheeks. What are their cause and treatment?

A.—It is not at all unusual for comedones to be present on the face of a very young infant, being symmetrically distributed on the nose and around the naso-labial folds. Unless they become inflamed it is probably best to leave them alone, for they will disappear without treatment in a short while. It seems likely that they have a somewhat different cause from the blackheads which are seen in adolescent acne (though the precise cause of the latter is by no means understood). The greasy skin and comedones seen in infants have been likened to a sort of miniature puberty.

Isopropyl Alcohol

Q.—Can isopropyl alcohol be used as a substitute for methylated spirits or industrial alcohol for hospital purposes? It is readily available, not dutiable, and cheaper than ethyl alcohol.

A.—Isopropyl alcohol is a colourless liquid which boils at 82° C. When used undiluted it is in some ways preferable to 70% ethyl alcohol as an antiseptic both for metal instruments, which tend to rust less, and for the skin, to which it is said to be less irritant. When taken by mouth it is about twice as toxic as ethyl alcohol and has an unpleasant and mildly nauseating odour and taste. Although it is not subject to duty, its use is governed by the Isopropyl Alcohol Regulations, 1927, and those who manufacture, sell, or use it must render returns to the Customs and Excise authorities.

Vitamin B and Flatulence

Q.—Is there any known association between the oral administration of vitamin B and flatulence?

A.—When vitamin B is taken as live yeast or as yeast tablets, some of which contain a certain amount of live yeast, fermentation may occur if the conditions in the alimentary tract are favourable, and this could produce flatulence. The vitamins of the B group could not, however, have this effect when administered in the pure state.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from your bookseller.

THE PLACE OF THE HOSPITAL IN A NATIONAL HEALTH SERVICE*

BY

Sir ALLEN DALEY, M.D., F.R.C.P., D.P.H.

I must first express my deep gratitude to the President and Censors for doing me the honour of inviting me to deliver the Croonian Lectures this year. I recognize my inadequacy when I see the long line of distinguished men going back for over 200 years who have preceded me in this lectureship. All except one—and he had outstanding qualifications to speak on his subject of "Professional Freedom"—have been eminent clinicians or laboratory research workers. My role has been that of the medical administrator whose main purpose has been to provide the tools, and persuade hard-headed finance committees to provide the money, with which clinicians and laboratory workers could undertake their best work. From that background and my special interest in preventive medicine I shall endeavour to put before you my reflections on some of the problems which confront us in the light of the first five years of the National Health Service and on the relationship of the work done by the hospital and specialist service to the other two pillars of the National Health Service: the general-practitioner service and the miscellaneous services provided by the local health authorities.

Definitions

We must first define our terms. The *O.E.D.*, after referring to the original meaning of "hospital" as a charitable institution for the aged (Chelsea Hospital) and for the education of the young (Christ's Hospital), says that in the current sense it is "an institution or establishment for the care of the sick or wounded or of those who require medical treatment." The definition of "hospital" in the National Health Service Act is longer and more specific. It reads that a hospital "means any institution for the reception and treatment of persons suffering from illness or mental defectiveness, any maternity home, and any institution for the reception and treatment of persons during convalescence or persons requiring medical rehabilitation, and includes clinics, dispensaries, and out-patient departments maintained in connexion with any such institution."

For the definition of "National Health Service" we must go to the preamble of the Act which established it. It simply states that it is an Act "to provide for the establishment of a comprehensive health service for England and Wales and for purposes connected therewith." This contrasts with the preamble of the first

National Health Insurance Act of 1911, which states that it is "an Act to provide for insurance against loss of health and for the prevention and care of sickness. . . ." I draw attention to the specific reference to prevention in the 1911 Acts and that prevention has been merged in the comprehensiveness of that of 1946.

Origins of Hospitals

An American author well known in this country, General Paul T. Hawley, now Director of the American College of Surgeons (Hawley, 1948), says: "It is scarcely an exaggeration to say that hospitals were set up for the primary purpose of abating a nuisance and that they were operated accordingly for many years. . . . The sick, the crippled, the insane—especially those unable to pay for private care—were public nuisances." But I am sure that General Hawley would agree that, both in this country and in his, it is probably true to say that purely humanitarian motives have provided the main-spring for the establishment and maintenance of hospitals within, at least, the last century. But the provision of "fever" hospitals was due to a desire to protect the public and to isolate the victims of infectious diseases because of fear of their spreading. Earlier examples were the "leprosaria" of the Middle Ages. Whatever the motives, the hospitals of to-day spring from four main sources.

It is not generally realized that the largest component in the number of beds is the group of hospitals for the mentally disordered and the mentally defective. One, the Royal Bethlem, has just celebrated its 705th anniversary. Along with St. Bartholomew's and St. Thomas's, it is among the five "royal" hospitals with whose administration the Corporation of the City of London was, at least until 1948, closely associated. The other mental hospitals were mostly provided by the local authorities or, their predecessors for this purpose, the justices of the peace.

In those days the purpose of mental hospitals was purely "custodial" and for the protection of society and of the lunatics themselves. In fact, it was only in 1930 that the term "lunatic asylum" was replaced by "mental hospital" and "lunatic" by "mental patient." Special institutions for the care and rehabilitation, where possible, of the mentally defective are a comparatively recent development. The next largest component originated in the sick bays of the "workhouses" or institutions of the boards of guardians. The guardians of the poor

*The first of the Croonian Lectures delivered before the Royal College of Physicians of London on July 7.

had the statutory duty to provide accommodation for the destitute, and in a considerable number of cases the destitution was caused by illness.

Many of the boards of guardians, and later the major local authorities who took over these functions from them in 1930, took their responsibilities for the destitute sick very seriously. Hospitals, some quite first-class, were built to replace the sick bays, and from 1930 many were administered under the Public Health instead of the Poor Law Act, with the result that "any inhabitant of the district" was eligible for admission, though always the "destitute sick" had a prior claim for admission.

The third most numerous group of hospitals, in the number of beds provided, was the then "voluntary" hospital group. Apart from the few ecclesiastical foundations they began to be established about 200 years ago. Many have just celebrated their first centenary. Most of the "cottage" hospitals are of even more recent foundation. The initiative in the establishment of a voluntary hospital usually came from a keen doctor or group of doctors who secured the interest of one or more wealthy laymen whose motives were purely humanitarian and philanthropic. It was felt that the sick poor should not be forced into the Poor Law hospitals or institutions, in many of which the medical services had lagged behind development elsewhere. Also, it was abhorrent to many of the respectable poor to have recourse to the "Poor Law," which at that time still adopted a "deterrent" policy. The voluntary hospitals had the great advantage over the public hospitals that, so long as their committees of management could find the money, they could develop as they wished, and if, as generally happened, the most capable doctors of that locality were on the honorary staff, the lay committees had the best medical advice at their disposal. It was therefore inevitable that when teaching of the science and art of medicine was systematized the voluntary hospitals undertook the training of medical students. There were, however, in 1948 only 23 general teaching hospitals in England and Wales, of which 13 were in London, and one of them, the Hammersmith Hospital for postgraduate teaching, was under municipal management. Many of the rest of the 930 voluntary hospitals were quite small and their financial and medical resources inadequate for the more complicated medical and surgical work. As a further development many voluntary hospitals during the past fifty years provided beds or even separate wings for paying patients. The voluntary hospitals were also pioneers in the training of nurses.

The fourth group of hospitals forming the pre-1930 complement consisted of those provided and administered by the local authorities. Most were hospitals for the acute infectious diseases, and only a few of these were large, well staffed and modern. This group also included a number of sanatoria and maternity hospitals.

Beginnings of a Hospital Service

In 1930, as already mentioned, the former Poor Law hospitals were transferred to the administration of the county and county borough councils, and there were, in effect, from then until 1948, and disregarding the few private profit-making hospitals, clinics, or nursing-homes, only two groups of hospitals: those maintained by public money raised from the rates and the independent voluntary hospitals. Some of the voluntary hospitals received public money from local authorities for "services rendered"—for example, by providing special clinics for venereal disease or for school-children. Before 1930 the only attempts at providing a hospital service were limited to highly specialized fields—

namely, the mental hospitals of three or four large mental hospital authorities and the service of the Metropolitan Asylums Board, which provided fever hospitals, sanatoria, and hospitals for long-stay cases in children.

Even before the outbreak of the second world war in 1939 most voluntary hospitals were finding it hard to make both ends meet, and this would have been impossible had they not received substantial support from hospital contributory schemes.

The larger public authorities had during the period 1930-48 the opportunity of developing a complete hospital service as distinct from an agglomeration of separate and semi-independent units. They were encouraged by the Ministry of Health to dissociate them from the Poor Law, and to administer them under the Public Health Acts, and many did so. This provision of a service ensured that no inhabitant of their district who applied for, and was considered suitable for, treatment failed to obtain it in one or other of the authorities' hospitals. It enabled, also, special units, often of a research type, to be set up. Some of the more progressive authorities took full advantage of these opportunities and, despite the difficulties of the war period, a first-class public hospital service was in process of being developed. On the other hand, some local authorities had neither the resources nor the will to bring about major improvements. Their general hospitals were still being administered under the Poor Law Acts; their patients were mainly in the chronic sick group, and little was done to improve staffing, equipment, or buildings. In all areas, however, the public health and the preventive and hospital services were under the same local administration, and this ensured effective liaison and co-operation between the various services.

The War and its Aftermath: The National Health Service

The war, through the emergency hospital service and the various sector schemes, brought the two separate hospital groups—the local authority and the "voluntary"—more closely together. And the National Health Service Act of 1946, which provided for complete fusion of the local authority and the voluntary non-teaching hospitals, took them completely away from local government and placed them under central government control. The fourteen regional hospital boards nominated by the Minister of Health act as the Minister's agents and under the directions of his Ministry; they are the planning authorities for hospitals and the employers of consultants. The 400 hospital management committees, nominated by the regional hospital boards, are responsible for day-to-day administration of the hospitals within their group, but again subject to regulations made by the Ministry, and their money is obtained through the regional boards.

The teaching hospitals were also nationalized, but remained independent units, separate from the regional board system, and responsible direct to the Ministry of Health, but subject also to control by the regulations made by the Ministry. There are 36 boards of governors of teaching hospitals (14 London postgraduate, 12 London undergraduate, and 10 provincial undergraduate). As London is divided between four regional boards there are no fewer than 30 separate hospital administrative bodies operating within the areas covered by the single executive council for London and by the local health authority—the London County Council. By interchange of membership between boards of governors and regional hospital boards, there is some provision for co-operation between teaching and non-teaching hospitals, but it cannot be regarded as close co-operation such as occurs in Scotland, where the teaching and the non-teaching hospitals alike are administered by the regional hospital boards.

Reversal of Administrative Trends

Thus has come about the reversal of the general trend, which had been for decades to build up the administrative

responsibilities of the major local authorities—that is, the counties and the county boroughs—and to make them responsible for all public health, medical, nursing, and mid-wifery work, including hospital work, paid for by public money and operating in their areas. The administration of hospitals has been taken out of local government, and the Ministry of Health, to an increasing extent, undertakes executive responsibility and issues directives about the management and staffing of hospitals. This is in substitution, so far as local authority hospitals are concerned, for executive control by the local authorities and their officers. I will not enter into a discussion on which is the more tolerable method of control. There are advantages and disadvantages in each. But we must remind ourselves of the old adage that "whoever pays the piper calls the tune," and whoever supplies the money, whether the committee, as in former days, of a voluntary hospital or a public authority, whether central or local, must have the last word on how much money is available and how it should be spent. There is no escape from this, though the reins can be held more loosely in some administrations than in others.

It may here be mentioned, as a further illustration of the previous trend, that in 1928 the Royal Commission on National Health Insurance (National Health Insurance, 1928) recommended that the insurance committees responsible for "medical benefit" should be abolished and their work transferred to the county and county borough councils. This was for the purpose of consolidating the administration of all public medical work in the hands of the same local authority; but the 1946 Act disregarded this recommendation, and the executive councils, which have replaced the insurance committees, have even wider powers and authority than the former insurance committees, though by allowing local health authorities to nominate one-third of the committees it has been recognized that the work of the local health authorities and that of the executive councils has much in common and that they should operate over the same areas.

Distribution of Functions Within the National Health Service

There is no clear or logical line of demarcation in the present distribution of function between the three branches of the Service. By and large, preventive work falls to the local health authorities, but Newman pointed out so long ago as 1926 that "preventive and curative medicine are in intimate association," and "preventive medicine . . . embodies the whole of medicine as regards disease which is preventable especially in its beginnings rather than its end-results." A recent publication of the Public Assistance Department of Paris (*L'Assistance Publique*, 1953) puts the matter even more strongly. After referring to the important part which a hospital can play in the prevention of illness, and giving examples, it states that preventive and curative medicine should conjugate until they fuse. It continues: "La distinction entre la médecine préventive et la médecine curative apparaît, en effet, de plus en plus arbitraire. En réalité, la médecine est 'une.'" At the extremes of preventive and curative medicine they, of course, do not inter-mingle. Vaccination, for example, and immunization are clearly preventive, and the alleviation of symptoms in those afflicted with a mortal disease is neither preventive nor curative but simply remedial. But the early diagnosis and treatment of diseases which are curable, however, often prevent serious disabling or even fatal illness.

The isolation of those suffering from an acute infectious disease was introduced as a measure of preventive medicine for the purpose of preventing the spread of the disease, and in some instances—for example, smallpox—this still has validity, but in many infectious conditions all likely spread has taken place before the diagnosis has been made and the patient removed to hospital. Fever hospitals, therefore, for many years have derived their main value from the treatment given to the patients therein. But the spectacular

reduction in recent years in the incidence of epidemic diseases followed the discovery of their cause and, consequently, of their mode of spread, and the application of that knowledge. Is it too much to hope that, with increasing knowledge of the aetiology of the non-communicable diseases, dissemination and application of that knowledge will have equally happy results?

Tuberculosis—an infectious disease—is another example of the close relationship between preventive and curative medicine. Improvement of living and economic conditions for the individual, as well as for the community as a whole, is undoubtedly in the preventive field. So is educational work on early danger signals which should take the patient to the doctor. The searching for early cases among contacts and others should be regarded as a function of the authority for prevention just as it is in smallpox, but the mass radiography units have been transferred from the local health authorities to the regional hospital boards, presumably because it is they who employ all, or most, specialists in the public service.

An example may be given of a change which is not an improvement and which follows the thesis that hospitals are responsible only for patients for whom treatment is likely to be beneficial, and if no further benefit is likely they become the responsibility of the local health authority. This is a thesis which, though it may follow the statutes, is contrary to the public good. When the taking of steps to reduce the toll taken by tuberculosis was entrusted, before 1948, solely to the local authorities they provided institutional accommodation not only for the tuberculous, for whom treatment was likely to be productive, but also for the ambulant chronic sputum-positive patient who had no suitable home in which he could live. The institutions used were not elaborately equipped or staffed, but they made their patients comfortable and kept them out of harm's way. Very often such people live now in common lodging-houses.

The Metropolitan Regional Hospital Boards, with the concurrence of the Ministry of Health, have declined to admit, and are reluctant to retain, patients who are unlikely to benefit from further treatment, even though they are infectious. The local health authorities are therefore faced with the dilemma of leaving these people in common lodging-houses or providing hostels for them. When hostels are provided, the patients have, under the present law, to make a contribution towards the cost of their maintenance. Before 1948 no charge was made to such patients. As most of them have had free treatment in hospitals and as there is no power to require them to enter, or remain in, a hostel, it is not surprising that such places are difficult to administer and that the patients are reluctant to enter or remain in them.

The thesis that hospitals are to be provided only for those for whom treatment is likely to be beneficial is worthy of a further note. Some thousands of beds are provided by hospital authorities for the mentally defective, for whom the only therapy which can be provided is training and education. It will be remembered that the statutory definition of hospitals specifically mentions the mentally defective. Again, mild cases of smallpox are admitted, without question, to a hospital. No treatment is needed or provided, but only isolation. It seems a pity that, with these precedents, the chronic infectious tuberculous can be excluded unless they need treatment.

The divorce between treatment of the tuberculous and their rehabilitation at colonies such as Papworth and Preston Hall is another example of the difficulties which arise when artificial fences are erected in the course of what should be one process, under the same administration—namely, the restoration of a sick person to the working community. I am limiting my remarks here to the tuberculous, for whom treatment and training are so interlocked.

The working definition of these entitled to hospital care includes those who require constant nursing and regular medical care: this being the line of differentiation between

convalescent homes (hospitals) and recuperative holiday homes (local health authorities) and between the chronic sick (hospitals) and the aged and infirm (local welfare authority).

The Chronic Sick (Hospital Responsibility) and the Aged and Infirm (Welfare Responsibility)

The line of demarcation here also is by no means clear. Those responsible for the institutions to which admission is sought decide whether or not they will accept an individual patient, and there is no appeal to anyone who can give a binding decision when neither authority will have him and maintains that it is the responsibility of the other. There is the further complication that if the hospital authority accepts the patient no charge is made. If the local health or welfare authority does so, the patient is assessed to pay. But, however broad the dividing line, one must be fixed somewhere, as a hospital authority cannot be expected to provide accommodation for the aged and infirm, though when local authorities were responsible for both hospitals and welfare institutions the exact definition was not of great importance. There is much to be said for an arrangement which was common before 1948, but which does not accord with the present statute, under which the hospital provided medical, nursing, and pharmaceutical services for homes for the aged which were then called "public assistance institutions." The same doctor then decided when a patient should be transferred from the hospital to the institution, or vice versa.

With regard to patients at home, for whom the general practitioner has recommended admission to hospital, there always will be difficulty while the number of beds available falls short of the demand. A scheme started by Dr. E. B. Brooke, then of St. Helier Hospital, has much to commend it, though strictly it goes somewhat beyond the statutory provisions. He went to see the case in the patient's own home and met the general practitioner there. He was familiar with the local authority and voluntary services available, and, by appropriate use of them and of the hospital out-patient department facilities, the patient could often be looked after satisfactorily at home. At the Montefiore Hospital in New York City, Dr. E. M. Bluestone has developed a large scheme under which hospital consultant and other staff supervise the treatment of the chronic sick in their own homes. A suggestion has been made by the paediatric department of one London teaching hospital that many child patients could be spared the "psychological trauma" of separation from their mothers if the hospital services, including that of the paediatrician, were taken to the homes instead of the children being taken to the hospital. Any such schemes, however, for home treatment supervised by hospitals bring in the other two branches of the National Health Service, and there are so many different people with whom the matter has to be discussed and agreement reached that progress is slow.

Mention should here be made of the "half-way" houses for patients for whom an acute general hospital can do no more but whose nursing needs are such that they are unsuitable for a welfare home. They are regarded as part of the hospital organization, and so co-operation and selection of patients are easy. But, despite the generosity of the King Edward Fund and of the National Corporation for the Care of Old People in finding the capital for such places, there are not enough of them. In consequence many of these patients are in welfare homes and others remain in hospital. The latter are maintained free, the former have to pay a contribution towards their maintenance and, despite the reduced sickness benefit paid to long-stay hospital cases and to the fact that welfare cases are mostly pensioners—contributory or non-contributory—the patients themselves regard it as an anomaly and resent the differentiation. It is difficult to understand why the recommendation in the Beveridge report that a "hotel charge" should be made to hospital patients was never taken up.

Interlocking of Preventive and Curative Services

As a further example of the interlocking of preventive and curative medicine, the local authorities, 35 years ago, started clinics, mainly in general voluntary hospitals, for the diagnosis and treatment of venereal diseases. The patient was diagnosed, treated, and rendered non-infectious as speedily as possible, and this is probably the most important and effective method of reducing the incidence of these diseases. But education of the public, case-holding, and contact-tracing were also essential parts of the scheme. Except for education of the public, all these functions with their important preventive aspects are now largely in the hands of the hospital boards, which thus carry out important preventive functions. Further, doctors in the clinical field are to an increasing extent giving advice to their patients on how to prevent a recurrence of the illnesses for which they have been consulted. But Dr. Edwin L. Crosby, President of the American Hospital Association (International Hospital Federation, 1953), says, and the same applies to this country, "Education of the patient and his family while he is being treated in the hospital . . . is a relatively unexplored area that merits increasing attention."

I hope that I have made it clear that there can be no clean-cut line of demarcation between the work of hospital and health authorities so far as preventive and curative medicine are concerned. While hospitals may work primarily on the curative side, they carry out important preventive work. On the other hand, health authorities have a vital interest in much of the work of the hospitals, particularly when, as in their child welfare and school health work, they discover children in need of hospital treatment. In consultation with the family doctor, they refer them to hospital and so often prevent a minor condition developing, because of lack of early treatment, into something serious.

Local health authorities have, moreover, many important functions which have no direct concern with preventive medicine, however widely defined. These have been placed upon them because their boundaries are defined, and between them they cover the whole country. When Parliament imposes a duty upon them to provide a service everyone knows where the responsibility lies, and it cannot be evaded. This is very important in some instances, such as, for example, the taking into institutions of persons of disordered mind for whom care is needed for the protection of themselves or others. A duty of the local health authorities is to provide a 24-hour service of "duly authorized officers" who proceed at once to any place where it is alleged that there is a person of unsound mind who is in need of institutional care. In the mental health and mental deficiency services the officers of the local authorities find the patients and the hospital authorities are supposed to find the beds, but, at least the mental deficiency services, there is a lamentable lack of an adequate number.

The work of the "duly authorized officers" was formerly a duty of the, now abolished, relieving officers. Before 1948 these officers could also require a public hospital to admit any sick person from their area for whom hospital care appeared to be essential. He relied for advice on medical matters on the "poor law medical officer." The hospitals then served specified districts. Many think unfortunate that with the nationalization of the hospitals there is no longer any special obligation on individual hospitals to find room for the sick in their vicinity: nor, now, any local official who can require them to make room. I should, however, make it clear that in my experience there is little or no difficulty in finding a bed forthwith for an acute medical or surgical emergency. The difficulties arise in the long-stay or potentially long-stay cases, the tuberculous, the mentally defective, the chronic sick, and the aged. It would appear that the prospect of obtaining a bed decreases materially with advancing age.

Another utilitarian service provided by local health authorities is the ambulance service. The accident ambu-

lance service takes the patients to the hospitals—that is, it provides clients for the casualty or in-patient departments. The reverse occurs in the removal or transport sections of the ambulance service. Here, the hospital or the general practitioner orders the free ambulance or transport and the local health authority has to provide the vehicle and the driver and foot the bill, recovering, however, half from the taxpayers' money distributed by the Ministry of Health.

This criss-cross of administration under which one authority must look to another to carry out some of its functions—and few things can be carried to completion by the same administrative body from initiation to completion—is bound to lead to slowing down of action, increased paper work, and added expense.

Another function of local health authorities is to provide domiciliary nursing. The "ordering" of this, generally, is done by a general practitioner, or, for a patient about to be discharged, by a hospital. A similar service is that of "home" or "domestic" helps, but it is not a statutory duty of local health authorities to provide this service. It is only a "power" which Parliament says the local authorities may exercise if they wish. The local authorities, therefore, can in this service decline to comply with the wish of a general practitioner or a hospital that a home help be provided. In practice, however, it is unusual for such a request to be declined, though there may be difficulty in meeting it fully. From my recent visits to other countries I gather that this type of service under a public authority is unique to this country.

The Maternity Services

It is perhaps in the maternity services that interlocking of function between the three branches of the National Health Service is most pronounced. Hospitals can provide a complete antenatal clinic service for their booked patients, and, though they are asked by the Ministry of Health, following advice given by the Central Health Services Council, only to book patients who need a bed on obstetrical or social grounds—the latter being determined by the local health department—some hospitals accept all comers.

Local health authorities have the duty to provide a service of domiciliary midwives, and they also provide antenatal clinics. Sometimes hospitals send their booked cases to municipal antenatal clinics for intermediate supervision and the clinics send them back at the 36th week, or immediately on the occurrence of any abnormality. Hospitals can also ask the midwives or health visitors of the local authority to look up those who should have attended the hospital antenatal clinic but have defaulted in doing so. Some hospitals which are training schools for midwives have an extern department which is part of the local authority's midwifery scheme and paid for by it. Some expectant mothers still book a domiciliary midwife and leave it to her to call in a doctor, as required by the rules of the Central Midwives Board, should any abnormality occur. In this case the doctor is paid by the local health authority. On the other hand, the patient may book a doctor for the domiciliary confinement, and he may be either a general-practitioner obstetrician on the special list or the patient's own doctor. In either case he is paid by the executive council. The patient in these cases also has the services of a municipal midwife, who, again, may either act as a midwife, if the booked doctor does not attend the actual confinement, or as a maternity nurse if he does.

The patient may receive all her antenatal care from the doctor and the midwife or she may attend the municipal antenatal clinic for educational lectures, blood tests, antenatal exercises, and medical supervision as well. The hospital is concerned in these cases in that they may be sent there if any serious emergency arises, and maternity hospital provision in every area must take account of this contingent liability. Again, if post-partum haemorrhage or other serious mishap occurs, the hospital may be asked to send to the home the "flying squad." The domiciliary doctor also may at any time call in a specialist obtained from,

and paid for by, the hospital board, for a consultation at the patient's home. Those with a liking for tidy administration are horrified by this jumble of authority, but, despite it, the maternal mortality has been reduced spectacularly in recent years, and preventable deaths are very rare.

Almoners and Health Visitors

Another overlapping field concerns the work of hospital almoners and of the health visitors employed by the local health authorities. Now that almoners are no longer concerned with the assessment of means and the collection of money, and now that doctors are more alive to the part played by occupational, environmental, and economic factors in the causation and prognosis of disease, almoners are increasingly called upon by hospital staffs to supply information on these matters. On the other hand, the duties of health visitors as set out in the National Health Service Act, 1946, are: "Giving advice as to the care of young children, or persons suffering from illness, and of expectant and nursing mothers and as to the measures necessary to prevent the spread of infection." The Ministry of Health has expressed the view that, normally, hospital almoners should not pay home visits and that information needed about home conditions should be obtained from health visitors, who should be the family case workers.

Again, local health authorities have responsibilities for aftercare, and some, by agreement with hospitals, follow up in their homes and as helpers of the family doctor cases of gastric and duodenal ulcer and of diabetes discharged from hospital. Some mental hospitals employ their own psychiatric social workers to make home inquiries; others ask the local authorities to do so. Some institutions for the mentally defective have their own staff to supervise their patients out on licence: others use local authority staff.

Local education authorities have statutory responsibilities for safeguarding the health of schoolchildren. They must provide for routine medical examinations, and if treatment is found to be necessary they must see that the child gets it from a general practitioner, at a hospital, or at a school clinic. Yet some hospitals steadfastly refuse to pass information to the school medical officer about schoolchildren under their care, on the grounds either of inadequacy of clerical staff or of a breach of the doctor-patient relationship. All would agree that the parents' consent to the transmission of the information should be obtained, but when it is put to the parents that it is in the interests of the child's education refusal is extremely rare.

The above are only examples of the interlocking of the health and hospital services and of some of the difficulties, actual and potential, met with in the desire to achieve adequate integration. Having regard to the "oneness" of preventive and curative medicine, any attempt to allot only preventive services to local authorities and only curative to hospitals would be doomed to failure.

General Practitioners and the Hospital Service

The Scottish Health Services Council (1952) has recently examined and reported upon the relationship between the general practitioner and the hospital service. It refers to the method of appointment of specialists, and points out that it is now difficult, if not impossible, for the general practitioner, even with the requisite qualifications and experience, to obtain a post as a consultant. It also discusses the use made of the general practitioner in institutional midwifery and the absence of full facilities for the general practitioner to follow his patients into hospital. A fourth point is the difficulty of access by the general practitioner to the ancillary services provided by the hospitals, particularly those of the x-ray and pathological departments.

It recommends that the specialist establishment of a hospital should include provision for doctors who are engaged

partly in general and partly in specialist practice. They commend as part of a long-term policy the establishment of general-practitioner wards or blocks associated with general hospitals and the continuance of existing cottage hospitals. It also recommends direct access of general practitioners to hospital x-ray and pathological departments. A step forward, however, is the new provision by which consultants can be called in for a domiciliary consultation under the Act. This provides that personal contact between consultant and general practitioner which is so desirable.

It may also be mentioned here, with regard to the relationship between general practitioners and the local authority health services, that the Act has, on the whole, tended to make it closer, particularly as compared with the relationship with the hospital service, where the Act has severed the former bonds. The practitioner can be helped materially by several of the local authority services, particularly the home help, the home nursing, and the ambulance sections. There is an interesting development in a few areas where a health visitor is attached to a general practitioner, and this, again, may well forge a link between all the services at the local level. The attendance of the medical officer of health at meetings of the local medical committee has enabled each to understand, and appreciate, the problems of the other. On the hospital side, it would help to close the gap if, to an increasing extent, medical officers of health were co-opted on to the medical staff committees of hospitals.

The National Health Service: A Divided House

It is recognized generally that a weakness of the new service is the division of its administration into three separate compartments, and that it is essential that all who work in it should realize that there is only *one* National Health Service, that all proposals for development and change should be discussed with representatives of the other services, whose own work, in some way or another, is likely to be affected. Professor James M. Mackintosh in an address to the Royal Medical Society at Edinburgh in February, 1951, said: "In the entire Act there is no broad conception of a national health policy, only a fragmentation. It has failed because it has set a gulf between divisions which ought to have been brought together—the hospital, the general practice of medicine, and the public health service." Above all, there must be a regular exchange of information so that all concerned may be aware of what is going on and what is proposed, so that they can put forward their comments before it is too late.

All this means more and more time on paper work and attendance at committee meetings, but it is part of the price we pay for rationalization, nationalization, or whatever word we use for attempting to do things comprehensively and on a nation-wide or large scale. A committee of the Central Health Services Council (1952) spent many months in 1951 considering how the National Health Service could be more closely integrated and function as one service instead of three separate dominions. It gathered much information and it was clear that in some localities valiant attempts are being made to bring together for consultation and discussion representatives of the three branches of the Service. It was felt that this could best be done at the level of the hospital management committees, but this is not easy if the local government area contains several such committees or if the normal gathering-ground of the hospitals in the group covers several local government areas.

A Unified Service

Some may feel that the only logical solution of all these administrative difficulties is to have for each area one, and only one, body responsible for the administration of all three branches. This involves many difficult questions.

In the first place, should the administrative responsibility be in the hands of nominated or elected bodies? It is the general experience that nominated bodies have not the same

sense of financial responsibility as elected ones. Possibly because of this, hospital boards and management committees have been subjected to tighter and tighter control by the Ministry of Health.

Comparisons are sometimes drawn between the hospital service, administered locally by a multitude of boards and committees whose members are unpaid, and corporate bodies like the B.O.A.C., and the Coal, the Gas, and the Electricity Boards. They are reputed to be administered on more business-like lines and are given more financial freedom than are hospital boards. The late Viscount Dawson was attracted by an administration based on that of the B.B.C., and Dr. Stephen Taylor (1951, 1952) would administer the service by small boards of paid directors. Not everyone would agree that the corporate bodies mentioned have the advantages claimed, but the essential difference between the two types of service is that all the corporate bodies are revenue-earning. They all sell something, and, despite the shocks received by the taxpayers when they show a deficit which has to be provided from public funds, they are, at least in theory, supposed to pay their way and to cover their expenditure by revenue. The B.B.C., however, is now an exception, though at first it conformed to the general rule that it should be self-supporting. It does now receive subsidies for its foreign broadcasts, but even this may be regarded as a sale to the Government of services which could not otherwise be provided economically.

Financial Problems

Unless, as is most unlikely, there is a radical change in the basis of our hospital service and, as in the U.S.A. and in certain States of Australia, hospital revenue is derived from contributory schemes—voluntary or compulsory—and from patients direct, hospitals will always be a heavy charge on public funds. It would not be impossible to devise a scheme which would substitute a small nominated body for the Minister of Health and his officers and put it in charge either of the hospital and specialist service alone or of the whole of the National Health Service, give it a global sum which would have to be settled annually by Parliament, and tell it "to get on with the job." But it is extremely doubtful if this would accord with Parliamentary principles as applied to the expenditure of such vast sums of public money. Further, in my view, their stick would be heavier than that of the Ministry and used more often. Also, in my opinion, it would in the long run cost more for administration.

Before 1948 a not unsatisfactory balance was maintained between the aspirations of those who wished to extend and develop hospital services and what could be afforded on hospitals by the fact that the spenders of the money—that is, the hospital boards and committees—had to raise it themselves. In the case of voluntary hospitals the members had to look round for sources of increased revenue, and in the local authority hospitals, where the money came from the ratepayers, they had to subject themselves to the electorate every three years and run the risk of being turned out if they had been either too parsimonious or too extravagant. In any case they were subjected to searching questions about the hospitals at election, and, indeed, at any other time.

It was hoped when this service started that hospitals would be provided by the Ministry with adequate funds, not only for the maintenance but also for the development of the hospital service, and that considerable freedom would be given to hospital boards and committees in the way they were spent. This might well have happened if hospital costs had not risen steeply during the past few years. Incidentally, they have risen just as steeply in other countries. With these rising costs and the amount of money which Parliament can properly vote, having regard to the total national income and the competing claims of other national services, being not unlimited, financial control becomes imperative at least as regards the total bill. The extent to which it needs to be detailed depends on the

importance attached in a national service to all parts of the country being provided with the same type and range of service and to people doing the same job getting the same rate of pay, and having the same conditions of service, and on staffing ratios being reasonably similar in comparable hospitals. Organizations representing staff insist on at least minimum rates of pay negotiated nationally for the same job, and the Ministry, as the paymaster, not unnaturally desires uniformity so that special rates of pay given to a particular individual may not be used as a bargaining-point for a general all-round increase.

Capital expenditure has had to be curtailed because of the licensing system, necessitated by the shortage of money, building materials, and building labour. One last point on finance which I have heard on my travels abroad is that unless rising hospital costs can be curbed, hospitals, except for the most serious illnesses, and then for the shortest possible length of stay, will almost price themselves out of existence, as neither the public nor any private purse will be able to afford them. There is little wonder that increasing attention is being paid everywhere to schemes for keeping people out of hospital and caring for them, whenever possible, at home.

All the above has a bearing on the question I am discussing—namely, should the administration of the three branches of the service be combined and should the local control be in the hands of nominated or elected bodies? If the administration of the three branches is combined—which, as I have indicated, would remove many anomalies—it could function only through nominated bodies if the whole charge were met from Government sources. If the rate-payers' money is involved, then, under our system of local government, elected representatives who are empowered to levy a rate must be included. It should be mentioned here that bodies nominated by the Minister, in effect appointees of the Minister, cannot bring pressure to bear on a Ministerial department to the extent that an independent elected body can, particularly if it is spending its own money and not entirely that of the Minister. There is a stronger case for a nominated body if the hospital service is to remain separate from the other two branches.

Local Government

The removal of the personal health services from local government would, however, be a very serious matter. Speaking quite generally, the local authorities have made a success of their health services, in which they have taken a deep interest. The occasional failure receives the headline; the success goes unnoticed. Another very important branch of local government work is the education service, of which the school health service is an integral part. It also makes a substantial contribution to the health of a very important age group. The school health service is outside the National Health Service, and the removal of the latter service to an independent body, outside local government, would be a major disaster to the education service. The anomaly of separate administrations dealing with the health problems of children under school age and of school-children, against which a Royal Commission reported in 1926, would be revived. It must be remembered that the school health service involves not only the routine medical examination of the children but also the selection of children for special education, and advice on school buildings, school furniture, and school meals.

It is essential also that the new children's departments dealing with orphans and neglected children and the welfare departments dealing with the aged and infirm and with handicapped persons should have expert medical advice readily available. In fact, there are few departments of local authority work which do not call on, from time to time, the medical officer of health for his advice. Sometimes the advice is unpalatable, but it is accepted from their own trusted officer when it might not be if it came from an officer employed, and paid, by the Government. All this is apart from the duties of the local health officer in connexion with the control of epidemics and environmental

hygiene. If the present health services of local authorities were transferred to a new organization of nominated members deriving all their money from Government sources, a major part of the scaffolding of local government would fall and incidentally there would be little or no case for local authorities employing whole-time trained health officers and medical administrators. Even if they did, the scope of the duties would be unattractive compared with other opportunities in the field of medical administration. Further, administrative difficulties which are not quite germane to our subject, and therefore will not be pursued, would arise if the work of the executive councils were transferred to a similar nominated body.

The answer, then, to the question whether the three branches should be combined and administered centrally by the Ministry of Health and locally by nominated bodies is that it would be inadvisable.

Local Administration by Elected Bodies

Next, let us turn to the possibility of their local administration by bodies wholly or partly elected. It will be assumed that there should be nominees of the professional interests concerned, though this is a departure from normal administrative procedure in this country, where, until 1948, professional experts were advisers, and not members, of the body which was in financial control and which determined policy. This is still the procedure at central and local government levels, though most local health authorities co-opt a few professional members on their health committees. It is interesting that the professional groups who insisted, and in the circumstances of the time did so properly, on being represented on every committee dealing with hospital work now complain of the long hours they have to spend attending committees to the detriment of their professional work.

A point against elected bodies for the control of hospitals is that there are invaluable members of hospital boards and committees who belong to no political party, who would decline to submit themselves to the electorate, and who would be unable or unwilling to take part in the general work of local authorities. Provision, therefore, would have to be made for the co-option of at least some of them. There are, on the other hand, many members of local authorities who are intensely interested in hospital and health problems and are prepared to devote much time to committee work. Some of these are giving, under the present organization, active and valuable service to local authorities as elected members, and to hospital boards and committees as nominated members.

Local health authorities now nominate one-third of the members of executive councils. If they were able to nominate a proportion of the members of a new body administering all three branches of the National Health Service, it would help to ensure that local opinion could be expressed by those who had, at least, the confidence of those who had elected them to the local authority. Moreover, it would help to bring the two administrations—local authority and the health services—more into alignment and might lead to the local medical officer of health holding a joint appointment, carrying out for the local authority, as their own officer, the various duties outside the National Health Service which would remain with them and, for the new authority, the duties which would be transferred to it, and which up to then would have been under his direct administration. If the money were not all provided centrally, that portion of the budget represented by services financed, partly or wholly, by the local rates would have to be submitted to the finance committee of the local authority concerned.

The conception of an *ad hoc* body elected specially by popular vote, and with power to precept on local authorities, for the administration of the combined service can be ruled out. The school boards and the boards of guardians, elected on such a basis, have now both disappeared. John Stuart Mill (1861) says "that there should be but one elected body

for all local business, not different bodies for different parts of it. . . . The local, like the national, Parliament has for its proper business to consider the interest of the locality as a whole." Except for later ideas involving two-tier government, as in county council areas, he is probably right.

[The second lecture, together with a list of references, will appear in our next issue.]

STAPHYLOCOCCAL INFECTION OF THE NEWBORN*

During the neonatal period minor staphylococcal infection is a frequent occurrence. The recorded incidence of such infection depends so much on the criteria adopted and on the care with which minor septic lesions are looked for that a close comparison of published figures is of limited value. The wide variation in recorded neonatal skin and conjunctival sepsis rates in

TABLE I.—Reported Neonatal Skin and Conjunctival Sepsis Rates in Maternity Units

Author	Period	Skin Sepsis	Conjunctivitis

Eastern General Hospital, 1951	1951	2.3%	4.2%

various maternity units in this country is shown in Table I. These figures do not refer to staphylococcal infection alone, but this is responsible for most of the skin and conjunctival sepsis in the neonatal period. Henderson (1948), for instance, has shown that the incidence of staphylococcal infection in neonatal conjunctivitis is approximately 80%. We have found, from 100 consecutive swabs from septic lesions of the skin and conjunctiva, that where an organism was isolated the incidence of staphylococcal infection was 91%. No growth was obtained from 18 swabs.

In the two main maternity units in our group of hospitals births numbered 1,093 and 1,296 respectively during 1951 and the sepsis rates given are derived from the routine records on the baby charts. An attempt is made to record all septic lesions, no matter how small.

*Based on a paper delivered to the Scottish Paediatric Society on June 13, 1952, by Dr. Forfar.

No deaths from staphylococcal sepsis occurred during the lying-in period, but one baby (Case 3) was re-admitted to hospital and died from staphylococcal infection, almost certainly acquired during his stay in one of the maternity units.

Most neonatal staphylococcal infections are trivial and short-lived, but they are potentially dangerous. A few years ago penicillin provided a weapon with which the severer types could be successfully treated, and its use soon spread to the treatment of minor lesions and even to prophylaxis (Wallace, 1947; Muhl, 1949). In recent years the emergence of resistant strains has rendered penicillin ineffective in the treatment of many staphylococcal lesions. There is a rising incidence of such strains (Barber, 1947; Barber and Rozwadowska-Dowzenko, 1948), particularly in hospitals (Forbes, 1949; Rountree and Thomson, 1949; Barber et al., 1949). The newer antibiotics aureomycin and chloramphenicol have so far provided effective therapy in most resistant infections (Banks, 1952; Lancet, 1952).

It is the purpose of this paper to report several cases of serious staphylococcal infection in the newborn in which resistance to antibiotic drugs played an important part, to record a few observations on the background of staphylococcal carriage and infection in one of the maternity units from which some of the cases arose, and to draw attention to some of the problems of diagnosis, of management, and of treatment which such staphylococcal infections raise.

Case 1

A baby girl, born in a nursing-home, birth weight 5 lb. 10 oz. (2.55 kg.), was admitted from her own home to hospital at the age of 4½ weeks with a swelling of the left upper arm of three days' duration. This had been accompanied by pyrexia, and on the day before admission she had been given 200,000 units of penicillin.

On admission a purulent discharge from the left eye was noted. No growth was obtained from an eye swab. No other septic lesions were found. The white-cell count was 6,000 per c.mm. Radiological examination of the affected humerus showed osteomyelitis with patchy destruction of the lower end. Intramuscular penicillin, 100,000 units three-hourly, was given.

On the following day an abscess had formed and was incised, a large amount of pus escaping. On culture a profuse growth of *Staphylococcus aureus* sensitive to penicillin, streptomycin, aureomycin, and chloramphenicol was obtained. Despite the continued administration of penicillin the pyrexia persisted and the child's condition deteriorated. On the third day after admission she developed a cough, rapid shallow respirations, moist sounds at both bases, and a slight haemoptysis. An x-ray film of the chest showed consolidation at both bases. The white-cell count was 19,200 per c.mm. Aureomycin, 250 mg., and chloramphenicol, 125 mg., six-hourly, were begun.

Two days later pus from the wound in the left arm grew on culture a coagulase-positive *Staph. aureus* resistant to penicillin but sensitive to streptomycin, aureomycin, and chloramphenicol. At this time an abscess developed in the left parieto-occipital region. This required incision after 48 hours, and appeared to have arisen from infection of the underlying bone. A coagulase-positive *Staph. aureus* highly sensitive to streptomycin and chloramphenicol, moderately sensitive to aureomycin, and resistant to penicillin, was grown.

Penicillin was given for 17 days after admission. Treatment with aureomycin and chloramphenicol was continued for almost a month on account of several relapses of respiratory infection. After a period of two months the child had

improved considerably and was discharged home. Radiologically, several post-pneumonic pneumatoceles still existed. The humerus had almost completely re-formed.

Comment.—Conjunctival sepsis may have been the original focus of infection in this case, which illustrates the widespread metastatic dissemination which staphylococcal infection in the newborn may undergo. The staphylococcus isolated from pus drained from the original abscess of the left arm was penicillin-sensitive. Four days later pus from the same source revealed a penicillin-resistant organism. Presumably two strains of staphylococci, a penicillin-sensitive and a penicillin-resistant, were present initially, as resistance could hardly have developed within four days. Growth on culture of the sensitive organism only, created a false sense of security, and although penicillin rapidly removed this strain it produced no clinical improvement. The response of the original osteomyelitis to chloramphenicol and aureomycin was satisfactory, although these drugs did not prevent further progress of the infection to the scalp. They produced no dramatic improvement in the chest infection, but it seems doubtful whether the child would have survived without them.

Case 2

Birth weight 8 lb. 9 oz. (3.98 kg.). Condition satisfactory at birth. Discharged home after ten days. Two weeks later paronychia was noted on several fingers of each hand and local treatment with gentian violet was given. Three weeks later a septic spot on the right arm developed into a subcutaneous abscess. Three days thereafter her breathing became distressed.

Now 6 weeks old, she was admitted to the children's unit acutely ill with severe dyspnoea, high fever, clinical evidence of pneumonia, and a pleural effusion. Diagnostic aspiration showed thin yellow pus. The white-cell count was 21,000 per c.mm. Penicillin was given, but next day the temperature rose higher and the effusion had increased. Penicillin, 50,000 units, was injected into the pleural cavity. Culture of the pleural fluid showed the presence of *Staph. aureus* resistant to penicillin and streptomycin but sensitive to aureomycin and chloramphenicol. She was then given aureomycin, 500 mg. daily. This produced constitutional improvement, but further chest aspirations and finally open drainage were required.

Thereafter gradual re-expansion of the lungs occurred, and was complete three months after the illness started. At that time the baby's health was excellent.

Comment.—On admission to the children's medical ward the diagnosis of empyema was made, but it was not appreciated that the infection could be traced back to staphylococcal skin sepsis immediately after discharge from a maternity unit. Consequently, valuable time was lost before effective antibiotic therapy was instituted. The final result was satisfactory, yet it seems likely that immediate treatment with aureomycin or chloramphenicol might have resulted in a much less serious and prolonged illness.

Case 3

A baby boy, birth weight 6 lb. 1 oz. (2.75 kg.), was discharged home on the ninth day, gaining weight. On the twelfth day slight conjunctival injection was noted in the right eye. The next day the eye was swollen and a purulent discharge appeared at the right nostril. The family practitioner began injections of procaine penicillin, 300,000 units daily. These were continued for five days without improvement. At the end of this time the left arm was thought to be paralysed. No signs of toxæmia were noted.

Now 18 days old, he was readmitted to hospital. The right eye and cheek were swollen and dusky with abundant purulent discharge from the left nostril. Over the inner aspect of the right ankle there was a fluctuant swelling. The left upper arm was swollen. Deep subperiosteal oedema could be detected with some difficulty. No radiological evidence of bone destruction was found. Pus obtained from the nose and ankle grew *Staph. aureus* sensitive to strepto-

mycin, chloramphenicol, and aureomycin and slightly sensitive to penicillin. Chloramphenicol was given before this result was available, and as the immediate clinical response was excellent it was continued. Three days after admission a subperiosteal abscess over the left humerus required incision. Antibiotic therapy was stopped on the eleventh day. Within 24 hours an acute relapse set in, involving all the previously affected areas. An x-ray film now showed gross destruction of the left humerus and some destruction of the right maxilla. Chloramphenicol again effected rapid improvement. Further sensitivity tests confirmed the original findings.

Progress, though slow, was satisfactory for four weeks. A persistent slight nasal discharge, however, suggested that the maxillary infection had not been entirely overcome, and after 28 days' continuous treatment with chloramphenicol an acute re-exacerbation occurred. A nasal swab grew *Staph. aureus* which was still reported sensitive to chloramphenicol. Aureomycin (125 mg. every six hours) was substituted for chloramphenicol, and improvement occurred within 24 hours. This treatment was continued for three weeks until repeated nasal swabs showed no evidence of staphylococcal infection. A solid involucrum formed over the left humerus and the patient was discharged home gaining weight and with full movement of the left arm. Routine surveillance over the next eight weeks showed satisfactory progress. At the end of this time he was readmitted to the ward with a reactivation of his humeral infection. The sensitivity of the *Staph. aureus* cultured remained as before and there was a rapid response to aureomycin.

Comment.—With an effective antibiotic it is unlikely that the initial infection would have undergone such widespread dissemination or that local bone destruction would have been so extensive. The rapidity of the relapse when chloramphenicol was stopped after 11 days suggests that large numbers of viable staphylococci were still present despite the absence of clinical evidence of activity for seven days, and is a warning against too early cessation of therapy with a drug which is bacteriostatic. The second relapse after 28 days' continued treatment emphasizes that even a sensitive organism may persist unhindered in abscess cavities.

Case 4

A baby boy, birth weight 7 lb. 10 oz. (3.4 kg.). On the third day, on account of suspected early respiratory infection, he was given chloramphenicol, 350 mg. daily, and this was continued until his discharge on the fourteenth day, when he appeared well. The cord had not completely separated.

Three days later he was readmitted on account of sudden anorexia and apathy. He was pale and listless. No cry could be elicited. No enlargement of liver or spleen was noted. The umbilicus was encrusted with a recent blood-stained discharge, but there was no exudate. The white-cell count was 4,800 per c.mm.

Chloramphenicol was started immediately—350 mg. daily, divided into four doses. During the next day he seemed somewhat improved, but the rectal temperature, which was 99° F. (37.2° C.) on admission, rose to 102° F. (38.9° C.). Two days after admission the respirations became a little distressed. The liver now appeared slightly enlarged. During the night the baby was found dead.

Post-mortem Examination.—Phlebitis of the umbilical vein was present with multiple abscesses throughout the liver. There were septic infarcts in the lungs, kidney, and heart; the latter involving a large coronary artery and resulting in severe muscle necrosis. Culture of various abscesses produced *Staph. aureus* resistant to penicillin, slightly sensitive to aureomycin, but markedly sensitive to chloramphenicol and streptomycin.

Comment.—The pathological findings suggest that infection originated from the umbilicus and spread via the umbilical vein. This spread must have developed during the time chloramphenicol was being given. In the presence of a

sensitive organism chloramphenicol was administered for 14 of the 19 days which this infant lived, and it must be concluded either that a dosage of 50 mg. per lb. (110 mg. per kg.) daily was incapable of maintaining adequate tissue levels or that on this occasion there was present a degree of *in vivo* resistance which the *in vitro* test did not reveal. That gross visceral infection may develop in the newborn without distinctive clinical signs and without leucocytosis was well illustrated.

Case 5

Birth weight 8 lb. 13 oz. (4 kg.). On the sixth day a purulent conjunctival discharge was noted, and culture produced *Staph. aureus* resistant to chloramphenicol and penicillin, but sensitive to aureomycin. Treatment was started with aureomycin, 500 mg. daily.

On the twelfth day, aureomycin therapy continuing, an abscess had developed in the left breast which on incision was found to originate from infection of the underlying rib. Culture produced a *Staph. aureus* sensitive to both chloramphenicol and aureomycin. The continued use of aureomycin was attended by prompt recovery.

Comment.—It is likely that two separate strains of staphylococci were involved in the initial infection, since it is unlikely on present evidence that a resistant organism could lose resistance to chloramphenicol within six days. The presence of two separate foci of infection strongly suggests blood spread, which, despite *in vitro* sensitivity to aureomycin, progressed while this drug was being given.

Case 6

Born by caesarean section at full term; birth weight 5 lb. 1 oz. (2.3 kg.). Some slight discharge from the eye was noted after twenty-four hours.

On the eighth day a few small pustules in both axillae and over the shoulders and a deep firm mass on the left side of the neck appeared. Chloramphenicol was started, 350 mg. daily. Despite treatment the mass increased in size and became fluctuant. Aspiration produced thick pus from which *Staph. aureus* resistant to chloramphenicol and penicillin but moderately sensitive to aureomycin and streptomycin was cultured. Aureomycin was given in a dose of 250 mg. daily, and with occasional further aspiration the abscess healed.

Comment.—Clinical chloramphenicol resistance was confirmed bacteriologically.

Bacteriological Studies

During the period when the majority of the clinical infections reported here occurred a limited number of tests were performed to identify the frequency and distribution of various types of staphylococci. In one of the maternity units concerned routine umbilical swabs were taken from the cord stump as soon as this separated, nasal swabs were taken from all the medical and nursing staff, and cultures were obtained from all cases with clinical infections, however benign, and sensitivity tests made. These results are presented in Tables II, III, IV, and V. The sensitivity tests were carried out with the impregnated disk technique described by Gould and Bowie (1952) modified in respect of the concentrations of

Clinical infection (infants)	76.6%	12.5%	17.4%	4.5%

antibiotics. The concentrations used were as follows: aureomycin 25 µg. per disk; penicillin, 1 unit per disk; streptomycin, 10 µg. per disk; chloramphenicol, 10 µg. per disk.

Results are expressed 0, 1, 2, or 3, corresponding with the diameter of the zone of inhibition: 0 represents resistance to the antibiotics in the concentrations noted above; 3 represents a high degree of sensitivity. The correlation between reported degrees of sensitivity, the size of the zone of inhibition, the coefficient of resistance of the tested organism, and the minimum inhibitory concentration of antibiotic is shown in Table VI.

During the period under review the staff nasal carriage rate for coagulase-positive staphylococci was 53%. Similar figures have been published for other units: 53% by Rountree and Thomson (1949), 50% by Felsen *et al.* (1951), and 56–68% by Barber *et al.* (1949). The percentage of nasal carriers of penicillin-resistant coagulase-positive staphylococci among the staff (16.3) compares with other figures 0–32% (Rountree and Thomson, 1949) and 40–54% (Barber *et al.*, 1949). Our figures for resistance refer only to organisms wholly resistant by the standard tests.

Our umbilical staphylococcal carriage rate of 60% for coagulase-positive organisms compares with neonatal carriage rates of 62% in the nasopharynx (Martyn, 1949) and 54% in the conjunctiva (Barber *et al.*, 1949), while the percentage of penicillin-resistant umbilical carriers (38.9%) compares

TABLE VI.—Approximate Relationship Between Conventions Used in the Text and (1) Coefficient of Resistance (Sensitivity of N.C.T.C. 6571 Staphylococcus/sensitivity of Tested Organism). (2) Minimum Inhibitory Concentration (µg./ml.)

Antibiotic	Degree of Sensitivity	Zone Diameter (mm.)	Coef. Resist.	Min. Inhib. Conc. (µg./ml.)
Aureomycin disk ≡ 25 µg.	3	>20	<4	<1
	2	12–20	4–40	1–10
	1	6–12	>40	>10
Chloramphenicol disk ≡ 10 µg.	3	>18	<1.6	<2
	2	13–18	1.6–7	2–10
	1	6–13	7–20	10–30
Penicillin disk ≡ 1 unit (1 unit = 0.6 µg.)	3	>20	<5	<0.15*
	2	12–20	5–20	0.15–0.6*
	1	6–12	20–50	0.6–1.5*
Streptomycin disk ≡ 10 µg.	3	>19	<3	<1.5
	2	12–19	3–10	1.5–5
	1	6–12	>10	>5

* Penicillin minimum inhibitory concentration expressed in units per ml. Conventions used: 3, highly sensitive; 2, moderately sensitive; 1, slightly sensitive; 0, resistant.

In the case of aureomycin and chloramphenicol the term "slightly sensitive" can be seen from the table to be equivalent to a minimum inhibitory concentration of over 10 µg. per ml. As serum levels greater than this are not normally attainable, these antibiotics are unlikely to be effective, when used systemically, against an organism reported as "slightly sensitive." With penicillin and streptomycin, however, the fact that an organism is reported as only "slightly sensitive" does not necessarily exclude the possibility of effective systemic treatment.

with a nasopharyngeal rate of 34% (Martyn, 1949) and a conjunctival rate of 43% (Barber *et al.*, 1949) for such organisms.

Of the staphylococci isolated from clinical infections 76.6% were penicillin-resistant. This compares with the reported figures of 53% (Rountree and Thomson, 1949), 53.4% (Rountree *et al.*, 1951), and 50% (Summers, 1952), for hospital staphylococcal infection in general.

A comparison of the antibiotic resistance of organisms isolated from adult staff, from routine umbilical swabs, and from clinical infections reveals a close correspondence between the latter two groups (Table V). This would suggest that in the production of septic lesions cross-infection within the nurseries is more important than infection from the staff.

Penicillin resistance is well recognized. Chloramphenicol and aureomycin resistance are so far much less common. The percentage of aureomycin-resistant organisms here agrees with the previous reports of Long *et al.* (1950) and of Fairbrother *et al.* (1951). Aureomycin has not been used nearly so extensively in this unit as chloramphenicol. Lowbury *et al.* (1952) have shown that the administration of aureomycin in a burns unit produced in a period of six months a rising incidence of aureomycin-resistant organisms and an increase in the degree of resistance of these organisms. They also showed that the routine oral administration of aureomycin did not reduce the nasal carriage rate of staphylococci, and that the percentage of aureomycin-resistant organisms among these staphylococci increased.

Only 12.5% of clinical infections were resistant to streptomycin. This drug thus retains its value where a bactericidal effect is required. On account of the speed with which resistance may be acquired we have used it rarely, and only in the presence of serious sepsis.

Dosage Employed

Throughout the period under review the dosage of antibiotics used has been standardized. Penicillin has been given by intramuscular injections of 50,000 or 100,000 units at intervals of four or six hours, according to the clinical indications. Depot penicillin has not been used.

We have given streptomycin (0.5 g. daily) by intramuscular injections at intervals of six or twelve hours.

Chloramphenicol and aureomycin have both been given by mouth as powder freshly removed from the capsule in a dosage of 50 mg. per lb. (110 mg. per kg.) daily. Adequate serum levels have been found previously with a dosage of 11 mg. per kg. daily of aureomycin and 44 mg. per kg. daily of chloramphenicol (Hunt *et al.*, 1950). These and other studies (Ross *et al.*, 1952) confirm that in young children such dosage can be expected to produce serum levels of 10 µg. per ml. even during severe infections. We lack knowledge of tissue levels in babies treated with the newer antibiotics. It would be of the greatest value in the proper assessment of therapeutic failure if these levels could be measured. We had supposed that free diffusion would occur to infected areas in bone, kidney, lung, and liver. Our present experience suggests that this is not necessarily so with the dosage used (Cases 3 and 4).

Discussion

The cases reported illustrate the dangers which may attend minor staphylococcal infection in the newborn. While the recognition of minor infection of the conjunctiva, the skin, and the umbilicus presents little difficulty, it may be difficult to determine when an infection has ceased to be local and external and has spread, as in Case 4, to involve deeper or more distant structures. In such cases the systemic response is often of value in differentiating a trivial infection from a more serious one. Inactivity, failure to feed, diminished crying, the onset of pallor, vomiting, and pyrexia, occurring in a baby who has suffered from minor staphylococcal infections are warning signs which should not be ignored. Where there is the possibility that the initial local infection has been overlooked or where an infant born in hospital has developed serious infection after returning home the awareness of the high incidence of minor staphylococcal infection in infants born in hospital and the knowledge that the majority of the staphylococci are penicillin-resistant should, in differential diagnosis, give serious staphylococcal infection its due place and should remind those responsible for treatment of the limitations of penicillin therapy.

In the control of antibiotic therapy the laboratory plays an important part, particularly in suggesting suitable treatment in individual infections both with regard to clinical result and to the avoidance of expensive drugs which may be ineffective. Broadly speaking, we have found that the *in vitro* assessment of antibiotic sensitivity has been paralleled by the clinical response to treatment with an antibiotic which was assessed as appropriate, but there have been individual variations to this, as in Cases 1 and 3. It is as well, therefore, to bear in mind the limitations of *in vitro* sensitivity tests and to be prepared to change the treatment on clinical grounds alone. It is often necessary, too, with an infection of the neonate to begin treatment before the bacteriological report and the result of sensitivity tests are available. Under such circumstances failure to respond to treatment is a much more significant clinical guide to the organism's sensitivity than rapid response, because of the frequency with which spontaneous improvement may occur.

On the basis of laboratory tests it is clear that resistance to antibiotics is an increasing problem, particularly in hospitals. There the high carriage rate of coagulase-positive staphylococci and the high incidence of drug resistance constitute a special danger to the peculiarly susceptible newborn baby.

From the point of view of therapy the frequent difficulty of judging the severity of clinical infection, the natural tendency of so many lesions to heal without treatment, the occasional lack of correspondence between *in vitro* sensitivity tests and *in vivo* response, the time lag before the result of the bacteriological examination becomes available, the occurrence of drug resistance, and the danger of ultimately inducing this make a logical approach difficult.

The prophylactic use of penicillin in hospitals had its advocates before the extent of resistance to it became so widely recognized. More recently it has been suggested that

aureomycin should be used in this way (Felsen *et al.*, 1951). In the knowledge of the dangers of drug resistance this practice can scarcely be justified.

The majority of minor staphylococcal infections heal without treatment. Records of such infections, and in particular accurate bacteriological data, may assume great significance in the light of any subsequent illness which the child may develop during the following weeks. For mild skin lesions antibiotic therapy is probably not indicated, local treatment with an antiseptic such as gentian violet usually being sufficient. With purulent conjunctivitis the position is rather different. The amount of infected pus to which such a lesion gives rise must be responsible for the heavy contamination of clothes, floors, dust, air, and personnel. There is thus a case for controlling such lesions as early as possible. We have found local therapy with sulphacetamide, chloramphenicol, or aureomycin eyedrops, instilled at minute intervals for 30 minutes and thereafter every half-hour for 36 hours, effective in the majority of cases. Most infections clear within a few hours, but stubborn infections may require more than four days' systemic therapy.

The development of more serious sepsis often occurs after the child has returned home, and confronts the general practitioner in the first place. When diagnosis is difficult the fact that a baby has recently been discharged from a hospital maternity unit should bring the possibility of staphylococcal infection to mind, and such infection becomes increasingly likely if he is known to have suffered previously from a minor staphylococcal lesion. When the diagnosis is not in doubt the difficulty may be in determining the severity of the infection.

In view of its widespread use penicillin will doubtless tend to be given early. Because of the synergism which exists between the two drugs there is a case for giving streptomycin in addition (Alexander *et al.*, 1950). These drugs produce a combined bactericidal effect, and if no improvement is manifest within 24 hours the baby should probably be admitted to hospital or treated with another antibiotic, such as chloramphenicol or aureomycin.

The ultimate disposal of such cases depends very much upon the hospital facilities available in the area. Where adequate facilities exist serious staphylococcal infection merits hospital admission without the delay incurred by a therapeutic test.

In hospital practice we now find that penicillin is only of very limited value in the treatment of neonatal staphylococcal infection, whereas chloramphenicol and aureomycin give satisfactory results. The fact that aureomycin and chloramphenicol are bacteriostatic drugs, however, is probably responsible for the relapses which may follow early cessation of treatment, as in Case 3, and which make it very difficult to decide on the length of time that treatment should be continued. Apparent cessation of activity as judged clinically is not necessarily an indication for stopping therapy, particularly in deep-seated infections such as osteomyelitis. Nor do the newer antibiotics abolish the necessity for surgical intervention in certain cases: this is still often necessary to eradicate foci of infection to which, on account of the poor blood supply, systemically administered drugs have little access.

There is evidence that the staphylococcus is beginning to acquire resistance to the newer antibiotics as it has done to penicillin. At present, however, the use of combinations of antibiotics and the introduction of new antibiotics are keeping pace with the development of drug resistance.

Summary

The incidence of skin sepsis in two maternity units was 2.3% in each case and of conjunctival sepsis 4.1% and 4.2%. Most of these infections were due to the staphylococcus.

Cases are described illustrative of the serious lesions which staphylococcal infection may produce in the neo-

natal period, and comments are made on these cases, with particular reference to drug-resistant organisms, to bacteriological control of therapy, and to the difficulties of diagnosis and management.

An analysis has been made of the antibiotic sensitivity of organisms isolated from 56 separate staphylococcal infections occurring in a maternity unit during the year 1951: 76.6% of these were resistant to penicillin, 12.5% to streptomycin, 17.4% to chloramphenicol, and 4.5% to aureomycin.

Nasal swabbing of the staff in this maternity unit showed that the carriage rate for coagulase-positive staphylococci was 53.0%, and out of these 30.7% were penicillin-resistant. None was resistant to chloramphenicol or aureomycin.

Routine swabs from the umbilicus just after the cord had separated showed that the infant carriage rate for coagulase-positive staphylococci was 60.0%, and that of these 64.4% were penicillin-resistant, 12.9% streptomycin-resistant, 30.0% chloramphenicol resistant, and 5.5% aureomycin resistant.

On the basis of relative drug resistance it is suggested that cross-infection may be more important in the production of neonatal staphylococcal lesions than infection from the attendant nursing staff.

Staphylococcal infections are discussed as they occur when the newborn infant is in hospital and when he has returned home. Particular reference is made to the significance of minor staphylococcal infection, to the importance of bacteriological investigation, to the type and dosage of antibiotic to be employed, and to the regimes of treatment which may be adopted under different circumstances.

We wish to thank the consultant obstetricians and the maternity and children's ward nursing staffs of the two hospitals concerned for their co-operation; Mr. J. J. Mason Brown for permission to quote Case 1; Professor T. J. Mackie and Dr. Helen A. Wright, Bacteriology Department, University of Edinburgh, for advice and facilities; and the university bacteriology technical staff.

The roll is for the guidance of local authorities and others responsible for appointing tutors in health visitor training centres.

A STUDY OF TWO UNUSUAL BLOOD-GROUP ANTIGENS IN WEST AFRICANS

BY

J. N. M. CHALMERS, M.D., M.R.C.P., D.P.H.

Clinical Haematologist, St. George's Hospital Medical School

ELIZABETH W. IKIN, B.Sc.

AND

A. E. MOURANT, D.M., D.Phil.

(From the Medical Research Council Blood Group Reference Laboratory)

In 1948 an investigation of the blood groups of Nigerian populations was begun and full ABO, MNS, and Rh genotype studies of some 550 Nigerians have been completed (Chalmers, Ikin, and Mourant, 1953). Early in this work two samples of blood—one from an Efik (Calabar) man and one from a native of the Cameroons—were found to be unusual. Both bloods were agglutinated by all available anti-N sera, but were agglutinated only by one out of several anti-M sera with which they were tested. This finding was briefly described by Ikin and Mourant (1951), who suggested that the antigen concerned might be identical with one described by Landsteiner, Strutton, and Chase (1934) as occurring in some American negroes.

Present Investigation

During the past two years we have been fortunate in getting generous samples of blood from one of the above-mentioned Nigerians, Mr. E. G. D. Henshaw, who is a laboratory technician in the Nigerian Medical Service, and who has been most helpful in this investigation, both as a donor and in arranging for the study of his relatives and other Nigerians.

It was not found possible by absorption of the exceptional anti-M serum with normal M cells to prepare a serum which was specific for the peculiar antigen, provisionally called the Henshaw, or He, antigen. It was therefore decided to give injections of the red cells of the original donor to eight previously unimmunized rabbits. After two courses of six daily injections each, all the rabbits were found to have made a specific anti-He antibody, readily separated by absorption with European A₁MN red cells from other antibodies present in the serum. After further courses of injections the titres of the sera of most of the rabbits rose and the sera gave clear-cut results by a tile technique, although the original tube technique was used wherever possible. A few further West Africans tested with the "new" antiserum gave positive reactions, and through the kindness of Dr. David Cannon and Dr. Andrew Kertesz, who sent us blood samples from Lagos, we were also able to show the presence of the antigen in several relatives of a person in whom it had previously been detected. At this stage we had already begun to suspect a connexion with the MNS blood-group system (Sanger, Race, Walsh, and Montgomery, 1948). It was therefore decided that one of us (J. N. M. C.) should make an expedition to West Africa in order to study the incidence and genetics of the antigen. Thanks to the local facilities given by various medical colleagues, it was possible to carry out tests with the anti-He serum on a series of 1,428 "random" blood samples from West African hospital patients and others, in Nigeria and the Gold Coast. Specimens from the majority of the positive reactors and from members of families of many of them were sent by priority air transport (with the kind co-operation of Sir Harold Whittingham, D.M.S., B.O.A.C.) to London for further investigations.

Shortly before this, through the kindness of Dr. Merrill W. Chase, we also obtained from America specimens of the rabbit serum prepared some 18 years previously by Landsteiner, Strutton, and Chase, together with samples of the red cells of the original negro propositus, Mr. C. Hunter, and some other positive reactors. The antigen described by the American workers has been named the Hunter factor (see Boyd, 1939) and is referred to subsequently as Hunter, or Hu. The serum, after absorption with European A₁MN cells, was found to be active and specific. The Hunter antigen was shown to be distinct from the Henshaw antigen. Specimens sent from West Africa to London were tested with anti-Hunter; there was insufficient of the serum to use for field work in West Africa.

The results of tests with the anti-Henshaw serum carried out on unselected Africans in Lagos, Calabar, and Kano (Nigeria), and Accra (Gold Coast) showed 38 positives in a total series of 1,428. This gives an overall frequency of the Henshaw antigen of 2.7% for this series. Positive reactors were found in many different tribes in both Colonies, but data on tribal incidence will not be considered in the present paper. Numerous members of the families of Henshaw-positive reactors were tested in the field with anti-Henshaw serum, but as tests with the anti-Hunter serum were carried out only in London, relatively few persons were tested with the latter serum, and of these only 138 could be regarded as unselected from the genetical point of view. Individuals so regarded were those from whom specimens were sent to London without any preliminary testing of themselves or their relatives, and those marrying into the families of selected He-positives but who would not themselves have been tested except for the fact of such marriage. Thirty of these people, or 21.7%, were found to be Hunter-positive. Owing to the relatively high general incidence of the Hunter antigen it was fortunately present in a large number of the African families selected for genetical investigation.

So far as the size and state of preservation of the specimens received in London allowed, they were also tested with anti-A, anti-A₁ where relevant, anti-B, anti-C, anti-D, anti-E, anti-c, anti-M, anti-N, anti-S, anti-s (generously supplied for the purpose by Dr. P. Levine), anti-P, anti-Lu^a, anti-Le^a, and anti-Le^b. Bloods positive with anti-E were tested with anti-e. The anti-C serum used actually had the specificity anti-C + anti-C^w; all specimens positive with this serum were tested with pure anti-C^w, but the results were uniformly negative.

Dr. Winifred Watkins, of the Biochemistry Department, Lister Institute, has examined the effect of periodate on the reactions of the Henshaw antigen as found on the surface of intact red cells, and has kindly allowed us to quote her results. Morgan and Watkins (1951) had previously shown that the M and N antigens, like the D antigen of the Rh system, are rapidly inactivated by periodate, whereas A, B, H, Le^a, and P are inactivated much more slowly. It has now been found that the Henshaw antigen, like M and N, is rapidly inactivated. The effects of periodate on the S and s antigens are unknown.

Relations to Other Antigens

From a consideration of the unselected material both from Africans and from African families there seems to be a close connexion between both the Henshaw and Hunter antigens and the MNSs system. There are no obvious relations with the other blood-group systems, but the material, together with further samples from "He-positive" families, is being analysed in detail for possible connexions. In this paper only relations with the MNSs system are considered.

Statistical Relations

In the course of this work and that which led up to it (Chalmers, Ikin, and Mourant, 1953) the MNS blood groups have been determined for a number of West Africans falling into three categories: (1) 326 Nigerians selected solely because of presumed unmixed Nigerian ancestry; (2) 33

West Africans, mostly Nigerians, selected as being Henshaw-positive; and (3) 26 West Africans, mostly Nigerians, selected as being Hunter-positive.

The results of these tests are shown in the Table. A few specimens from known Henshaw-positives and Hunter-

Incidence of the MNS Blood Groups in Unselected West Africans and in Henshaw-positives and Hunter-positives

MNS Phenotype	Unselected Nigerians	Henshaw-Positives	Hunter-Positives
MMS	23	0	0
MsMs	55	0	0
MNS	45	15	6
MsNs	121	0	5
NNS	16	17	1
NsNs	66	1	14
Total	326	33	26

positives, because they were inadequate, were not fully tested for the antigens of the MNSs system. It is for this reason that the numbers given here are smaller than the totals already stated.

All 33 Henshaw-positives were found to carry the N gene, whereas among the unselected class only 248 out of 326 carried it. The probability of such a distribution occurring by chance if the Henshaw and N antigens were unrelated is about 1 in 1,000.

Of the Henshaw-positives 32 out of 33 had the S antigen, while only 84 out of the 326 unselected persons had it. The probability of such a chance occurrence is 1 in 10^{11} . If the subdivisions chosen are (1) N and S both present; and (2) N, S, or N and S absent, the probability of chance occurrence is found to be, if possible, even less: 1 in 10^{22} . A regular relation of the Henshaw antigen to the MNS system is thus completely established.

All of the 26 Hunter-positives carried the N gene. The probability of this occurring by chance if the Hunter and N antigens were unrelated is about 1 in 200. Consideration of the S antigen adds little to the argument, but the relation of the Hunter antigen to the MNS system is very firmly established.

Such statistical considerations do not directly determine the nature of the connexions between the antigens concerned, but the only hypothesis which seems to be capable of explaining the observations is that the genes for the Henshaw and Hunter antigens are each linked to the genes of the MNS system in the close manner characterizing the CDE complexes of the Rh system. It should be noted that only a very close linkage with a cross-over frequency not exceeding about 1 in 1,000 can explain these results, hence crossing over should be found absent or almost completely absent in any series of family data.

Family Data

The next step in the investigation was to test the above hypothesis on families. An effort was made to obtain specimens of blood from as many relatives as possible of all Henshaw-positive propositi. Tests were made in London with all available grouping sera, including anti-Hunter. In every case in which both parents of a He-positive person were tested, one was He-positive, this being characteristic of a Mendelian dominant character. The Hu antigen showed similar behaviour. As expected from the individual data, the only obvious linkages of the Henshaw and Hunter genes are with the MNSs system, and only these relations are described here. A full linkage analysis of the material is, however, being carried out and a report on it will be published elsewhere.

Ten families in all were tested, varying from two individuals to 38 extending over four generations. Some of the families were highly complex owing to many of the men and women each having had several partners. In one or two instances an unexpected result was obtained, but it is likely that erroneous information with regard to family relationships was the explanation.

In nearly every case, however, the data are consistent with complete linkage (as found in the Rh system between the genes at the C, the D, and the E loci) between the Henshaw gene and NS or Ns, and between the Hunter gene and Ns or (each in one family only) NS or Ms. Two families which show the relationship especially clearly are illustrated in the Diagram. All individuals in these families were tested with anti-M, -N, -S, and -s.

In the Bo. family the MNSs genotypes are each directly fixed by the serology except those of the mother and the eldest child.

Since two of the children are homozygous NS/NS, the mother must carry NS and is therefore Ms/NS. The eldest child has therefore received s with M from his mother and is also Ms/NS.

Without making use of our knowledge of the Henshaw and Hunter observations we can moreover determine from which parent each child received each one of its MNSs chromosomes. It then follows that every child receiving NS from the father also received the Henshaw antigen and each getting his Ns did not receive Henshaw. Similarly, each child with NS from the mother has the Hunter antigen and each with the mother's Ms failed to receive Hunter.

In the Os. family the MNSs genotypes of the mother and of both children are completely determined by their serological phenotypes. Since the second child is of the genotype NS/Ns she must have received the S gene with N from her father, who is therefore Ms/NS. Hence the Henshaw gene was transmitted from the father along with the NS combination and the Hunter gene with the Ns from the mother. The elder child received the father's Ms chromosome without his Henshaw antigen and an Ns chromosome without the Hunter antigen from the mother. Since the mother has two Ns chromosomes, one of these presumably carries the Hunter gene and the other does not. The data are thus consistent with a linkage between Ns and Hu, but cannot be used to prove it.

The Henshaw antigen has also been detected in a very small number of individuals in the Far East. In two Sea Dyaks from Borneo it appears to be linked to MS, while in Negritos from Malaya it accompanies Ms (P. Sneath, 1952, unpublished observations). A total of 1,500 Europeans have so far been tested for the Henshaw antigen with uniformly negative results.

We thus have very strong evidence that the Henshaw antigen is closely linked to the genes for M or N and S or s. The Hunter antigen is also similarly linked. We have, so far, no clear evidence of whether the genes for the two newly described antigens are or are not alleles of one another. In the few families in which both occur the two segregate separately, but this does not rule out the possibility that they may be alleles—a possibility which could be disproved if they were found to segregate together in a family. The only slender piece of evidence in favour of the coexistence of the two new genes on a single chromosome is the finding of two unrelated West Africans both of phenotype MNSs and positive for both Henshaw and Hunter antigens. If the genes for both of the latter key to their partnership with N, which is otherwise almost invariable among Africans tested, then both genes must be on one chromosome. It unfortunately has not been possible to obtain specimens from their families.

The Henshaw and Hunter antigens are for the moment unique among well-established human blood-group antigens in that the corresponding antibodies have never been found

Two families illustrating the linkage relationships of the He and Hu genes.

in human sera. It is, however, probable that as blood transfusion and serological testing become commoner in Africans such human antibodies will be found, and it is not improbable that there will be occasional clinical manifestations of incompatible blood transfusion and even of haemolytic disease of the newborn arising from the corresponding antigen-antibody reactions.

Summary

An investigation has been carried out into the distribution in West Africa and the genetics of the Hunter antigen of Landsteiner, Strutton, and Chase (1934) and of the newly discovered Henshaw antigen. The genes for both of these antigens appear to be closely linked to those of the MNSs blood-group system.

Thanks are due to the Rockefeller Foundation for a grant given to one of us (J.N.M.C.) in defrayment of part of the expenses. We wish to thank Dr. Ada C. Kopec for statistical advice, and Miss P. J. Brooks, Miss K. E. Garner, and Mr. Kenneth Rogers for technical assistance in London. In West Africa, the I.G., Medical Services, Nigeria, and the D.M.S., Gold Coast, and their staffs gave every facility for work there. In particular we thank Dr. D. A. Cannon, Dr. G. M. Edington, Mr. S. O. Williams, and Mr. E. G. D. Henshaw.

USE AND EFFECTIVENESS OF ANTIMALARIAL DRUGS

EXPERIENCE OF NON-NATIVE RESIDENT POPULATION OF NIGERIA, WEST AFRICA

BY

B. M. NICOL, O.B.E., T.D., M.B., Ch.B.
Colonial Medical Service, Nigeria

The question most often put to the medical profession by European and other expatriates resident in West Tropical Africa is, "What antimalarial drug should I and my children take, and in what dosage?" The claims made in advertisements, the advice of friends, and the recommendations of employers conflict and confuse. More often than not the doctors themselves disagree, and recent comment in the medical press is even more confusing and conflicting (*British Medical Journal*, 1949; *Colonial Med. Res. Com.*, 1949; Covell, Nicol, Shute, and Maryon, 1949a, 1949b; Davey and Smith, 1949; Garnham, 1949; Bruce-Chwatt, 1951; MacLeod, 1951; Messent, 1951; Manson-Bahr, 1952).

In view of this present disagreement on the part of the medical profession an inquiry into the use and effectiveness of antimalarial drugs was conducted in Lagos in 1951 and 1952, employing the past and present experience of a group of non-natives resident in Nigeria as a yardstick. A study with the same object in view was carried out in 1948 and 1949 by the Bruce-Chwatts (1950). They collected data by sending questionnaires to all doctors practising clinical medicine within the Colony and Protectorate. The investigation here reported was carried out by personal interview with a group of expatriates, many of whom lived in and around Lagos.

Method

The group investigated was composed of all the non-natives who reported to my out-patient clinic at the Creek Hospital, Lagos, between November 1, 1951, and March 31, 1952, irrespective of the complaint which brought them to hospital. Each individual was questioned regarding the following particulars:

Nationality, age, sex.

Antimalarial drug at present being taken: name of drug, dose, duration, and regularity of taking it.

Previous history of malaria while taking this drug. If present, was malaria diagnosed by a doctor, with or without laboratory confirmation, or by the individual himself?

Antimalarial drug, if any, used in the past: name, dose, duration, and regularity of taking it, previous history of malaria, grounds for diagnosis (see above), and reason for changing to another drug.

The age, sex, and nationality distributions of the sample of the non-native population of Nigeria, numbering 531 in all, are set out in Table I.

An estimate of the incidence of malaria in the group at the time of interview was made as follows. If a patient was found to be pyrexial or to present any clinical feature raising the question of the differential diagnosis of malaria, a thick blood film was made and sent to the laboratory. "Clinical malaria" was diagnosed on those occasions when the report on the film was negative, but the history and examination suggested malaria and the response to therapeutic doses of mepacrine or chloroquine was satisfactory. The possibility that cases of influenza and other short-term spontaneously remitting fevers were included as clinical malaria cannot be ruled out, nor can it be stated that all cases of parasitaemia were discovered by these simple methods; it is believed, however, that a reasonably good estimate of the incidence of overt malaria was obtained.

Blood films were made for the reasons mentioned above from 78 of the 441 patients aged 10 and over, and from 17 of the 90 children under 10 years. The infecting organism in all the blood films reported as positive was stated to be *Plasmodium falciparum*.

Results

The antimalarial drugs in use by the individuals forming the sample of the non-native population at the time of interview are shown in Table II; it will be seen that proguanil was used at all ages more often than any other drug. Proguanil was the drug chosen by the majority of all races except the Lebanese, Syrians, and French, who prefer quinine to any other antimalarial drug. A bigger proportion of the French (16%) than of any other race took chloroquine.

Changes from One Drug to Another

Many individuals, regular takers of an antimalarial drug, were found to have changed for various reasons from one drug to another during the course of their stay in West Africa. Among adults the swing was away from quinine or mepacrine to proguanil or chloroquine (Table III). An increase in the dosage of proguanil from 100 mg. to 200 mg. daily had also occurred. Such changes indicate dissatisfaction with the drug initially taken.

The reasons given for stopping quinine were repeated attacks of "fever" (80%), dyspepsia, and tinnitus. In 89% of cases the reason given for relinquishing mepacrine was the yellow staining of the skin, but gastric upsets were also blamed by a small number of patients. The sole reason given for increasing the dose of proguanil, or for changing to another drug, was the occurrence of fever while taking the lower dose. Proguanil was never given up as a result of loss of appetite (*British Medical Journal*, 1949; Shearer, 1949). Proguanil in doses of 200 mg. daily and chloroquine 300 mg. twice or thrice a week were found satisfactory by the few who have taken them regularly and without change since starting to live in the Tropics.

TABLE I.—Age, Sex, and Nationality Distribution of the Group of Non-natives Resident in Nigeria Investigated in 1951-2

Nationality	Age in Years												Total No.	
	0-9		10-19		20-29		30-39		40-49		50-59		60+

Nothing	0	0	0	0	0	1	1	
								0.2

* All doses of chloroquine refer to "base" and not "salt."

TABLE III.—Changes from One Antimalarial Drug to Another Which Have Taken Place in the Non-natives Resident in Nigeria 20 Years of Age and Over who are Regular Takers of One or Other of these Drugs

Drug Initially Taken, and Dosage	No. Starting on this Drug	No. Changing to					No. now Taking	% Unchanged
		Proguanil 100 mg. Daily	Proguanil 200 mg. Daily	Mepacrine 100 mg. Daily	Quinine 4 or 5 gr. Daily	Chloroquine 300 mg. 2 or 3 Times Weekly		
Proguanil:								
100 mg. daily	235	0	27	1	2	2	245	86
200 " " " " " " " "	15	0	0	0	0	0	48	100
Mepacrine:								
100 mg. daily	46	20	2	0	2	1	30	46
Quinine:								
4 or 5 gr. daily	91	22	4	8	0	2	59	60
Chloroquine:								
300 mg. 2 or 3 times weekly	3	0	0	0	0	0	8	100

The overall figures show that 60% of those starting on quinine have remained faithful to it, 46% to mepacrine, and 86% to a dose of 100 mg. of proguanil. The remainder have thought fit to try a different antimalarial drug.

Incidence of Malaria Prior to the Interview

The data presented in Table IV were obtained from individuals who had taken only one antimalarial drug, and this regularly, since starting to live in Nigeria. They depend upon such doubtful factors as the patient's memory and knowledge of the method of diagnosis of his or her case. Making due allowance for these factors, it was still apparent at the interview that many non-native adults taking 4 or 5 gr. (260 or 320 mg.) of quinine, 100 mg. of mepacrine, or 100 mg. of proguanil daily had suffered from

repeated attacks of malaria in the past. A previous history of malaria was reported by 50% of those patients who had never changed from quinine, the corresponding figures for those taking mepacrine and proguanil being 15% and 17%. The difference is statistically significant ($P=0.01$), but it is necessary to remember that the group taking quinine had been exposed to infection for much longer periods of time, on the average, than had those taking the other two drugs. The figures given in Table IV, however, indicate that this factor does not account for the higher incidence of malaria among those using quinine.

A previous history of malaria was not obtained from anyone who had been taking either a daily dose of 200 mg. of proguanil or 300 mg. of chloroquine twice or thrice a week, but in these subgroups the numbers are small and the length of exposure to infection was short.

Incidence of Malaria Discovered at the Interview

The overall incidence of malaria among the group of adult patients who had taken one or other of the antimalarial drugs regularly was found to be 8% (Table V). The figure of 8.2% for those taking 100 mg. of proguanil daily agrees well with that reported by the Bruce-Chwatts (1950). A significant difference does not exist between the

TABLE IV.—Incidence of a Past History of Malaria in Non-native Residents in Nigeria 20 Years of Age and Over, Regular Takers of Only One Antimalarial Drug, Time the Drug has been Taken, and the Distribution of Malaria Throughout this Period

* The dose in the case of chloroquine is taken thrice weekly.

incidence of malaria discovered in the groups of patients taking 100 mg. of proguanil, 100 mg. of mepacrine, or 4 or 5 gr. (260 or 320 mg.) of quinine. The evil effects of using any of these drugs intermittently are clearly demonstrated in Table V.

The data obtained from children under 10 years are set out in Table VI. Although few in number, the figures suggest that proguanil in adequate doses is a satisfactory antimalarial drug for this group. For infants 1 to 1½ gr. (65 to 100 mg.) of quinine seems to be an efficient prophylactic dose.

Discussion

Past experience with antimalarial drugs in Nigeria has led many of the individuals included in this investigation to relinquish quinine or mepacrine in favour of proguanil or chloroquine. The high incidence of a previous history of malaria in the group initially taking quinine provides good reason for the swing away from this drug, but no such reason exists in the case of mepacrine. The yellow discoloration of the skin associated with the regular use of mepacrine provided most of the Europeans with a ready excuse for changing to something else.

The incidence of malaria discovered in those patients taking quinine at the time of the interview was not significantly higher than that among patients taking 100 mg. of proguanil or of mepacrine. This fact cannot be used as an argument to offset the high incidence of the disease in the past histories of those taking quinine. It was impossible to decide if the cases of malaria encountered at the time of the interview were fresh infections or were relapses of earlier infections.

The information disclosed by this investigation indicated that malaria will occur in about 10% of those using a daily dose of 100 mg. of proguanil, but that daily doses of 200 mg. of proguanil or doses of 300 mg. of chloroquine twice or thrice a week provide efficient prophylaxis against the subtertian malaria endemic in Nigeria. In the experience of the group of people which has been studied, and in my own and that of my family, the higher dose of proguanil causes no unpleasant side-effects.

It is impossible to say whether the high dosage of proguanil recommended as a result of this investigation is necessitated by a developing resistance of the local strains of plasmodium to this drug or if the dosage used in the past was too small to accomplish efficient prophylaxis.

Conclusions

The data presented and discussed lead to the general conclusion that, in the present state of knowledge and in view of past experience, proguanil in adequate dosage is the most satisfactory drug to use in Nigeria at the present time for the prevention of malaria. Chloroquine has been taken by so few people, and for such a short time, that it would be unwise to draw any premature conclusions about its efficiency, but the information so far available is of a satisfactory nature. The conclusion that a daily dose of 100 mg. of proguanil or of mepacrine is more effective as a suppressant than 5 gr. (320 mg.) of quinine against the local strains of *P. falciparum* is based upon good evidence.

Proguanil, in daily doses of 200 mg. for those 10 years of age and over and 50 mg. for children under the age of 1 year, with proportionate intermediate doses, is an efficient prophylactic. Quinine in daily doses of 1 to 1½ gr. (65 to 100 mg.) is satisfactory for infants.

These conclusions are not intended to belittle the importance of applying all the other means available to prevent infection being acquired by the non-immune population of Nigeria.

Summary

An account is given of an investigation carried out in Lagos, Nigeria, which was designed to discover which of the many available antimalarial drugs are being, and

FEMALE FERTILITY

BY

DEREK LLEWELLYN-JONES, M.B., B.Ch., M.A.O.
Obstetrician, General Hospital, Kuala Lumpur, Malaya;
Late Registrar, Hope Hospital, Salford, Lancashire

In 1866 Matthews Duncan noted that "whilst a large number [of women] are fertile for a first time in each of the first three years of married life, only 7% of the fertile bear children after three years of marriage." From this it has been concluded by most British authors that sterility should be investigated after three years of marriage. In the United States of America most of the gynaecological textbooks suggest that two years of potentially fertile coitus should elapse before investigation. This may well be due to the work of Pearl (1939), who concluded, after investigating the case records of 199 white American women, that it took a woman, on an average, 24 months to conceive.

Recent editions of American and British textbooks voice this confusion. Four give four years as the time which should elapse before investigation of sterility, five give three years, three give two years, and two give one year. The others give no time. It is noted that those writers who have made a special study of the problem tend to investigate infertility after a shorter time than the others. As an example of this, Meaker's (1934) definition of infertility may be quoted. He defines sterility as "the inability to initiate the reproductive process on the part of a couple who have desired and attempted to reproduce for a reasonable length of time, ordinarily at least one year."

The incidence of infertile couples is estimated variously as between 8.5 and 15% of all marriages. In these unsettled times it becomes more important to determine the average length of time between the desire to conceive and the actual conception, so that those who exceed this average may be investigated with the minimum of delay. For nowadays, with poor housing conditions, voluntary contraception, occupations which entail longer or shorter periods of separation of the couple, later age of marriage, and impending separation for military reasons, those who are anxious to conceive should be helped as much as possible. As time passes and a woman still finds herself barren, much marital unhappiness and stress (which Stallworthy (1948) contends is itself a factor in infertility) accrues, and it is little comfort to her to be told by her doctor to "go away and don't worry, for you are still young."

That the fertility of a woman is related to her age has been believed from the time of Matthews Duncan onwards. In his investigations in Glasgow in 1866 he found that while 90% of women between the age of 20 and 24 would conceive for a first time within two years of marriage, only 63% of women between the ages of 30 and 34 and only 15% of women between the ages of 40 and 44 would do so. The Royal Commission on Population (1949) also gives interesting figures regarding the decline of fertility and the duration of marriage. It appears that the risk of conception in the second five years of marriage is reduced to about 50% of the risk in the first five years, and is again halved in the third five years.

Fertility in Salford

This survey was therefore undertaken in order to determine the average interval between the desire to conceive

and the conception itself. All the patients were primigravidae attending the antenatal clinics of Hope Hospital, Salford, between August 1, 1950, and June 1, 1951. In all, 1,202 women were interviewed. If conception had occurred within nine months no further questions were asked regarding coital habits, contraceptive technique, or absence of the husband from home. But when conception had been delayed for a longer period than this, all these points were studied and allowance was made for them. Later all the women were examined physically and further questions were asked as a check. In 136 cases (11.3% of the total) for contraception or coitus interruptus had been practised for longer or shorter periods, and the calculation was made from the date of abandoning these methods and desiring to conceive. There is no evidence to show that contraception, by whatever method used by these women, is harmful to fertility.

The results of the survey are shown in the Table. If women who conceived prenatally are included it can be seen that 90.25% of those studied were pregnant within

Desire-to-Conception Interval in Months	Age at Time of Desiring to Conceive						% Pregnant	Total
	15-19	20-24	25-29	30-34	35-39	40 and Over		
Prenuptial conceptions	86	96	18	7	4	0	17.5	211
0-3	54	263	112	20	3	3	38.0	455
3-6	26	116	62	13	3	1	18.5	221
6-9	5	52	32	15	6	2	9.25	112
9-12	2	40	27	5	7	2	7.0	83
12-18	0	10	10	6	1	0	2.25	27
18-24	0	5	7	8	0	0	1.5	20
24-36	0	5	12	2	0	0	1.5	19
36+	0	5	24	19	6	0	4.5	54
	173	592	304	95	30	8	100	1,202

one year of desiring to conceive, 92.5% were pregnant within 18 months, and 94.0% were pregnant within 24 months. In other words, only four more women in every hundred had conceived after two years than had conceived within one year.

It may be objected that the prenuptial conceptions should not be included. But since almost half of such conceptions occurred to girls between 15 and 19 years and almost all to girls under 25, it can surely be argued that these have rarely practised coitus consistently and without contraception for more than one year. When questioned, most of these girls said that coitus had occurred only during the two months before the first missed period. The figure of 17.5% of first prenuptial conceptions is reasonably close to that of 16.0% given for the country as a whole by the Registrar-General in 1938-9.

Comparison with Other Surveys

In 1946 Scott Russell, working at Oxford, surveyed 293 women, of whom 197 were primigravidae and 96 multigravidae. In his paper it is not noted whether any of the conceptions were prenuptial, but it is assumed that there is little difference in morals between Salford and Oxford, and that unless questioned directly on this point most women who conceived prenuptially will say that they conceived directly after marriage. It is thought that this may be the reason for the high figure of conceptions noted by Scott Russell to have occurred after marriage but before there had been a menstrual period. He found that of 162 primigravidae, 51 (31.5%) conceived within a month of marriage, 51 (31.5%) conceived within three months, and a further 19.1% had conceived within the first year. Thus 87.7% of 162 primigravidae had conceived within a year of marriage.

Diddle *et al.* (1947), working among families in the U.S. armed Forces at Key West, Florida, surveyed 1,192 women, of whom 799 were pregnant. Of these latter, 261 were primigravidae about whom there were full data, including coital rates. They found that 190 (72.7%) of them conceived within six months and 226 (86.8%) had conceived within one year. By two years 249 (95.4%) had conceived. Bender (1952) found that of 714 primigravidae seen 77.4%

had conceived within one year of first coitus or marriage, and 86.7% within two years. Tietze *et al.* (1950), reviewing the time required for conception in 1,727 pregnancies, found that more than 90% had conceived within one year. These surveys bear out the findings in Salford, and indicate that if pregnancy has not occurred within twelve months of the desire to conceive then the couple should be investigated on the grounds of infertility.

Discussion

A major factor influencing conception in women with normal genital tracts is that coitus between a fertile male and an ovulating female should take place at the time of ovulation (or, it may be, that in some cases it should be able to initiate ovulation). Barton and Wiesner (1946) thought that the ovum is viable only for about 24 hours. Hotchkiss (1945) believed that the spermatozoon is capable of fertilizing the ovum only for 24 to 72 hours after ejaculation into the posterior fornix of the vagina. These two facts mean that a woman is capable of conceiving on only three days of each month, or a maximum of 39 days a year. The important thing is when coitus occurs, not how often.

Davis (1929) investigated the sexual habits of 971 women, and found that, on an average, coitus takes place twice nightly in the first three months of marriage, once nightly in the first year, and twice weekly in the first three years. Thus in the first year of marriage the average woman will have the maximum opportunity of conceiving. After the first years the frequency of coitus is dropping and pregnancy becomes less likely. This may be, in part, the explanation of lowered fertility indices which are said to occur (see above) as a woman grows older.

That psychosomatic factors may influence fertility has long been recognized. Stallworthy (1948) asks, "Is it not probable that a woman may deprive herself of the conception she desires because of the very strength of the desire or the fear of it?" "Hysteria" may produce tubal spasm (Stallworthy), changes in the cervical mucus (Barton and Wiesner, 1945-6), premature maturation of the follicles and discharge of unripe ova (Dunbar, 1946), and possibly anovulation.

Is it not possible, as the months go by and the long-desired conception remains unfulfilled, that this tension mounts and manifests itself in many ways—in general psychological disturbances, in frigidity (and thus in less frequent coitus), and in marital upsets? And from this it is but a short step to the establishment of the vicious circle of "hysteria"—absence of conception—"hysteria."

There is far more to the investigation of a barren marriage than the finding of a "potent male and patent tubes."

Conclusion and Summary

In a survey of 1,202 primigravidae attending Hope Hospital, Salford, between August, 1950, and June, 1951, it was found that 90.25% had conceived within a year of so desiring. Evidence is brought forward which suggests that many cases of infertility are due to as yet inexplicable psychosomatic factors. It is suggested that many of these factors can be corrected by simple investigation and reassurance of the infertile couple. Since only 4% more women conceive between 12 and 24 months after deciding to have a baby than do within the first year, it seems reasonable to investigate infertile couples as soon as one year has passed without pregnancy occurring.

The advantages of this earlier investigation are that (1) the psychosomatic factors involved can be tackled earlier; (2) the sexual drive is greater in the earlier years of marriage; (3) both sexual drive and psychosomatic factors are probably aggravated by non-conception; (4) minor anatomical defects can be remedied earlier; (5) if an absolute bar to conception exists adoption of

have been, used by a group of non-native residents in that country, and what is the past and present incidence of malaria in this group.

The group was composed of all the non-native residents in Nigeria who reported to my out-patient clinic between November 1, 1951, and March 31, 1952.

The following antimalarial drugs were being used at the time these patients were interviewed: proguanil by 68%; quinine by 16%; mepacrine by 6%; chloroquine by 2%. Of the whole group, 6% admitted to being, or were known to be, intermittent in their habits. One individual did not take any antimalarial drug.

Among the adults who had taken only one antimalarial drug daily with regularity since starting to live in Nigeria, a past history of malaria was reported as follows: those taking 100 mg. of proguanil, 15%; 200 mg. of proguanil, 0%; 100 mg. of mepacrine, 17%; 4 or 5 gr. (260 or 320 mg.) of quinine, 50%. Chloroquine in doses of 300 mg. twice or thrice weekly had been taken regularly by three individuals, none of whom reported having had malaria.

The overall incidence of malaria in the group at the time of interview was found to be 11%, of which total 10.9% occurred in those 10 years of age and over and 12.2% in children below this age. Excluding all individuals self-admittedly irregular takers of any antimalarial drug, the incidence of malaria was found to be 9%, and if children are excluded the incidence in adults 20 years of age and over was 8%.

It is concluded that the most satisfactory prophylactic to use at the present time against the subtertian malaria endemic in Nigeria is proguanil, taken in doses of 200 mg. daily by those 10 years of age and over and 50 mg. daily for babies under 1 year. Quinine in doses of 1 to 1½ gr. (65 to 100 mg.) daily is a satisfactory suppressive for infants.

I am indebted to the Inspector-General of Medical Services, Nigeria, for permission to publish this paper.

The perennial problem of over-population is again stressed in the report for 1951 of the health conditions in the Maltese Islands and of the work of the Medical and Health Department, which was published recently. Cardiac conditions and cerebral vascular accidents accounted for the highest proportion of deaths, the figures being 148 and 102 per 1,000 respectively. Research is being carried out on the radical cure of malignant growths; deaths from this cause increased during the year under review. Progress is reported in the fight against tuberculosis: a good proportion of the population is being radiographed, and the incidence of the disease has shown a considerable decrease. An attempt has been made to integrate the laboratory services in Malta, which are at present divided into several sections and spread over a wide area. All this and much more information is contained in the report, which is available from the office of the Chief Government Medical Officer, Malta.

a child can be made earlier; (6) the investigation of infertile couples extends over many months.

My thanks are due to the medical and nursing staff of the obstetrical and gynaecological department of Hope Hospital, Salford, for their help in the preparation of this paper.

"COLIFORM DIARRHOEA" IN ADULT HOSPITAL PATIENTS

BY

WILLIAM McNAUGHT, M.B., Ch.B.

AND

JOHN S. STEVENSON, M.D.

(From the Department of Bacteriology, Stobhill General Hospital, Glasgow)

This report contains the results of an investigation of adults' faeces for the presence of those type-specific coliform organisms known to be closely associated with diarrhoea and vomiting in infants. The work was undertaken as an extension of two smaller investigations previously reported by Stevenson (1950, 1952), who described the isolation of *Bact. coli* O111.B4 (D433) from adults.

Most of the published work on type-specific strains of *Bact. coli* concerns their presence in the faeces of infants; their occurrence and effects in the adult have not yet been fully studied. Fourteen cases of diarrhoea in adults from whom *Bact. coli* O111.B4 was isolated were reported by Stevenson (1950), and Kirby, Hall, and Coackley (1950) described enteritis in adult volunteers, caused by drinking milk inoculated with an organism of the same type-specific group. Stevenson (1952) investigated specimens of faeces from more than 1,000 adults and found *Bact. coli* O111.B4 in nine, four of whom had diarrhoea. Further evidence that this coliform can produce intestinal upset in the adult was provided by Ferguson and June (1952), who described a large-scale experiment in which adult males developed enteritis following the ingestion of milk artificially infected with the organism.

The six strains of *Bact. coli* from which antisera were prepared and used in the present investigation have been described by Taylor and Charter (1952) and Charter and Taylor (1952). They are designated at present as follows: *Bact. coli* O111.B4, O55.B5, O26.B6, Canioni, E611, and E990.

Methods and Results

The investigation covered the period October, 1951, to October, 1952. At the outset, O and OB antisera were prepared to *Bact. coli* strains O111.B4, O55.B5, and O26.B6; a "pooled" serum was made, and was checked before use. In March, 1952, the strains *Bact. coli* Canioni, E611, and E990 became available; individual and pooled sera were

also prepared from these strains. Thus three type-specific antisera were available for the first six months and six antisera for the second six months of the investigation.

The faecal specimens, most of which were from cases of diarrhoea, were inoculated on to MacConkey, D.C.A., and Difco "SS" agar plates and into a "selenite F" enrichment broth. The subsequent growth on the MacConkey plate was used to detect type-specific coliform strains by slide agglutination; final identification of the organisms was made by tube-testing for the O and B antigens. The other media were employed to detect the *Salmonella* and *Shigella* groups. Each MacConkey plate was examined by testing the inoculation "well" and five separate colonies with the two pooled sera; positive colonies were checked against individual sera and subcultured for tube agglutination tests.

The figures obtained over the twelve-months period are summarized in Table I. *Shigella* and *Salmonella* results

TABLE I.—Results of Examination of 894 Adult Stools

Total	Type-specific Strains of <i>Bact. coli</i> Isolated						<i>Shigella</i> Isolated	<i>Salmonella</i> Isolated
	O111 B4	O55 B5	O26 B6	E611	E990	Canioni

1.7%	0.6%	0.2%	0.9%	—	—	—	1.8%	0.4%

TABLE II.—Analysis of Cases

Case No.	Age and Sex	Clinical Notes	Organism Isolated	Type of Case
1	F 20	Nurse in children's wards. Sharp attack of diarrhoea	O55.B5 19/10/51	Sporadic
2	F 64	Senile dementia. Sharp attack of diarrhoea. Death	O26.B6 22/11/51	"
3	F 52	Abdominal adhesions. Diarrhoea	O26.B6 1/1/52	"
4	M 51	Early ulcerative colitis	O26.B6 8/1/52	"
5	M 46	Pleural effusion. Diarrhoea	O26.B6 19/5/52	Ward outbreak
6	M 68	Pulmonary tuberculosis. Diarrhoea	O26.B6 20/5/52	
7	M 50	Acute rheumatism. No diarrhoea	O26.B6 20/5/52	
8	M 67	Pulmonary tuberculosis. Diarrhoea	O26.B6 21/5/52	
9	M 79	Gangrene of leg. Amputation. Good recovery. Diarrhoea and vomiting. Death	O111.B4 27/5/52	Sporadic
10	F 59	Glaucoma. Diabetes. Diarrhoea	O111.B4 29/5/52	Ward outbreak
11	F 73	Senility. Diarrhoea	O111.B4 3/6/52	
12	F 84	Senility. No diarrhoea	O111.B4 8/6/52	
13	F 66	Hypertension. No diarrhoea	O111.B4 8/6/52	
14	F 26	Mitral stenosis. Diarrhoea	O26.B6 10/9/52	Sporadic
15	F 22	Diarrhoea and vomiting for 24 hours	O55.B5 27/10/52	"

have been added to the table for comparison, but no member of these two groups was isolated from any of the cases yielding type-specific coliforms. A brief analysis of the cases is shown in Table II.

Description of Cases

Case 1.—An otherwise healthy nurse aged 20 reported sick with diarrhoea on October 18, 1951. Next day *Bact. coli* O55.B5 was isolated. She had been employed in a paediatric ward in which were cases of gastro-enteritis, none of whom was known to be associated with *Bact. coli* O55.B5. Rectal swabs were taken from all the infants in the ward concerned, and *Bact. coli* O55.B5 was isolated from a male infant aged 5 months who was convalescing from gastro-enteritis associated with *Bact. coli* O111.B4, but who at this point had no gastro-intestinal symptoms. The nurse made an uneventful recovery within a few days; the baby remained symptomless.

Case 2.—A woman aged 64 had been an in-patient for one year and suffered from senile dementia. There

was severe progressive debility, and bronchopneumonia developed a few days before her death on November 23, 1951. The day before death the patient began to have profuse diarrhoea, and *Bact. coli* O26.B6 was isolated from the stools. At necropsy, forty-eight hours after death, moderate congestion of the terminal ileum and transverse colon was found in addition to the pneumonia. Swabs taken from organs and tissues did not produce any type-specific coliforms on culture. Rectal swabs taken from every patient in the wards concerned were also negative.

Case 3.—A woman aged 52 was admitted to hospital on December 28, 1951, with a history of intermittent diarrhoea of several years' duration, apparently dating from appendectomy some five years previously: there had been an operation for separation of adhesions three years later. *Bact. coli* O26.B6 was isolated in pure culture on January 1, 1952. No type-specific coliform was isolated from any other patient in the ward. After full investigation the case was labelled "nervous diarrhoea." The patient was discharged on February 2, still having two or three soft stools a day, but negative for type-specific coliforms.

Case 4.—A man aged 51 was admitted to hospital on December 4, 1951, with a history of intermittent diarrhoea accompanied by blood and mucus, for a period of eight weeks. On January 8, 1952, *Bact. coli* O26.B6 was isolated from his stools. All other investigations were negative, though sigmoidoscopy suggested early ulcerative colitis. Further examinations of his faeces were negative, and no type-specific coliforms were isolated from any other patient in the ward.

Cases 5, 6, 7, 8.—There seems to be no reasonable doubt that these four cases constitute an outbreak. On May 18, 1952, a specimen of fluid faeces consisting of almost pure blood was received from a patient (Case 5) in a male ward; he had been admitted on May 14 suffering from a pleural effusion. The MacConkey plate showed an almost pure growth of *Bact. coli* O26.B6 on May 19, and rectal swabs were taken immediately from each of the 32 patients in the ward. The following morning two more patients (Cases 6 and 7) were found to have *Bact. coli* O26.B6 in their stools. When the ward staff was notified of these two new cases, information was received that both patients were convalescent and neither had diarrhoea. Case 6, however, developed severe diarrhoea six hours later, with blood and mucus in the stools. No diarrhoea was reported in Case 7. The same day (May 20) another patient (Case 8) developed severe diarrhoea, and twenty-four hours later the MacConkey plate from this patient was found to have a pure growth of *Bact. coli* O26.B6. No other positives were found in this ward, and within 72 hours all diarrhoea had ceased and the four positive cases were negative for the specific coliform.

Case 9.—A man aged 79 was admitted to hospital on February 10, 1952, suffering from gangrene of the left leg. Mid-thigh amputation was performed on April 22. His condition was satisfactory until May 24, when he had slight diarrhoea. This was followed by violent vomiting and diarrhoea twenty-four hours later. On May 27 *Bact. coli* O111.B4 was isolated in pure culture from the faeces. The patient died the following day; permission for necropsy was refused. One point worthy of comment is that a simultaneous case of diarrhoea associated with *Bact. coli* O111.B4 occurred in a child of 9 years in a ward immediately below that where Case 9 was a patient. Rectal swabs from other patients in both wards were negative for type-specific coliforms.

Cases 10, 11, 12, and 13.—This group constitutes another ward outbreak, though less definite than that involving Cases 5, 6, 7, and 8. Case 10, a woman aged 59, was admitted to hospital on May 15, 1952, suffering from glaucoma and diabetes. Diarrhoea developed on May 28 and *Bact. coli* O111.B4 was isolated in pure culture from her stools the following day. Two days later a specimen of faeces was received from another patient in the same ward (Case 11); this patient had had bouts of diarrhoea with blood and mucus on four occasions during the previous

three weeks. *Bact. coli* O111.B4 was isolated from this specimen on June 3 and from subsequent specimens on June 4, 8, and 24, after which date the diarrhoea ceased and the stools became negative. On June 7 rectal swabs were taken from every patient (a total of 32) in the ward concerned, and *Bact. coli* O111.B4 was isolated from two further cases (Nos. 12 and 13). Neither of these patients had diarrhoea, though Case 12 gave a history of having had intermittent diarrhoea some four months previously, when no salmonella, shigella, or type-specific coliforms had been found. The diarrhoea in Case 10 ceased within 72 hours and the stools were thereafter negative.

Case 14.—This woman, aged 26, was admitted to hospital in March, 1952, suffering from mitral stenosis with severe decompensation. On September 6 she began to have loose stools amounting to five or six motions a day, and on September 10 *Bact. coli* O26.B6 was isolated. No blood or mucus was noted in the stools, and no type-specific coliforms were present in specimens of faeces three, four, and five days after the first isolation, the diarrhoea having ceased by this time. No other cases of diarrhoea occurred and no type-specific coliform was isolated from any other patient in the ward concerned.

Case 15.—This patient was a woman aged 22 who was sent to hospital by her family doctor on October 26, 1952, with a diagnosis of acute appendicitis. She had pain in the right iliac fossa, vomiting, and some diarrhoea of 24 hours' duration. On admission it was thought she had bacillary dysentery, so she was isolated and barrier-nursed. The day after admission, *Bact. coli* O55.B5 was isolated in pure culture from a faeces specimen. The patient made an uneventful recovery and was well within a few days, no type-specific coliforms being found after the first isolation. An interesting feature of this case is that her 5-months-old child was in another hospital suffering from gastro-enteritis: no type-specific coliform is known to have been isolated from the child.

Discussion

Among adult hospital patients, small localized outbreaks of diarrhoea of unknown cause, affecting perhaps as many as one-third of the inmates of a ward, are a common experience, as are also sporadic isolated cases which occur from time to time. Frequently the diarrhoea is ascribed to dietary factors of uncertain origin, but from the results of the present investigation we believe that some of these cases are what may be called "coliform diarrhoea"—that is, diarrhoea caused by type-specific strains of *Bact. coli*. There does not at present appear to be any other explanation for the results obtained; the figures suggest that *Bact. coli* O111.B4, O55.B5, and O26.B6 can be the causal agents in a small proportion of cases of adult enteritis. The ward outbreaks affecting the two groups of cases (Nos. 5, 6, 7, and 8, and 10, 11, 12, and 13) provide good evidence for this belief. Here, small groups of patients developed diarrhoea directly related in time of occurrence to the presence of specific coliform organisms isolated in pure culture from the stools. Further evidence is provided by the sporadic cases, especially the two fatal ones (Nos. 2 and 9). These two patients were elderly and were weakened by previous illness; they developed sudden severe diarrhoea, coincident with which *Bact. coli* O26.B6 and O111.B4 respectively were isolated from their stools, and the resulting dehydration and exhaustion were enough to cause death.

It has been suggested in a previous communication (Stevenson, 1950) that these coliform organisms might appear in the stools as the result of the washing-down effect of diarrhoea. That this is untrue is shown by the many hundreds of adult enteritis cases investigated in this series from which no type-specific coliforms were isolated. Smith, quoted by Taylor and Charter (1952), has had similar negative findings in bacillary dysentery of infants. In only two of our positive cases (Nos. 3 and 4), both of whom had prolonged diarrhoea, has a type-specific coliform appeared in the stools as a transitory phenomenon unrelated to any marked exacerbation of intestinal symptoms. Moreover,

three cases (Nos. 7, 12, and 13) excreted type-specific coliforms when no diarrhoea was present, and in Case 6 *Bact. coli* O26.B6 was isolated and identified immediately before any looseness of stools began.

Certain conditions seem to be necessary before type-specific coliforms can exert a pathogenic effect in the intestine. From the cases described, debility and general weakness are evidently important predisposing conditions, but there is evidence of another, unknown, factor. In Cases 1 and 15 there was no history of previous illness, and both patients were young and in relatively good health; nevertheless they developed severe diarrhoea, and type-specific coliforms were isolated in pure culture from each. This other factor may be related to the virulence of the strain concerned. That Cases 1 and 15 developed symptoms could be explained by the particular organisms being highly virulent. As both these patients had enteritis on admission to hospital, they were barrier-nursed, and thus it was not possible to assess the virulence of the organism by observation of a subsequent case-to-case spread. In general, however, the pathogenicity to adults of the type-specific coliforms seems to be of a low order. Thus Cases 7, 12, and 13, despite age and debility, were able to harbour certain of these organisms without developing diarrhoea: the transitory appearance of the organisms in these three patients suggests that there is no true carrier state.

Over the period of the investigation coliform diarrhoea had the same incidence as bacillary dysentery. This, plus the fact that several of the cases in the coliform series had blood and mucus in their stools, suggests that coliform diarrhoea in adult hospital patients may present itself in a manner similar to the shigella infections. There is, however, one main difference between the two types of diarrhoea: dysentery organisms tend to remain in the intestinal tract over a relatively long period, whereas infection with a type-specific coliform is usually transient. In most of the cases in the present series, particular coliforms could be identified only for about 48 hours, after which the stools became negative.

Only two patients in the series had any contact with young children (Cases 1 and 15), and in neither instance was there any definite link of infection so far as can be ascertained. Case 9 had a remotely possible contact with the infected child in a neighbouring ward, but here again the chain of infection is obscure. Contact with infants therefore does not seem to play an important part in the infection of adults with the type-specific coliforms.

Summary

During the examination of 894 faecal specimens from adult hospital patients, type-specific strains of *Bact. coli* were isolated from 15 cases. These strains belonged to O groups 111, 26, and 55; none of the E611, E990, or Canioni strains was found. Twelve of the positive cases had diarrhoea of varying severity; two of these patients died, the associated organisms being *Bact. coli* O26.B6 and O111.B4.

It is suggested that diarrhoea in adult hospital patients can be caused by type-specific strains of *Bact. coli* and that it constitutes a definite syndrome for which the term "coliform diarrhoea" may be used; the predisposing factors are discussed.

We wish to thank Dr. Joan Taylor for supplying cultures of the type-specific strains from which antisera were prepared, and also for confirming the 15 strains isolated during the investigation. Our thanks are also due to Dr. A. D. Briggs, medical superintendent, Stobhill General Hospital, for permission to make use of clinical notes.

INFECTED URACHAL CYSTS

BY

H. I. REES, M.B., B.Ch., B.Sc., F.R.C.S.

Senior Surgical Registrar, Luton and Dunstable Hospital

The first undisputed report of cyst formation in the urachal relic was contributed by Lawson Tait in 1883. It was, however, the researches of R. C. Begg (1927, 1930) which established the nature of development and anomalies of the urachus on a firm basis. The following facts emerged. The urachus and bladder develop exclusively from the ventral cloaca. The urachus arises by a narrowing of the cranial end of the cloaca and shares with the bladder in its post-natal descent from the umbilicus. In its descent the urachus drags down the adventitia of the obliterated umbilical arteries and, at the same time, its apex becomes broken up, leaving behind its epithelial cells. These epithelial cells may proliferate to form adenomata or, by central degeneration, give rise to cyst formation.

Although containing pus and debris, many cysts are sterile, others grow *Bact. coli*, streptococci, or staphylococci. The route of infection is probably haematogenous in most cases.

Incidence.—In reviews of the literature, Weiser (1906) collected 89 cases and Kantor (1939) a further 38. Since 1936 32 references to the condition have been found in the literature. Yoerg (1942) found only 3 cases in 12,500 admissions to the Brady Urological Institute. The recorded literature gives the impression that anomalies of the urachus are rare, but few experienced surgeons fail to claim one or two cases, and my own experience of four and possibly five cases in a short period strengthens the belief that they are not uncommon. Sex incidence is difficult to establish, but Kantor's analysis suggests an approximately equal incidence. Age incidence in his series varies from 20 months to 69 years.

Classification (Long, 1931).—(1) Those communicating with the bladder. (2) Those communicating with the umbilicus. (3) Those communicating with the bladder and umbilicus. (4) Those communicating with neither. Group 4 cases are most common, and it is easy to understand how these may become group 1 or group 2 as a result of infection.

Diagnosis and Treatment

It is probable that the majority of group 4 cases never come to light unless they become infected; they may give no symptoms and are discovered only at necropsy. The presence of a urachal cyst should always be suspected in any midline abdominal-wall swelling lying between the umbilicus and the symphysis pubis. Differentiation from vitelline cysts is facilitated when it is remembered that the latter are not continued downwards as a sinus towards the symphysis pubis (Yoerg, 1942). Cystoscopy helps in group 1 and group 3 cases, and a patch of bullous oedema in the apex of the bladder may lead to the suspicion of an infected cyst.

The ideal treatment is complete excision of the cyst and tract extraperitoneally. When infected, incision with drainage is often safer. In many cases this is curative, and in any event does not make complete excision at a later date much more difficult. Infection of the peritoneal cavity can generally be well controlled with chemotherapy, and, though undesirable, spillage does not lead to the serious peritonitis of former days. Opening the peritoneum need not be feared if that is necessary for the complete removal of the cyst and its tract.

Case 1

A roadman aged 46 was admitted to hospital complaining of difficulty in passing urine for three days, and of complete retention on the day of admission.

On examination his temperature was 99° F. (37.2° C.); his abdomen revealed an old puckered appendicectomy scar with surrounding fibrosis, and the scar of a right inguinal hernia repair. The bladder was distended half-way to the umbilicus. After unsuccessful catheterization he passed 14 oz. (400 ml.) of urine and continued to do so, although at first with some difficulty.

Investigations.—Urine: deposit of red blood cells, polymorphs, and Gram-negative bacilli. Blood urea, 40 mg. per 100 ml. Straight x-ray film and intravenous pyelogram normal. Cystoscopy showed general congestion of mucous membrane only. A diagnosis of acute cystitis was made, and after a course of penicillin the patient was discharged free from urinary symptoms.

Two months later he was readmitted because of sub-umbilical pain before, during, and after micturition. He was now tender below the umbilicus, and a plaque of induration was noted between the symphysis and the umbilicus but no swelling or inflammation. He had a mild fever and his urine contained mucoid material and a few red blood cells. Cystoscopy revealed a very prominent anterior commissure to the prostate and a small rosette of bullous oedema in the dome of the bladder. These findings were interpreted as being probably due to a urachal diverticulum. A cystogram showed an ill-defined extension from the fundus of the bladder.

Operation (See Figs. 1a and 1b).—Under penicillin cover a midline incision was made from the umbilicus to the symphysis pubis. This was deepened through the

Figs. 1a and 1b.—Diagrammatic representation of operation findings in Case 1.

rectus sheath to expose a glistening mass of fibro-fatty tissue. The bladder was opened and a mass the size of a billiard ball was palpable in the dome, but no diverticulum could be made out. In an attempt to dissect out this mass it ruptured, with the escape of cheesy material and pus. Running up from the cavity thus exposed was a track lying extraperitoneally and extending almost to the umbilicus, the surrounding tissues being almost cartilaginous in consistency. As much as possible of the anterior wall of the track and cyst was excised. The interior was then curetted and finally treated with the diathermy button to destroy any epithelial elements. The bladder was closed about a Pezzer catheter and the cyst and its track were packed with paraffin and flavine gauze. The wound was left widely open.

Pathology.—Sections of the walls of the cyst and track consisted of fibro-muscular tissue with inflammatory cell infiltration and exudate. Smears of pus showed fibrinous debris with epithelial cells and a few polymorphs. There were no organisms and no growth after 48 hours' incubation.

The wound slowly granulated to the surface; the de Pezzer tube was then removed and complete epithelization followed, leaving a very firm abdominal wall. Cystoscopy before discharge showed a completely normal bladder, and five months later he had no urinary symptoms and the abdominal scar was firm.

Case 2

A bricklayer aged 31 was admitted to hospital, having had soreness and swelling at the umbilicus for two weeks, followed by some vague abdominal pains. For the last four days the abdominal pain had become more severe. Meanwhile the swelling at the umbilicus had become larger, tender, and red. For three days he had not had his bowels open or passed flatus. He felt sick, but had not vomited. He had not previously noticed a swelling at the umbilicus, although it had never been a depressed scar. There had never been any discharge from the umbilicus or any urinary symptoms.

On examination his temperature was 100.6° F. (38.1° C.), pulse 80, and respirations 20. Protruding from the umbilicus was a red glistening swelling, about 2.5 cm. in diameter, which was very tender on palpation. At first sight this looked like a knuckle of bowel protruding through the umbilical cicatrix, but more careful examination showed it to be covered with skin, continuous around the margin of the umbilicus with the skin of the anterior abdominal wall. There were tenderness and guarding in both iliac fossae and in the umbilical region. Bowel sounds were accentuated. A provisional diagnosis of inflamed umbilical hernia with strangulated contents was made.

Operation.—The swelling was explored through a transverse elliptical incision and an infected urachal cyst was found. To its peritoneal surface the omentum was firmly adherent, and when this was separated the thin wall of the cyst ruptured, with discharge of pus and necrotic material. The whole cyst and the urachal cord were dissected out along with the umbilical arteries and their peritoneal coverings. The abdominal wall was repaired with stainless steel wire.

Apart from minor wound sepsis he made an uneventful recovery. The wound healed completely, leaving a firm abdominal wall.

Case 3

A carpenter aged 28 was admitted to hospital. Seven days previously he had noticed a stiffness in the region of the umbilicus after lifting some heavy weights. This persisted, and for four days there had been a yellowish discharge from the umbilicus. On the day of admission he developed a pain around the umbilicus, which became worse and at the time of examination was constant and severe. He had no alimentary or urinary symptoms.

On examination his temperature was 99.4° F. (37.4° C.), pulse 100, and respirations 20. In the umbilicus was a small red nodule from which yellow pus exuded on pressure around. There was generalized abdominal tenderness. The bowel sounds were normal and cystoscopy was negative. A provisional diagnosis of infected urachal cyst was made.

Operation.—Under penicillin cover, an elliptical incision was made around the umbilicus, and on deepening it through the rectus sheath a small urachal cyst was found in the extraperitoneal tissue below the umbilicus. A well-marked urachal cord continued down from this. The cyst, cord, and obliterated hypogastric vessels, as well as a portion of the ligamentum teres, with the peritoneum covering their posterior surface, were then excised. The wound was closed in layers, using stainless-steel wire for the rectus sheath. The subcutaneous tissues were drained with corrugated rubber. He made an uneventful recovery.

Pathology.—Microscopically no epithelial lining to the cyst was present and no lumen was visible in a transverse section of the distal end of the urachus. There were many pus cells and mixed organisms in the pus, but no growth on culture.

Case 4

A storeman aged 33 was admitted to hospital, having had a discharge from the navel for three weeks. His doctor had given him penicillin cream to apply. Three days before admission he began to have pain below the umbilicus which

was griping and spasmodic but not very severe. There was no nausea or vomiting, and no alimentary or urinary symptoms.

On examination a purulent discharge was seen coming from the umbilicus, and just below it there was a small spheroidal swelling in the abdominal wall. Cystoscopy and cystography were normal.

Operation.—A midline incision with an ellipse was made around the umbilicus. A urachal cyst was defined and dissected free. The urachal cyst was followed down to the dome of the bladder, where it was clamped and divided. The bladder wall was repaired in two layers with catgut. The obliterated hypogastric arteries were also dissected out, the whole procedure being performed extraperitoneally. The linea alba was repaired with wire and the skin closed about a corrugated drain.

Pathology.—Microscopically there was no epithelial lining to the cyst, and no lumen was present in a transverse section of the distal end of the urachus. The appearances were those of an infected urachal cyst.

Comment

Cases 1 and 2 fall into Long's group 4, and Cases 3 and 4 into group 2. They show several interesting points in the ways they presented, in diagnosis, and in treatment. Case 1 presented first as acute retention of urine, and there was difficulty in deciding how this arose. A possible explanation is that inflammation in the urachal relic caused a block in the lymphatic territory, which it presumably shares with the bladder-neck, since both derive from a common ancestor—namely, the ventral cloaca. This would cause oedema around the neck of the bladder, and a "congestive stricture" would result. Some support is given to this theory by the finding, on cystoscopy, of "a prominent anterior commissure" to the prostate which was probably due to oedema, since it had completely disappeared at the final examination. The ring of bullous oedema in the dome of the bladder which gave the first clue to the diagnosis was very striking indeed. Case 2 presented as an inflamed umbilical hernia with strangulation, and only at operation did the true nature of the condition become apparent. Cases 3 and 4 complained of a discharge from the umbilicus with an associated midline swelling, and a pre-operative diagnosis was made with confidence.

Case 1 was treated by saucerization of the cyst and track combined with diathermy cauterization of the epithelial lining. In Cases 2 and 3 the umbilicus and the urachal cyst and track were excised with their covering peritoneum; while in Case 4 the cyst and track were dissected out without opening the peritoneum. The final result was similar in each case.

In the last year one other case has been seen, which, although not capable of complete proof, is highly suggestive of urachal pathology.

A housewife aged 64 complained of a painful swelling in the lower abdomen of one week's duration. She had recently had an attack of influenza and bronchitis, but no symptoms referable to her genito-urinary or alimentary tracts. On examination there was a large rounded swelling in the anterior abdominal wall, extending up from the symphysis pubis, half-way to the navel. There was central fluctuation beneath red and oedematous skin, and obviously pus lay underneath. The mass was incised and a large quantity of foul-smelling pus escaped from a subcutaneous abscess. The latter led through a hole in the linea alba to another abscess cavity lying behind the recti muscles but in front of the peritoneum, which was intact. The abscess was saucerized and drained through two lateral stab drains with suture of the midline incision about a central drain. She made an uneventful recovery, and when seen eight months later the lower abdomen was quite healed and soft. Pathological examination of the pus showed numerous pus cells but no organisms. There was no growth on culture.

The midline situation of the abscess, its "collar-stud" nature, and the fact that the communication between its two compartments was so strictly midline suggested an

infected urachal cyst as a possible diagnosis. Of course, the alternative diagnosis of an infected haematoma brought on by her recent coughing is equally admissible.

These cases seen in a short period seem to indicate that the urachal remnant is a more frequent cause of disease in the umbilicus and anterior abdominal wall than is perhaps generally realized.

Summary

The development of the urachus and the pathogenesis of urachal cysts are discussed.

A note is added on their incidence, diagnosis, and treatment.

Four cases of infected urachal cysts and possibly a fifth case are described and the clinical and operative findings commented upon.

I should like to express my gratitude to Mr. D. P. Marks, of Stratford-upon-Avon Hospital, and Mr. Henry Clarke, of Luton and Dunstable Hospital, for permission to publish these cases and for assistance with their management; to Mr. L. R. Broster for encouragement and criticism in writing this paper; to Dr. J. Bradley Watson for the pathological reports; and to the librarian of the B.M.A. Library for considerable help with references.

LINGUAL THYROID

BY

K. SICHER, M.D., D.M.R.

Radiotherapist in Charge, Coventry and Warwickshire Hospital

Lingual thyroid is a rare occurrence. It appears that Hickman recorded the first case in 1869. Buckman (1936) collected 242 cases from the literature up to and including 1935, but Montgomery (1935, 1936), studying probably the same material, reduced this number to 144 which he accepted as genuine lingual thyroids. Crispell and Parson (1950) stated that up to 1949 a total of 276 cases had been reported. Between 1949 and 1951 I was able to find seven more reports of lingual thyroid, including the case described below. In all these cases the lingual thyroid was causing symptoms; the incidence of silent cases will never be established.

Montgomery recognized as authentic lingual thyroids only those cases in which a specimen was examined and proved histologically to consist of thyroid gland tissue and when the lesion was situated in the tongue substance between the epiglottis and the circumvallate papillae. From the embryological point of view, it is natural to expect that the most common site for its occurrence in the tongue should be in the region of the foramen caecum.

According to Montgomery (1935, 1936), Goetsch (1948), and Nordland and Nordland (1950) "lingua thyroid" and "lingual goitre" should not be confused with "aberrant thyroids," as they accept the view of Warren and Feldman (1949) that the latter are metastatic deposits from carcinoma of the thyroid gland.

A great majority of reported lingual thyroids were histologically diagnosed to be benign. A definite malignancy in lingual thyroids was reported in few

instances (Graham and McWhirter, 1947). Most cases resembled the normal thyroid tissue, but adenomatous changes have been observed in some. In most of them, normal type of epithelium predominated, and in others the foetal type was present. Simple goitre of colloid type has also been seen.

Lingual thyroids or goitres are detected usually when their size is such that they give rise to symptoms. It has been postulated that thyroid insufficiency is responsible for most, if not all, simple hypertrophies of lingual thyroid tissue. No case has been reported with hyperthyroidism. The thyroid insufficiency may arise when a special stress such as puberty, pregnancy, or lactation exists, and in the total absence of the thyroid in the normal anatomical position these factors excite a compensatory hypertrophy of the ectopic thyroid tissue. This view is well supported by the histories of the recorded cases. The menopause was also described as a possible factor. Most of the patients were females.

The interesting feature in the following case is the unusual presenting symptom of haematemesis, which was misleading enough to cause considerable delay in establishing the diagnosis. The rarity of this condition precludes learning from one's own experience. The main object of this paper is to draw attention to its existence and to give guidance in management of a similar case.

Case Report

A married woman aged 30 was admitted as an emergency case in December, 1950, because of haematemesis, but giving no previous history of vomiting or dyspepsia. She was of small stature, 4 ft. 8 in. (142 cm.), fairly well nourished, and of limited intelligence. She had two children, both delivered by caesarean section. She was now six months pregnant. There had been amenorrhoea for the past seven years. Abdominal examination revealed no epigastric tenderness. Her pulse was rapid, of poor volume; heart sounds were good; blood pressure was 120/70. Her blood count was: Hb, 50%; colour index, 0.7; red cells, 3,500,000; white cells, 20,000 (polymorphs 85%, lymphocytes 10%, large monocytes 4%, eosinophils 1%). Three pints (1.7 ml.) of blood was transfused, following which her blood count was brought to normal limits. She remained under observation for about a fortnight, and as there were no further symptoms she was discharged and advised to attend the antenatal clinic. She was delivered of a stillborn baby by caesarean section on March 15, 1951.

She was well until June, 1951, when she was again admitted as an emergency because of another haemorrhage. This time, however, she said that she "felt fluid at the back of her throat" which she kept swallowing. She vomited about $\frac{1}{2}$ to $\frac{1}{4}$ pint (140 to 280 ml.) of blood in the ambulance. At the same time she noticed that her voice became "thick." Examination of the mouth with the help of a laryngeal mirror revealed a pale-pink, globular, and firm mass, approximately 2.5 cm. in diameter, which was attached to the tongue in the region of the foramen caecum. The mucous membrane running over it was intact, and there were numerous dilated veins which were probably responsible for the haemorrhage. The suprasternal space appeared to be much emptier than usual, and the trachea was easily palpable. Thyroid could not be felt in the neck. A lateral x-ray film of this region confirmed the existence of a well-defined swelling at the far end of the tongue. The opinion was expressed that the mass was most probably a lingual thyroid.

Her family history revealed that both parents are rather small, approximately the same height as she is. She has three sisters and one brother. One sister and the brother are of normal height, but two other sisters are not much taller than she. Her two boys are of right size and weight

for their age. She knew that she was thyroid-deficient, as her family doctor had been giving her thyroid tablets from 2 years of age. Her voice became thicker after the first haemorrhage (December, 1950), when she was six months pregnant, and during the last month or two of pregnancy she began to have difficulty in swallowing.

Because of the risk of a haemorrhage, a diagnostic test with radioactive iodine was advised instead of biopsy. A tracer dose of 100 μ c. of I^{131} was given orally, and the measurements were started six hours later with a Geiger counter. These demonstrated that the iodine was taken up by the mass in the posterior third of the tongue, and that there was no evidence of any uptake in the neck. The 48-hours urinary excretion of I^{131} was about 60%. The B.M.R. was +1%. The diagnosis of a lingual thyroid was therefore confirmed. In view of the history of thyroid deficiency, treatment with Lugol's iodine was begun. After six weeks of this treatment the swelling showed no change in size. As it was thought that surgical removal would involve a great risk, especially of haemorrhage, it was decided to treat her with radioactive iodine. Because of her age, only 5 mc. of I^{131} was administered in September, but as there was no change in size of the thyroid after three months a further dose of 20 mc. was given in January, 1952. Its urinary excretion increased to 78% in the first 48 hours. The B.M.R. taken at the same time was -19%. Even after this dose the swelling did not appear to shrink, but in fact it looked larger. She began to complain of more difficulty in swallowing, dysphonia was more pronounced, and she had two more small haemorrhages. Her weight increased slightly and her face was somewhat puffy. At the end of March her B.M.R. was -24%. It was then decided that the thyroid had to be removed surgically. Operation was carried out on May 12; the tongue was pulled well out, and, with a finger supporting the tumour from behind, access was surprisingly good. An incision was made over the anterior part of the swelling, which was then shelled out without any difficulty. Haemorrhage was easily controlled by interrupted sutures.

The post-operative course was uneventful, and she was discharged after nine days. The pathological report was as follows: "The specimen is well encapsulated, roughly spherical in outline, and about 4 cm. in diameter. The cut surface suggests thyroid tissue. Section confirms that it consists of thyroid tissue which shows marked variation in structure from active epithelial hyperplasia to involution and quiescence. There is no evidence of malignancy."

On August 12 her swallowing was good and her voice was normal. Myxoedematous signs and symptoms became, however, much stronger. The B.M.R. dropped to -38%, and she was given thyroid extract. Since then she has remained well and symptom-free.

Diagnosis

According to Goetsch, lingual thyroid has to be differentiated from adenoma, angioma, salivary tumour, fibroma, non-thyroid cysts, and the rare instances of malignancy such as sarcoma, lymphosarcoma, and carcinoma. Apart from the characteristics associated with thyroid insufficiency, which are frequent, most symptoms are caused by the pressure and obstruction of the lingual swelling. Various degrees of dysphagia, dysphonia, and dyspnoea are the most common symptoms. Occasionally, tightness in the throat or a choking sensation is the only complaint. Recurrent haemorrhage from the mouth was one of the symptoms recorded.

It is important to remember that in examination of the mouth extreme protrusion of the tongue is essential, as a small nodule can easily be overlooked. Inspection with a laryngeal mirror should not be omitted. Lateral x-ray films of the soft tissue of the face and neck will help in locating the lesion.

Nachman *et al.* (1949), and Crispell and Parson (1950), diagnosed their cases with a tracer dose of I^{131} and physical

measurements with a Geiger-Müller counter. In my case this test was found to be most helpful, and it is strongly recommended because of its accuracy, simplicity, and absence of risk. Biopsy, the obvious procedure in diagnosis of most tumours, seems to be superfluous. It is worth noting that the results of the tracer dose corresponded with those of the B.M.R. in this case.

Treatment

Lingual thyroid has never been successfully treated medically. Montgomery tried Lugol's solution without success. In some goitres thyroid extract could perhaps be of some benefit, but it is doubtful whether it would adequately reduce the symptoms caused by obstruction, nor would it eliminate a recurrence of a haemorrhage. The only other methods available are radiotherapy and surgery. It seems hardly justifiable to treat a simple goitre with high dosage of deep x rays, which would result in severe skin and mucosal reactions. Small dosage would be of little if any effect.

Treatment with radioactive iodine, mainly because of its simplicity and its effectiveness in other thyroid conditions, would seem to be an obvious method to explore. Hamilton and Lawrence (1942) have demonstrated that the administration of I^{131} to rabbits was followed by a decrease in size of the normal thyroid. Since then this isotope has been successfully used in the treatment of toxic goitres in various centres. Buck and Guthrie (1949), and Schilling *et al.* (1950) have reported cases of lingual goitres treated with I^{131} , but, although decrease in size was claimed, in neither case was the resolution of the swelling complete, and some of the symptoms persisted. Myxoedema was produced in each case. A study of the concentration of I^{131} in thyroid by radioautography revealed that the absorption of iodine depended greatly on the type of predominant tissue, and it was seldom homogeneous. It was said that thyroids with abundant colloid are more likely to concentrate the isotope. In my case no beneficial effect whatsoever was observed. Once the lingual thyroid reaches the dimensions when the patient starts to have more than occasional discomfort, and especially when a haemorrhage occurs, one is forced to remove the tumour and disregard the thyroid function in order to eliminate the symptoms.

Furthermore, it is generally accepted at present that no radioactive substance should be given in therapeutic doses to young patients. As the result of treatment with this isotope is doubtful it seems ill-advised to break this rule in the case of a lingual thyroid, which occurs mostly in children or young adults, unless there are strong contra-indications to surgery.

It was stated by some authors that surgery is technically difficult and because of anaesthetic hazards and the difficulty in controlling the bleeding it should be replaced by therapy with radioactive iodine. My experience in this single case was to the contrary. In fact, the extirpation of this goitre was characterized by absolute simplicity in every respect. Others who have also chosen the oral route in recent years found no apparent difficulties, and one wonders if modern anaesthesia and surgery would not remove the above-mentioned objections. The extraoral route was adopted by some in unusually large tumours. The most commonly expected sequel is thyroid insufficiency, which, however, can be easily controlled by giving small doses of thyroid extract. This complication might be avoided in cases of thyroids which are not encapsulated, and it seems reasonable to follow the advice given by Goetsch, that complete removal or destruction need not be attempted.

Summary

A case of lingual thyroid is reported in detail, and a short survey of the literature regarding this rare condition is made with reference to its incidence and pathogenesis. Its diagnosis and treatment are more fully

discussed, and evaluation of radioactive iodine as a diagnostic and therapeutic agent is attempted. On the basis of recorded cases in the literature and from my own experience it is concluded that I^{131} serves as the most valuable test towards the diagnosis, but in treatment the surgical approach is found to be preferable.

I wish to thank Mr. T. H. Berrill, who performed the operation, for his helpful co-operation and Dr. W. C. MacCullagh Wilson for his pathological investigations.

Medical Memorandum

"L.E." Cells in Acute Disseminated Lupus Erythematosus Treated with A.C.T.H.

Many cases of acute disseminated lupus have now been treated with A.C.T.H. or cortisone (Montgomery and McCright, 1949; Brunsting *et al.*, 1951; Haserick *et al.*, 1951). However, the initial detection of L.E. cells in this disease after treatment with A.C.T.H. or cortisone has rarely been recorded (Haserick, 1951; Michael *et al.*, 1951). The following case showed this phenomenon.

CASE REPORT

A single woman aged 23 was admitted to hospital on August 21, 1951, with a two-months history of a rash around the eyes, cheeks, nose, and "V" of the neck. She had taken four tablets containing phenolphthalein a few days before the rash appeared. Five weeks later she complained of malaise, nausea, shivering, pains in the limbs, and swelling of the face. The following week the rash had spread to involve the hands and feet. Her past history was uneventful, apart from an attack of "influenza" which was treated with sulphonamides at the age of 17 years. She denied being given sulphonamides on any other occasion, and gave no history of sensitivity to sunlight.

On examination she appeared seriously ill. Her temperature was 103° F. (39.4° C.), pulse 120, respirations 20, and blood pressure 110/60. A violaceous erythema extended over her face, ears, scalp, and "V" of the neck, and scaling and crusting were present on her cheeks. The swelling on her face was such that her eyes could be opened only with difficulty. The pulps of the fingers and toes showed erythematous patches, and telangiectases were present around the nail-folds. The mucous membranes of the mouth and lips were superficially eroded. Moderate painless enlargement of the axillary, cervical, and epitrochlear glands was present, and the spleen was just palpable on inspiration. No abnormality was detected in the chest or locomotor or nervous system.

Investigations.—Hb, 12.58 g. per 100 ml.; red cells, 4,200,000; white cells, 4,000, with a lymphopenia and toxic granulocytic changes; platelets, 90,000 per c.mm. (Lempert). The iliac marrow smears showed changes consistent with a severe toxic process. Plasma proteins, 7.19 g. per 100 ml.

(albumin 3.3 g., globulin 3.8 g.). Urine, normal. Blood urea, 83 mg. per 100 ml. Urinary creatinine, 1.41 g./24 hours; plus creatine, 1.54 g. Blood culture, negative. Paul-Bunnell reaction, negative. No L.E. cells found, using the technique of Eppes and Ludovic (1951).

A diagnosis of acute disseminated lupus erythematosus was made. Over the next few days the patient's clinical condition deteriorated, and she became very drowsy.

Starting on August 28, 50 mg. of A.C.T.H. daily was given by intravenous drip in 5% dextrose solution for four days, followed by 40 mg. daily for a further four days. Within 12 hours the temperature had fallen to normal, and there was subjective improvement. On August 29 numerous L.E. cells were found in the peripheral blood for the first time.

A.C.T.H. was discontinued on September 4 because signs of pneumonia developed at the right lower lobe. By this time all the skin manifestations had disappeared. Chloramphenicol, aureomycin, and penicillin were given without any exacerbation of the lupus erythematosus, and she was discharged home on October 13 still complaining of general weakness, but afebrile and with no abnormal physical signs. Coincident with the clinical improvement the number of L.E. cells in the peripheral blood decreased, and two days before discharge could no longer be demonstrated. The A/G ratio had also reverted to normal.

During the next three months she felt very well and was symptom-free. Her weight steadily increased, and there was no clinical evidence of lupus erythematosus.

Investigations on January 31, 1952, showed: Hb, 13.32 g. per 100 ml.; red cells, 4,800,000; white cells, 6,000, with normal differential count. E.S.R. (Wintrobe) had fallen from 38 mm. in one hour on October 25 to 28 mm. on January 31. Plasma proteins, 6.9 g. per 100 ml. (albumin 4.5 g., globulin 2.4 g.). Urine, normal.

At this time, however, L.E. cells were again found in the peripheral blood, and one week later the rash recurred on the face. On February 16 she was readmitted to hospital and given 50 mg. of A.C.T.H. intramuscularly daily for 10 days, followed by 100 mg. daily for two days. Then for 200 mg. of cortisone was given intramuscularly daily for three days, but, except for a transient initial response, her condition steadily deteriorated and she died on March 3. During this relapse L.E. cells were repeatedly found in the peripheral blood, there was a steady fall in the haemoglobin, erythrocytes, leucocytes, and platelets, the E.S.R. increased, the urine contained albumin, casts, and red cells, and the blood urea rose. The A/G ratio again became inverted, although the total protein values remained within normal limits.

DISCUSSION

This case initially showed a dramatic response to A.C.T.H., but the response during a relapse was almost negligible. The reason for this acquired resistance is not clear.

Hargraves *et al.* (1948) first reported the finding of L.E. cells in heparinized bone marrow. They are usually polymorphonuclear leucocytes containing a rounded body, which is most often homogeneous, but may at times show a reticular or granular pattern. The presence of the inclusion body causes the lobes of the polymorph nucleus to be flattened out at the periphery of the cell. Occasionally similar bodies may be found in eosinophils or histiocytes. The inclusion bodies are derived from either polymorph or lymphocytic nuclei, and have been shown to contain desoxy-ribose nucleic acid. The production of the L.E. cell has been shown to depend upon an abnormal factor present in the gamma-globulin fraction of the patients suffering from lupus erythematosus.

Although L.E. cells have been found most often and in greatest number in the acute and subacute varieties of lupus erythematosus, they have also been found in a few cases of the chronic discoid variety and occasionally in small numbers in other diseases. In a few cases of systemic

lupus erythematosus these cells could not be found ever after repeated search. Thus the significance of the L.E. cell is not finally settled.

In the present case L.E. cells were found only after A.C.T.H. had been given, and not before the start of treatment. Haserick (1951) and Michael *et al.* (1951) report a similar finding in cases treated with cortisone. Haserick thought that in his case the initial negative finding may have been associated with the low level of gamma globulin in the plasma resulting from marked proteinuria. A positive L.E. test was obtained eight days after starting cortisone therapy. The interval between starting cortisone and the finding of the L.E. cells is not stated in the case of Michael *et al.* (1951).

Although the original plasma globulin was raised in the present case, estimation of the separate fractions was not undertaken. Perhaps this might have shown the gamma fraction to be low and thus account, as in Haserick's case, for the negative result. There was no proteinuria at this time, and, although the blood urea was elevated, it has been shown that the *in vitro* addition of urea does not inhibit the formation of L.E. cells (Haserick, 1951).

Another explanation might be that the A.C.T.H. had in some way stimulated the production of the L.E. plasma factor contained in the gamma-globulin fraction. On the other hand, it is realized that L.E. cells may disappear during treatment with A.C.T.H. or cortisone, although cortisone *in vitro* has been shown to exert no inhibitory effect on the plasma factor (Haserick, 1950).

From the practical point of view it is suggested that when initial negative L.E. cell examinations have been obtained repeated tests should be undertaken, and in some instances it might be justifiable to administer A.C.T.H. or cortisone provocatively. So far as I am aware L.E. cells have not been demonstrated in other diseases following the use of A.C.T.H.

The reappearance of L.E. cells in the peripheral blood occurred at a time when the patient was symptom-free. Other laboratory findings were normal, and the E.S.R. was still falling, although it had not returned to normal. The presence of L.E. cells was thus the first indication of the relapse that was to follow, and therefore was of prognostic value. Haserick (1951), however, thought that the finding of these cells is an indication of systemic involvement and not of value in prognosis. He also found that as the general condition improves the number of L.E. cells diminishes and may even disappear. There is no doubt that the finding of L.E. cells is a valuable aid in the diagnosis of systemic lupus erythematosus, and, although many other diseases have been investigated, positive results have only rarely been reported (Berman *et al.*, 1950).

It was originally thought that anticoagulants were necessary for the demonstration of L.E. cells, but their presence has been shown to be unnecessary (Eppes and Ludovic, 1951; Marten and Blackburn, 1953).

I am very grateful to Drs. H. R. Vickers and I. B. Sneddon for permission to publish this case and for their constant help and encouragement, and to Dr. E. K. Blackburn for the haematological findings and help in the preparation of this paper.

R. H. MARTEN, B.M., M.R.C.P.,
Senior Registrar in Dermatology, Middlesex Hospital.

Reviews

BRINGING HEALTH TO AFRICA

African Highway: The Battle for Health in Central Africa. By Sir Malcolm Watson, M.D., C.M., D.P.H., LL.D. With introduction by Sir Eric Macfadyen. (Pp. 294; illustrated. £3 3s.) London: John Murray. 1953.

The discovery of copper in Northern Rhodesia led to the establishment of four mines situated from thirty to sixty miles apart across the so-called Copper Belt. During the preliminary stages of the construction of the camps it became obvious that tropical diseases were rampant in the area and that, unless active measures were taken, ill-health would inevitably ruin the enterprise. In 1929 the mine directors sought advice from the Ross Institute of Tropical Hygiene, where Sir Malcolm Watson was at that time director of the Department of Malaria. Practical guidance and help were at once forthcoming, and a team of experts was dispatched to investigate the situation and carry out whatever recommendations they made. In this they received the active support of the mine officials.

Part I of this book describes the measures which brought about the evolution of the original primitive disease-ridden camps into the healthy up-to-date settlements which now occupy the same sites. The author acts as compère to a series of articles written by mine officials, medical officers, and research workers, together with copious extracts from official reports, and himself writes many chapters. The principal disease was malaria, and the vectors were *Anopheles gambiae* and *A. funestus*. The former was controlled without great difficulty, but the latter presented many problems which would have daunted a less experienced malariologist than Sir Malcolm. By the application or modification of methods which he had evolved in Malaya, mosquito breeding was quickly brought under control. As often happens, the recession of malaria was accompanied by a corresponding improvement in the general health of the community, which was aided in no small measure by a progressive housing policy and strict attention to general hygiene and sanitation. The results can be assessed from the annual death rates among the African workers, which fell from 34.6 to 6.6 per 1,000 between 1930 and 1938. Perhaps an even more significant pointer is the fact that in 1946 the life insurance rates in the Copper Belt were the same as in the Witwatersrand and other parts of South Africa.

The second part of the book gives some account of matters which have an important bearing on the health and well-being of the African village.

African Highway is neither a textbook nor, strictly speaking, a book of reference, though it contains in an easily accessible form a great deal of information of interest to those concerned with health problems in Africa. Rather it is a record of an outstanding achievement in tropical hygiene which redounds to the credit of the industrialists who had the vision to give it their unstinted support. It is not inappropriate that this book should be published in the year of the Rhodes centenary, for, as the author points out, the story it tells gives much food for thought to those who are disposed to denigrate so-called imperialism and private enterprise.

J. S. K. BOYD.

LUNG RESECTION

Die Lungenresektionen. By Professor A. Lezius. (Pp. 143; 149 figures. M. 49.80.) Stuttgart: Georg Thieme. 1953.

This monograph is based on a personal experience of about a thousand cases of operations on the lungs carried out in the university clinic of Hamburg by Professor Lezius. It deserves the most careful study by every surgeon engaged in this special field. It is in two sections. The first or general section deals with the indications for resection of the lung,

carcinoma, bronchiectasis, chronic infections, tuberculosis, and non-malignant tumours. The main characters of each condition are discussed in brief but accurate detail. A description follows of the investigations required to establish the possibility of operation, where due weight is given to pathological anatomy and essential features of the patient's condition. The author then considers the general technique of operations on the lungs, and describes in precise detail the closure of the pulmonary root.

The special section describes in succession the exact and varied technique required for resection of the different lobes of the lung. In every instance the methods are illustrated by large-scale drawings of great precision and superb draughtsmanship, in which every detail of each operation can be followed with ease. They form a remarkable tribute both to the skill of the surgeon and to the patience of the artist. The section concludes with an interesting and important account of closure of tuberculous cavities by resection of the bronchus.

Based as it is on a wide practical experience and most careful work, the volume is an example of all that a monograph should be on a new and difficult field, success in which has been achieved only by recent advances in our knowledge of the anatomy and pathology of the lungs, the discovery of antibiotics, and new methods of anaesthesia. It is of interest that the author regards as most important of all the rise of the professional anaesthetist in Germany, a circumstance which may have an effect on Continental surgery quite outside the region of the chest.

HENRY SOUITAR.

THE PHARYNX

The Pharynx: Basic Aspects and Clinical Problems. Edited by Professor Abraham R. Hollender, M.D., F.A.C.S. (Pp. 560; illustrated. £5 10s.) Chicago: Year Book Publishers, Inc. London: Interscience Publishers Co. 1953.

In his preface the author writes: "Recent developments and advances in Medicine in general and in Otolaryngology in particular have made it desirable that there should be available for students and practitioners a separate work dealing with direct and related problems concerning the Pharynx." Since all parts of the upper respiratory tract are anatomically continuous, the wisdom of separating off one part is doubtful for the instruction of the student. Further, it is impossible to avoid some inclusion of adjacent parts. Dr. Hollender has invoked the collaboration of nineteen colleagues, and some overlapping and repetition are unavoidable. And as the contributors write in great detail on their special subjects the student at least will find the reading heavy going. Fortunately the editor has written a foreword to each chapter and at its end has summed up the gist of the article, giving an appreciation of its contents. Both of these are so good and clear that the student might confine his reading to them. The advanced inquirer will find detailed knowledge on the pathological and clinical problems of all aspects of the subject and a wealth of facts and opposing opinions. There is, too, a comprehensive list of references at the end of each chapter. As is to be expected, the references are mainly to American literature, though a few British are included; but one misses some that are standard in this country.

The book is divided into thirty chapters. The first six are respectively on anatomy, physiology, pathology, bacteriology, methods of diagnosis, and x-ray examination. The last is admirable—profusely illustrated with clear reproductions of radiographs of all possible lesions. There follow four chapters on the clinical problems of the nasopharynx; the fourth is on stenosis of the posterior choanae, and operations for its relief are described in detail, with illustrations that should be helpful to the surgeon faced with one of these rare cases. Eight chapters are devoted to the mouth and oropharynx; the one on the manifestations of blood diseases is full and instructive. For removal of tonsils it does not appear that the Davis gag is used. For children under 16 open ether is advised, a view that certainly would

not appeal either to the patient or to the surgeon in Britain. For adults local analgesia is advocated. The uvula, salivary glands, and infections in the neck are considered in the next section. There are clear pictures of the fascial planes and the spread of infections in relation to them, but enough stress is not laid on how much fewer and less dangerous these infections have become since the advent of the antibiotics.

Tuberculosis, syphilis, and neoplasms are described adequately and their treatment given in detail. The statement that tuberculous lesions are comparatively common in the nasopharynx has not been recognized in British textbooks. A chapter on the relation of tonsillectomy and poliomyelitis is excellent. Opinions for and against operation during epidemics are supported by many statistics, but leave the question open. The final advice is to avoid operation during the summer months, when poliomyelitis is at its worst. The discussion on tonsils and rheumatism brings out the opinion generally held in Britain.

Shortly, this work is a book of reference for the E.N.T. specialist. The illustrations are unequal in quality; some are good, notably those of radiographs and pathological sections, but the clinical ones need knowledge for their interpretation.

W. M. MOLLISON.

EXAMINING THE NERVOUS SYSTEM

Diagnostic Tests in Neurology. A Selection for Office Use. By Robert Wartenberg, M.D. Forewords by Sir Gordon Holmes, M.D., F.R.S., and Stanley Truman, M.D. (Pp. 228; 62 figures. \$4.50 or £1 13s.) Chicago: The Yearbook Publishers, Inc. London: Interscience Publishers Ltd. 1953.

The author, who works at the University of California School of Medicine, thinks that diagnosis in neurology, as in some other branches of medicine, is coming to depend too much on laboratory and other special methods of investigation, while the bedside examination of the patient is too often neglected. His book is an attempt to correct this fault, and he clearly describes a large number of simple methods of neurological examination and the conclusions that can be drawn from them. He does not attempt to give a systematic account of examination of the central and peripheral nervous systems, nor does he mention some important aspects such as the investigation of disturbances of speech. The numerous tests are well described and many are illustrated. Some of them are rarely used in Britain, and might with advantage be adopted. In his account of the signs of a lesion of the pyramidal tract he refers to eversion of the foot on the affected side, but what he is in fact describing and illustrating (p. 109) is external rotation of the hip and not eversion of the foot. His account of the reflexes, of which he has previously published a detailed study, is especially good, and he rightly avoids the use of eponyms to describe various ways of eliciting the same reflex; but it is doubtful whether his name of "triceps surae reflex" is ever likely to replace the more familiar "ankle jerk." This book is a useful addition to accounts of clinical examination of the nervous system.

J. W. ALDREN TURNER.

ROYAL VICTORIA HOSPITAL, BELFAST

Fifty Years on the Grosvenor Road: An Account of the Rise and Progress of the Royal Victoria Hospital, Belfast, during the Years 1903-1953. By Robert Marshall, M.D., F.R.C.P., F.R.C.P.I., D.P.H. (9, College Gardens, Belfast.) (Pp. 139; illustrated.)

The Royal Victoria Hospital, Belfast, had its origin in the year 1792 in a house, but as the city grew the need for larger premises led to the building of a hospital of 100 beds in 1815 and the increase in the number of beds to 186 in 1870. In 1903, when the population of the city was 350,000, the present fine hospital in Grosvenor Road was opened. The (then) new hospital was original in design, with clerestory lighting and the plenum system of ventilation, but in the course of 50 years many alterations and additions have taken place, and it is the story of this period

of development in the new building that is graphically described in this book of 137 pages. The history of the Belfast General Hospital has already been written by Malcolm (1851), and the intervening period awaits a historian.

The author divides the 50 years into 10 quinquennia, and in each period he first gives the main events of world history followed by a description of the chief changes in the hospital so that (as he intended) the pageant of the growth of the hospital passes before us with the panorama of the world's activities as a background. This method makes it a little difficult to read the book straight through, but it serves to give a proper perspective to the picture.

Many famous medical men have come from the Queen's University and from the Royal Victoria Hospital, and an account of many of them will be found in this book. Many of them (85%) have sought a career in other countries, chiefly in England, rarely in Scotland. The reader will note with interest that the distinguished men who 12 years ago were elected respectively President of the Royal College of Physicians and President of the Royal College of Surgeons of England, and who later were both created peers, were both of them sons of graduates of the old Queen's University of Ireland.

This is a faithful account of a celebrated institution which will be welcomed by all who have been connected with it, and it contains many facts which will be of interest to a much wider circle. We wish there had been an index of names.

ZACHARY COPE.

HINDU PSYCHOLOGY

Mental Health and Hindu Psychology. By Swami Akhilananda. Introduction by Professor O. Hobart Mower. (Pp. 229. 16s.) London: George Allen and Unwin. 1952.

In Hinduism the philosophic background of religion in the widest sense cannot be reached without mental training, and so religion and psychology are inseparable. Hence the place given to the technical training of the mind by Hindu thinkers. Our author, after long residence in America, believes that Hindu psychology has some qualities missed by Western psychology. The relative failure of much psychological treatment, particularly psycho-analysis, he attributes to the almost total separation of religion and psychology.

His argument is that acceptance of the pleasure principle as a primary objective in life must lead to repression. But this is a wrong objective. Hinduism teaches that transformation of the emotions obviates repression. The standard of life in America, judged by wages and physical amenities, is high. If the resources of science could remove mental ill-health, America would be free of it. But mental disabilities are increasing, owing to an inherent defect in the customary Western outlook on life. In Hindu thought, the ideal is the unfolding of inner possibilities. "In the west, the problem is how much a man can possess . . . in India the problem is, on how little a man can live." When the comforts of the world are paramount the result is apprehension and anxiety.

Freud and his followers, who regard religion as illusion, come in for criticism; they lack a personal understanding of religion itself. To explain religious strivings in terms of a preconceived hypothesis produces distortions, not interpretations, of religious experience. The damage to human society arising from a confusion of mature and immature religious sentiment is immense.

The complacency of some psychiatrists and their facility in providing psychopathological explanations for all human frailties is no guarantee that they have the answers. This volume does not claim to provide all the answers, but it does claim, with justification, that there is much in Hindu thought which could enrich Western psychological thought and practice.

SATURDAY JULY 25 1953

THE CARDIFF MEETING

The only thing over which the organizers of the Cardiff meeting had no control was the weather. With everyone contributing so much and so freely, the skies, not to be outdone, determined to show that in the United Kingdom Welsh rain was as good as anywhere else. It dampened a few clothes but no one's spirits. The topography of the Civic Centre, the glory of Glamorgan and of Wales, was quickly mastered by the visitors, and a quick dash from the City Hall to University College took one easily from one form of splendour to another. It was in the City Hall that a fortunate few from the B.M.A. had the privilege of lunching with the Queen. It was in the City Hall that the Representative Body met during three of its four daily sessions. And it was here that distinguished doctors of Britain, Canada, the U.S.A., and Sweden received their honorary degrees from the University of Wales. This was as it should be, because Cardiff as a city identified itself with the B.M.A. for the ten days of its meeting more closely, perhaps, than any city in any previous meeting. The Lord Mayor, Sir James Collins—knighted by the Queen on the first day of the meeting—was a host in himself, and was benevolently present on numerous occasions, saying the right word at the right time, and never too long at that. His example of kindness was followed by the policeman in the street, by the trolley conductor, by the shopkeeper, the hotel staffs, and by the taxi driver (English in origin) who said that Llandaff was the largest city in Europe. For many, if not most, of the visitors, Cardiff was previously but a local habitation and a name. But they soon learned that it was a centre of civilization, a city rightly proud of its civic advancement, of its contributions to learning, of its bustling prosperity, of its spotless cleanliness in the midst of coal and steel and great ports. Within the confines of the castle the remains of a Roman wall and a Norman keep are monumental reminders of Cardiff's long history, and the Tudor rose set on three ostrich feathers in the city's crest bears witness to the close historical relationship between the land of the Saxons and the Angles and the land of the Ancient Britons.

It was in the City Hall too that the retiring President, Dr. P. T. O'Farrell, invested with his chain of office the new President, Mr. J. W. Tudor Thomas, around whose person the Annual Meeting revolved. The ethnologist a millennium hence may detect in these annual meetings of the Association a pattern which has the qualities of a ritual dance in which the Church, the State, and the local citizens join with the profession of medicine, celebrating by speech and ceremony their interrelated works for the health of society. Mr. Tudor Thomas moved through the complicated ritual with dignity and a self-effacing ease which belied the unremitting effort and attention to smallest detail he has given in preparing those many activities the sum of which set the seal of success on a meeting which combines traditional ceremony, the hard business of medical politics, and scientific exposition. There was so much to do, so much to see, so much to learn, that at times the visitor found it hard to choose between alternative functions proceeding simultaneously. If the President, by his qualities of mind and character, compelled the visitors' admiration, Mrs. Tudor Thomas captured their hearts with her grace, friendliness, and charm. Seldom have the ladies who come to these meetings as wives and daughters been so surrounded with thoughtfulness and pleasure. It is always invidious to mention among so many the names of those who helped the President in his task, but Dr. John D. Spillane, the honorary local general secretary of the meeting, deserves special thanks. Needless to say, the arrangements for receiving and entertaining the visitors made by the various local committees, not forgetting the ladies' committees, went with a swing from start to finish.

As science secretary, Professor Gilbert I. Strachan, who was general secretary of the Cardiff meeting in 1928, may well feel satisfied with not the least important aspect of an Annual Meeting. There was a good attendance at the seventeen scientific sections, and welcome confirmation of the value of the experiment started last year in Dublin—the holding of plenary sessions in which panels of experts make their varying contributions on subjects of general interest and in which members of the audience can subsequently take part. The three subjects chosen this year—coronary disease, "fibrositis," and overweight—proved attractive to large audiences, and the chairmen and speakers had learned much from the Dublin experiment. There can be no doubt the plenary sessions have come to stay, and will prove to be of increasing value and interest to the general physician. This year the section on child health arranged a panel discussion on the care of the newborn—an innovation which

proved to be highly successful and worthy of imitation at subsequent meetings. At Dublin last year a scientific exhibition was staged for the first time. Again, many lessons were learned as a result, and those who planned the exhibition this year showed how well they had learned them in putting on a scientific exhibition of exceptional interest and merit, though there is still room for more simplicity in presentation. Especially notable were the exhibits of the Departments of Pathology and Bacteriology of the Welsh National School of Medicine and of the M.R.C. Pneumoconiosis Research Unit, Cardiff. In the trade exhibition this year there was an attractive display of drugs, appliances, and books of value to doctors in their daily work. It was unfortunate that these two interesting and helpful exhibitions were housed—though excellently housed—just far enough away from the main meeting-places to make attendance at them a bit of an effort. And hosts at Cardiff in their generous hospitality filled the day so full that it was difficult to give the time to these exhibitions they so well deserved.

So another B.M.A. year comes full circle. Mr. Tudor Thomas and his colleagues and the Cardiff Division can look back at the result of their labours with the satisfaction that comes from doing well a job that was worth doing, and they carry forward with them the gratitude of those who attended a memorable meeting and the affection of old and new friends. All who went to Cardiff for the first time last week will be anxious to return there.

THE A.R.M.

This year's Annual Representative Meeting was faced with a full agenda, and on the first day its business was happily interrupted by the visit of the Queen to Cardiff. In spite of this the meeting came to an end at a reasonable hour on the Monday, and no important item on the agenda was scamped. The Representative Body, if in a congenial mood, was thoroughly alert and the hall of the meeting was always full. Dr. S. Wand, who was unanimously elected for another year as Chairman of the R.B., conducted the business of the meeting in a masterly fashion, and also showed himself on other occasions as an admirable spokesman for the Association.

The meeting was fully reported in last week's *Supplement*, and here reference may be made to some of the outstanding matters debated. Perhaps the most important was the motion from the Winchester Division, which was carried, that a Constitution Committee should be set up to "consider and report on a reorganization of the Representative Body

and such other constitutional matters as the Council may decide." It was also resolved that not more than 50% of the members of this committee should be members of Council. The jubilee year of the Representative Meeting is an appropriate time to choose for a review of the Association's constitution. The position of the profession and of the B.M.A. in relation to their work and especially to the State is vastly different from what it was in 1903. Each section of the profession in a nationalized health service has its own peculiar problems, and in attempting to solve them two powerful autonomous committees of the Association have been active over a very wide field—a field co-extensive with general and consultant practice. It would seem inevitable that their place in the B.M.A.'s constitution will be looked at afresh, as well as such other matters as the size of the Representative Body and the way in which it is constituted. At the meeting general practitioners showed their concern over the possible interference with their work by industrial medical officers and health visitors—a matter principally, it would seem, of establishing good relationships. In the Lincolnshire motion (carried) urging the establishment by the Ministry of Health of geriatric units, the voice of the general practitioner was again heard expressing fear that another part of his work might be taken out of his hands. Other motions showed that practitioners continue to press for general-practitioner hospitals and for better access to diagnostic facilities—and their concern for their patients was expressed in the vote given against the shilling tax on prescriptions.

The debate on a motion (carried) that the Council of the Association "should produce a scheme for the return of goodwill" and report to the R.B. next year showed there is still a lively interest in the buying and selling of practices, and that experience of the past five years has convinced many that the abolition of this custom has, as one speaker put it, caused as many difficulties as it set out to solve. But, as Dr. Wand pointed out, the passing of the motion has not altered the Association's policy: the Council has been instructed to produce a scheme, and the policy of the Association in relation to it will be determined when that scheme is presented to the R.B. next year in Glasgow. The outstanding matter in the report of the Central Consultants and Specialists Committee was the remuneration of hospital medical staffs. Dr. T. Rowland Hill, in presenting the report, made it clear that his Committee was insisting on the implementation of the Spens Report, "which had been publicly accepted by the Government immediately before the inauguration of the Service, and which had also been accepted by the medical profession." Any wavering

on this would be of the greatest disservice to the consultants of to-day and to-morrow. The unanimous vote of the R.B. in support of the consultants' claim has given them a firm backing. Linked with this theme is one of immediate importance—the establishment of an independent Court of Arbitration. It is incredible that the Minister of Health and the Secretary of State for Scotland have recently refused to meet the Staff Side of the Whitley Councils to discuss this matter, especially as in 1947 the then Minister of Health promised to help if there were any difficulty in setting up the Whitley machinery. The absence of an independent Court of Arbitration to which either side may have the right to take a matter in dispute is something that cannot be tolerated much longer, and Dr. K. Cowan, in presenting the report under "Public Health," put the whole matter before the R.B. with great clarity. As the Chairman of Council, Dr. E. A. Gregg, said earlier in the meeting, arbitration is "a right which is a matter of common human justice"; and it is a right which the Association will press with every determination to secure.

MORBIDITY OF CHRONIC RHEUMATISM

One of the most important aims of the Health Service must be to relate the hospital service to the needs of the community. Clearly, accurate knowledge of the morbidity of various diseases is needed if it is to succeed. In certain groups of diseases, especially those of low mortality, this information is difficult to come by, and, as the Empire Rheumatism Council has recently pointed out, particularly is this so for the chronic rheumatic diseases. The Newman Report¹ of 1924 was based on general practitioners' records and referred only to employed people covered by National Health Insurance, thus excluding large sections of the population. Although Dr. J. Alison Glover wrote his classic report in 1928² from the Ministry of Health drawing attention to the need for special study of this group, little further official action was taken until 1945, when the Department of Health for Scotland published the results of a further survey³ subject to much the same defects as the Newman report. Fortunately, as a result of a generous gift from the Nuffield Foundation, a Department of Rheumatism Research was founded⁴ in 1947 in the University of Manchester, and at last it has been possible to carry out a field survey, giving adequate information. This survey, of the industrial town of

Leigh in Lancashire, of about 50,000 inhabitants, was on a carefully calculated sample of 3,515 inhabitants over the age of 15. The results have been published by Drs. Kellgren, Lawrence, and Aitken-Swan,⁴ and they are of the greatest interest both to clinicians and to administrators.

While the more advanced cases of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and gout are clearly recognizable, the earlier cases may not be, although, as in other diseases, the more expert the examiner the earlier the diagnosis. The "large variety of more transient painful syndromes, which are usually called fibrositis, neuritis, or lumbago" are less easily defined, and where these workers were unable to make a firm diagnosis they wisely classified them as indeterminate. The controversial and perhaps fashionable "slipped disk" had to be faced, and they divided cases into two categories: the frank prolapse, and disk degeneration, the former being less common and occurring in younger people.

Among the mass of interesting information that comes out of this study we learn that the overall complaint rate was 33% over the previous five years and 19% at the time of the survey. 4.5% of the males and 7.9% of the females were suffering from osteoarthritis, 1.4% and 3.3% from rheumatoid arthritis, and 4% of the males had symptoms referable to a disk lesion. The findings in the older people are of special interest in view of their increasing proportion in the population. Of the females over 60 25% had osteoarthritis; 4% of the males and 9% of the females had rheumatoid arthritis. The vertebral disk is a greater cause of symptoms in males, cases being twice as common as in females. The maximum incidence (12%) occurred in the fifth decade of life, though in the fourth decade 7% had symptoms. The undetermined diseases affected an earlier age group than osteoarthritis or rheumatoid arthritis, and the incidence fell off with increasing age, when the incidence of osteoarthritis or rheumatoid arthritis was rising, suggesting that at least some of them are due to as yet undiagnosable manifestations of these diseases. Half the patients with rheumatoid arthritis lost no working time, showing that rheumatoid arthritis is by no means necessarily a crippling disease. Nevertheless, 20% of the males and 31% of the females lost three months' work or more during the preceding five years. Disk disorders were also an important cause of lost working time, and even in the undetermined groups some 30% of affected males had lost one week or more and 6% as much as three months from work. As to the economic effects of these disorders, they must be more impoverishing to the country than is commonly realized.

The consultation rate with the general practitioner varies with the condition. In the undetermined group it was as low as 50%, but of men with rheumatoid arthritis only 19% failed to consult their doctors, and a similar figure applies to those with disk disorders. Of the women 38% with rheumatoid arthritis and 50% with osteoarthritis failed to consult their doctors. The triviality of the symptoms is not the only reason for failure to see the doctor; the general belief that rheumatism is incurable accounts for part of it undoubtedly. Perhaps the most disturbing feature of the whole story is the figure for attendance at hospital. The numbers of patients referred correspond with the numbers of those losing three months or more of work, and then only a quarter of these obtained in-patient treatment. Curiously, patients with equivalent disability from disk disorder or undetermined pain are more frequently sent to hospital than patients with rheumatoid arthritis.

The writers of this report are careful to point out that these figures apply only to an urban industrial community in the north-west of England. The results of the East Anglian Survey carried out in a similar manner on a rural community are awaited with great interest. The report deserves the most careful study by all concerned with the planning of the hospital services from the Minister downwards, and it is to be hoped that every regional board and board of governors will examine its implications.

MEDICINES CLASSIFIED

Doctors in the National Health Service—whether in general practice or hospitals—will have received from the Ministry or Department of Health a list of proprietary medicines classified by the Joint Committee on Prescribing of the Central and Scottish Health Services Councils. This Committee was appointed in 1949, under the chairmanship of Sir Henry Cohen, to consider whether it was desirable and practical to restrict or discourage the prescribing by general practitioners of drugs and medicines of doubtful value or of unethical character, and of unnecessarily expensive brands of standard drugs. In an interim report in June, 1950, the Committee gave its views on the questions put to it in terms of reference. It asserted that absolute restrictions on prescribing were impracticable. A doctor must be free to prescribe any drug which in his opinion was necessary for the patient. The Committee, however, thought that the prescribing of certain proprietary preparations could, and should, be discouraged. For instance, those advertised to the public should be avoided on the grounds that the responsibility for prescribing should rest entirely with the doctor. The Committee went on to suggest the classification of proprietary preparations as a

guide to economy in prescribing. Six categories were proposed: (1) new drugs of proved value not yet standard; (2) proprietary brands of standard drugs, singly or in combination; (3) standard preparations, and new remedies of proved value, in elegant form or vehicle; (4) qualitative and/or quantitative modifications in the composition or combination of standard preparations, or new remedies of proved value, which are not accepted as therapeutically superior to preparations included either alone or in combination in the *British Pharmacopoeia*, *British Pharmaceutical Codex*, or *National Formulary*; (5) preparations not in the *British Pharmacopoeia*, *British Pharmaceutical Codex*, or *National Formulary* which in the Committee's view have not been proved of therapeutic value; (6) preparations which are a combination of (4) and (5).

Apart from preparations in categories (5) and (6) the Committee did not suggest that these proprietary preparations should not be freely prescribable in the National Health Service, except when advertised direct to the public. It recommended that proprietary preparations in category (1) should be freely prescribable, and that preparations in categories (2), (3), and (4) should be prescribable subject to their not being designated as foods or toilet preparations, or not as drugs for N.H.S. purposes by the Definition of Drugs Joint Subcommittee; their not being advertised direct to the public; and satisfactory arrangements for price being made between the Health Departments and the manufacturers.

The lists now circulated with a covering letter from the Chief Medical Officer represent a review during the last two and a half years of some 5,000 preparations. So far only those falling into categories 1, 5, and 6 have been classified; those not mentioned may be assumed to be in categories 2, 3, and 4. Additions and amendments will be made from time to time. Arrangements for pricing medicines in categories 2, 3, and 4 are now under discussion with the manufacturers and a list of prices is being prepared for circulation to show the cost of standard and proprietary preparations in the *National Formulary* and other proprietaries.

Whether the hard labour of Sir Henry Cohen's Committee will have a commensurate effect on the drug bill remains to be seen. It is good that its recommendations are to be circulated to hospital staffs. As for the already paper-bound general practitioner one wonders if the irritation of more printed reference matter will defeat its purpose. For a busy general practitioner to be asked, as the Chief Medical Officer does in his letter, "only to prescribe preparations not included in the enclosed lists after you have ascertained the cost and compared it with that of identical or similar standard preparations and not to prescribe preparations of which the price is not readily and conveniently ascertainable" promises on the face of it some forbidding research. His request that "both the frequency and the quantities of orders for standard products" should be reduced is practical and should be complied with. A welcome reaffirmation of the doctor's right to prescribe whatever he thinks necessary is overshadowed by a reminder that he may be called upon to justify himself before a local medical committee. The

reader might be forgiven if he recalls a certain lord high executioner who sang:

"Some day it may happen that a victim must
be found,
I've got a little list—I've got a little list."

However, the cost of prescribing threatens to jeopardize much-needed improvements in the National Health Service, and it is the duty of all who prescribe to respond with good will to any appeal for co-operation in any reasonable measures of economy.

THE BANNING OF HEROIN

Diamorphine, or heroin, is the most potent drug of addiction known. Addiction to it is produced more rapidly than to morphine, and it is generally agreed that the subsequent effects are worse. The addition may on occasion become a danger to society as grave as an epidemic of virulent infectious disease. Thus in Egypt in 1930 it was estimated that, out of a population of 14 million, 500,000 were diamorphine addicts, and most of them were young men. Although the incidence of this addiction has been reduced since then by vigorous restrictive measures, it still constitutes a formidable problem in many parts of the world, particularly in Finland, in the United States, and in Middle Eastern countries. Fortunately it is insignificant in Britain, where there are at present not much more than 300 registered drug addicts, and of these only about 60 are addicted to diamorphine.

In 1949 the World Health Organization's Expert Committee on drugs liable to produce addiction agreed that, although 50 countries had banned the use of diamorphine, adequate control of the illicit traffic in it would not be achieved until the ban was world-wide. The Committee therefore decided to renew its attempts to persuade the remaining countries, particularly the United Kingdom, which exports large quantities of diamorphine, to make the manufacture and use of the drug illegal. It was pointed out that a world-wide ban on its production would greatly facilitate the fight against the illicit drug traffic, as control bodies would then know that diamorphine discovered anywhere could only be contraband. In May of this year a further unanimous recommendation was made at the Sixth World Health Organization Assembly that the production and importation of diamorphine be abolished throughout the world.

If diamorphine were an essential and unique drug with no satisfactory alternatives it would be unjustifiable to ban its use in this country simply because it is abused in others. It thus becomes of interest to inquire to what extent diamorphine is an indispensable drug. The conclusion of properly controlled studies, as distinct from empirical clinical impressions, which are notoriously fallacious, is that diamorphine is qualitatively almost identical in its action with morphine, is somewhat more powerful (hence the smaller dose), and is relatively more toxic. Much has been said about the advantages of diamorphine over morphine, but these are probably only two in number: its psychological effects are more

pleasurable (hence its greater danger as a drug of addiction), and it is somewhat less nauseating. For these reasons it is probably the drug of choice, though by no means irreplaceable, in the terminal stages of painful incurable disease, and some surgeons consider it superior to morphine as a post-operative analgesic, especially for children, not only because it is a little less nauseating but also because of its undeserved reputation for being less constipating. If these are the only indications for the use of diamorphine in preference to other drugs, they do not perhaps constitute very convincing arguments for its indispensability in comparison with the cogent reasons for its abolition. The situation now is different from what it was, because other morphine derivatives are available and powerful new synthetic analgesics such as amidone and pethidine have been introduced. If appropriate choice of these remedies is made, and if they are skilfully used in proper dosage, the necessity to use diamorphine must be slight. In Britain 50% of the diamorphine goes into cough linctuses. Such preparations have no particular advantage over those containing opium, morphine, amidone, or codeine in adequate dosage, and the loss of diamorphine as a cough suppressor would therefore not be a serious disadvantage. It is significant that the monograph on diamorphine hydrochloride has been omitted from the 1953 *British Pharmacopoeia*. There would thus be the most respectable precedent for Government authorities should they decide on the revolutionary step of making the use of the drug illegal in Britain.

A MEMORIAL TO SIR JACK DRUMMOND

It is nearly a year ago since Sir Jack Drummond, his wife, and daughter were brutally murdered while on holiday in France. Lord Woolton, in letters to *The Times* and *Daily Telegraph* last week, recalls Drummond's work as scientific adviser to the Ministry of Food during the war, work which led to the introduction of measures "that have left their permanent mark on the social structure of our country." In order that Drummond's outstanding contribution to his country's victory in the war and his countrymen's welfare if peace should not be forgotten a committee has been formed under Lord Woolton's chairmanship for the purpose of obtaining funds to endow a Drummond Research Fellowship in the subject of nutrition. "This fellowship," Lord Woolton writes, "would cost about £25,000, would be administered by a body of university trustees, and be tenable in any university or appropriate research institution." Among the members of the committee who join with Lord Woolton in this appeal are Lord Horder, Professor E. C. Dodds, and Sir Harold Himsforth. Doctors have had better opportunity than most to observe the benefits to health which have followed the practical application of the advice that Drummond gave the Government during the war, and they will give unqualified approval to the method that has been chosen of perpetuating his name.

*The address of the Drummond Memorial Fund is c/o The Westminster Bank Ltd., 154, Harley Street, London, W.1.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

INDIGESTION IN CHILDHOOD

BY

NORMAN B. CAPON, M.D., F.R.C.P.

Professor of Child Health, University of Liverpool; Senior Physician, Royal Liverpool Children's Hospital and Alder Hey Children's Hospital, Liverpool; Senior Paediatric Physician, Liverpool Maternity Hospital

Indigestion, or dyspepsia, occurs frequently in childhood, and it may be acute or chronic. Sometimes the symptoms are due to a particular disease, such as hepatitis or tuberculous peritonitis, that can be recognized and demonstrated; but many patients with indigestion recover without a definite pathological cause being discovered. It is to these patients that I want especially to call attention, and for two main reasons: though recovery takes place the child suffers discomfort and his parents have a worrying time; and the doctor may be faced with a perplexing clinical problem while he is searching for the cause of the illness. To compare dyspepsia with other examples of disordered function, such as dyspnoea or dysuria, is to realize that careful clinical examination, supported when necessary by special investigations such as radiography, blood studies, etc., will usually show the reason for a child's shortness of breath or difficulty with micturition; but the cause of dyspepsia often remains a matter for speculation. Has it been due to some peculiar sensitivity to certain foods? Is it that the secretion of saliva, or of gastric juice, of trypsin or bile, is temporarily disordered? Has the detoxicating action of the liver decreased temporarily? There are many possible theories and explanations, and the doctor—perhaps feeling dissatisfied with "indigestion" as a diagnosis—should have a satisfactory plan to follow.

There are four stages in the medical handling of these cases. The first is to recognize the clinical picture (grouping of symptoms and signs) justifying a provisional diagnosis of indigestion; the second is to consider, and if possible exclude, those pathological states that might be responsible for the symptoms and signs noted; the third is to weigh up the possible effects of (a) constitutional type; (b) faults in dieting; (c) unhygienic habits; (d) subnormal general health, and (e) nervous factors in causing the illness; and the fourth is to recommend treatment. It is not, of course, intended that these stages should be considered independently; each has a relationship to the others, and together they form a basis for the proper study of each case. In discussing them I shall begin by taking stages one and two together, dealing first with the acute and then with chronic indigestion.

Acute Indigestion

The common symptoms of acute indigestion (due, for instance, to overeating, or to taking unsuitable food) are malaise, then nausea, then vomiting, and sometimes abdominal pains of a colicky type. Diarrhoea may begin soon after vomiting has started, and the motions quickly become watery, and perhaps green in colour. The temperature may rise to about 99.5 or 100° F. (37.5 or 37.8° C.) after the child has been ill for an hour or so. His breath often becomes offensive, his tongue quickly shows a coating, and frequently he looks pale and anxious. Dehydration may develop if there is much vomiting or diarrhoea, but by this time the provisional diagnosis of indigestion may have been

discarded in favour of, say, acute gastro-enteritis. Acute indigestion may be expected to subside within two or three days, but illness such as gastritis, gastro-enteritis, and enterocolitis usually last longer, and vomiting or diarrhoea—or both—are likely to be more persistent.

Every child presenting the clinical picture described above should be carefully examined at least once daily until recovery has occurred or an alternative diagnosis has been made. There are, of course, many illnesses that begin with nausea and vomiting, abdominal discomfort, coating of the tongue, and other symptoms commonly found in simple indigestion, and experience shows that confusion occurs particularly with the following:

Tonsillitis and sometimes pharyngitis. (The throat of every ill child should be examined, with a good light.) The temperature usually rises quickly, the tonsillar lymphatic glands are often found to be slightly tender when carefully palpated, but few children with tonsillitis complain that the throat feels sore. There may be pain and tenderness in the right iliac fossa—sometimes resulting in an unnecessary appendicectomy.

Pneumonia, especially in the earlier years of life. It is important to note even an occasional cough, tachypnoea, and movements of the alae nasi. Abdominal tenderness—and perhaps even some "guarding" may occur when the pleura is involved.

Measles.—Some cases start with vomiting, diarrhoea, and pyrexia.

Urinary Infection.—The child's genitalia should be examined and a drop of the urine should be seen under the microscope, to exclude the presence of pus cells. This is especially important when a febrile child is found to be shivering.

Intra-abdominal inflammation and intestinal obstruction—for instance, appendicitis, peritonitis (usually streptococcal or pneumococcal), intussusception, volvulus, etc. In this group occur the most serious diagnostic errors, but in the space available I cannot do more than make brief comments upon them. Emphasis must be placed upon the need for a detailed history and accuracy in abdominal and rectal examination. Appendicitis is fairly common at all ages, except perhaps in the first year of life, and in childhood the localizing signs are often less distinctive than in the adult. It is essential that abdominal examination should be carried out with great care and gentleness, and as soon as possible after the onset of symptoms. When this is done the significance of localized tenderness in the right iliac fossa or under the lower edge of the liver is great, and there may be some reflex spasm of the overlying abdominal muscles; but these signs may disappear again within a few hours, especially when generalized peritonitis develops.

Pneumococcal peritonitis causes fever, vomiting, abdominal pain (generalized, but especially in the lower half of the abdomen), diarrhoea, and sometimes a vaginal discharge of a yellow or greenish-yellow colour. The child's general appearance may suggest a pulmonary rather than an abdominal infection, and there may be herpes labialis. Intussusception causes intermittent attacks of colic, at first lasting only a few minutes and waking the child from sleep. Careful abdominal palpation between the bouts of colic will usually reveal the tumour. At first the motions are normal, and then a little blood-stained mucus may be seen. Henoch's purpura presents a very similar clinical picture,

except that there is no abdominal tumour and petechiae may be found on the skin. Intestinal obstruction complicating hernia is less common in children than in adults; it is unlikely to be missed if a thorough examination is made, including inspection of the hernial orifices.

"*Acidosis*."—This term, though unsatisfactory as a diagnosis, calls attention to a clinical syndrome of some importance. A highly strung child, usually with parents of a similar constitutional type, is seized with severe and repeated vomiting. Even drinks of water may be returned, and the child becomes pale, distressed, and restless; there is oliguria and constipation, and a dangerous metabolic upset develops rapidly. Many different causes may bring on an attack—eating too many chocolates, a head-cold or tonsillitis, excitement, or a nervous shock, and it is obvious that the clinical picture is dependent mainly upon the constitutional make-up of the patient.

Chronic Indigestion

Though the clinical picture of subacute or chronic indigestion comprises a rich variety of symptoms and signs, the cases may be usefully divided into two main types. The first, often associated with excessive or unwise dieting, includes children that are well-built—frequently oversized—and with some of the following complaints: coated or "geographical" tongue, offensive breath, a sallow, muddy, pale, or pasty complexion with dark lines (described by the mothers as blue or black) under the eyes, hiccup, flatulence, epigastric discomfort, frontal headaches, and an appetite that may be excessive or impaired. The second type is illustrated by the thin, lanky child with flabby flesh, faulty posture, rather bluish and cold hands and feet, laxity of ligaments, and in general an appearance that makes his mother comment that he is going thin and looks very weedy, especially when he is with other children of the same age. Usually his appetite is said to be very small, but in other respects his symptoms may include any combination of those noted in the first type.

More detailed analysis of the symptomatology shows how wide may be the variations from case to case. In some, the abdominal discomfort is trivial; in others there may be severe pain in any part of the abdomen, and the child may cry, double-up, and become pale. These pains are usually of short duration, but they recur and may be excited by taking food. Sometimes they are accompanied by a desire to defaecate, but this does not always relieve the pain. The abdomen is often distended, especially when the child is thin and has flabby muscles; the distension is gaseous. The motions vary in character—sometimes normal, sometimes constipated, and often of a pale, grey, and greasy appearance for several days in succession. It is at these times that the abdominal discomfort and distension are likely to be most troublesome. In some of the more highly strung children with indigestion the motions may be mucoid, "like jelly," and either white or almost translucent. In these cases the descending colon may be spastic. Often there are curious changes of behaviour; the child is abnormally restless and active, but tires quickly and becomes apathetic. Many are said to behave as if they are unhappy; they become irritable, quick-tempered, moody, and may be rude to adults. At night their sleep is disturbed, they are restless, grind their teeth, dream about frightening experiences, and have night-terrors. When they wake up in the morning their sleep does not seem to have done them good. Some—and especially those that have been given food late in the evening—wake after about an hour of sleep and scream with abdominal pain. A cough of "habit spasm" type is quite common; migraine and vertigo are less frequent. Pains in the limbs are sometimes troublesome, and may arouse suspicions of rheumatic infection, especially when there is a low-grade fever.

It will be appreciated that in childhood chronic indigestion is more likely to show itself by general ill-health than by well-defined symptoms and signs pointing to an alimentary disorder. Hence, in the differential diagnosis, infec-

tions such as tuberculosis, rheumatic disease, and intestinal parasites must be included; and in some cases the coeliac syndrome (including fibrocystic disease in the pancreas), megacolon, intestinal malformation, recurrent intussusception, peptic ulceration, and Krohn's disease may require consideration, perhaps with the aid of radiography, and examination of the blood and faeces. Usually, however, it is reasonable to order treatment and to postpone further clinical investigation until its effect is observed.

Treatment

The treatment to be recommended for a child suffering with subacute or chronic indigestion is largely a question of common sense; but it must also take account of the possible influence of those factors, such as constitutional type, whose assessment formed the third stage in investigating the patient (see p. 197). Some children are born with a sub-normal capacity for digesting their food, especially fats, and any attempt made to fatten them up by giving cream, eggs, and extra butter is likely to cause indigestion, and especially when the child's appetite is not as hearty as the mother would wish. There is an obvious tendency in these cases for the child to be offered an unusually varied diet, the mother searching for any kind of food that the child likes and can take without ill-effects; and soon the child is virtually in charge of his own diet. The position should be carefully explained to the parents, and it is best to recommend rather small helpings of as normal a diet as the child can take, provided that the fat content (butter, cream, egg yolk, meat fat, etc.) is kept rather low. As a result, the child's appetite increases, he makes better use of the food taken ("Now good digestion wait on appetite"), and he will gradually learn to digest his food more satisfactorily. To encourage this there should be a very gradual increase of the amount of fat and other ingredients offered to him, and by this means the patient can usually be saved from becoming a food faddist in adult life.

Dietetic faults account for many cases of indigestion in childhood, and they concern feeding habits (the technique of feeding) as well as the food itself. The history must be taken in considerable detail, and it is best to make a complete record of all solids and liquids taken during an average period of 24 hours, and to ask whether the child feeds in company with other children and whether persuasion is used. One of the commonest stories is that the child "eats nothing"; and there is no doubt that some of these children have developed "negativism" towards feeding as a reaction to the mother's attitude at meal-times, and they may, in fact, take less food than is desirable. On the other hand, a detailed history often shows that the mother is mistaken and the child is taking more nourishment than he needs, usually as extra milk, cream, and butter, and perhaps with cocoa at bedtime. Useful rules are to forbid foods (which include milk, biscuits, and cake) between meals; to offer a relatively small first helping, with a second helping if the child asks for it; and to have the child take his food in company with other children if this can be arranged. Many of these patients make better progress when they are taking their meals at school than at home, because they are not bothered by attempts at persuasion and they imitate the feeding habits of the other children. It is often difficult to convince the conscientious, over-anxious parents of an only child that they would get better results—and much happier results—both for themselves and the child if they were to allow their child to become hungry. It is indeed sad that some children are denied the pleasure of having hunger to satisfy, and are at the same time condemned to indigestion, hunger being the normal initiator of the digestive processes.

The dyspeptic children of educated parents suffer more often from excess of fat than excess of carbohydrate; but the child that is eating large quantities of bread, cakes, pastry, sweets, and potatoes is undoubtedly liable to indigestion with gaseous distension of the abdomen. Food that is eaten too quickly and is not masticated thoroughly

may cause trouble, and parents should see that their children pay regular visits to the dental surgeon and clean their teeth properly. In childhood general hygiene seems to play a more important part in relationship to digestion than it does in adult life; hence such questions as sleep and rest, exercise, sunshine and fresh air, cleanliness of the body, and the maintenance of reasonable discipline all need consideration in the treatment of chronic indigestion. Similarly general ill-health—for instance, anaemia and sub-acute respiratory infections—impair digestion and should receive appropriate treatment.

Finally, nervous instability and indigestion are intimately related in childhood. Parents who worry unnecessarily, or disagree about the management of the child, create a fretful environment; and there are many other circumstances, including infidelity between parents, or death of one of the parents, that disturb the atmosphere of security found in a normal, happy home-life, and upset a child's nervous system and his digestion. These cases are perhaps the most difficult to treat effectively, requiring tactful and sympathetic understanding.

Medicines play a secondary part in the treatment of chronic indigestion, but they have their uses. A rhubarb and soda mixture is often helpful; and the pale child with a poor appetite and coated tongue will usually be helped by a mixture containing 5 to 10 minims (0.3 to 0.6 ml.) of dilute hydrochloric acid, and 10 to 15 minims (0.6 to 0.9 ml.) of glycerin of pepsin (*B.P.C.*), taken thrice daily immediately after food. Medicinal charcoal is useful when there is gaseous distension of the abdomen; and the passage of pale motions is an indication for 5 gr. (0.32 g.) doses of pancreatinum (*B.P.*), given with 10 gr. (0.64 g.) of sodium bicarbonate two hours after food. Pancreatin granules (enteric coated) can be obtained, and are palatable to children.

Next Refresher Course Article.—"Cortisone and A.C.T.H.," by Dr. C. L. Cope.

Refresher Course Book.—The first collection of articles of this series (fully revised) are available as a book containing 55 chapters, price 25s. Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

THE MEDICAL RESEARCH COUNCIL'S REPORT FOR 1951-2

This year clinical research is the subject for the introductory essay in the Medical Research Council's annual report.* The choice is timely. Plans for developing clinical research within the framework of the Health Service were published last week as a White Paper (*Journal*, July 18, pp. 140 and 147), and there have been signs elsewhere, notably from the College of General Practitioners, that the profession as a whole is becoming more research-minded in its approach to clinical problems. The Medical Research Council speaks with authority on this subject. It is therefore particularly interesting to learn that, although the first research unit to be set up by the Council after the first world war was a clinical one—the Department of Clinical Research at University College Hospital Medical School—the promotion of clinical research at that time is now thought to have been premature. True, the department proved outstandingly successful, both in the work emanating from it and, but even more, as a school for clinical investigators. This was owing to the genius of the unit's director, the late Sir Thomas Lewis, a man in advance of his age. For the most part clinical problems defied investigation—as

**Report of Medical Research Council for the Year 1951-2.* Cmd. 8876, H.M.S.O. Price 6s. 6d. net.

distinct from observation—because the necessary chemical and instrumental methods were lacking. Medical research was therefore concentrated on the pre-clinical subjects where appropriate techniques were available. By the middle 1930's, however, Lewis's pupils were filling university chairs of clinical medicine and taking up research appointments; at the same time new techniques of investigation were being elaborated. The stage was set for bringing the scientific method to the bedside. By 1939 the Medical Research Council had three clinical research units: by 1948 there were 18. In 1948, also, the National Health Service began, and virtually all clinical facilities passed to the Health Departments. The time had clearly come to review the administrative arrangements for clinical research, particularly those concerning access to patients, and to define the fields of the Health Departments and the Council. Against this background discussions began between the Standing Medical Advisory Committee of the Ministry of Health and the Medical Research Council which have culminated in the issue of the White Paper.

Review of Research

In its last two annual reports the Council has selected a few branches of research for extended review; the rest of the Council's work is given in summary fashion. This practice is helpful, as it allows for the presentation of a new advance in historical perspective and often makes it possible to forecast its future; but it has the disadvantage that the picture of the Council's work is necessarily only fragmentary. This year 11 subjects are reviewed in the report: chromatography, mental deficiency, preventive medicine in obstetrics, nervous control of glandular function, food-poisoning, drug resistance, haemophilia, diseases of the ear, the thyroid gland, poliomyelitis, and the physiology of the erythrocyte. In all these fields there have been interesting, and sometimes spectacular, advances: it is possible to describe only a few of them here.

While in the last 20 years the maternal mortality has been quartered, stillbirths and neonatal deaths have shown no comparable decline. In Aberdeen socio-medical studies are defining some of the causes of this wastage. It is known that those stillbirths which occur without warning and for no obvious reason are generally due to asphyxia. Now it has been shown that they are associated with post-maturity, and further that the post-mature infant has an abnormally low blood-oxygen level; a low foetal blood-oxygen is also found in some other pathological states of pregnancy.

New ideas on the training of high-grade mental defectives have been developed. Until quite recently it was the practice to teach them skilled or semi-skilled trades such as carpentry and boot-repairing; but it was found in a group investigated that not one was able to support himself outside hospital in the trade he had been taught. The answer is to train them for unskilled work. This has had remarkable results: boys who had previously been idle were able to go out on licence to work in neighbouring factories and on building sites, with benefit to themselves as well as to the community. In 1951 patients on daily licence from the colony where these experiments were done earned £30,000, of which over half was returned to the Treasury for their board and lodging. There are 20,000 feeble-minded patients of working age in hospitals in Britain, and the importance of this work is obvious.

Clinical advances have included the recognition of a new form of bacterial food-poisoning, the development of methods for testing the hearing of very young children, and the separation of "Christmas disease" (*Journal*, December 27, 1952, p. 1378) from true haemophilia.

Knowledge of the causes of food-poisoning has advanced far since the days when ptomaines were blamed; now all are familiar with the cases caused by salmonella organisms, staphylococcal toxin, and, less commonly, unusual proliferation of bacterial types not ordinarily pathogenic to man,

*Svenska Läkartidningen, May 8, 1953.

theatres was approved of, but students should be cautious in their dealings with the other sex lest they fall into the hands of the barbers and suffer from "salivation"—a reference to mercurial treatment. In Roberg's time there were as many as fifteen royal grants available for poor medical students, but as there were never as many as fifteen medical students under Roberg at the same time it is pretty safe to conclude that these grants were not over-generous. Even after qualifying as doctors Roberg's pupils encountered many difficulties, including the competition of foreign doctors. Of these Roberg wrote: "The country is flooded by 'agyrtas circumforaneos' to be branded as contraband goods." He was also critical of "perigrinerande medicinae candidater" who returned home primed with knowledge picked up at Halle, Leyden, Oxford, Rheims, and other famous university towns.

CLAUDE LILLINGSTON.

Preparations and Appliances

OXFORD INFLATING BELLOWS

Professor R. R. MACINTOSH, Nuffield Professor of Anaesthetics, University of Oxford, writes: A hundred and fifty years ago the domestic bellows were commonly used for artificial respiration. It was unfortunate if the bellows were fouled with cinder grit,¹ but a more cogent objection to this method of inflating the lungs was that it often was not available at all for the riverside emergency, so it was replaced

by manual methods (Hall, Silvester, Schafer) which can be applied on the spot without the help of extraneous apparatus.

Some 12 years ago I incorporated in the Oxford ether vaporizer² a Connell concertina reservoir bag, but inserted in it a spiral spring whose function is automatically to refill the bag as soon as the patient has partially emptied it by inspiration. If artificial respiration is required the bellows prove a simple method of inflating the lungs.

A common feature of present-day anaesthesia is deliberately temporarily to depress or abolish spontaneous respiration. The bellows previously incorporated in the Oxford vaporizer are now available separately as a small hand unit to inflate the patient's lungs with air or, if required, with anaesthetic gases. An inlet stopcock is provided in case additional oxygen is required. The two valves, seen under the glass domes in the photograph, ensure unidirectional flow so that rebreathing is avoided. Pressure on the bag transfers its contents to the patient's lungs. Slightly raising the facepiece is one way of allowing expiration to take place through passive recoil of the thoracic structures. For the past three years I have used only this unit to inflate the lungs when normal respiration has been suspended during

major thoracic and abdominal surgery. It would, of course, provide equally effective artificial ventilation in paralysis from poliomyelitis or nerve gases.

I have to thank Dr. H. G. Epstein and Mr. R. Salt for advice and help in the design of the Oxford inflating bellows, which can be obtained from Messrs. Owen Mumford, 10, Norreys Avenue, Oxford, or from Messrs. Medical and Industrial Equipment, Ltd., 12, New Cavendish Street, London, W.1.

CARDIFF INFLATING VALVE

Dr. WILLIAM W. MUSHIN, Director, Department of Anaesthetics, Cardiff, writes: Recent epidemics of poliomyelitis, notably the one in Copenhagen last year, have shown the need for an efficient means of maintaining artificial respiration for periods of time varying from hours to weeks in patients with respiratory and bulbar paralysis. The Oxford inflating bellows (Fig. 1) are an efficient, simple, and com-

CARDIFF VALVE

Fig. 1.—Complete assembly showing position of the Cardiff inflating valve close to the endotracheal tube or face-mask.

paratively cheap means of doing this. However, before the can be connected to, say, an endotracheal tube, some interposed device is required which will ensure that the patient's lungs empty quickly and freely to the outer air at the end of each inflation. The valve illustrated in Figs. 2 and 3 is designed to do this. When the inflating bellows are compressed the Tufnol piston (A) and its valve move a short distance towards the patient, blocking the expiratory slots (B). When the shoulder (C) of the valve reaches the end plate, the piston continues its travel, opening the ports (D). The patient's lungs are then inflated easily. As soon as the end of the inspiratory cycle is reached, the pressure within the chest and the light spring (E) move the piston in the reverse direction (Fig. 3), so uncovering the expiratory apertures. The patient's lungs empty easily to the outer air. Artificial respiration can by this means be carried out with air, and the expense and trouble of using soda lime and absorbers are avoided. Comparatively little skill is needed to ventilate the patient's lungs and little can go wrong with the whole apparatus.

The design and development of this valve is the work of Dr. W. W. Mapleson and Mr. E. K. Hillard, both of this department. It has worked well in the laboratory, and in the operating-theatre on apnoeic patients. The working of the valve is unaffected by moisture inside it. It can be obtained from the makers of the Oxford inflating bellows.

British Medical Association ANNUAL MEETING, CARDIFF, 1953 SUMMARY OF PROCEEDINGS

FIRST PLENARY SESSION: CORONARY DISEASE

Tuesday, July 14

Three Plenary Sessions were held during the Cardiff meeting. The first, over which Professor H. SCARBOROUGH, of Cardiff, presided, was on "Coronary Disease," and about 350 members were present to hear a most interesting series of papers.

Introduction

Dr. D. EVAN BEDFORD (London), in introducing the subject, said that the most frequent form of coronary disease was coronary atherosclerosis and its consequences—namely, the various forms of ischaemic heart disease. Minor coronary occlusions might be quite silent or, in particular areas, might cause disturbance of rhythm. The more serious occlusions caused cardiac pain, cardiac infarction, congestive failure, and sometimes sudden death.

The terminology was becoming somewhat confused. Angina pectoris and cardiac pain were terms which related to clinical symptoms; cardiac ischaemia and coronary insufficiency related to the physiology of the pain; while coronary occlusion and cardiac infarction related to the pathological anatomy of coronary disease. The diagnosis of acute infarction should be restricted to cases with evidence of cardiac injury; severe or prolonged anginal attacks without such evidence should be attributed to protracted cardiac ischaemia or coronary insufficiency.

Fifty years ago coronary disease was rarely mentioned, but to-day everyone recognized it as one of the main causes of heart failure in adults. This suggested either that coronary disease was increasing by leaps and bounds or that it had been overlooked in the past. He had no doubt that it had been overlooked. Undue attention was paid in the early days to the fatal forms and very little attention to the milder. Nevertheless it was probable that coronary disease was actually increasing. Once recognized, coronary thrombosis reached almost "epidemic" proportions in a few years. He did not believe that any comparison of prevalence to-day as compared with, say, 1918 was valid.

The causation of coronary disease urgently demanded attention. The stress and strain of life was readily blamed. The disease was being correlated with abnormal cholesterol metabolism and with endocrine factors. The established fact that the coronary arteries of women were less liable to disease than those of men, at least up to middle life, needed investigation. This suggested that oestrogens might explain the relative immunity of women to coronary disease prior to the menopause. The whole question of prevention demanded recognition in the pre-occlusive stages of atheroma. It might be that the detection of metabolic errors would achieve this where clinical tests had failed. With regard to treatment, the main advances had been in the introduction of anticoagulant therapy and improved methods of treating severe shock complicating cardiac infarction. It was still not finally decided whether anticoagulants should be used in all cases or only in selected ones.

Incidence, Mortality, and Morbidity

Dr. WILLIAM PHILLIPS (Cardiff) said that it was the experience of them all that there was an enormous variation in survival figures. His own experience included two people whose original attack of myocardial infarction dated 35 years before their death. Family history was not necessarily ominous. In myocardial infarction optimism was reasonable once the urgent phase of infarction was past. In presenting certain statistics Dr. Phillips said that their object was to give a clue to aetiology and prevention.

The first account of angina appeared in the *Medical Transactions* of the Royal College of Physicians in 1758 under the name of William Heberden. Between 1748 and 1782 Heberden saw 100 cases, and it was of some interest to reflect that for 150 or more years afterwards no one collected anything like that number. The speaker showed a graph indicating the expectation of life from early times (500 B.C.) to the present, and pointed out that only comparatively recently did this expectation rise much above 35 years from birth. The increase would appear to show that in earlier times people who survived to old age were exceptional, but this was by no means true. People in positions of responsibility in former times lived to ages which to-day would be regarded as old. Heberden himself lived to be 90. George Washington died at 67, but his half-dozen immediate successors in the Presidency of the U.S.A. lived to well over 70. In ancient Greece apparently the expectation of life at birth was under 20, in ancient Rome little more, and in the Europe of the Middle Ages down to the French Revolution it was about 35. By 1900 the figure had increased to nearly 50 and was now 65 or more. According to the Registrar-General's statistics for England and Wales in 1947 the number of deaths attributed to heart disease was 28% of the total, the next most common cause being cancer (15%). Certification of death in the elderly was probably not very accurate. Certainly in patients referred for consultation, whether in hospital or in private practice, one had the impression that the label of coronary artery disease was often applied incorrectly, and many patients with such disease diagnosable now by reasonably reliable methods were thought to be suffering from other conditions causing chest or upper abdominal pain or from rheumatism. It was too soon to employ statistical approaches to this subject in view of the possible fallacy in the material.

Pathological Physiology

Professor G. W. PICKERING (London) said that coronary arteries had only one function, the transport of blood, and only one abnormality of function, the transport of too little blood. Most of the knowledge about coronary occlusion came from experiments on animals, and these had shown that the diameter of the coronary arteries was influenced by the autonomic nerves. The most important factors were the effect of arterial pressure on coronary flow and the influence of muscular work, which also increased coronary flow, and which presumably depended on the effect of metabolites. One of the peculiarities about coronary flow was that the oxygen tension appeared to be a good deal lower than in other parts of the body.

The pain of angina pectoris was believed to occur through the same kind of mechanism as the pain of intermittent claudication, which was much easier to study, and this had been shown to be due to the accumulation in the tissue spaces of substances released from the muscle and normally removed by the circulation. The explanation of coronary arterial spasm was to his mind quite unnecessary and most unlikely. The difficulty was, of course, that in these conditions the work of the heart and the coronary flow could not be measured, but in paroxysmal tachycardia it was reasonable to suppose that the rate of metabolism of the heart was increased. In severe anaemia both angina pectoris and intermittent claudication could occur and both were abolished or diminished by relief of the anaemia. In aortic regurgitation pain occurred in association with paroxysmal rises in arterial pressure.

Coronary occlusion might be followed by one of three things: (1) nothing untoward at all; (2) angina of effort; and (3) myocardial infarction. Whether or not the individual perished when the coronary artery was occluded depended to some extent on the degree of narrowing and on the size of the collateral vessels. In coronary occlusion, therefore, there were two separate events—namely, thrombosis closing the artery, and the pre-existing arterial conditions out of which it developed. The underlying disease

was atheroma, which was most probably a disturbance in cholesterol metabolism. There was no doubt about the correlation of atheroma and obesity. The present evidence showed that atheroma was due to a disturbance in the lipid metabolism, but it was not known to what extent it was a preventable disease in man. Monkeying with diet was not without its dangers. There should be properly controlled clinical trial of the low-fat diet before patients were deprived of one of the reasons for remaining alive—the pleasures of the table.

Pain in the Chest

Dr. CLIFFORD G. PARSONS (Birmingham) said that most patients with coronary heart disease sought medical advice because they had pain in the chest, but pain in the chest did not necessarily indicate such disease, and the correct interpretation of this one symptom might be of great importance. The pain of angina pectoris was felt behind the sternum. It might or might not radiate to the neck, one or both arms, or the upper abdomen. It was an aching, restricting, or burning pain, provoked by exercise or emotional stress, and varying from one day to the next. The pain mounted rapidly to its peak, continued unrelieved until the patient was able to rest or regain equanimity, and then disappeared quietly in a few minutes. From time to time this familiar picture was modified so profoundly that it was almost impossible to recognize that the pain was angina, but one characteristic always remained—namely, the association of the pain with effort or with something that increased the burden on the heart. Sometimes the pain might be confined to an elbow or the jaw or neck. More commonly there was upper abdominal discomfort. The correct evaluation of dyspeptic symptoms was not always easy.

The newspapers had made the public fully aware of coronary artery disease, and chest pain frequently aroused anxiety about the heart. Emotional stress of any kind made the individual heart-conscious. In women angina was rare before the menopause and was then almost invariably evidence of heart disease or hypertension or well-marked anaemia.

Mild cardiac infarction caused pain which was usually more severe, more widely spread, and longer lasting than that of coronary insufficiency, and nitrites did not affect it. Vomiting and shock were common. The diagnosis could be substantiated by demonstrating signs of myocardial damage and tissue necrosis. Electrocardiographic changes were nearly always present.

Treatment of the Patient in Hospital

Dr. A. RAE GILCHRIST (Edinburgh) said that the three pain-producing syndromes of coronary sclerosis—namely, angina pectoris, coronary insufficiency, and acute myocardial infarction—overlapped and might on occasion be difficult to distinguish, yet the methods employed in their treatment could be sharply defined. The patient suffering from angina pectoris seldom required hospital treatment. In the patient with coronary insufficiency, if nitrites did not control the recurrent attacks, then other drugs such as khellin, papaverine, and phenobarbitone might provide some protection. Cervical sympathectomy should be considered for the more resistant cases of angina decubitus. Acute myocardial infarction varied so greatly in severity at the onset that the subsequent course was difficult to predict, and there was no alternative but to treat all hospital patients on the assumption that serious complications would occur. For this purpose anticoagulants were the most effective remedy so far known. As soon as the diagnosis was established the patient should be given morphine and from 10,000 to 15,000 units of heparin, preferably intravenously. He had found "dindevan" given by mouth a safe and effective anticoagulant, though laboratory control was still needed; 200 mg. a day gave a very steady prothrombin-time level. Shock was more readily handled under hospital than home conditions, and he had found digoxin useful in its treatment. It was generally wiser to send the patient at once to hospital than to move him

some days later when his condition might be more precarious. Ambulances should be equipped with oxygen and staffed by first-aid men trained in its administration. Complete immobility in bed should be discouraged as soon as shock and fever had abated. Chair-rest by the bedside might be started within two or three weeks. Usually the patient with an infarction was kept in bed for six weeks and very gradually returned to duties. At the same time prolonged rest favoured thrombosis and rest might be over-emphasized.

Treatment in General Practice

Dr. J. H. HUNT (London) dealt with the contribution which the family doctor could make to the treatment of coronary disease. In an emergency such as an attack of coronary thrombosis the very sight of the doctor helped, and the sooner the doctor could see the patient the more confidence the doctor was able to impart. Emergency calls of this sort were really emergencies in nearly every case. The doctor would probably find on arrival that the relatives had already given the patient brandy; sweet tea was perhaps better, but alcohol did give confidence. It was of the greatest importance to relieve the patient's anxiety and the assumption that he was going to get better must be conveyed to him as soon as possible.

Should the patient with coronary thrombosis be treated at home or at hospital? Much depended upon the doctor's personal assessment of matters administrative rather than medical. The speaker had seen many an old person made anxious, confused, or depressed by being moved away from his customary surroundings. One question commonly asked was about smoking. Not long ago he had a patient, a sea captain, who smoked 50 cigarettes on the bridge on ordinary days and 80 when there was a fog, but he was a strong-minded man and after an attack of coronary thrombosis he gave up smoking entirely. With many patients, however, this was more difficult, and sometimes enforced abstinence from tobacco led to an undesirable increase in appetite, and the consumption of large quantities of sweets. It was hard to believe that smoking in moderation always made coronary disease worse.

As for anticoagulant therapy, it was impossible more often than not to give this as a routine in the patient's home because of the difficulty in having control tests performed, but he desired to see short-term anticoagulant therapy more used by the general practitioner. By no means all cardiologists agreed on the necessity for anticoagulant therapy, and when experts disagreed it was for the general practitioner to judge for himself.

Twenty years ago a diagnosis of coronary thrombosis was regarded as a death sentence. Nowadays it was by no means so sinister, especially when it occurred in middle age. He had one patient who had had mild attacks of cardiac infarction at 55, 62, and 75 years of age, and died at 82 from something quite different, 27 years after the first attack. The family doctor must be ready to assume some responsibility whatever the future held for his patient, and in coronary disease no one could foretell the future. But the taking of responsibility was the fascination of general practice and the pride of the practitioner.

Questions

Very little time was left for questions from the large audience. Asked whether a considerable proportion of patients who died from coronary disease generally showed only a narrowing of the coronary artery, Dr. PICKERING said that he understood from his pathological colleagues that the examination of the coronary artery was extremely difficult, but he thought such a circumstance was uncommon.

Dr. PARSONS was asked about the exercise tests with electrocardiography. He said that very often these tests were carried out by the technician, but they were useful when supervised by the doctor. One other limitation was that they did not always work. He had a colleague who had had three attacks of mild cardiac infarction and the other

day tried to do the exercise test by running up the stairs of the three-storied hospital, but there was still no effect on the electrocardiograph.

Dr. EVAN BEDFORD, in reply to another question, spoke of the great variability of the results with the electrocardiograph. He was asked whether the electrocardiograph was infallible in the diagnosis of coronary thrombosis, and replied that he could only give an answer which would need a great deal of qualification. The electrocardiograph could not detect coronary occlusion; it detected only the consequence in the heart muscle. But he thought it most unlikely that cardiac infarction would escape detection by a complete set of electrocardiograph leads, though the single record might not show it. On the question of hospital versus home treatment, he believed that some patients under certain conditions were better treated at home. He agreed that the newer anticoagulants were much safer than the older ones.

SECOND PLENARY SESSION: "FIBROSITIS"

Thursday, July 16

The second plenary scientific session was held in the Reardon Smith Theatre, with Mr. A. LAWRENCE ABEL in the chair. The subject of the discussion was "Fibrositis."

The Point of View of the General Practitioner

Dr. A. TALBOT ROGERS (Bromley), who put forward the point of view of the general practitioner, said that this subject was in a state of confusion and it was hoped that the present discussion would enable them to look afresh at the causation of the syndrome and at methods of attacking it in their practice. In earlier days fibrositis was regarded as a definite clinical entity, though it was true that there was no general agreement as to what constituted the condition. But to-day the very existence of the condition was doubted. The general practitioner found that this diagnosis was not available for him to fall back upon. Why was it that what was a straightforward diagnosis years ago was no longer available? The position was made more difficult in that nothing had been put in place of the diagnosis which had been taken away. As a general practitioner he had a certain liking for the term "fibrositis." Quite apart from the fact that it was an easy thing to say that a patient had got fibrositis, it was a term which did not arouse alarm and despondency in the patient, his family, or his employer. Fibrositis was a term which the patient understood; if the term "prolapsed disk" were substituted the patient would imagine that it must mean some weeks of unemployment. When it was announced that Hutton had fibrositis no one was particularly disturbed, but if it had been said that he had a prolapsed disk the search would have begun for another English captain.

Could the fibrositic syndrome be explained by any single cause? If not, what conditions entered into the differential diagnosis? On what treatment could a general practitioner wisely and safely embark? Could the general practitioner be sure of finding in this classification the complete diagnosis for all the cases of aching in the back, the neck, and the shoulders that presented themselves to him, or were there still cases not falling into any other category that might be regarded and treated as cases of fibrositis?

Symptomatology

Dr. A. H. DOUTHWAITE (London) said that it was Sir William Gowers who in 1904 first coined the term "fibrositis," and he did so on a false premise. There was no recognized pathological basis for the diagnosis, which must therefore be clinical. They must turn to the pathologist to see if he could help, but it would be found that there was no characteristic pathological change which justified this diagnosis. Pathologists were shy of the term.

Fibrositis was characterized by pain and stiffness, erratic in its occurrence, coming and going for no apparent reason.

The pain was made worse at first by movement, but if movement was persisted in it passed off, and after rest, especially rest in bed, the pain was worse. The distribution was of great importance. It was almost always confined to the back of the trunk. All the common forms of alleged fibrositis of back, neck, and shoulder girdle were in fact derived from spinal disease or strain. The supposed nodules, which must not be confused with the true inflammatory nodules of rheumatoid arthritis, were areas of muscle spasm which disappeared (1) if the nerve-root irritation was removed; (2) under the influence of curare; and (3) when the patient was subjected to heat and massage. The so-called brachial neuritis—a very bad term—was applied frequently to patients who had pain radiating from the shoulder girdle down the arm to the fingers. Such brachial neuritis was almost always due to cervical spondylosis or cervical injury.

There was a general form of fibrositis to be seen in rheumatoid arthritis, but it was quite unnecessary and even undesirable to draw special attention to this involvement of the connective tissue. The sedimentation rate in fibrositis was normal as a rule, but in old persons who developed the condition it might be raised. He had never satisfied himself that any case of fibrositis had been cured by the elimination of focal sepsis. It was inconceivable that this condition could be due to any of the common pathogenic organisms seeing that the powerful chemotherapeutic and antibiotic agents now available had failed completely to relieve the symptoms. He thought it was highly probable that they were now discussing a disease which no longer existed.

The CHAIRMAN said that even if the disease no longer existed it might be as well to continue the discussion, and he called upon Dr. Spillane to discuss the psychiatric aspects.

Psychiatric Aspects

Dr. J. P. SPILLANE (Cardiff) said that Sir Henry Cohen had recently emphasized that a complete diagnosis should tell them where the disease was, what functional disturbances were present, and how they had arisen. The label "fibrositis" had been applied indiscriminately. In fact, the reference in many textbooks to the aetiology of fibrositis bore a striking resemblance to that of pernicious anaemia before Minot and Murphy. It confirmed one's impression that this was a medically fashionable diagnosis which had supplanted visceroptosis, pleurodynia, disordered action of the heart, and others of that ilk in which no organic pathological lesion could be demonstrated.

What was overlooked was the fact that the symptoms in the majority of these cases represented but one facet of a psychoneurotic illness, or a disturbed emotional state finding expression in altered muscle tension. When they reflected that non-articular rheumatism was one of the main causes of incapacity in industry, the size of the problem became apparent. The omission of the psychosomatic approach was one reason for the prolongation of much "fibrositic" invalidism. Many examples could be quoted where fibrositis had been solely due to abnormal emotional stress. There was a type of personality particularly prone to this type of disturbance. Symptoms of soreness and stiffness might well represent the patient's feeling of being hurt by circumstances and resenting them. He felt "sore" about some things and expressed his feelings somatically. When such inward feelings became expressed in this way they were, so to speak, pushed out of mind so that the patient's attention was distracted from his problems and became absorbed in his bodily feelings. Because of this conversion of interest the patient did not volunteer—nor under questioning readily admit—that he had emotional difficulty. He might well be unaware of the relationship of such factors to his affection. The speaker contended that the psychosomatic approach would justify any time expended on it, and treatment should be directed towards the abnormal emotional stresses rather than to the obvious local symptoms.

Orthopaedic Abnormalities

Mr. J. S. BATCHELOR (London) opened with the remark that he did not believe in fibrositis. The aches and pains which were attributed to this condition were usually due to various orthopaedic abnormalities of the trunk and spinal column. These abnormalities fell into two groups—namely, strain and inflammation. A common cause of strain was defect of posture, which was responsible for many of the symptoms attributed to fibrositis. The deformities, which began in early life, became fixed and were often overlooked. Trauma, sometimes apparently trivial, but often sustained during heavy lifting, produced what was essentially an acute strain or sprain of one of the lower lumbar joints and was often followed by recurrent attacks of lumbar pain of acute onset (lumbago). The tendency to label such strains as "slipped disks" was to be deplored. Congenital anomalies in the lumbosacral region constituted a structural weakness which might lead to strain symptoms.

Into the group of inflammations fell osteoarthritis, ankylosing spondylitis, and tuberculosis. Osteoarthritis of the whole spine or one of its regions was usually due to long-standing postural defect. When localized to one spinal articulation it was often the result of an old injury followed by disk degeneration. Ankylosing spondylitis in the fully matured stage was easily recognized, but in the early stages the diagnosis might not be easy. The possibility of spinal tuberculosis should always be borne in mind.

Gynaecological Causes of Backache

Mr. LESLIE H. W. WILLIAMS (London) said that in this condition gynaecologists had a limited field. Nevertheless they had referred to them many cases of low backache which were often labelled "fibrositis." Among these cases of low backache were a number with some gynaecological abnormality. The gynaecologist's problem was to decide in these cases whether the pelvic abnormality was really the cause of the backache. His first reaction was to look for something else—muscular, articular, or ligamentous. When there was nothing obvious in this direction he tried to find out whether the gynaecological lesion could justly be incriminated. The testing was fairly simple in such conditions as prolapse, which could be temporarily supported by a ring pessary. Should this relieve the backache it was some evidence that the prolapse was responsible. In other cases such as retroversion correction of the position and the temporary fitting of a Hodge pessary was indicated.

In cases of more serious nature, such as fibroids or ovarian cysts, no one could say whether these tumours were causing the backache until the tumours were removed, but since such removal was necessary in any case the correct course was being followed when surgery was adopted. Much the same was true of cases of endometriosis and chronic salpingo-oophoritis. But a word of caution was necessary. As surgery might mean a radical pelvic clearance, and that in a young woman, palliative treatment should first be given a prolonged trial. The question whether disease of the uterine cervix did or did not cause backache was still disputed. Most types of cervical abnormality were in any case the better for active treatment, and if this happened to cure the backache all was well. But failure to remove backache by this treatment must not be regarded as unexpected or as serious.

Primary Fibrositis an Imaginary Disease

Dr. J. H. CYRIAX (London) said that fibrositis was the commonest misdiagnosis to-day. The word was coined to explain lumbago, and this view remained unchallenged until his own paper in 1945 attributing it to a disk lesion. The mere fact that lumbago fixed the patient's lumbar spine in flexion showed that the sacrospinalis muscles were not in spasm and that the fatty lobules which these muscles contained were not responsible.

Fibrositis meant pain felt by the patient in a muscle of the trunk. From what source did the pain originate? Usually from articular lesions at the spinal joints. When

these squeezed the dura mater pain of extra-segmental reference resulted and referred tenderness was prominent. This provided the misleading tenderness responsible for the concept of fibrositis.

Proof was simple if the examiner tested muscle function against resistance, tested articular function by passive movement, looked for fibrositis when the pain was absent, and moved the fibrositis about by manipulative reduction at the appropriate spinal joint. In the end many lesions got worse, root pressure resulted, and the clear neurological signs appeared which made the diagnosis of a disk lesion obvious.

If the function of the moving parts was examined in this way and logical deductions were drawn, the concept of fibrositis would be replaced by a correct diagnosis. Often this entailed manipulative reduction of the relevant spinal joint, but never heat and massage to the area of referred tenderness. Palliative treatment at an area of referred tenderness must be prevented, and manipulation by trained physiotherapists should be prescribed. Swift relief was then attained within the medical sphere instead of the credit being given to bone-setters.

Methods of Treatment

Dr. G. D. KERSLEY (Bath) said that he was not quite sure where fact ended and fiction began in a discussion on fibrositis, a term which was now described as the refuge of the diagnostically destitute. He agreed that the term was a "wastepaper basket." Many of the cases were suffering from postural defects or visceral derangements, and many others were psychosomatic. But in his opinion it was ridiculous to say this of all cases. Some academic gentlemen who denied the existence of this condition were burying their heads in the sand.

There were two types of true fibrositis. One was rheumatoid, particularly common in the elderly, and associated with a raised sedimentation rate, often loss of weight, and generalized muscular pain and stiffness. This reacted well to rest, A.C.T.H., and cortisone. The other was associated with gout.

Dr. Kersley said that he himself had had three attacks of acute myalgia in different localities during the last four years. On the last occasion he woke in the morning with severe lumbago, and arranged with a colleague to have an intravenous hypertonic saline injection early in the afternoon. Something occurred to postpone this, and in the late afternoon the pain entirely subsided. Had he had the injection, no doubt the cure would have been ascribed to it. There were several names in medicine which disguised ignorance, and he thought "fibrositis" should remain; an alternative suggestion would be P.U.O. (pain of unknown origin).

Much could be done for these patients by advice on mode of life, avoidance of occupations which entailed a group of muscles being in a state of spasm, and avoidance of severe unaccustomed exercise. Patients should be told to do a few limbering-up exercises for two minutes every morning, followed by a hot bath, and in hot weather a cold shower and a vigorous rub-down. Excessive weight should be removed by diet, and any food to which the patient was allergic should be cut out. Heat in the form of a hot bottle or electric pad might be applied, and deep heat was sometimes useful. Manipulation was of definite value—usually in between attacks, when these were frequent. "Some experts say there is no fibrositis, because of lack of scientific demonstration. I do not want to be unkind to them, but I do feel like wishing them just one attack."

Discussion

Dr. KENNETH N. LLOYD (Cardiff) said that the essential lesion was muscular tension, whether local or general. Fibrositis was a diagnosis of exclusion. Dr. W. N. LEAK (Windsford) referred to certain abdominal causes of fibrositis, and spoke particularly of chronic appendicitis as a cause of backache. Chronic appendicitis also caused a certain amount of muscle spasm and nervous tension. Dr. R. C. B. BARBOR (Hoddesdon) endorsed from his experience as a general practitioner the value of Dr. Cyriax's

methods of examination and treatment. Dr. DAVID HUGHES said that he had often suspected that patients were exaggerating their symptoms until he had an attack himself, when he discovered that the pain was very real. He obtained complete and dramatic relief by massage and manipulation. He found himself talking about the attack in exactly the same way as that in which his patients had talked. In reply to Dr. ELSIE WARREN, Dr. DOUTHWAITE said that neck, back, and shoulder ache were made worse by knitting. In reply to another question, Dr. KERSLEY said that a lot of people declared that they began to feel the benefit two or three weeks after spa treatment had ended, but he could not say that this was within his own experience.

Mr. A. STAVELEY GOUGH (Watford) spoke also as a victim who had been relieved 48 hours after a well-placed procaine injection. In some cases the condition could be explained as caused by a disk, but in some cases it could not. There was a future for general-practitioner research on this problem.

Dr. A. TALBOT ROGERS, in replying on the discussion, agreed that this was a subject for general-practitioner investigation. He hoped it would be one of the research projects of the College of General Practitioners. In his view the title "fibrositis" should not be discarded, but the name should remain within inverted commas.

THIRD PLENARY SESSION: OVERWEIGHT

Friday, July 17

Clinical Survey

The third Plenary Session, over which Lord HORDER presided, was opened with a paper by Dr. J. H. SHELDON (Wolverhampton), read in his absence owing to illness. He thought a general clinical survey might be useful, as there were numerous aspects which impressed the clinician but for which experimental medicine had not provided the answer. Appetite played the fundamental role in obesity, and here the recent discoveries of the part played by the hypothalamus in the control of appetite were of great importance. Rats, after hypothalamic damage, showed a voracious appetite, which gradually subsided to more normal levels. A clinical study of maternal obesity showed a close parallel with such experimental demonstrations. In the initial stage, again, there was a voracious appetite, but presently a "plateau" stage was reached. The gain in weight began with dramatic rapidity and then fell off, this process taking in these maternity patients about a year. One woman, in January, 1940, weighed 133 lb. (60 kg.); by April her weight had gone up to 168 lb. (76 kg.). After this she refused to face the scales until April, 1944, when her weight was 218 lb. (99 kg.)—a gain of approximately 0.4 lb. (0.18 kg.) per week over the period.

Some fat people gained their weight slowly and steadily, but others showed initial rapidity. One woman whose weight went up at the rate of rather more than 3 lb. a week took her normal meals, with second helpings, but had sweets and other eatables in the intervals, a special supper immediately before going to bed, took food to bed with her in case she starved in the night, and insisted that her husband bring her bread and cheese with the morning cup of tea, and yet she refused with some anger to say that she was overeating and stated that she never had more than her "fill." Some patients showed a progression from "I am never satisfied" to "I get hungry again within an hour." When a woman had reached the "plateau," observation showed that frequently she was not taking an excessive diet. Many fat individuals might not deserve to be fat on their present intake, but they had at some time in the past deserved to become fat and had been able to maintain their added weight on the basis of normal intake. Theoretically this could be done only on a diminution of activity, and general observation suggested that that might be the case.

There were several types of clinical obesity in which a cortical factor must be assumed. The well-known gain in weight which followed abstinence from tobacco might have a similar cause. Emotional tension might be eased by the taking of food and a disturbance of an endocrine factor might be involved. Maternal obesity began immediately after the birth of the baby. Some studies had suggested that the appearance of a male infant might affect the emotional state of the mother, resulting in an increase of appetite.

In general it was true that obesity occurred at the epochs of growth and puberty, maternity, and the menopause, all of which were accompanied by an endocrine departure from a relatively static state. It would be interesting to know more about the menopausal middle-age spread, and here was a field for clinical observation. One's general impression was that the gain in weight at this period was slow. It might be due to taking dietary risks at a time when expenditure of energy was diminishing. Women who developed diabetes in middle life were apt to have given birth to larger babies than non-diabetic women. Present knowledge could not go much further than the general statement that the adrenal cortex was undoubtedly concerned in the production of obesity. The use of cortisone and A.C.T.H.—particularly the latter—might be accompanied by an increase in weight, but the link between the adrenal cortex and the appetite was still a mystery. One could not avoid the surmise that alterations in steroid function might influence the appetite by direct effect on the hypothalamic control.

The Control of Appetite

Professor R. A. McCANCE (Cambridge) said that he must be allowed as a scientist to say a word about thermodynamics. If more potential energy than it expended were put into a living organism in the form of food the energy would be stored up inside, usually in the form of fat. The adjustment of calorie intakes to requirements was usually very exact, and people got fat because they lost control, often only temporarily, of this fine adjustment. The whole future for the control of obesity lay in finding out what were the mechanisms which controlled the appetite. Until these were known, corrections could not be applied. There must be something very fundamental about these mechanisms, because they made their appearance very low down in the scale of evolution, being exhibited by animals like hydra, with the humblest of nervous systems. In man the cortex, both at the unconscious and particularly at the conscious level, had become very important. It would probably be promising to look for the control of food intake in some change in the chemical anatomy of the nervous system, possibly in some specific cells or centres. If the responsiveness of the nerve cells or receptors was found to depend upon their chemical structure, and if these in their turn depended upon the nutritional state of the organism, it would be possible to explain all the elementary facts about the control of appetite as we now knew them. He added (though this was questioned by other speakers) that clinical obesity was never due to retention of water.

Dangers of Obesity

Dr. A. P. MEIKLEJOHN (Edinburgh) agreed that the fundamental problem of obesity lay in the appetite, though plenty of people who suffered from it would like to believe that their surplus tissue arose as a result of spontaneous generation. In every case appetite led to greater intake of food, and the body did not always get rid of it by expenditure of energy. In many cases overeating was just a bad habit. People could become addicted to food just as easily as to alcohol. Some people, particularly women, overate because they were unhappy; they were driven to the bun or the pastry for the same reason which sent their husbands to the public-house. Psychological overeating generally affected the poor much more than the rich in view of the quality of the surplus food which the poor consumed. There were, however, whole groups of patients who did

not lose weight on a low-calorie diet as fast as should be expected, and it was a common observation that many people ate prodigiously without putting on weight.

Why was obesity a menace to health? There was a time when obesity was considered normal in middle age, but experience of life assurance companies showed the other side of the picture. In some figures published by the Metropolitan Life Assurance Society it had been shown that a man (not a woman) aged 45 who was 25 lb. (11 kg.) above standard weight for that age was likely to die at 60, when he might otherwise have lived to 80. Obesity rendered its victim more prone than the normal person to a variety of ills, including accidents. At home he was more liable to trip over carpets, and at work to get entangled in machinery. There could be no doubt that obesity was the commonest nutritional disorder in Great Britain to-day, and it was the duty of the medical profession to be vigilant in its prevention and wage war against it whenever it was seen in their patients.

Estimation of Overweight

Dr. H. M. SINCLAIR (Oxford) pointed out that estimation of obesity by comparing the weight of a person with certain standards for sex, age, and height was often fallacious for various reasons. One of them obviously related to the build of the person: muscular persons might be heavier than fat persons of the same height and yet have much less body fat. The simplest way of measuring body fat was to take the thickness of a skin fold with a simple type of calliper and measure the subcutaneous tissue. This correlated highly with the density of the body. One-half of the whole fat of the body was subcutaneous. Overweight was particularly difficult to estimate in children because of the two characteristic growth spurts—at the age of 5-7 and at puberty. Over-nourishment caused early maturity, and this was an extremely bad thing, particularly in man, because the characteristic of the species was the very long time it took to reach maturity, and to speed up the process might mean early death.

The speaker gave a list of disorders which accompanied obesity. These included degenerative arthritis, hernias, atherosclerosis, hyperpiesis, diabetes mellitus, chronic nephritis, gallstones, and complications in pregnancy and childbirth. He also exhibited a table showing the influence of overweight on mortality in persons aged 45-50 years:

Overweight	Increase in Death Rate Over Average
lb. (kg.)	%
10 (4.5)	8
20 (9)	18
30 (13.5)	28
40 (18)	45
50 (22.5)	56
60 (27)	67

Treatment of Obesity

Dr. LEONARD H. HOWELLS (Cardiff) spoke on the role of the amphetamines in the treatment of obesity. In the ordinary case of obesity, he said, strict adherence to a low-calorie, restricted-fluid diet would normally result in a satisfactory loss of weight; but in many cases the use of a supportive drug was necessary, and of these the most valuable was dextro-amphetamine sulphate. It was time that this drug was put in its proper place in the therapeutic armamentarium. It encouraged the obese patient to learn new dietary habits; it promoted a sense of well-being, and it enabled the patient to carry on when he would not otherwise do so. It did not in itself bring about any loss of weight; it was supportive in its action. It was a safe drug to use for children when required. It might also be used to help the pregnant woman to lose weight. He gave the results in an unselected series of cases of obesity referred to the dietetic department of the United Cardiff Hospitals (see next column).

Dr. Howells added a few words on diabetes mellitus and obesity. Overweight people developed diabetes much more

Treatment	No. of Patients	Defaulted Attendance	Attended Regularly	Satisfactory Weight Reduction	Some Weight Lost	Failed to Lose Weight
Diet alone	156	56	100	46	27	27
Dextro-amphetamine while dieting	39	11	28	22	6	0

commonly than normal people. Among insured persons diabetes was five times more common among those with overweight. The death rate also was higher among overweight diabetics. Of 364 patients attending diabetes clinics in Cardiff, 32% of the females and 8% of the males exceeded their standard weight by more than 20%.

Female diabetics were much more liable to overweight than males. It was essential in the treatment of diabetes to bring about a reduction of weight, first, because obese diabetics died early, and, secondly, because complications were much more common in this group.

Obese Patients in General Practice

Dr. EMRYS WILLIAMS (Cardiff) said that two principal classes of patients suffering from overweight were commonly encountered in general practice. The first were the patients who were above average weight and wanted to slim because they were worried about their figure. The others were those who were suffering from definite pathological conditions either caused or affected by overweight, and these conditions included, in addition to those which other speakers had mentioned, a number of others such as skin affections. Many overweight patients showed emotional immaturity. Lack of emotional satisfaction led to overeating. Nevertheless his own impression was that obese people were on the whole agreeable companions. He gave illustrative cases from his own practice of the response to dieting. Sometimes the condition might be due to heredity or possibly psychological factors came in, and not much could be done about it. The results to be anticipated in hyperpiesis, arthritis, and dyspepsia were noted.

Dr. R. A. PALISTER (Malaya) asked whether reduction of fluid in addition to calories was necessary. On this point Dr. HOWELLS said that, contrary to the view expressed by Professor McCance, he believed there were a certain number of people in whom fluid retention did play an important part, and that reduction of fluid helped to bring about loss of weight. It was a personal point of view based on experience.

Wednesday, July 15

The Use and Abuse of Antibiotics

With the president, Professor A. M. KENNEDY (Cardiff) in the chair, Dr. R. W. FAIRBROTHER (Manchester) opened the discussion on the use and abuse of antibiotics. He urged close collaboration between bacteriologist and clinician in achieving the best results from antibiotic treatment. Choice of the correct antibiotic for a patient was not always easy. It was most important that the antibiotic used should be effective against the bacteria responsible for the disease. If bacteriological control was not available judgment must be based on the rapidity of clinical response. The dose of antibiotics was important, especially with penicillin. The tendency was to use doses which were too large and too infrequent. An adequate initial dose was essential, and treatment should be continued for some time after clinical improvement occurred. In spite of theoretical considerations, there was little justification for using mixtures of antibiotics in clinical practice except when dealing with mixed infections. When two antibiotics were used together their effect on infecting bacteria might be no greater than when one was given alone; sometimes the effect was

much less. The alleged synergistic effect of antibiotic mixtures probably had no practical application to clinical medicine.

The main toxic effects were due to intestinal upsets, hypersensitivity, and depression of the bone marrow. Additional dangers were the production of resistant bacteria, the risk of overwhelming secondary infections by insensitive organisms, and the masking of the true clinical picture of the disease. The indiscriminate use of antibiotics was dangerous, and laboratory control should guide their use whenever possible.

Dr. THOMAS ANDERSON (Glasgow) said that the use of any antibiotic always entailed a risk of its abuse. Although precise diagnosis was needed, clinical evidence often sufficed to incriminate certain organisms and justified the choice of an antibiotic. In local infections it was not sufficient to achieve a systemic concentration of the drug; the local site must be reached. But local applications of antibiotics were dangerous, since bacterial resistance soon appeared and skin sensitization was commoner when treatment exceeded five days. Penicillin was still by far the most widely used, and the most useful, antibiotic. Chloramphenicol, aureomycin, and terramycin should be used only when there were clear indications—for example, when dealing with a penicillin-resistant infection, in tracheo-bronchitis in childhood, or in specific infections such as enteric fever, typhus, or psittacosis. The newer antibiotics had no place in treating the common cold, influenza, or gastro-enteritis.

In assessing the correct dose, blood levels of penicillin were not as important as the sensitivity of the organism. Crystalline penicillin in aqueous solution was still the best and safest preparation to use parenterally. More use might be made of oral penicillin in doses of 200,000 units five times daily. Streptomycin was not a useful drug and should be used only in the treatment of tuberculosis and, possibly, brucellosis. It should never be used in urinary infections, because bacterial resistance rapidly developed. The risk of dihydrostreptomycin producing deafness precluded its use as a therapeutic agent.

Mr. J. S. JEFFREY (Edinburgh) said he thought that antibiotics were abused more in hospitals than in general practice. The tendency was to give too much antibiotic for too long and to neglect frequent reassessment of the clinical picture. In surgical practice it was necessary to consider not only the sensitivity of the infecting bacteria but also the blood supply to the site of infection. Surgeons often used penicillin to try to prevent secondary infections. This increased the proportion of penicillin-resistant staphylococci in hospital practice, but some resistant strains would respond to high doses. In treating minor surgical infections six-hourly injections of soluble penicillin were best. If there was no improvement another antibiotic should be substituted. Local applications of penicillin were often harmful because they produced skin sensitization and encouraged secondary invasion by non-sensitive bacteria. Aureomycin and chloramphenicol were much more effective than penicillin—applied locally. The prophylactic use of penicillin to surgical patients was justifiable because it did no harm. Streptomycin was more dangerous and should be used only in appropriate cases. Chloramphenicol, aureomycin, and terramycin should never be used in prophylaxis, since they destroyed the normal intestinal flora and so interfered with vitamin metabolism. The convenience of oral administration was no excuse for the indiscriminate use of these newer antibiotics.

Antibiotics for Pulmonary Tuberculosis

Dr. H. M. FOREMAN (Sully, Glam.) spoke on the use of antibiotics in the treatment of pulmonary tuberculosis. Streptomycin should be regarded as an adjunct to other forms of treatment. Streptomycin was of most value in treating acute forms of tuberculosis. When given alone, most patients developed resistant organisms. Streptomycin resistance could be almost eliminated by simultaneous treatment with para-aminosalicylic acid (P.A.S.). P.A.S. should never be given alone, since drug resistance soon occurred.

At least 20 g. of P.A.S. should be given daily when the daily dose of streptomycin was 1 g. Intermittent streptomycin therapy, 1 g. every three days, was probably equally as effective as continuous treatment, and it was certainly less toxic and less liable to produce drug resistance. Streptomycin sulphate was the least painful preparation when injected; dihydrostreptomycin had no advantages and was more toxic. Isoniazid had recently been introduced and was an effective agent against tuberculosis. Here again, drug resistance quickly developed if the drug was given alone. A combination of streptomycin and isoniazid had proved very effective; it had not yet been determined whether this should replace the combination of streptomycin and P.A.S. in the treatment of pulmonary tuberculosis.

Dr. KENNETH S. MACLEAN (London) considered that the therapeutic use of combinations of antibiotics, or of antibiotics with chemotherapeutic agents, should be more fully explored. Penicillin and streptomycin when used together gave the best results in bacterial endocarditis. The treatment of a series of patients with advanced excavated pulmonary tuberculosis was described. Some patients had been treated with isoniazid alone and the others with isoniazid and streptomycin. It had been found that isoniazid alone had no place in the treatment of tuberculosis. Isoniazid and streptomycin together were effective, the results of second courses of treatment being equally as good as the first. This combination offered more hope to people with chronic advanced pulmonary tuberculosis. Such treatment might be undertaken by the general practitioner.

Dr. F. A. WHITLOCK (Truro) described the use of antibiotics in dermatology. There were very few skin complaints in which antibiotics were indicated. Penicillin should never be used in a creamy preparation, since sensitization was so common. Penicillin lotions were safer, but should not be used for more than five days. Streptomycin should never be used locally. Chloramphenicol and aureomycin were much more valuable and less liable to produce skin sensitization. In most skin infections it was best to use older remedies such as ammoniated mercury or "vioform." Antibiotic therapy did not play a big part in dermatology.

In the discussion which followed Dr. V. COTTON-CORNWALL (Liverpool) emphasized the danger of tuberculous patients, while under treatment with antibiotics, infecting other patients with drug-resistant organisms. He thought that the treatment of tuberculosis in general practice would enhance this danger. Dr. T. A. BLYTON (Chesterfield) made a plea for the routine use of the sulphate salt of streptomycin and warned against mixing different streptomycin preparations, which might prove to be incompatible.

INTRATHORACIC NEW GROWTHS

The meeting of the Section continued in the afternoon with the president, Professor A. M. KENNEDY (Cardiff), in the chair. Dr. A. BRIAN TAYLOR (Birmingham) opened a discussion on the early diagnosis of intrathoracic new growths. The death rate from this disease was increasing, he said. Although this might partly be explained by more accurate diagnosis, it was probable that there was an actual increase in the incidence of the disease. Successful treatment depended on early diagnosis, but even so surgical treatment was not entirely satisfactory. With early diagnosis more patients were found to be suitable for operation at the time of diagnosis, and more patients were cured by successful surgery. Radiography was the most important investigation in early diagnosis, and whenever possible radiological facilities should be made available to the general practitioner. When an abnormality was discovered in chest radiography it was vital not to temporize but to pursue fuller investigation. Bronchoscopy should be done in all doubtful cases. It had been possible to see 82% of bronchial neoplasms on bronchoscopy, although biopsy confirmation was available in only 57%. Examination of the sputum for malignant cells was not a reliable test, and negative results were of no value in diagnosis.

In deciding on which patient should be suspected of having bronchial carcinoma and fully investigated, the general practi-

tioner should bear in mind certain facts about the disease. Bronchial carcinoma occurred most commonly in men between the ages of 50 and 60; it was commoner in town dwellers than in country dwellers. The four common early symptoms were cough, pain, dyspnoea, and haemoptysis. Haemoptysis always necessitated full investigation. It was depressing to recall that in more than one-fifth of the patients the presenting symptom indicated that the disease was already inoperable.

Mr. VERNON C. THOMPSON (London) said that carcinoma of the lung was now the commonest cancer in the male and caused more deaths than did tuberculosis. The problem was not entirely one of early diagnosis, but for the patient this was vital, because surgery offered the only chance of cure. Even when delay in diagnosis was minimized many growths were not curable by surgery. Probably there was a long latent period between the evolution of bronchial carcinomata and the production of symptoms. During this period there were no symptoms, signs, or radiological changes. From the surgeon's point of view it was important that diagnosis should be made before the growth had spread outside the lung, for once spread had taken place the post-operative survival rate fell from 60% to 15%. Early diagnosis depended on full investigation following rapidly in any patient in whom the disease was suspected. Unfortunately there was still a delay of about six months between the appearance of the first symptom and confirmation of the diagnosis. Delay was often caused by the patient's failure to seek medical advice, or by the doctor's hesitation in referring cases to special centres.

The family doctor should suspect bronchial carcinoma when cough persisted in a patient over 40 years of age. The most important physical sign was a persistent localized rhonchus. Pain, dyspnoea, and haemoptysis all deserved full investigation, as did some of the rarer manifestations, such as polyarthritis and clubbing of the fingers. The general health of the patient was a poor guide to diagnosis. Mass radiography offered the only hope of diagnosis in the symptomless phase. Sputum examination for malignant cells was invaluable in expert hands. The most difficult cases were those with a peripheral radiological shadow but no other positive findings.

The Pre-symptomatic Period

Dr. PETER J. KERLEY (London) said that after symptoms occurred in bronchial carcinoma the prognosis was bad, and emphasized the importance of diagnosis in the pre-symptomatic period. He had known of many patients in whom radiological changes had been present for many years before symptoms occurred. It was probable that the life history of bronchial carcinoma was longer than had been thought. The two most important radiological changes in the pre-symptomatic phase were slight unilateral hilar enlargement and small rounded peripheral opacities. Hilar enlargement was often difficult to gauge, but could be demonstrated clearly by tomography. Peripheral rounded foci owed their round shape to the abundant vascular supply. Round shadows in the lung could also be caused by tuberculosis, developmental tumours, cysts, and dissociated lung segments. It was usually possible to differentiate peripheral carcinomas, because they grew more slowly, contained no areas of calcification, tended to have striated outer borders, and occurred in any part of the lung field. In contrast, tuberculosis occurred almost entirely in the apex of the upper and lower lobes and hardly ever in the anterior half of the lung. Angiography had not helped in differentiating peripheral shadows, but it was hoped that radioactive isotopes would give much help in the future.

Mr. DILLWYN M. E. THOMAS (Cardiff) thought the best way to appreciate the problems in diagnosis of bronchial carcinoma was to approach them from the viewpoint of the general practitioner. He had analysed a hundred cases referred from general practitioners because bronchial carcinoma had been suspected. Dramatic or sudden onset of symptoms was not very common, although pneumonia or

haemoptysis sometimes attracted urgent attention. In South Wales carcinoma of the bronchus was hardly ever found in women. The onset was usually insidious and was often masked because previous respiratory disorders were so common in that locality. In patients with previous bronchitis, chest pain was often the new symptom which suggested carcinoma. The clinical history was often more important than physical signs in arousing suspicion of bronchial carcinoma.

In answer to questions by Dr. E. A. DANINO (Swansea), Dr. EMILY V. SAUNDERS-JACOBS (Woolwich), and Dr. T. W. DAVIES (Swansea), Dr. A. BRIAN TAYLOR said that he did not rely on respiratory function tests before operation, because the patients were suffering from a fatal disease. Pulmonary tuberculosis was not commonly found in conjunction with bronchial carcinoma. The cough in bronchial carcinoma was often non-productive. Mr. DILLWYN M. E. THOMAS thought there was a place for respiratory function tests, especially in a locality where chronic pulmonary disease was so common.

SECTION OF SURGERY

Wednesday, July 15

Toxic Goitre

With the president, Professor LAMBERT C. ROGERS (Cardiff), in the chair, Mr. ROBERT V. COOKE (Bristol) opened a discussion on the treatment of toxic goitre. He felt bound to confess that he had spent too much time operating and too little time thinking about the all-important question of the cause of thyrotoxicosis. A brief review of the physiology and pathology of this gland served only to emphasize our lack of knowledge about facts of fundamental importance. Until recently there had been little real advance in our knowledge for many years, but it was to be hoped that investigations with radioactive iodine would elucidate many obscure points. In the absence of much fundamental information they had set about treatment and, for want of a better method, had resorted to surgical removal for many years. Good surgery had become safe and satisfactory, but that safety had been slowly won, step by step. Most of the shortcomings of surgery were well enough known, but the speaker contended that many of the errors were avoidable. But the best surgery was essentially a crude weapon and was often an ordeal for such patients. He did not intend to discuss the treatment of the mild case.

As for medical treatment, until quite recently it had been suggested that this was largely a question of preparing the patient for a decent operation. It was no wonder that the antithyroid drugs had at first seemed an attractive alternative to operation. But after extensive trials the results had proved too unpredictable and relapses too frequent for these drugs to be considered a reason for avoiding good surgery. He did not favour the routine use of antithyroid drugs prior to operation and felt that many patients were adequately prepared with iodine. The method of tissue irradiation by means of selective absorption and accumulation of a radioactive isotope was a fascinating idea with seemingly great prospects. Despite many disappointments there could be no doubt of the value of radioactive iodine in the treatment of hyperthyroidism. The problem of assessing optimum therapeutic dose with so many variables to consider was exercising workers the world over. A glass or two of almost tasteless solution must be an attractive alternative to a surgical procedure, especially in those cases where there were no pressure effects or possibility of malignancy. Many of the problems of dosage were analogous to those which had formerly faced the surgeon in deciding how much gland should be removed. Radioactive iodine did seem to be the treatment of choice in older patients and in recurrent cases.

Mr. D. IOAN-JONES (Cardiff) said that he would like to confine himself to the more elementary aspects of this sub-

ject. He stressed in particular the importance of assessing each patient carefully and the value of sympathetic handling. In taking the history of the case it was often of real value to have the opinion of a close relative. Turning to the examination of the patient, he emphasized that a palpable gland, however thin the neck, was an abnormal gland, and that thyrotoxicosis was unrelated to the size of the goitre. He also referred to the difficulties experienced in recognizing tracheal displacement and compression and retrosternal extensions of the gland. In his experience doctors were apt to suspect malignancy unjustifiably, often in cases with hard glands. The modern tendency to prepare the patient before admission to hospital could be carried too far, and the surgeon might be tempted to be in too much of a hurry. The patient needed quiet but not an unduly restrictive atmosphere. Phenobarbitone could be used too often. He observed that it was of value to see how the patient responded to rest before deciding between iodine and thiouracil for pre-operative preparation. In conclusion he emphasized the importance of a gradual return to normal activity if the patient was to reap the maximum benefit from operation.

Mr. R. J. MCNEILL LOVE (London) pointed out the dangers of diagnosing neurasthenia and psychasthenia in cases of toxic goitre. He referred also to those cases with impalpable goitre. He endorsed some remarks of Mr. COOKE's drawing attention to the danger of damaging the recurrent nerve and said that the vocal cords should be examined both before and after operation, otherwise damage could frequently be overlooked.

Mr. P. R. HAWE (Liverpool) thought that the general practitioner must find it hard to decide whether to send his patients to a physician or a surgeon, and he thought it best that the mild cases should go to the physician. There appeared to have been some doubt about the value of the antithyroid drugs, but he felt that they were most valuable in preparing the patient for operation. Routine exposure of the recurrent nerves was important, and he himself had been in the habit of looking for the parathyroid glands, although he saw the superior glands in only about half his cases.

Mr. J. H. PIERRE (Trinidad) said that many of his patients had been treated by the general practitioner with iodine and thiouracil before admission to hospital, and in assessing whether the patient was ready for operation he had found palpation of the gland to be of some help. He asked whether the opening speakers could advise on the management of thyrotoxicosis cases at puberty and on the use of insulin in severe cases.

Mr. SOL M. COHEN (Dartford) asked whether estimations of the basal metabolic rate were thought to be of value. He referred to the possibility of liver damage in these cases and the use of high-protein diet and the vitamin-B complex. For the young patient surgery was to be preferred, but the other methods of treatment were useful in the older patients without nodular glands.

Mr. ROBERT V. COOKE, in reply, stated that he placed little reliance on the B.M.R. investigation. It had not been his practice to look for the parathyroid glands. Where a recurrent nerve had been damaged at a previous operation and the patient was unaware of it he avoided drawing attention to the condition. In pubertal cases he thought that the best method of treatment was to prepare them for operation as quickly as possible; but he was reluctant to comment on Mr. Pierre's inquiry about the use of insulin in severe cases. Doubtless it might be of value to give a high-protein diet and vitamin B, but he did not feel that his patients had suffered from omission of this therapy.

Treatment of Gall-bladder Diseases

With Mr. C. JENNINGS MARSHALL (London), vice-president, in the chair, Mr. R. J. MCNEILL LOVE (London) opened the discussion by saying that biliary disease caused more ill-health than was generally realized. He referred to those cases in which gall-stones were discovered accidentally, those

presenting with flatulent dyspepsia, and lastly those that developed various complications. He said that most cases of acute cholecystitis would settle down well without operation. Many patients with cholangitis secondary to stones were wrongly diagnosed as having "liver trouble." External fistulae were rarely seen these days, but internal fistula was not uncommon, and elderly patients sometimes presented with gall-stone ileus. Carcinoma in the gall-bladder was more common than was generally realized. Mr. Love went on to discuss the results of surgical intervention for gall-stones and some of the causes for disappointment. Referring to the relief of biliary colic, he advocated the use of pethidine rather than morphine. He next summarized some of the points of operative technique, and first drew attention to the liability of pulmonary embolism. For this reason he was very particular about supporting the heels on a special pad to prevent pressure on the calf veins. The value of cholangiography on the operating table was emphasized, and he showed a number of x-ray films of such cases. It was his invariable practice to do this simple investigation in all cases; it took but a few minutes for the processed films to be returned to the theatre, and the surgeon could be busy taking out the appendix in the meantime. He favoured diathermy dissection of the gall-bladder, which made drainage unnecessary.

Mr. Love concluded by referring to the management of the jaundiced patient. Gradual decompression of the liver was the method of choice in cases with prolonged back pressure due to carcinoma of the pancreas, and improved results were obtained by this method as compared with those of sudden decompression.

Mr. HAROLD C. EDWARDS (London) said he agreed with most of Mr. Love's paper and he particularly congratulated him on his exposition of cholangiography. He felt, however, that the interpretation of the results in the hands of anyone less expert might be misleading. He himself had relied on the history and on visual and digital exploration of the bile passages. Although he had not practised cholangiography at operation, he used it as a routine before removal of a drainage tube from the common duct, and it had never yet revealed any residual pathology. Confining his remarks on treatment to uncomplicated affections of the gall-bladder, he said that the two absolute indications for operation were gall-stone colic and recurrent cholecystitis, which in his experience was always associated with stones. He emphasized the risk of cancer in these cases. In the absence of these two absolute criteria great caution should be exercised. Especial care was necessary in non-calculous cases in which radiography showed merely a sluggish function of the gall-bladder, with fat intolerance, flatulent dyspepsia, and no localizing signs in the gall-bladder. The extent of the relief from operation was certainly proportional to the degree of morbidity found. Cases with no obvious disease were sometimes suffering from biliary dyskinesia, but he referred to the dangers of assuming the presence of biliary hypotension or hypertension. It was doubtful whether there was any justification for the various forms of nerve section which were practised abroad. In some cases he thought that there was persistent spasm of the sphincter of Oddi, causing recurrent attacks of pain with occasional jaundice, and in these cases he thought that choledochoduodenostomy was superior to sphincterotomy by any method.

In the ensuing discussion Mr. D. IOAN-JONES (Cardiff) referred to the occasional finding of carcinoma in a stone-containing gall-bladder removed during the course of some other operation. Mr. L. J. HORN (Ebbw Vale) said that the treatment of the case with spasm of the sphincter of Oddi had been referred to, but what of those patients who seemed to have a patulous sphincter, and what was the prognosis in these cases? Mr. R. V. COOKE (Bristol) said that cases of silent obstructive jaundice were frequently retained too long by the physician, who failed to recognize their true nature until rather late. Mr. R. D. RICHARDS (Merthyr) referred to certain elderly patients with coronary

insufficiency and indubitable biliary disease which aggravated the cardiac trouble, and he advocated operation in these cases. Dr. E. A. DANINO (Swansea), speaking as a physician, mentioned the frequency with which he saw cases of chronic pancreatitis giving rise to severe symptoms. He thought that in some cases of otherwise successful surgery pancreatitis might account for persistent flatulence and other symptoms. Mr. J. DUNBAR (Glasgow) said that, contrary to Mr. McNeill Love, and speaking from personal experience, he had found that morphine was a valuable pain reliever in these cases, but it must be given in large doses. He thought that there was still a place for drainage of the gall-bladder in some cases of cholecystitis. With regard to stones and carcinoma of the gall-bladder, it was his view that the latter seldom occurred unless the stones had been causing symptoms. Mr. SOL M. COHEN (Dartford) asked if gall-bladder disease was getting steadily less common in this country. The operation seemed to appear less frequently on operation lists.

Mr. H. GORDON UNGLEY (London) drew attention to a method of cholangiography taught him by Mr. Rodney Smith. In the jaundiced patient it was relatively easy to insert a needle percutaneously into the liver and by seeking a dilated hepatic duct to make a cholangiogram. Mr. R. S. MURLEY (London), referring to Mr. McNeill Love's remarks about pulmonary embolism, said that a pad behind the heels on the operating table was by no means a certain preventive of this complication. He had records of many cases of pulmonary embolism where this and other precautions had been taken. He also said that a completely normal cholangiogram could be obtained with a stone in the common duct, and gave details of a recent case. Dr. F. A. ANDERSON (Connecticut, U.S.A.) also referred to possible misinterpretation of cholangiograms owing to the presence of air bubbles in the opaque medium. Mr. C. JENNINGS MARSHALL (London), summing up before the opening speakers, made some general observations on the relationship of cholesterol to carcinoma. He had been glad to hear some support for cholecystostomy. At a certain stage in cholecystectomy the Rubicon was crossed and in the occasional case one was glad to have even a shrivelled remnant of gall-bladder available later. He warned against the dangers of ligating the cystic duct too far distally, and said that he himself was not averse to leaving a short stump.

Mr. R. J. MCNEILL LOVE, in reply, said that he was sorry that Mr. Edwards had not provoked him more. He agreed that one should not remove a "lazy" gall-bladder. He himself had frequently divided the sphincter of Oddi with a special sphincterotome, with complete satisfaction. A patulous sphincter was probably of little harm. He emphasized the value of slimming the fat patient and agreed with Dr. Danino's remarks about the frequency of chronic pancreatitis and pancreatic insufficiency. As to Dr. Anderson's remarks, the answer was not to inject air into the bile ducts: it was not necessary. He agreed that there was still a place for cholecystostomy.

Mr. HAROLD EDWARDS confined himself to remarks about the post-cholecystectomy syndrome. An American colleague had assured him that the best treatment for these cases was to put the gall-bladder back.

PAIN OF VASCULAR DISEASE

In the afternoon, with Mr. D. IOAN-JONES (Cardiff) vice-president, in the chair, Sir JAMES PATERSON ROSS (London) opened a discussion on the relief of pain of vascular disease in the lower limb. He said that he would confine his remarks to pain of arterial origin. Intermittent claudication, rest pain, the pain of inflammation, and that of ischaemic neuritis were all due to inadequate blood supply, and treatment must be directed to improving the blood supply to the limb. The treatment of the whole patient must come before treatment of the limb, special attention being paid to the condition of the heart and blood, the state of the arteries elsewhere, and to any associated or intercurrent disease. Intermittent claudication was generally due to main-vessel

disease and called principally for an improvement in collateral circulation. This might be achieved by rest in bed, physiotherapy, and drug treatment. The results of sympathectomy were generally good with main-vessel disease but poor where disease was diffuse and there was severe wasting of the affected muscles. He had little experience of intra-arterial drug injection and would leave this to subsequent speakers. A second method of attack in the relief of claudication was arterial grafting, which would be discussed by Professor C. G. Rob. The third method was to decrease the muscle work in suitably affected groups by neurectomy or tenotomy.

Rest pain was due to small-vessel disease and, where the foot was affected, might respond to physiotherapy and vasodilator drugs; but if it did not, then lumbar ganglionectomy might be expected to relieve it in the uncomplicated case. Such pain was not necessarily a manifestation of advanced disease. When complicated by ulceration, sympathectomy should certainly be combined with constitutional measures, but might have to be followed by amputation of a toe. If this wound failed to heal, amputation would be required at a level determined by the pulse in the main vessels of the limb. Rest pain complicated by oedema necessitated treatment of any infection and elevation of the limb. The latter measure might make the pain temporarily worse, and morphine should then be freely given. If oedema could be dispersed, the measures already outlined might be successful; if they failed a major amputation was required.

Mr. J. BAGOT OLDHAM (Liverpool) said that venous lesions might cause pain from thrombosis or venous incompetence. Superficial phlebitis was not infective, and therefore antibiotics were not indicated. Active movement was essential in all cases. While it was exceedingly unlikely that embolism would occur from this condition, he did advocate immediate ligation of the saphenous vein at the groin in those cases where the thigh was involved. Firm bandaging below the knee was of value, but with marked varicosities ligation of the veins was the best treatment. The pain of deep thrombosis might be less, but the risk of embolism was infinitely greater. Heparin not only arrested the process but was usually the best pain reliever. Active movements were started as soon as the process was under control, and firm bandages were applied. The important rule was never to let the leg swell. For the pain of venous incompetence, if this was confined to superficial varicosities, ligation was the best answer.

When the deep veins were involved it must be recognized that there was no really satisfactory cure. The main essential was to teach the patient how to make the best of his disability by avoiding undue standing, resting as much as possible with the foot raised, and, when standing, keeping the muscles active. Support by bandages or elastic stockings and reduction of weight were also very important. The greater the venous incompetence, the firmer the support must be, and the patient must be provided with the type of support best suited to his needs and carefully instructed in its use. A patient who would not co-operate in this regime should not be considered for surgical treatment. Night cramp in the calves was common in association with varicose veins, and in his experience patients chose to relieve this by standing on the cold linoleum. The pain was relieved when the veins were tied, and usually by taking quinine at night.

Mr. Oldham finally referred to his experience in the use of intra-arterial drugs. Alcohol, "prisco," and papaverine had been tried, but he now used only the latter. The dose had varied between 40 and 120 mg., and the procedure was painless, harmless, and simple. He believed that the treatment had been of value.

Mr. HAROLD DODD (London) confined his remarks to the treatment of varicose veins. So far as the pain from deep venous incompetence was concerned, he believed that if one looked after the superficial veins the deep ones would look after themselves. After describing the full examination of these cases, he referred to those patients with small veins, the so-called "early" cases. Mentioning the isolated distribution of the affected groups of veins in these cases, he

added that others had drawn attention to the warm skin in relationship to them and the high oxygen content of the contained blood. He accepted the view recently put forward that these varicosities were directly due to arteriovenous communications in the limbs, and pointed to the value of vein-stripping procedures in these cases.

Arterial Grafting

Professor CHARLES ROB (London) then explained, with illustrative cases, the place of arterial grafting in the treatment of certain very carefully selected patients with arterial insufficiency. He thought it valuable for those cases of so-called primary popliteal thrombosis in young people; also for certain cases of popliteal aneurysm and arteriovenous fistula. In some elderly patients with early gangrene it was justifiable to put in a graft, and he did not think that anything had been lost if such cases subsequently came to amputation. Patients with generalized arterial disease were very rarely suitable candidates for this procedure, and he particularly emphasized the very great importance of considering the whole patient.

Mr. SOL M. COHEN (Dartford) said he thought that much of the effort made to effect vasodilatation was ill-considered. Nature was no fool, and the ischaemic limb was cold and loaded with natural vasodilators. He thought that it would be the verdict of posterity that, in this era, anticoagulants had been a development of infinitely greater value than the vasodilator drugs. Heparin was the drug of choice in patients with arterial lesions, and he also praised the steady and predictable effects of phenylindanedione. He believed that there was no need to depress the prothrombin level below 50% in these cases and thought that it was wrong to aim at the very low levels sometimes advocated. He had a number of questions to ask the earlier speakers. If pain was due to localized vascular disease, why did it radiate so widely? Why did sufferers from claudication not remember the exact day of onset of their trouble, and why didn't they sit down to relieve their pain? In assessing the results of intra-arterial injections, surely we should remember the tendency for claudication to improve spontaneously in many of the milder cases.

He then referred to the value of sympathectomy in arterial disease. This operation was contraindicated in acute thrombotic lesions, legs with "sunset" cyanosis, and those with extensive arterial disease. Diabetic patients also did not do well. He did not think that Buerger's exercises were of the slightest value, and intermittent venous occlusion should be abandoned. It was stupid to draw the patient's attention to his disease by local measures of this kind, and it was imprudent to refer tactlessly to his "hardening arteries." He disagreed with Mr. Oldham in that he believed that anticoagulants should be used for cases of superficial thrombophlebitis. He had no faith in paravertebral block for deep thrombosis.

Mr. H. GORDON UNGLEY (London) spoke in favour of intra-arterial injections for arterial disease. He also thought that paravertebral block was of value. Mr. J. T. RICE EDWARDS (Newport) asked Sir James Paterson Ross whether stripping the posterior tibial nerve was of any value, and he also asked how Professor Rob stored his arterial grafts. Professor ROB then explained the different methods of storage, and said that he favoured freeze-drying, which enabled the graft to be transported quite easily in a tube in one's bag. He did not like venous grafts for most cases. The other opening speakers dealt with further questions raised in discussion. Mr. COHEN said that it was simpler and better to warm the patient than to do a paravertebral block, and he referred to plethysmographic studies which had shown that intravenous injection of drugs produced an effect which lasted almost as long as intra-arterial injection.

Mr. BAGOT OLDHAM detailed some of the evidence which showed that drugs were retained in the limb after intra-arterial injection. He disagreed with Mr. Cohen's remarks about patients with claudication not remembering the exact time of onset of their trouble. He underlined the dangers of injecting long-acting analgesic agents round the nerves in an affected limb.

Sir JAMES PATERSON ROSS said that he had been interested to learn from Mr. Oldham that papaverine seemed to be the only drug of value in intra-arterial injection, for this was the drug which his colleague Mr. J. B. Kinmonth had found of value when applied to the surface of the main vessels of experimental animals. He agreed with Professor Rob's advocacy of attempting to save more limbs, and he was especially interested in Mr. Cohen's remarks about the use of the anticoagulant drugs. He himself was not surprised to find that the muscular pain in some cases radiated so widely, for this fitted in with Sir Thomas Lewis's findings in his experimental injection of the intervertebral ligaments. In reply to Mr. Rice Edwards, he said that the stripping of nerves, or neurectomy of predominantly sensory nerves, was of no value.

SECTION OF OBSTETRICS AND GYNAECOLOGY

Wednesday, July 15

The Modern Forceps Operation

With the president, Professor G. I. STRACHAN (Cardiff), in the chair, Professor T. N. A. JEFFCOATE (Liverpool) opened a discussion on the place of the forceps in present-day obstetrics. Remarking on the shift from a conservative to a radical outlook in obstetrics in the last quarter-century, he pointed out that in many circumstances forceps extraction and caesarean section had become safer for mother and child than spontaneous delivery. Their increased use had not only improved the maternal results but had also effected a dramatic fall in the number of stillbirths and neonatal deaths attributable to the process of birth. The increased safety of forceps delivery was due chiefly to four factors: (1) the disappearance of the high-forceps operation and the replacement of most difficult mid-forceps extractions by caesarean section; (2) insistence on an accurate cephalic grip; (3) the application of forceps earlier in the second stage of labour, often before there is any evidence of distress; and (4) the prevention of maternal risks such as post-partum haemorrhage and anaesthetic complications.

Despite the greatest care in selection of cases unexpected difficulty, usually due to contraction of the pelvic cavity, occasionally confronted even the expert. There must therefore be a place in hospital practice for a considered "trial of forceps," with resort to caesarean section in cases of failure. The proper place for forceps in modern practice, concluded Professor Jeffcoate, was whenever they offered less risk to mother and foetus than did further prolongation of labour. These relative risks must be assessed in the light of the circumstances of each case, and this meant that in domiciliary practice forceps should be applied only when the vertex was below the level of the ischial spines.

Mr. GAVIN BOYD (Belfast) compared the forceps rate in four groups of patients in Belfast. For women booked by midwives the rate was about 5%; for those delivered by general practitioners it was 8.8%. The higher rate of 16.4% in deliveries at the Royal Maternity Hospital reflected a tendency in hospital to anticipate the orthodox indications for the application of forceps. In private cases in hospital the rate was over 36%, probably because forceps extraction tended to become part of a technique which included pethidine and scopolamine analgesia, followed by cyclopropane anaesthesia for delivery.

Failed Forceps

Dr. WILLIAM HUNTER (Newcastle-upon-Tyne) reviewed the problem of failed forceps, a complication which was being less often seen as the standard of obstetrics rose. The three main causes were premature application, disproportion, and an unrecognized posterior position of the head. Premature application of forceps was most likely to occur when a doctor, urged by the patient and her relatives to expedite matters in a prolonged labour, was tempted against

his better judgment to apply forceps before full dilatation of the cervix. He himself considered that any woman whose delivery was not imminent after 36 hours in labour should be transferred to hospital, where it was easier to deal with the patient both as a woman and as an obstetrical problem, unembarrassed by her relatives. Again, a doctor, considering the cervix to be fully dilated, might find under anaesthesia that a rim of cervix was still present. He must then be strong-minded enough to abandon the operation rather than risk injuring mother and baby.

Disproportion was more likely to be overlooked when due to a large baby than when due to pelvic contraction. Ideally, the possibility of disproportion should be suspected antenatally, and if it was not excluded by bimanual examination, aided if necessary by x-ray pelvimetry, the patient should be admitted to hospital for delivery.

The third cause of failed forceps was the unrecognized occipito-posterior position. This malposition was much easier to diagnose antenatally, when it could be corrected abdominally by a manoeuvre he had recently described. Correction was also indicated when there was failure of progress in the first stage of labour and would probably then be followed by spontaneous delivery or low-forceps extraction. When the second stage of labour exceeded two hours or was marked by foetal or maternal distress, then, if the head was in the pelvic cavity, manual rotation of the occiput to the front followed by forceps extraction was the treatment of choice.

Dr. E. PARRY JONES (St. Asaph) discussed the methods of rotating the head before forceps delivery. Manual rotation within the pelvic cavity was the easiest and safest method. When it failed the operator had to decide whether to displace the head upwards and rotate it above the pelvic brim or to effect rotation with forceps. The former manoeuvre involved the risks of prolapse of the cord and, if labour had been long obstructed, of rupture of the uterus: it was a rational procedure only if the shape of the pelvis would allow the moulded head to re-enter the pelvic cavity in its new position.

If forceps rotation was preferred the classical instrument could be used with advantage only if the head was low and there was no bony obstruction at the level of arrest. Kielland's forceps were much better for the purpose, first because they were easier to apply accurately so as to grip the biparietal diameter without displacing the head upwards; secondly, because rotation could be effected with little force and with a minimum of trauma to mother and baby; thirdly, because traction in the line of the handles was in the pelvic axis at all levels; and fourthly because rotation, traction, and delivery could be accomplished with only one application of the forceps.

Mr. GLIDDELL (Melbourne), Mr. HOPKINSON (Church Village), Dr. D. McKAY HART (Glasgow), Mr. O. V. JONES (Bangor), Mr. C. G. ROWORTH (Swindon), Dr. E. NOEL REES (Llanelli), Dr. A. J. MACLEOD (North Uist), Dr. A. BARKER (Whitstable), Mr. LESLIE H. W. WILLIAMS (London), Mrs. P. M. NAIDU (Hyderabad), Dr. M. I. COOKSON (Gloucester), and the PRESIDENT of the Section participated in the ensuing discussion, to which Professor JEFFCOATE replied.

Placental Blood Flow in Toxaemia

Professor J. C. McCLURE BROWNE (London) gave a short paper on the placental blood flow in pre-eclampsia. Many workers had postulated that toxæmia resulted from placental ischaemia, but none had proved it. Together with Dr. Veall he had therefore first devised a method of locating the placental site, using radioactive sodium (Na^{24}). Next, in women in whom the placenta was on the anterior uterine wall, the tracer substance was injected directly into the choriodecidual space, and its rate of disappearance was timed with a Geiger counter. In seven hypertensive women the rate of disappearance of the tracer substance was three times as slow as in eight normotensive women. This indicated that in hypertension the rate of placental blood flow was markedly reduced. Other conclusions reached in this study were that placental ischaemia was the effect, not the

cause, of the hypertension; that the marginal sinus was not the path of venous outflow from the placenta; that the placenta had a large reserve; and that this technique could be applied in other conditions of alleged placental insufficiency, such as post-maturity.

The Climacteric

The meeting of the Section continued in the afternoon, with Professor H. HARVEY EVERS in the chair. Mr. ALECK W. BOURNE (London) discussed the clinical aspects of the menopause. He said that the symptoms were primarily caused by the endocrine readjustment following functional ablation of the ovaries. The severity of the symptoms was probably determined by three factors: (1) Variations in the secretion of androgens and oestrogens by the adrenals in different women at the menopause. (2) An intrinsic factor dependent upon the sexual type of woman. The gynaeoid woman might expect a menopause in accord with her previous reproductive functions, relatively easy and short. The android woman would pass through the change with maximum symptoms. (3) An extrinsic factor in the form of emotional stress. In treatment, a mixture of the male and female hormones was more efficacious than oestrogen alone. Their synergistic action allowed a small dose to relieve both physical and psychological symptoms, and their effectiveness could be estimated objectively by the vaginal smear. Implantation of oestrogen pellets was to be avoided unless the uterus and ovaries were removed at operation.

Mr. T. N. MACGREGOR (Edinburgh) said that the climacteric endocrine derangement caused an upset in the autonomic nervous system. In most women symptoms were absent or negligible, but in a minority psychological factors were paramount in precipitating symptoms. Therefore explanation and reassurance must be the first line of treatment, with oestrogen therapy reserved for severe cases only. He emphasized that no woman with irregular bleeding around the climacteric should be treated with hormones without a preliminary curettage. If both curettage and hormone therapy failed total hysterectomy was indicated.

The Artificial Menopause

Professor H. C. McLAREN (Birmingham) spoke about the methods of inducing artificial menopause. Surgery entailed some small risk both to life and to health, and the likelihood of acute menopausal symptoms if both ovaries were removed. A radiotherapeutic menopause was safer, but in almost half the patients severe hot flushes required treatment later. For cases of non-malignant bleeding, therefore, he was experimenting with the intrauterine application of radioactive phosphorus and cerium. In this way it was hoped to produce the menopause by destroying the endometrium without affecting the ovaries.

Mr. M. D. ARWYN EVANS (Cardiff) compared the incidence of symptoms in three groups of women after artificial menopause. The first group had had the uterus and both ovaries removed; the second had had hysterectomy but conservation of some ovarian tissue; and the third had been treated radiotherapeutically. There was little difference between the groups in the incidence of symptoms in women over 45. Therefore when the menopause was produced surgically removal of the ovaries with the uterus caused no deprivation in older women. In women under 45, however, the conservation of ovarian tissue was desirable, since this was associated with a low rate of menopausal symptoms.

Mr. J. R. E. JAMES (Cardiff), Dr. G. S. FOSTER (Cardiff), Professor J. C. McC. BROWNE (London), Dr. WILLIAM HUNTER (Newcastle-upon-Tyne), and Professor G. I. STRACHAN (Cardiff) joined in the subsequent discussion, to which Mr. BOURNE replied.

Dysmenorrhoea

With Mr. LESLIE H. W. WILLIAMS (London) in the chair, Dr. D. McKAY HART (Glasgow) read a short paper on dysmenorrhoea. The subject bristled with difficulties in

definition, classification, pathology, and treatment. In secondary dysmenorrhoea the treatment was that of the cause, which was usually obvious except sometimes when endometrial tissue was present in abnormal situations. The primary type of dysmenorrhoea was said to occur only in ovular cycles and to be cured by pregnancy, but it might first appear after a delivery. The various theories of causation had little in common. General regulation of the patient's life was important, and operative measures should be reserved for resistant cases, with presacral neurectomy the last resort.

SECTION OF ANAESTHETICS

Wednesday, July 15

A Return to Simplicity?

With Dr. C. LANGTON HEWER (London), the president, in the chair, Dr. M. D. NOSWORTHY (London) opened the session with a discussion of the nature of simplicity. He defined anaesthesia as a combination of central depression and peripheral suppression in varying proportions, depending on the combination of drugs used. He contrasted the older methods, in which central depression predominated, with modern techniques—used since the introduction of relaxants—in which the period of reflex depression was much shortened by the addition of pure peripheral suppression. The advantage of a shortened period of central depression was shorter recovery time. Dr. Nosworthy then emphasized the disadvantages of modern techniques. Relaxants had made inflation of the lungs a common practice and thus abolished the fear of apnoea. For this reason some anaesthetists had also lost the fear of large doses of thiopentone, despite its dangerous circulatory depression and prolonged recovery time. He recommended that thiopentone should be used only in "sleep doses," and should be followed by 75% nitrous oxide in oxygen with a relaxant. He doubted whether in some patients nitrous oxide alone produced surgical anaesthesia, the lack of which might be the cause of circulatory disturbances and hiccups. In these cases the addition of pethidine, procaine, or a volatile anaesthetic was more rational than administration of thiopentone.

Dr. Nosworthy concluded by defending the terms applied to pulmonary inflation: it was called "passive ventilation" when the respiratory arrest was due to central depression, muscular paralysis, or both; "controlled respiration" indicated that breathing would be suspended but for hyperventilation. He believed that these techniques, like that of endotracheal anaesthesia, should not be used unless clearly indicated.

Dr. Nosworthy was followed by Dr. W. W. MUSHIN (Cardiff), who said that simplicity depended on understanding, and apparent complexity of anaesthetic technique should be condoned only if it was understood by the anaesthetist and beneficial to the patient. He said that teachers should remember that many undergraduates were future general practitioners, to whom anaesthesia would be only a part of their work, and the circumstances in which they would later administer anaesthetics would be different from those of a well-equipped hospital. He thought that all generations believed contemporary techniques in anaesthesia were unduly complicated, and the methods of to-day would seem remarkably simple to those who came after.

In the discussion afterwards, Dr. G. HOYLE (Tamworth) raised the problem of analgesia for domiciliary midwifery, and made a plea for the administration of chloroform to be taught to medical students. This seemed in many cases the only practical agent.

Dr. M. H. ARMSTRONG DAVISON (Newcastle-upon-Tyne) agreed that the problem of anaesthesia for domiciliary midwifery was a neglected one. He felt that open ether was a difficult anaesthetic, and that students should be taught to administer nitrous oxide and ether; if they were taught the basic principles of the subject thoroughly they would

be able to master other techniques. Dr. H. R. YOUNGMAN (Cambridge) believed there was no serious danger of an explosion when ether was used in the presence of an open fire if there was a draught up the chimney; but Dr. N. S. WALLS (Southport) disagreed with this.

Dr. H. M. MOHELSKY (Vienna) said that the surgeon should be taught simplicity. Dr. RONALD JARMAN (London) wondered whether the results of modern anaesthesia were better than those obtained by older anaesthetists: the modern operation caused less strain to the surgeon and more to the anaesthetist, and he wondered how long the anaesthetist should pander to the surgeon. Dr. R. BLAIR GOULD (London) said that the anaesthetic techniques used in teaching hospitals were wholly unsuitable for teaching medical students, and Dr. J. E. GILLESPIE (Melbourne) pointed out that ether had the advantage of illustrating clearly the stages in anaesthesia. Dr. K. S. THOM (Newport) thought that students were well taught and agreed that chloroform was the most satisfactory practical anaesthetic for domiciliary midwifery. Dr. T. CECIL GRAY (Liverpool) believed that a mixture of 75% nitrous oxide and oxygen would always keep a patient unconscious, but this was doubted by Dr. J. G. BOURNE (London). Among others taking part in a lively discussion were Dr. C. LANGTON HEWER, Dr. R. P. HARBORD (Leeds), Dr. R. F. WOOLMER, and Dr. D. H. ISAAC (Port Talbot).

Hypothermia and Anaesthesia

At the afternoon session Dr. Hewer relinquished the chair to Dr. RONALD JARMAN (London). The session opened with a short paper by Dr. E. J. DELORME (Edinburgh) on hypothermia and anaesthesia. Dr. Delorme explained that, when the temperature of the tissues was reduced, less oxygen was required to sustain cellular life; if the body could be uniformly and reversibly cooled, the supply of oxygen to the tissues by the blood might be suspended. Degrees of hypotension and ischaemia which would be injurious at normal body temperature might then be tolerated and—in theory—the advantages of the hypotensive techniques retained without hazarding the safety of the patient. Experimental studies on dogs had shown that the circulation could be stopped for relatively long periods at lowered body temperature, and was followed by complete recovery. This was also true for the local circulation of various organs, including the brain. Dr. Delorme described the technique for cooling the body by the extraction of heat from an exteriorized circulation of the blood, and he discussed its advantages over surface cooling.

Hypotension

A discussion on the case against hypotension was opened by Dr. M. H. ARMSTRONG DAVISON (Newcastle-upon-Tyne). He said that his case depended upon the side-effects of the profound circulatory disturbance of hypotension, and the dangers in the methods by which it was achieved. Hypotension itself might cause cerebral anoxia, which, because of its frequency and serious consequences, was the most important argument against the use of the technique during operation. It might also cause cerebral thrombosis, renal or hepatic damage, haemorrhage from a large vessel during the period of hypotension or reactionary haemorrhage afterwards, cardiac failure, massive pulmonary collapse, and paralytic ileus. There was a risk of failure to restore normal blood pressure, and the production of cardiac arrhythmias by pressor drugs used for this purpose. Of the methods for achieving hypotension, deep chloroform anaesthesia had the particular danger of delayed poisoning, spinal analgesia might produce neurological lesions, and arteriotomy could lead to clinical shock. He concluded that hypotensive techniques should be used only when the operation was impossible without a bloodless field and could not be more safely obtained by some other means.

Supporting Dr. Armstrong Davison, Dr. R. F. WOOLMER (Bristol) said that hypotension might make surgery easier, but its price was morbidity and mortality. He quoted a

recent analysis of the experience of 178 British anaesthetists who had used hypotensive techniques: 57% of their patients received methonium compounds, and 33% high spinal analgesia; 10% underwent arteriotomy, and in 9% of cases hypotension was obtained with other methods. The number of cases was 21,125, of which the number of complications was 549. There were 190 cases of delayed post-operative recovery, 164 of reactionary haemorrhage, 37 of thrombosis, and 24 of other acute cardiovascular complications. Forty-six deaths were reported in the series, and he felt there was reason to believe that at least 39 of them were directly the fault of hypotension. Dr. Woolmer said he thought 39 deaths which were otherwise preventable was a high price to pay for a means of diminishing bleeding. Dr. H. C. CHURCHILL-DAVIDSON (London) said he did not believe that the kidney was inevitably damaged during hypotension: red blood corpuscles and albumin appeared in the urine in many conditions, and oliguria could be caused by deep anaesthesia. Dr. W. W. MUSHIN (Cardiff) said that deaths after operations in which hypotension had been used occurred within six days, but deaths after operations in which other techniques had been used occurred up to 28 days afterwards. Dr. T. M. WILLIAMS (Swansea) stated that the complications of blood transfusion should be set against those of hypotension, and Dr. S. H. GRAHAM (Cardiff) speculated on the critical figure for the blood pressure. Dr. C. LANGTON HEWER (London) complained that anaesthetists had not completely exploited the simpler methods of haemostasis, such as infiltration with dilute adrenaline. Dr. RONALDSON (Hull) gave an account of 500 cases of hypotension and stated that safety depended on careful selection of patients. He mentioned the work of the anaesthetic out-patient department that he had instituted. Dr. M. D. NOSWORTHY (London) agreed with Dr. Ronaldson, and Dr. JARMAN stated that as long as the pulse rate of his patients was below 100 during the period of hypotension he did not feel any anxiety. Drs. J. MIDDLETON PRICE (London) and S. M. ANDERSON (London) also contributed to the discussion.

SECTION OF CARDIOLOGY

Wednesday, July 15

Pulmonary Heart Disease

With the president, Dr. J. MAURICE H. CAMPBELL (London), in the chair, Dr. A. J. THOMAS (Cardiff) opened a discussion on pulmonary heart disease. He said that there were many diseases of the lung fields, or of the pulmonary vasculature, or of the muscular and skeletal cage of the thorax which would cause pulmonary hypertension or increased pulmonary blood flow, and so affect the right heart by causing increased work for the right ventricle. The progressive massive fibrosis of pneumoconiosis caused considerable right ventricular hypertrophy, with eventual right heart failure of low-output type. The electrocardiograph frequently showed typical changes of right ventricular hypertrophy when the weight of the right ventricle exceeded that of the small left ventricle. He thought that the clinical and other findings of advanced pneumoconiosis indicated an obstructive type of pulmonary vascular lesion. Intercurrent bronchiolitis could cause anoxic failure at any stage, but eventually severe pulmonary hypertension was present and heart failure was irreversible.

In emphysema the cardiac output was increased, the pulmonary blood flow was ample, and pulmonary hypertension was only moderate. Infection and anoxia would increase the pulmonary hypertension, but this condition was reversible. The degree of right ventricular hypertrophy was less than in pneumoconiosis, and the cardiographic signs were later in appearing. Bronchiectasis was of importance in the causation of pulmonary heart disease, but the mechanism was not yet fully understood.

Professor J. GOUGH (Cardiff), reading a paper on the pathological anatomy of the lungs associated with some forms of cor pulmonale, said that death certificates showed that heart disease in the anthracite miners of South Wales was 50% more common, and in the non-anthracite miners 30% more common, than in the general male adult population of England and Wales, and there was good evidence that this excess heart disease was pulmonary heart disease consequent upon pneumoconiosis. The majority of these cases were associated with the characteristic massive fibrosis found in coal workers, associated with severe endarteritis and thrombosis in the blood vessels. A notable feature was the extension of granulation tissue through the walls of the vessels into the lumen, causing disruption of the elastic laminae of the vessels. Injection with radio-opaque material showed a great reduction in the pulmonary arterial tree as a result of these changes. He had studied, by means of the large-section technique, thin sections representative of the whole lung in cases with non-industrial chronic bronchitis and emphysema. He regarded chronic bronchitis with dilatation of the bronchi as an important and striking feature in many cases of cor pulmonale, and the blocking of the bronchi with pus could readily account for the anoxia that developed during the recrudescence of infection. The large-section technique showed clearly the importance of the emphysema element in the development of cor pulmonale in chronic bronchitis and emphysema, but the emphasis was now on the changes in the bronchi and in the communications between bronchial and pulmonary arteries.

Dr. WILLIAM EVANS (London) thought that the most important factor in the production of pulmonary heart disease was obstruction within the pulmonary arteries, and that in any discussion on pulmonary heart disease the emphasis was on pulmonary hypertension. He described two groups of patients with pulmonary hypertension. In the first, the pulmonary vessels were blocked with material arising elsewhere, such as massive pulmonary emboli, bilharzia ova, or carcinomatosis. In the second group, the obstruction arose locally with the changes of endarteritis fibrosa of the lesser pulmonary arteries. This occurred in some patients with patent ductus arteriosus, auricular or ventricular septal defect, idiopathic dilatation of the pulmonary artery, congenital pulmonary polycystic disease, emphysema, and possibly mitral stenosis. The most noticeable symptom of pulmonary hypertension was progressive breathlessness. Cough was seldom distressing. Syncope was a characteristic symptom, and might cause sudden and unexpected death in this condition. He described the signs of pulmonary hypertension, including cyanosis, distended neck veins, increased pulsation in the pulmonary area, an added sound in early systole and a terminal triple rhythm. The electrocardiogram showed right heart preponderance; radiology showed enlargement of the right heart with prominent pulmonary arteries. In some cases there were signs of an associated condition such as a patent ductus or septal defect. The mechanism of the pulmonary hypertension was extensive endarteritis fibrosa blocking innumerable small pulmonary arteries. A preliminary arteriogram of the lung at necropsy indicated the area most affected by arterial blockage, and histological examination showed that the endarteritis fibrosa affected particularly arteries whose media showed a congenital aplasia or hypoplasia.

The PRESIDENT (Dr. J. Maurice H. Campbell, London) spoke of the difficulty in deciding when the heart was involved in patients with dyspnoea from chronic lung disease. Signs of right heart failure provided a certain but late indication of heart involvement, but a sudden increase in dyspnoea, not associated with a pulmonary infection, was often an earlier sign. In mitral stenosis he had not so far found irreversible pulmonary hypertension. After mitral valvotomy the pressure usually came down by a half and might return to normal. In young patients with an atrial septal defect or patent ductus arteriosus pulmonary hypertension was uncommon, whereas in ventricular septal defects it was common. Pulmonary hypertension with a ventricu-

lar septal defect might cause the Eisenmenger complex, and pressure changes were more important than the degree of overriding of the aorta.

Dr. R. A. PARKER (Cardiff) said that thickening of the intima of the small pulmonary arteries was part of the process of ageing and that the changes in emphysema were an accentuation of the normal old-age changes. In mitral stenosis there was medial hypertrophy and often an acute arteritis. He had not encountered in normal people the hypoplastic lesions described by Dr. William Evans, but had found them in mitral stenosis. Dr. JOHN C. GILSON (Pneumoconiosis Research Unit, Llandough) found clinical or cardiographic signs of cor pulmonale in one-sixth of the last 150 cases with progressive massive fibrosis that he had studied; these often followed an acute infection of the lung. He thought that dust-suppressive measures would eventually prevent pneumoconiosis, and his unit was studying the effect of removal of the factor of tuberculous infection in lowering this attack rate of progressive massive fibrosis in patients with simple pneumoconiosis. Dr. A. RAE GILCHRIST (Edinburgh) spoke of the concept of malignant hypertension in the pulmonary circuit which, by analogy with malignant hypertension in the systemic circulation, might be reversible. Mr. H. R. S. HARLEY (Cardiff) thought that pulmonary hypertension in mitral stenosis was due partly to the valvular stenosis and partly to changes in the small vessels. He regarded these changes as secondary to the pulmonary hypertension, which he thought was reversible.

Professor GOUGH, in reply to points raised in this discussion, said that environmental factors were largely responsible for the amount of dust found in the lung. In young patients developing progressive massive fibrosis there was histological and laboratory evidence of tuberculous infection. In this condition he thought the arterial changes were primary and not secondary.

Dr. I. K. R. McMILLAN (London) showed a colour film on the action of normal and pathological heart valves. This showed in a startling way how the heart valves worked and illustrated the difficulties encountered in the surgical treatment of valvular stenosis.

SECTION OF CHILD HEALTH

Wednesday, July 15

Care of the Newborn

The president, Professor A. G. WATKINS (Cardiff), was in the chair when a panel consisting of Professor W. C. W. NIXON (London), Professor WILFRID F. GAISFORD (Manchester), Dr. E. NOEL REES (Llanelli), and Dr. DOROTHY H. ALDIS (Cardiff) answered "Any Questions?" on the care of the newborn.

The panel was unanimous that there was no advantage in withholding the first feed of the full-term baby for more than six to eight hours; that there was no evidence that the administration of hormones to premature babies was worth while; that no benefit to the mother or child followed antenatal relaxation exercises; and that the main duties of the father in the antenatal period were household chores and baby-minding where necessary. No ill-effects followed the administration of oxygen to full-term babies, but there was a real danger of causing retrolental fibroplasia in premature babies. Oxygen saturation should never exceed 40% and should be given for as short a period as possible. B.C.G. vaccination of newborn babies was thought to be well worth while, not as a routine but in selected cases. On both the last questions Professor A. WALLGREN (Stockholm) concurred with the panel.

On the remaining questions there was a division of opinion among the panel. Some felt that there were advantages in nursing a baby naked in hospital, but the majority opinion of both the panel and other members was that a moderate

amount of clothing should be used. On the question whether babies should be nursed in communal nurseries or at the mother's bedside it was stated that there was no difference either in the incidence of infection or in the rate of breastfeeding whichever method was used. Those with personal experience favoured having the baby with the mother during the day but removing it at night, and with this view those fathers who spoke agreed. Getting the mother up on the third or fourth day after childbirth was favoured by those who were concerned mainly with hospital practice, but opposed by the family doctors and mothers; the latter made the point that the mother would probably not have the opportunity for similar rest for the remainder of her life, unless a subsequent pregnancy occurred. No difference was seen in lactation whether early or late rising was practised.

Surprisingly, the panel and the meeting were evenly divided on whether routine circumcision of the newborn should be performed, the family doctors in the main being in favour of it. The common failure of lactation when a mother returns home from hospital was discussed at length without any general agreement. Some felt that the main reason was laziness, while others felt that sociological or psychological factors were most important; failure to empty the breasts completely was thought to play a part, and it was stated that the incidence of breast abscess was as high as 5%. Here again the beneficial effects of adequate rest were stressed. On the question of the most satisfactory feed interval for babies a lively discussion on demand *versus* régime feeding took place, the majority favouring the latter. The matter was epitomized by Dr. V. MARY CROSSE (Birmingham), who thought that with an intelligent mother demand and régime feeding would amount to the same thing.

Lastly, on whose should be the care of the breasts, the obstetrician thought the paediatrician should look after them, the paediatrician had no opinion and thought it a matter of individual preference, the family doctor thought it was his responsibility throughout, while the mother was heard diffidently to mention the mother.

Accidental Poisoning in Childhood

Professor A. V. NEALE (Bristol), vice-president, then took the chair, and Dr. D. SWINSCOW (London) opened a discussion on accidental poisoning in childhood. He said that the age group for which the death rate from acute accidental poisoning was highest was 1-2 years. In England and Wales, in 1950-1 the rate for that age group was 37 per million of the population, only slightly less than the corresponding rate of 41 for influenza. Boys were more commonly involved than girls. Figures obtained from the Registrar-General showed that most of the poisons were medicaments and that the number of deaths caused by them was tending to increase. In 1950-1 the principal medicaments responsible were iron and strychnine preparations, antihistamines, and anodynes. Many of the preparations were not normally regarded as being poisonous, and were relatively harmless to adults while being dangerous to children. The best method of prevention seemed to be to label prominently as poisonous even such supposedly innocuous drugs as aspirin and ferrous sulphate. The unpleasant taste of many of the preparations causing death suggested that the sugar coating of pills was not the danger that had been sometimes contended.

Dr. J. O. CRAIG (Edinburgh) reported a similar increase in accidental poisoning in Edinburgh and Aberdeen. Here, too, the main rise had been in poisoning by medicaments. The most important at the present time was ferrous sulphate, and the most lethal were strychnine and methyl salicylate, while the antihistamines came high on the list. It was necessary to educate the public in the idea that all medicines were poisonous to children. There were some substances—for example, linimentum A.B.C.—which could well be removed from the pharmacopoeia, and others in which modification of the vehicle—for example, lin. meth.

sal.—or in the composition of compound tablets—for example, purgatives containing strychnine—was indicated.

In the subsequent discussion the frequent difficulty of inducing vomiting was stressed. Attention was drawn to the danger of prescribing medicaments which tasted nice, the rarity of metaldehyde and vitamin poisoning, and the differences between country and city in the frequency of the various poisons encountered.

SECTION OF DERMATOLOGY

Wednesday, July 15

With the president, Dr. R. M. B. MacKENNA (London), in the chair Dr. LOUIS FORMAN (London) opened the symposium on practical problems in the management of disorders of the skin in general practice with a paper on the management of pruritus. He said the origin of the sensation of itching was in the nerve endings of touch and pain in the skin. The appreciation of itching depended on the attention paid to the sensation. The sensual element of itching and scratching was a matter of common experience. The causes of generalized pruritus in childhood were food or epidermal allergy or an infestation. In youth, anaemia, metabolic factors—for example, diabetes—and renal disease might be additional causes. In mature age, deficiencies and glandular factors might play a part. An important but uncommon cause of pruritus was malignant disease or the reticuloses. Toxic or allergic reactions to drugs also led to itching. The nutritional deficiencies might lead to hyperkeratosis and atrophy of the skin seen in old age. The nutrition of the skin might suffer at the menopause and be improved by hormones. Testosterone was known to increase the amount of oxygenated blood in the skin. Circulatory insufficiency might be the cause of the pruritus occasionally observed with mitral stenosis, cardiac insufficiency, and hypertension. Pruritus excited emotional reactions, and the experimental work of Cormia had showed that the threshold value of itching was lowered by psychic trauma and restored by reassurance. With long-established pruritus the patients might be found to suffer from an anxiety state, tensions, obsessions, and even delusions. The antihistamines applied to the skin were capable of sensitizing the patient. Sedatives internally were indicated only to relieve anxiety or tension states.

Dr. W. J. O'DONOVAN (London) said that encephalography might show changes suggestive of epilepsy when specific remedies such as soluble phenytoin might relieve the pruritus. Tinct. opii in large doses for a month might break a vicious circle of itching.

Ringworm of the Feet and of the Scalp

Dr. JOHN T. INGRAM (Leeds) opened a discussion on the differential diagnosis and the treatment of ringworm of the feet. Any affection of the toes or feet, he said, which suggested the possibility of tinea pedis—and that meant almost every affection—required examination for fungus before a diagnosis could be made. As to treatment, it had to be remembered that tinea pedis was very prevalent in certain sections of the community, that it was very contagious under certain circumstances, and that it was often incurable. Nevertheless the condition could be controlled in the majority of patients and apparently cured if treatment was thorough and embraced the contacts and fomites. Relapses in hot weather were to be expected. Sandals or well-ventilated shoes, cotton socks, cleanliness, careful drying of the feet and toes, and the use of a dusting powder spelled salvation.

Dr. L. FORMAN (London) said that demonstration of fungus in exudative phases could be difficult, and repeated examinations were necessary.

Dr. W. N. LEAK (Winsford) found ointments containing dithranol were better if dispensed in metal tubes.

Dr. J. MARTIN-BEARE (Belfast) read a paper on difficulties in the diagnosis and treatment of scalp ringworm; it was based on an epidemic which involved 1,000 children. 12.6% of all schoolchildren and 25% of schoolboys were affected. With *Microsporon audouinii* infection x-ray epilation was the treatment of choice but was not necessary with *M. canis* infections. Routine cultures were necessary. Infection with *Trichophyton sulphureum* was relatively common (55 cases in the series) and was difficult to treat. Local epilation was attempted in 40 cases, with 6 failures, and was not recommended.

Nummular Eczema

Dr. C. HOWARD WHITTLE (Cambridge) opened a discussion on the problem of nummular eczema. He discussed the differential diagnosis from ringworm, psoriasis, seborrhoeic dermatitis, and contact eczema, and analysed a pilot series of 100 cases. His conclusions were that drying and decreasing agents prepared the ground, but atopy frequently provided a favourable soil. Local trauma might select the site and time of onset. Stress factors were very important and might precipitate, and maintain, activity.

Dr. W. J. O'DONOVAN (London) hoped the word "plurifactor" dermatitis would not be introduced into our literature. The recognition of atopy and genetic factors was a throwback to the French concept of diathesis.

Interpretation of Tests for Syphilis

Dr. C. S. NICOL (London) spoke on difficulties in the interpretation of the serological tests for syphilis. There should be a complement-fixation and a flocculation test, he said, and only positive or negative results, no doubtful results. Other diseases were capable of giving positive results besides syphilis, but there was a prospect that the treponemal immobilization test might elucidate this problem. A positive result in a newborn baby might be due to carry-over of reagin from the mother and would become negative after a few weeks.

Hypostatic Ulcers

Dr. D. S. WILKINSON (Amersham) spoke on the prevention of recurrences of hypostatic ulcers. He said the problem of the hypostatic ulcer was not only one of healing but of keeping healed. The same measures used at the outset to reverse the conditions leading to the ulcer should be continued as a long-term policy to prevent recurrence. In a series of cases thus treated by a routine of varying efficiency at different hospital clinics, it was found that when this was efficient the recurrence rate was 12.5% in two years, and when inefficient 45%. A large proportion of breakdowns, therefore, were prevented by good management. Accounting for the 12.5% were patients in whom poor intelligence, arthritis, hypertension, bad social conditions, and a poor psychological attitude were commonly found.

Overtreatment

Dr. I. B. SNEDDON (Sheffield) discussed overtreatment, which arose more often in dermatology, he thought, than in other branches of medicine because the patient and his relatives adopted a more critical attitude to the doctor, the signs of disease being visible. A high standard of cure was expected. The patient contributed to overtreatment by applying homely or proprietary remedies. The keynote to successful treatment was correct diagnosis.

A simple classification of skin disorders was: (1) those which got better spontaneously, such as pityriasis rosea; (2) those due to infection requiring active treatment; (3) those requiring skin rest; and (4) those which were incurable. The use of antibiotics in pyogenic infection over long periods caused sensitization of the skin. Fungicides, particularly the mercurials, were also potent sensitizers.

In the eczema-contact-dermatitis group the inflammatory reaction of the skin was often confused with infection, and antiseptics and antibiotics were applied. All the skin required

was rest, and this was best obtained by the use of inert evaporating lotions. Occlusive tar bandages had a wide evaporating lotions. Occlusive tar bandages were useful in subacute dermatitis and infantile eczema.

The Home and the Skin

Dr. GEOFFREY A. HODGSON (Cardiff) read a paper on the influence of home conditions on skin diseases, emphasizing the effect of unsatisfactory home conditions on common skin diseases. Household chemicals, clothes, plants, and washing agents produced eczematous skin damage. Unsatisfactory home conditions often comprised work, financial, and housing problems, difficult personal relationships, and problems peculiar to the housewife. The mechanism of their effect upon skin diseases was discussed, with particular reference to alteration of skin reactivity, sweating, and scratching, and with special reference to the types of dermatoses produced or aggravated by it.

The Clinical Meeting

About 50 members were present in the afternoon at the clinical meeting in the Cardiff Royal Infirmary. The discussion of cases, conducted by Dr. R. M. B. MacKENNA, was lively and interesting, and the simple explanatory notes on the rarer conditions were helpful and much appreciated, especially by the general practitioners present.

SECTION OF PATHOLOGY

Wednesday, July 15

Gastro-enteritis in Young Children

With the president, Professor J. B. DUGUID (Newcastle-upon-Tyne), in the chair, Professor ROBERT CRUICKSHANK (London) opened a discussion on gastro-enteritis in young children. In children over 1 year of age acute enteritis was mostly due to salmonella and shigella infections; subacute enteritis might be caused by giardia. Sonne dysentery had occurred in recent years in epidemic waves, with greater prevalence in winter. Salmonella infections might occur sporadically as well as in family or larger outbreaks. Investigations had been made into the possibility that a virus might be a cause of mild diarrhoea affecting both adults and infants and of epidemic nausea and vomiting. Infantile diarrhoea and vomiting was mainly a disease of artificially fed infants under 1 year of age in poor-class urban communities.

Deaths from this disease had fallen considerably since 1900, when some 30,000 infants died from it annually. In 1951 deaths numbered 891. Nevertheless the disease remained a problem of some magnitude and affected a large number of infants.

Great advances had been made in treatment, especially by rehydration and chemotherapy. Recent investigations in many countries had shown a close association between infantile diarrhoea and vomiting and certain specific types of *Bact. coli*, particularly O 111, O 55, and O 26 (Kauffmann's classification). Encouragement of breast-feeding, improved hygienic standards, early recognition of infection, and adequate treatment were measures which should help to eliminate this preventable disease.

Incidence of Types of *Bact. coli*

Dr. J. SMITH (Aberdeen) reported that in North-east Scotland the peak epidemic year of infantile gastro-enteritis was 1947, when 240 cases were reported with 104 deaths (40% fatality rate). In 1952 there were 24 cases and no deaths. In 1947, O 111 strains of *Bact. coli* predominated, the sucrose-positive H2 variety being isolated from 227 cases and the sucrose-negative H12 from 6. In 1948, H12 strains were more prevalent, but they had not been isolated since 1951. O 55 strains were first isolated in 1947; their prevalence increased until in 1949 109 strains were isolated, but in 1952 the O 55 strain was isolated on only four

occasions. From 1947 to 1951 only the H6 variety was found, but later a few H7 and H21 strains had been isolated. O 26 strains, first looked for in 1950, had been obtained from 18 cases and one carrier. In 1952 O 119 strains were identified in 11 cases and 10 carriers. Since 1949, 20 cases of gastro-enteritis had been observed in which none of these *Bact. coli* types had been found. Dr. Smith considered that from the association of cases and outbreaks of this disease with specific *Bact. coli* types, it must be presumed that they were the aetiological agents.

Dr. JOAN TAYLOR (London) described an attempt to throw light on the extent of the problem of infantile gastro-enteritis. Specimens from infants living in their own homes and from infants admitted to an infectious diseases hospital were examined. During 1952 and 1953 317 infants were investigated. No bacterial cause could be isolated from 225 infants (71%), though possibly virus infection might have accounted for some of them. Specific types of *Bact. coli* were found in 55 (17%). *Sh. sonnei* was isolated from 33 infants (10%), and other pathogens (including some paracolon, some *Giardia*, and one *S. typhimurium*) from 6 (2%). The previous history of the infants was also investigated. Those who had been in institutions accounted for 7 of the 170 infants with no bacterial cause found, for 10 of 27 with coli sero-types, and for 4 of 35 with *Sh. sonnei*. On two occasions infants with O 111 strains of *Bact. coli* had been admitted to nurseries, and these strains had spread without causing illness.

Prevention of Gastro-enteritis in Hospital

Dr. K. B. ROGERS (Birmingham) described a trial organized to prevent epidemics of gastro-enteritis in a children's hospital. Infants who had gastro-enteritis, irrespective of bacteriological findings, were admitted to one of the three floors of an infants' block. The other two floors were reserved for infants suffering from diseases not associated with gastro-enteritis. Infants who had been in any institution during the previous month or who were vomiting without obvious cause formed a third group. They were admitted to cubicles elsewhere in the hospital, and bacteriological investigations were carried out. If the specific *Bact. coli* types were isolated the infant was sent either home or to the gastro-enteritis ward, but otherwise they were sent to a "clean" ward. The duration of hospital stay during the trial year was compared with that during preceding years. Infants with pyloric stenosis, intussusception, and pneumonia were particularly studied. He found that *pari passu* with the elimination of the specific types of *Bact. coli* there was a very marked reduction in the incidence of gastro-enteritis and that the infants were not so long in hospital. In previous years between one-fifth and one-quarter of the cots were occupied because of gastro-enteritis, which seemed to be an avoidable condition.

Cross-infection

Dr. M. T. PARKER (Manchester) reported an investigation on hospital cross-infection with salmonellae. During the last four years he had investigated 213 infections (85% of which were due to *S. typhimurium*) in children under 2 years of age. Most of the cases occurred in a few large outbreaks. Spread from ward to ward and from hospital to hospital occurred easily and could usually be traced to the transfer of infected patients. Infection became established only in wards in which most of the patients were less than 2 years old. Spread occurred as easily in cubicle wards as in open wards. Salmonella infection in the general population was common only in the summer months, but cross-infection in hospitals occurred at all seasons. The behaviour of the disease suggested that the infant excretor was the main source of infection and that the organisms were transferred from patient to patient without preliminary multiplication in food. The hands of attendants might become contaminated not only by direct contact with faeces but by contact with equipment and surfaces near the infected

infant. The relative importance of direct contact and of dust in the transmission of infection was not yet known.

Dr. A. T. RODEN (London) described an investigation, undertaken with Dr. Joyce Wright (London), in a large isolation ward for infantile diarrhoea. Between January 27, 1949, and January 10, 1950, 142 cases were admitted to the ward. Rectal swabs were taken from each infant on admission and then at intervals of two or three days until discharge. *Bact. coli* type O 111 was found in 30 infants on admission and type O 55 in 11 infants. From one swab, both O 111 and O 55 types were grown, and results were negative in 100 cases. Of 111 infants at risk, 55 (50%) became cross-infected with type O 111, and of 130 infants at risk 46 (35%) with type O 55. The proportion of cases found to become cross-infected rose progressively with length of stay in hospital. Thus, among the cross-infections with type O 111 the proportion rose from 8 out of 39 cases (21%) staying less than four weeks to 13 out of 15 (87%) staying more than 12 weeks; and, among the cross-infections with type O 55, from 3 out of 43 cases (7%) staying less than four weeks to 11 out of 15 cases (73%) staying more than 12 weeks. Fifty-three of the 55 cross-infections with type O 111 and 42 of the 46 cross-infections with type O 55 were found during the first six weeks of hospital stay. This finding supported the presumption that the long-stay cases did in fact have to have their treatment extended because they became cross-infected.

The Importance of Breast-feeding

Dr. SCOTT THOMSON (Cardiff) discussed the difficulties and importance of breast-feeding. Professor W. F. GAISFORD (Manchester) considered that prevention of gastro-enteritis lay in actual breast-feeding and not the provision of breast-milk from human-milk banks. Dr. T. J. RENDLE-SHORT (Cardiff) said that severe gastro-enteritis was not often seen after 18 months of age, and asked whether there might not be some protective factor in human milk. Professor DUGUID mentioned the possibility that bottle-fed infants might be more exposed to the risk of infection. Dr. JOYCE WRIGHT reported the finding of unsatisfactory conditions in the preparation of infants' bottle-feeds, both of cow's and of human milk. Dr. BERYL CORNER (Bristol) stated that only the rigorous application of isolation techniques in cubicles had prevented the spread of *Bact. coli* O 111 and O 55 among infants in hospital. Dr. I. G. INNES (Hull) stated that he rarely saw severe infantile gastro-enteritis in general practice.

SECTION OF PSYCHIATRY

Stresses within the Family

With the president, Dr. T. J. HENNELLY (Cardiff) in the chair, Dr. H. V. DICKS (London) opened a discussion on family tensions and the work of the general practitioner. He deplored a tendency for practitioners not to look after the whole family, since family relationships affected the type of reaction of the individual to stress. Doctors had been insufficiently educated in holistic thinking to include the human environment. A man of 39 in mild cardiac failure went into hospital to die, as he said, and might have done, but for the chance discovery that his father had died at 39 and his lifelong expectation had been to do likewise.

With the fragmentation of the family due to modern industrial civilization, there were fewer possibilities of the child's making the family a safe place. A minority might thereby reach a higher state of maturity because of their greater independence; the majority were left with comparatively little scope for their emotions. The minute family group of three had to contain an over-condensed mass of feelings. Not all conflicts could be resolved by giving way to the feelings. Other mechanisms such as repression or

dissociation prolonged the conflict and could lead to character and even to somatic structural changes. We needed to know more about how bad feelings arose in the patient; and in this the importance of the early mother-child relationship had been emphasized by Bowlby, Spitz, and others.

The ailing, regressing child who was showing symptoms of deprivation was in the grip of a self-perpetuating mechanism. When married, he or she might look for a parent in the spouse and not for a partner. Worse, they might accept in the partner only their own highly subjective image of the other, thereby angering the spouse by rejection of much of the latter's real personality. To such an unstable marriage the birth of a child might well be an intolerable strain.

Technological change was often blamed for psychological ills, but doctors needed a more proximate vision to see, within the social phenomenon, the play of interpersonal relationships in the family. With such a view, many otherwise ill-defined disorders fell into a recognizable pattern.

Marriage and Security

Dr. W. S. MACDONALD (Leeds) said that he learnt very early as a general practitioner to deal with people rather than with diseases. He had also learnt to look beneath such reports as that 35% of all girls marrying at 20 or under were pregnant at the time of marriage, and to consider the stresses latent in this situation. What insecurity for mother and child might be contained in this state of affairs? Matrimony was a great provider of security and a sense of parental responsibility was scarcely possible outside it.

The modern practice of having confinements in institutions was excellent for almost everything except for family stability. It might hinder the growth of maternal love and hence baby security; anxiety was a prime reducer of maternal milk; and it was essential to the mother to maintain close links with her family during the lying-in period. Modern social devices were good so long as it was remembered that the character of the ancillary worker was perhaps the most important factor.

School provided many areas of stress: the drive to pass the "11+" examination, the valuing of academic success above character, insufficient time to think, and insufficient emphasis on the responsibilities of adolescents were notable examples. Girls were rushed from school into work and into marriage without consideration of possible future motherhood. Boys lacked proper help in vocational choice. The changing pattern of age distribution, the disappearance of the unattached spinster aunt, and the plight of the old people with no place of their own added to the burden on the apparatus of social care.

Beyond all the medical investigations lay the mysterious factor in human reaction to illness, sometimes called "guts"; perhaps found more often in women; perhaps more truly a spiritual factor, and closely linked with contentment and dissatisfaction in life. Why was one person knocked out of life by a trivial injury while another surmounted the most fearful handicaps? He agreed with Dr. Dicks that previous stress successfully overcome was a great strengthener, but to do this needed security.

Acting Spontaneously

Dr. R. F. BARBOUR (Bristol), speaking out of experience in child guidance, raised the question of the adult's preconceptions in their dealing with a child. How could mothers break through the child-rearing systems they had adopted and act spontaneously when necessary? They, as doctors, needed to question such assumptions as: Must a child be admitted to hospital, running the risk of damage greatly? Were green vegetables necessary for health? and so on. The level of the child's mental ability needed to be kept in mind, particularly so that a relatively dull child should not be forced to attempt too much. Parents should

reconsider their attitude to discipline—the admissibility of self-expression for the child, and the need of the child to develop independence.

Dr. DORIS ODUM (London) reported that recent evidence on adoption had shown that third-party adoptions arranged on adoption had been proving notoriously unsuccessful. Too by doctors had been proving notoriously unsuccessful. Too often such adoptions were not made in the interests of the child, but possibly out of a mistaken notion that a neurotic woman needed a child to make her well. Doctors must adopt a more responsible attitude to adoption and make the child's interests paramount. She added that the changing social pattern due to the emancipation of women had altered many women's readiness to devote their entire lives to their children. However, the 24-hour presence of the mother with the young baby was not absolutely inescapable; but undoubtedly many neurotic breakdowns had their roots in an insecurity of the basic home relationship.

Dr. F. A. BLVAN (Woodstock) had found as a rural general practitioner that a greatly disproportionate number of problems which came to him arose in that quarter of his own area which was really a dormitory suburb of Oxford and not a true village community. Here there were small families living remote from their relatives and with no secure social roots.

Dr. F. H. BODMAN (Somerset) particularly agreed with Dr. Dicks's remarks on immature character formation of parents. Dr. MacDonald's emphasis on stress at school was equally valid. A survey of Somerset children had had the interesting result that the highest incidence of maladjustment in schools was in the 5-6-year-old age group. This represented a measure of the child's failure to develop from his home ties, and it was an area in which mothers needed help. He deplored leaving too much responsibility on adolescents to choose their own careers, but agreed that reasonable stress was a character-building influence.

Dr. J. P. HORDER (London) thought that in these days of contracting responsibilities of general practitioners the field under discussion was one in which general practitioners could well expand, if only the problems of expenditure of time and of selection of "short cases" could be solved.

Dr. W. LINFORD L.L. REES (Cardiff) drew attention to the contribution of maternal overprotection to tensions. It was a paramount factor, for example, in asthma, and predated the symptom in 75% of cases. Parental guidance had good results.

Dr. DICKS in summing up the discussion said that training the child should be an automatic process in infancy and should become explicit only when the child could both understand and use language. In principle the balance should always be on the side of gratification rather than frustration of the child. One difficulty of the over-protective parent was that she was too insecure to say "no." In marital tensions it was notable how the sounder partner would consult the doctor first. Dr. Dicks re-emphasized that medicine is indivisible and that much could be done in the field under discussion by the general practitioner once he had acquired the necessary conceptual tools.

SECTION OF RADIOLOGY

Wednesday, July 15

Radiology of Congenital Heart Disease

The president, Dr. PETER J. KERLEY (London) took the chair and introduced Dr. R. E. STEINER (Hammersmith), who opened the discussion on the radiology of congenital heart disease. Dr. Steiner discussed the acyanotic forms of congenital cardiac anomalies, and, in his introductory remarks, stressed the need for complete radiographic investigation and the value of fluoroscopy. The varying patterns of the heart shadow and pulmonary vessels were described, and the importance of pulmonary plethora or ischaemia was stressed. Dr. Steiner gave a broad classification of acyanotic cases as follows: (a) cases with intracardiac shunt;

and (b) cases without intracardiac shunt. Of the first group, coarctation of the aorta, pulmonary stenosis, and patent ductus arteriosus were described in detail: mention was made of the rarer lesions of this group. Of coarctation, Dr. Steiner thought that venous angiography was necessary, not so much for diagnosis as for anatomical definition of the aortic constriction and of the condition of the adjacent aorta and subclavian artery. Pulmonary stenosis in its two main types was described and the value of angiography in diagnosis was emphasized. The radiographic appearances in patent ductus arteriosus were listed and the variability of the heart shadow in this condition was indicated.

Atrial and ventricular septal defects, which comprised a large part of Dr. Steiner's second group, were described in detail. The complicated septal defects presented problems in diagnosis, and the confusion that could occur between a large ventricular defect and the Eisenmenger complex required resolution at venous angiography.

Dr. T. H. HILLS (London) described the cyanotic forms of congenital heart disease. The indiscriminate use of angiography was deplored and the considerable number of fatalities that had occurred in angiography of cyanotic cases was mentioned. Team-work and planning could do much to obviate the dangers of the examination, but the most vital preventive measure was careful case selection. Continuous blood pressure and electrocardiographic recordings were necessary, and a thoracic surgeon and anaesthetist must be constantly available to carry out bronchial suction or cardiac massage should these measures prove necessary. Dr. Hills described the direct fluoroscopic appearances in Fallot's tetralogy at length, and stated that angiography was of value only where surgery was contemplated. Venous angiography as against selective angiography via a catheter was preferred on the ground that the hazard was less with the venous route. Where there were complicated lesions, angiographic interpretation was difficult and the relative timing of chamber filling was often needed in differential diagnosis. For this purpose the angiograms must be obtained at sufficiently short intervals. Tricuspid atresia was then discussed and the angiographic picture in these cases described as diagnostic. Dr. Hills stressed the comparative rarity of Eisenmenger's complex and the fact that a normal pulmonary blood supply might hinder recognition of this lesion.

Dr. J. NORMAN PATTINSON (London), in an occasional paper on the anomalies of the aortic arch, traced the development of the arch and its derivatives and proposed a simple classification of the anomalies encountered. He gave his own clinical experience with these lesions and pointed out the value of the simple procedures of barium swallow and tomography in diagnosis.

Technical Improvements

Dr. R. A. WILLIAMS (Newport, Mon) foresaw the need for technical improvements in angiography and hoped that the recently developed technique of image amplification together with cineradiography would allow the radiologist to obtain 25 frames per second. Dr. JOSEPH JACOBS (Cardiff) agreed with Dr. Hills that angiography had a circumscribed place in diagnosis. He pointed out the importance of left atrial enlargement in the diagnosis of patent ductus arteriosus and thought that this was one of the earliest signs of this anomaly. Mr. H. R. S. HARLEY (Cardiff) had found angiography of little help in the diagnosis of left-to-right shunts and of occasional value in defining abnormalities of the great vessels. In his opinion retrograde aortography was preferable in complicated cases of coarctation or patent ductus.

Dr. PETER J. KERLEY (London) demonstrated a series of pulmonary-vessel anomalies in asymptomatic adults which had been discovered at routine or mass miniature chest radiography. He believed the condition to be far commoner than was generally assumed.

Dr. J. MAURICE H. CAMPBELL (London) reported a large series of paired superior venae cavae seen over the past few years and thought that this condition was not uncommon.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Alcohol and Barbiturates

SIR.—Attention was drawn in your annotation (*Journal*, June 6, p. 1269) to the lack of information concerning the effects of ethyl alcohol and barbiturates taken together. Some clinical evidence exists that these two substances potentiate markedly the effects of each other. In addition, Billie and Ahlquist¹ reported that, in rabbits, alcohol potentiates the hypnotic effect of sodium pentobarbitone, and Ramsey and Haag² found that alcohol increased the toxicity

Doses of Sodium Amytal and Ethyl Alcohol Necessary to Produce 50% Mortality in Mice

Sodium Amytal 0 mg./kg.	Ethyl Alcohol 14.25 ml./kg.
200	11.5
350	6.5
500	4.75
675	0

of various barbiturates administered to mice. Experiments have been performed in this laboratory to determine the acute toxicity of sodium amytal and ethyl alcohol administered simultaneously.

Male albino mice weighing approximately 20 g. were used. Sodium amytal was administered orally as a solution containing 20 mg./ml., and ethyl alcohol (50 v/v in water) was given by the same route. The median lethal dose of each of these substances, administered alone, was determined. Subsequently the amounts of ethyl alcohol required to produce 50% mortality in mice which had been given approximately one-quarter, one-half, or three-quarters of the median lethal dose of sodium amytal were determined. The results of one typical experiment are shown in the Table and Graph.

When the results are plotted graphically with the dose of sodium amytal as ordinate and the dose of ethyl alcohol as abscissa, all the points lie on the straight line joining the median lethal dose of sodium amytal to the median lethal dose of ethyl alcohol. Therefore a synergism exists between sodium amytal and alcohol. However, the effects are simply additive and our results provide no evidence that the toxicity of sodium amytal is potentiated by alcohol.—We are, etc.,

Manual Methods in General Practice

SIR.—I like Dr. R. Barbor's article (*Journal*, July 4, p. 18), and I am sure that his patients are grateful too. We too easily forget how often mother "rubbed it and made it better." Her examination was less thorough—this did not matter much, because her patient already had faith in her.

Unfortunately there are many soft tissue "lesions" which more often than not fail to resolve spontaneously—for example, those of rheumatoid arthritis. When he turns to disk fragments that pop out and obligingly pop in again—and stay in—when the spine is moved this way and that, those of us who stand by scientific evidence and controlled experiment reluctantly draw back. When one has excluded such conditions as tubercle, ankylosing spondylitis, tumours, and recognizable trauma, there remain a number of syndromes, relating to the back and neck whose natural history is but poorly known. Here surely is a chance for general-practitioner research.—I am, etc.,

Sheffield.

H. F. WEST.

SIR.—Dr. R. Barbor is to be congratulated on his most interesting account of manipulation and accurate manual methods in general practice (*Journal*, July 4, p. 18). He does well to bring attention to the very real place these methods have in the treatment of those conditions he groups together as "soft-tissue lesions," and to describe the existing difficulties in obtaining physiotherapy for those of our patients who require it, when they require it.

I am surprised, however, at the high figure (17%) Dr. Barbor gives for the incidence of his patients requiring manual methods of treatment, while I feel that he has over-simplified the diagnosis and choice of treatment. I agree that manipulation may be of value in some cases of prolapsed intervertebral disk, but I would not dare manipulate any patient's spine without first seeing radiographs in order to exclude a lesion other than the simple mechanical one in question. I have seen in the last two years a young man whose backache could easily have been diagnosed as a "minor disk lesion" and manipulated—he had a tuberculous lesion in the first lumbar vertebra. Another patient's backache was due to a secondary carcinoma, even though there was at that time no evidence of a primary growth anywhere. This patient also could easily have been mistaken for a case of "lumbago."

In order to compare my own experience with that of Dr. Barbor I have checked through a survey of the patients I saw during the last six months of 1951 in my own practice. Only 5% of the total number seen in that time were suffering from "soft-tissue lesions." The accompanying table shows their incidence according to sex and diagnosis.

Diagnosis	Male	Female	Total
Joints:			
Ankle, acute inversion strain	2	—	2
Elbow, "tennis"	1	—	1
Intervertebral—prolapsed disk	2	6	8
Knee, ruptured medial meniscus	3	—	3
Sacro-iliac, acute subluxation	—	1	1
Stero-clavicular, subluxation	—	1	1
Muscles:			
Contusion to fore-arm	1	—	1
Contusion to thigh	1	1	2
Contusion to chest wall	1	—	1
Multiple muscular pains	—	4	4
"Pulled" sacro-spinalis	1	1	2
Ruptured plantaris	—	1	1
"Stiff neck"	—	3	3
Tendons:			
Partial rupture supraspinatus	1	—	1
Ruptured extensor indicis ("mallet" finger)	—	1	1
Traumatic tenosynovitis at wrist	1	2	3
Total (percentage of total number of patients seen)	13 (4.2%)	22 (5.4%)	35 (4.8%)

Of this small number, only five were thought to be fit for manipulation: three with acute "stiff neck," one with "tennis elbow," and one with acute subluxation of the left sacro-iliac joint. All but one were completely relieved by one manipulation. The patient with the tennis elbow required one further treatment. Of the eight patients in whom some degree of disk prolapse was diagnosed, six were seen by a consultant orthopaedic surgeon. Two of them were so severe that they did not respond to rest or plaster jackets, and later required surgical treatment. At operation both showed a condition which would have defied any manipulation. The others recovered with rest in bed (four) for periods from two to six weeks, or in plaster jackets (two).

During this time I saw several other patients with "backache," but in view of the complete absence of physical signs they were not treated as "soft-tissue lesions." A brief history of one of these demonstrates the efficacy of psychotherapy. A 30-year-old woman had had low backache for over a year. She had attended two hospitals, and had been seen by orthopaedic surgeons, neurologists, and physical medicine experts. All types of treatment had been tried, including manipulations. She was told radiography showed no abnormality, but still her backache persisted. When I asked her to describe to me when and how the pain had started she was silent. Following much encouragement she "confessed" that the backache started the day after she had permitted her fiancé sexual intimacy. She felt she had sinned terribly—she "deserved her punishment." After an hour's discussion she said she felt better, and when seen a fortnight later she was able to tell me that she had been free from the backache for the whole time. She is still well.

Here, then, lies the danger in physical methods of treatment. Underlying psychogenic causes may be left undiscovered and patients left to suffer in spite of all efforts to help them. Dr. Barbor is right to emphasize the importance of accurate diagnosis, and of the need for preliminary careful examination. It is left only to stress that this should be of the whole patient and not just the part that hurts.—I am, etc.,

PHILIP HOPKINS.

Hampstead, N.W.3.

SIR.—Dr. R. Barbor is to be congratulated on his presentation of manipulation and accurate manual methods in general practice (*Journal*, July 4, p. 18). The attainment of accurate diagnosis and treatment in the all too frequent patient suffering from "rheumatism" or "fibrositis" is highly desirable. To have one's own St. Thomas's trained physiotherapist to treat these cases must be indeed satisfactory.

There are, unfortunately, many factors which preclude such an ideal set-up. The first is the general practitioner's interest in these cases. This is of necessity the preliminary requirement, as everything else will follow to a degree. The second of importance is his ability to acquire sufficient experience in this wide field. The majority of us live far away from London. The need of learning such detailed knowledge so that it can be applied quickly and methodically in a busy surgery is obvious, and it can only be learnt from a teacher of such merit as Dr. Cyriax. Until it is possible for the general practitioner to acquire the necessary experience this rich field of manipulation and manual treatment will be sadly neglected. Perhaps it would not be too much to ask to have several two-week courses at St. Thomas's included in the list of G.P. refresher courses. This seems the only satisfactory way to enable many doctors to get the experience they desire.

I would like to associate myself with Dr. Barbor and add that my experience during the last four years has been greatly enriched by being able to give these patients a diagnosis, treatment, and advice which is, on the whole, not only accurate and lasting but also surprisingly well appreciated.—I am, etc.,

TREVAN HAMBLY.

Ryde, I.O.W.

SIR.—Dr. R. Barbor's article on the physiotherapy arrangements in his practice (*Journal*, July 4, p. 18) was most stimulating to the ideal of family practice and damning to the hospital clinic. The physical medicine arrangements in this area have the same limitations owing to transport difficulties and lack of supervision in hospital. This gap in the N.H.S. hospital facilities was pointed out to the regional board two years ago. The gap was filled in one parish by using surplus funds from the old Nursing Association to pay a St. Thomas's trained physiotherapist. It was an entirely parochial idea.

However, Dr. Barbor does not make it clear whether his firm employs the physiotherapist and charges the patient, or whether the patient pays her direct. I hope it is the former, with the executive council's approval, as this will be the thin end of the inevitable wedge: the efficient N.H.S. practitioner providing better service for his patients than can the hospital, and repaying his capital outlay by charging for the service legally.—I am, etc.,

ROBERT HOWARD.

Burley, Hants.

Cerebellar Dysfunction

SIR.—I was interested in Dr. Basil Seltzer's medical memorandum on a case of glandular fever presenting as cerebellar dysfunction (*Journal*, July 11, p. 83). On reading the case report, however, I could find no evidence which would support a view that Dr. Seltzer's patient did in fact suffer from cerebellar dysfunction. The term ataxia is not synonymous with cerebellar affliction and should be specified—for example, sensory, vestibular, or cerebellar—after appropriate physical signs have been elicited to establish the type of incoordination.

Later in the report it is stated that there were no sensory disturbances in the arms and legs, followed by: "Romberg's sign was present." This is contradictory, since Romberg's sign, if any specific significance is to be attached to it at all, depends on dysfunction of proprioceptive sensibility. Hence this sign is present in sensory ataxia—for example, tabes dorsalis or polyneuritis—and is not a feature of the cerebellar type of ataxia (although here, too, as in nervous or intoxicated patients, the sign may be present).

This misconception of the significance of Romberg's sign and the unspecified use of the term ataxia are often encountered, and I have recently seen an instructional medical film spoiled by this blemish on the authority of its producers.—I am, etc.,

Sheffield.

JAMES O. NEWMAN.

Post-inoculation Poliomyelitis

SIR.—Dr. J. Grant (*Journal*, July 11, p. 66) concludes his article with the statement that "there was no doubt of the increased risk to a child of developing a paralytic attack of poliomyelitis as a result of intramuscular immunizing injections at a time when poliomyelitis was prevalent." The evidence presented is that 3 out of a group of 354 recently inoculated children developed poliomyelitis compared with 9 out of 2,743 uninoculated children in the same age range. This difference in attack rates is not statistically significant.

Thus there does not seem to be any firm evidence here to show that recent inoculation has produced additional cases of paralysis. On the other hand, there is clear evidence in this and other inquiries that the distribution of paralysis sites among recently inoculated children differs from that in those not recently inoculated. Examination of the distribution of paralysis sites for inoculated and uninoculated children as given by Bradford Hill and Knowlton¹ suggests that at any rate the main effect of recent immunization is to add an additional paralysis site.

Taking the paralysis sites for, say, 100 uninoculated children and adding to them the immunization sites for 100 children (given elsewhere by Gray and Cartwright²), except where by chance the two sites would coincide, one arrives at a distribution of sites closely in agreement with the paralysis sites for 100 recently inoculated children. Furthermore, the number of paralysis sites per child as calculated in this way shows good agreement with the number found in the recently inoculated children. It is perhaps worth noting that this hypothesis does not preclude the occurrence of paralysis only in the injected limb. This would occur by chance in a proportion of cases.—I am, etc.,

P. G. GRAY.

Bornholm Disease

SIR.—General practitioners should read the articles in the *Journal* of June 20 on Bornholm disease with great interest, for this illness presents a diagnostic problem which, if not kept in mind, could give rise to considerable difficulty and might lead to the uneconomical occupation of both surgical and medical beds. One's main reaction to these articles is of gratification for the simplification of yet another symptom complex. The elucidation of the epidemiology and symptomatology of many virus infections has often fallen to

the lot of the general practitioner, for few of the sufferers from them reach hospital. That we are now in a position to understand more clearly the symptomatology they present is due to the team work of practitioners, public health workers, and specialists, and of course the outstanding work of Dr. Pickles.

Appreciating the symptomatology of Bornholm disease, influenza, benign lymphocytic meningitis, and non-paralytic poliomyelitis, to say nothing of the varied symptomatology of mumps and other virus diseases where the organism may show a predilection for the cerebrospinal system¹ and the gonads, the practitioner must become aware of the widespread and often unrecognized prevalence of virus infections in his own practice during the summer months.

In a rural practice centred on a small town I find there were, spread over the month of June, 13 cases of probable virus infections. Ten of these presented with an acute febrile illness lasting about 48 hours, the main symptoms being severe headache, vomiting, malaise, and some abdominal pain. Eight came from the same small housing area and the two others from the same school. Only three were female, and all were under 35 years of age. In the week when most of these patients were seen six cases of acute diarrhoea and vomiting occurred in the same housing area—perhaps owing to a similar infection, for their illnesses were just as short and sharp. The only other virus infections seen in the practice during that period were two cases of infectious hepatitis from two miles away, and, next door to them, a boy from the same school as the others developed acute vomiting, malaise, and headache. It is tempting to trace a link between all these cases.

These personal experiences and those of previous summers suggest that virus infections are relatively common in general practice at this time of year and that they crop up in various forms. I am sure that the investigation of the relationships of these forms provides in the work of the general practitioner a subject of great interest.—I am, etc.,

Lockerbie, Dumfriesshire.

Proctalgia Fugax

SIR,—The article by Mr. M. R. Ewing on proctalgia fugax (*Journal*, May 16, p. 1083) raises several points of interest, and I would like to make one comment on the symptomatology and another on therapy.

I have had diurnal and nocturnal attacks for some years, and the former are always the more severe. Whereas the nocturnal attacks never progressed beyond the pain as described, the diurnal attacks always went on increasing in severity for about 10 minutes and invariably ended in drenching perspiration, violent nausea or vomiting, extreme pallor, bradycardia, and, perhaps once in three times, syncope. The whole attack from beginning to end would last about half an hour. These attacks were not frequent, but sometimes happened during an operating session and would occasion considerable distress. I also suffer badly from travel sickness (unless I drive the car myself), and if very tired a long cross-country bus ride or a fast journey on winding roads downhill would induce the complete vaso-vagal syndrome as described. I found that amphetamine taken before a journey, or even if only taken when the symptoms first made themselves apparent, would abort an attack with certainty. I then applied this same treatment to the attacks of proctalgia, hoping that it might relieve the complicating symptoms, and to my very considerable delight I found not only that the vaso-vagal symptoms were entirely controlled but the pain itself rapidly subsided.

I had suspected that perhaps a hypoglycaemia was responsible for the attacks and that it induced both the muscle spasm and the vagotonic state, but I could never prove that this was so, and, although the treatment described by Mr. Ewing might at first sight suggest that hypoglycaemia was a factor in the aetiology of the attacks, the speed of recovery probably rules out the elevation of the blood sugar as the factor aborting an attack. This also follows, of course, if taking a glass of cold water is equally effective as food. Mere swallowing is quite definitely not enough, for the salivation induced when the attack has developed, and which occasions much swallowing, only aggravates the nausea. It would be interesting to hear if others also find relief by the taking of amphetamine.—I am, etc.,

Shillong, Assam.

R. ARTHUR HUGHES.

Deceptive Acute Abdomen

SIR,—We would like to add a few remarks in answer to the letters by Drs. S. A. Gueukdjian (*Journal*, July 4, p. 42), and E. Saphier (*Journal*, July 4, p. 46). In this hospital where there are both surgical and infectious diseases units working in close co-operation, we see many cases of acute appendicitis in children which have been sent in under other diagnoses.

Such a case as that reported by Dr. Gueukdjian is by no means uncommon. Mild symptoms and minimal physical signs occur in children even at the age of 14, and it has long been known that is a waste of time trying to correlate them with the degree of the pathological changes. This is perhaps even more so in those of our cases who develop pain in the right iliac fossa during an attack of measles or chicken-pox. The differential diagnosis in these cases between acute appendicitis and lymphatic glandular enlargement is extremely difficult. Many examples could be quoted, but one that stands out particularly is a child of 5 years who had been suffering from chicken-pox for five days. He developed a slight pain in his right iliac fossa but this did not stop him from eating, two hours before admission, a good meal of fish and chips. He, too, had a general peritonitis and a perforated gangrenous appendix.

We are also in entire agreement with Dr. Saphier. Acute appendicitis may be a complication of gastro-enteritis (it is more often misdiagnosed as such), and pain in the right iliac fossa occurring in a case of "gastro-enteritis" demands extra special care and caution on the part of the examining doctor. We are, etc.,

A. G. ELLERKER.

H. E. PARRY.

London, N.W.3.

The Post-operative Chest

SIR,—I think Dr. W. S. Davis (*Journal*, July 11, p. 97) has misread my letter (*Journal*, June 20, p. 1388). I did not suggest that anaesthetists could prevent post-operative chests. To do so would be to carry flattery beyond all reasonable bounds. Nor did I venture to discuss the aetiology of these conditions, and I am sure that Dr. Davis is right in everything he says about the mechanics of respiration. I did, however, try to emphasize that the immediate prognosis of the post-operative lung complications of general surgery is excellent, and to underline the findings of a previous contributor, which suggested that the remote prognosis is equally good. In fact, it is practically impossible to stop them getting better.

I hope I may be forgiven for saying that anaesthetists are apt to dogmatize on this subject whilst keeping at such a respectful distance from the wards that their patients are usually quite unaware of their identity. On the other hand, surgeons, especially the whole-time variety, often have nothing better to do than wander about looking at their patients, and are apt to see them at frequent intervals. Having done this for a number of years, one cannot escape the conclusion that pyrexia persisting for more than a few days after operation is invariably due to something other than an acute lung complication. Usually it is found to be due to a wound infection or residual abscess, but in a significant number of cases x-ray examination of the chest discloses unsuspected tuberculosis, and one is entitled to wonder if tuberculosis is sometimes disseminated in the operating theatre. There is something incongruous in the sight of an apparently healthy anaesthetist covering his own face with a quite ineffective gauze mask while allowing a succession of patients to breathe in and out of a filthy rubber bag.

I have no objection to encouraging the patients to cough, but, as cough is one of the symptoms of a post-operative chest, one is rather in the position of preaching to the converted. It is certainly true that coughing is painful for a few days, and equally true that the pain soon passes off.

An x-ray examination of the chest soon after an abdominal operation almost invariably shows some areas of collapse, and I cannot share Dr. Davis's anxiety about his patient who left hospital feeling perfectly well but unaware that part of her lung had not yet expanded fully. I'm sure it has by now.—I am, etc.,

Barnet.

V. J. DOWNIE.

Possible Sequel of Treating Infants in the Erect Posture

SIR,—I am interested to read Professor John Craig's suggestion (*Journal*, July 11, p. 98) that the shape of the skull of infants who have been treated for hiatus hernia by being placed in the erect posture may be affected by such positioning. I have not observed this, but it has occurred to me that prolonged treatment in the erect posture may lead to some disturbance of the normal growth of the pelvis. The plaster chair designed by Dr. Hill and described by her in the *Lancet* (1953, 2, 71), in so far as it leads to immediate control of the vomiting, is of great value. But in its construction there is no device whereby the weight of the infant's body is kept off the soft bones of the pelvis. Are we encouraging the development of further problems for the next generation of obstetricians?—I am, etc.,

Birmingham.

FRANCES BRAID.

Time of Eruption of Permanent Teeth in British Children

SIR,—The opening statement in the article by Drs. E. M. B. Clements and E. Davies-Thomas and Miss K. G. Pickett (*Journal*, June 27, p. 1421), that the most recent study on this subject was in 1925,¹ in my opinion appears not quite correct. In 1951 an original communication appeared in the *British Dental Journal*, on "Time of Eruption of Permanent Teeth and Shedding of Deciduous Teeth," by Stones *et al.*² The children examined were from the National Children's Home, Frodsham, near Liverpool. Although British nationality was not specifically stated, there was nothing in this paper to suggest otherwise.—I am, etc.,

A. SANDER.

Controlled Respiration and Apnoea in Anaesthesia

SIR,—In reply to Dr. Gordon M. Wyant's letter (*Journal*, June 13, p. 1334), in which he says apnoea is an unphysiological state, the answer is, surely, that anaesthesia itself is "unphysiological." Apnoea, with adequate manual ventilation, gives a more desirable physiological state than that following half-way measures of relaxation induced by either the muscle relaxants or general anaesthesia alone. Any degree of relaxation produced by an agent such as succinylcholine must result in a concomitant decrease of respiratory movement, reduced tidal volume, and the tendency to carbon dioxide retention.

A continuous intravenous infusion of a dilute solution of succinylcholine to give relaxation for tracheal intubation, as advocated by Dr. Wyant, seems both time-consuming and unnecessary. Does it really matter that a patient is given 40 mg. rather than 20 mg. of succinylcholine to achieve relaxation, when the higher dose in the more sensitive patient produces no untoward effects? Need one worry if the period of apnoea following a single injection of succinylcholine is 30 seconds, or 5 minutes, or even 10 minutes? I believe it is better to achieve complete relaxation knowing that passive inflation will be required than to risk "bucking" and possible trauma with intubation as well as having to assess whether assisted respiration is required.

Finally, in reference to Dr. Wyant's point of semantics, the definition of "controlled respiration" given by him ("that state wherein spontaneous respiration has been abolished by means of hyperventilation . . . and a varying degree of central respiratory depression, but in which spontaneous respiration will resume soon after manual ventilation has been discontinued") was made before the advent of muscle relaxants. However, when a patient is rendered apnoeic by one of these relaxant drugs and the anaesthetist takes over ventilation, he is said by Dr. Wyant to be instituting "artificial respiration" but not "controlled respiration."

The term "artificial" can be applied to both situations. Similarly, since the expression "controlled respiration" as generally used covers all techniques by which the anaesthetist can control at will the patient's tidal volume and respiratory pattern, a student of semasiology might well accept this broader meaning of the term which has arisen to include more recent developments. Whether or not the anaesthetist shows a singular lack of control by being left to "hold the bag" at the end should not affect the definition.—I am, etc.,

London, S.W.3.

TREVOR T. CURRIE.

SIR,—Please allow me to preface my remarks by saying that I am well aware of the benefits to the patient that may result from controlled apnoea in anaesthesia in certain cases, and that I fully appreciate the debt owed by all anaesthetists to the Liverpool school. Nevertheless, the letter from Drs. G. Jackson Rees and T. Cecil Gray (*Journal*, July 11, p. 97) must compel a few critical observations, and I hope your correspondents will accept these as an old-fashioned but well-intentioned dose of sweet vitriol.

Dr. Gordon M. Wynant (*Journal*, June 13, p. 1334) and Professor E. A. Pask (*Journal*, May 9, p. 1048) are taken to task for suggesting, in their reactionary ignorance, that apnoea in anaesthesia may not always be beneficial to the patient, and Dr. Wynant is said to have used the term "unphysiological" loosely. It is only reasonable and humanitarian, I think, to state that patients requiring anaesthesia for a wide variety of pathological conditions may not invariably be ideal subjects for revolutionary technical exercises, physiological or otherwise.

I doubt if I am being unjust to Drs. Jackson Rees and Cecil Gray when I quote in its entirety point (2) in the last paragraph of their letter: "Many in the vanguard of modern anaesthetic progress still maintain a regard amounting almost to superstition . . . for the authority of the 'old-fashioned' anaesthetist. We are not, however, prepared to believe that the virtue of being old-fashioned gives any doctrinal authority in respect to the matters under discussion." "The vanguard of modern anaesthetic progress" is a good phrase unless one reads the word "anaesthetic" in its meaning of "unfeeling." Still, a position of self-acknowledged leadership must be very reassuring. I wonder how many protagonists of the wholesale use of hypotension in anaesthesia not so long ago wrote letters and papers in an equally hubristic and dogmatic mood, and how many of that advance party are now fighting rearguard actions—with their own consciences.—I am, etc.,

Chesterfield.

ANDREW G. HEGARTY.

Medical Semantics

SIR,—The article by Dr. Ffrangcon Roberts on medical semantics (*Journal*, June 27, p. 1444) must have been read with much interest, not only by members of the medical profession but also by many non-medical men who, like myself, have to read widely in the medical literature. He has compressed much information into a short space, but there are one or two points which call for comment.

Dr. Roberts asserts that *mater* is derived from the Arabic word for *mother*. I am informed that the word for *mother* in Arabic, at least as spoken at the present day in Egypt, is *umm*. Even if a different word is used in other dialects, or was used in the Arabic of the Middle Ages, *mater* is undoubtedly the Latin word for *mother* (from the Greek *μητηρ*) and it would be interesting to know on what evidence Dr. Roberts dismisses this derivation. Neither the *Concise Oxford Dictionary*, nor the *American Illustrated Medical Dictionary* (Dorland), nor *Stedman's Medical Dictionary* gives any support for this. All these works of reference likewise derive *basilic* and *cephalic* (as applied to the veins of the arm) from the Greek. *Basilic* is also used in the sense of *chief* or *important* in other connexions. Dr. Roberts's suggestions are ingenious, but more definite evidence would be needed before accepting them.

Dr. Roberts also makes the curious statement that the Germans lived too far north to be in the stream of classical culture. A glance at the map will show that a large part of Germany lies farther south than the British Isles, but perhaps he meant to write "too far east." In any case, Latin has been widely studied in Germany for centuries and French was once the language of the courts. At the present day, most German doctors have a more thorough knowledge of Latin than their English colleagues, and, whereas in English medical writings the Latin terms are often anglicized, in German the original Latin is usually employed.

In order to illustrate the clumsiness of the German vocabulary it is scarcely fair to compare *Zwölffingerdarmgeschwür* and *Wurmfortsatzentzündung* with duodenal ulcer and appendicitis. It would be correct to compare *Zwölffingerdarm* and *Wurmfortsatz* with duodenum and appendix; but when compared in this way the difference in length is no longer very great. The fact that in German two words forming a single idea are joined together to form one word has nothing to do with the argument. Incidentally, *Entzündung* is the normal word for inflammation, so why translate it as *burning*, whatever its derivation?

The fact of the matter is that for most parts of the body, both in German and in English, the common names, usually of Teutonic origin, exist side by side with the medical names derived from Latin or Greek. It so happens that English has no words of Teutonic origin corresponding to *duodenum* and *appendix*, whereas German has (though *Wurmfortsatz* is not in popular use, appendicitis being colloquially but incorrectly referred to as *Blinddarmentzündung*). The German words for most parts of the body are no longer than, if as long as, their English equivalents—for example, *Kopf*, head; *Magen*, stomach; *Darm*, intestine (gut); *Niere*, kidney; *Auge*, eye; *Bein*, leg; to say nothing of the many words which are almost identical. Even when we come to the more medical terms, *Blutbildung* is not as clumsy as *haematopoiesis* (now shortened to *haemopoiesis*), *Schnecke* is just as simple as *cochlea*, and *Erreger* is far more convenient than *offending organism*.

I am not making a plea for the use of more German terms in medicine, and I have no doubt Dr. Roberts could produce a further list of comparisons to counter mine (so could I). My point is that the scarcity of German medical terms in English has nothing to do with their clumsiness or otherwise, and I think it a pity Dr. Roberts dragged this red herring into his instructive article.

In conclusion, may I support Dr. Roberts in his suggestion that the ligatures æ and œ should be abolished? As he says, we have already dispensed with them in many words in everyday speech. Some medical journals have made a start by writing *etiology* instead of *aetiology*, and *pediatrics* is becoming increasingly common; so why cannot we have *anemia*, *hemoglobin*, *fetus*, and *celiac*? Perhaps, Sir, you would give us a lead.—I am, etc.,

Ariesheim, Switzerland.

A. M. WOOLMAN.

Iron Therapy

SIR,—May I please make the following comments on the article of Dr. D. Haler (*Journal*, December 6, 1952, p. 1241)?

The opinions given so far about the utilization of various iron salts have to be regarded with caution, because all investigators did not consider two important facts: (1) The age of the investigated persons. Rechenberger¹ proved that the absorption of iron strongly diminishes with increasing age. In fact, it practically stops above the age of 50. But neither Dr. Haler nor Gram and Leverton² consider the age of their patients. Dr. Haler says that "the cases were selected at random," and the latter investigate 83 women between the ages of 18 and 42. (2) The influence of the different meals taken with the iron. L. M. Sharpe *et al.*³ showed that the absorption of iron is 30% less when given with

milk than it is when given with a sip of water, 65% less if given with oats in milk, and 85% less when it is taken with a regular breakfast. Besides the phytic acid which is to be found in a remarkable quantity in wholemeal bread, oats, maize, and nuts,⁴ other chemical and physical influences, among them the size of the meal, are responsible for reduced absorption of iron. Unfortunately, these facts also have not been considered so far by the investigators.—I am, etc.,

Berlin-Dahlem.

Claims for Negligence

SIR,—I would like to reply to the letter from Dr. W. E. Hick (*Journal*, July 4, p. 44). The application of the doctrine of *res ipsa loquitur* is very difficult to follow, and even if it is applied in accordance with the definition contained in the first paragraph of your legal correspondent's article (*Journal*, June 20, p. 1398) or any other definition, the persons to be satisfied are the jury, the "reasonable laymen" referred to by the various Lords Justices. The leading case on *res ipsa loquitur* is that of a barrel rolling out of an open doorway on the upper floor of a warehouse and falling on the head of a passer-by in the street below. I am sure that any jury would be convinced that such an accident would not have happened if proper care had been taken.

It is difficult, on the other hand, with all respect to the Court of Appeal in the Cassidy case, to see how a jury could reach a similar decision regarding the after-effects of an operation for Dupuytren's contracture (which Mr. Cassidy had undergone) without possessing the appropriate special knowledge.—I am, etc.,

Liverpool.

NIGEL RYLAND,
Legal Adviser,
Liverpool Regional Hospital Board.

Electroconvulsive Therapy

SIR,—It is sometimes difficult to tell whether or not a stimulus of convulsive strength has been given after a relaxant has been injected. Drs. E. Thomas and B. F. Honan (*Journal*, July 11, p. 97) use the immediate contraction of the pupil as a sign that a subconvulsive dose has been given. They do not state which apparatus they use for the stimulus. With the Ediswan machine an immediate contraction of the pupil occurs both with adequate and with subconvulsive doses. This is in all cases followed by a dilatation lasting a second or so. The pupil then begins to contract and dilate rhythmically, with an accompanying suffusion of the conjunctivae.

In an article in the *Journal* of January 24 (p. 195) Dr. Max Hamilton and I suggested that this oscillation of the pupil was a sign that a "fit" had taken place. It now seems that this occurs with smaller stimuli as well. The method which we then described, that of blocking one limb from the effects of the relaxant and observing the convulsion therein, is very reliable and can be used with safety as a routine if it is desirable to control the stimulus accurately.—I am, etc.,

Epsom.

DAVID J. ADDERLEY.

Reaction to Blood Transfusion

SIR,—May I add to the literature another case of alarming reactions to the transfusion of blood in the absence of any demonstrable incompatibility?

A patient was referred to me by his own doctor for the surgical treatment of a long-standing "bleeding" duodenal ulcer. The patient looked anaemic. The haemoglobin content was 62%. The blood group was B, Rh negative. Rh-negative blood was

The Role of the Pathologist

SIR,—We feel the time has come to make a further protest at the new role the pathologists appear to have assumed—that of self-appointed judges and jury of their clinical colleagues. Rarely does a day pass by without a report appearing in the national press of yet another pathologist's criticism of the management of a case which he himself has only seen at necropsy.

Are we to assume that the pathologist is not only an expert in his own sphere, but also an infallible clinician as well? Without even seeing or examining the patient during life he is able to prescribe treatment for cases which, in his considered opinion, have been mismanaged by able physicians and surgeons.

We submit, Sir, that pathologists should be confined to a statement of facts and, at the most, an expression of opinion as to the cause of death.—I am, etc.,

M. GOLDMAN.

Treatment of Accidental Poisoning

SIR,—With regard to Professor John Glaister's article in the Refresher Course series, on the treatment of accidental poisoning (*Journal*, May 30, p. 1214), I am surprised that no mention is made of the use of intravenous picrotoxin in the treatment of barbiturate poisoning. I have found that with an adequate dose of the 0.3% solution given in divided doses of about 5 ml. up to 20 or 30 ml. a comatose patient can become restless and sufficiently conscious to be made to vomit without risk, and subsequently to take a good dose of Epsom salts without risk or complaint. This avoids the sometimes difficult task of gastric lavage and possibly the necessity for hospital treatment.—I am, etc.,

Brighton.

R. S. SAXTON.

POINTS FROM LETTERS

Cartridge Syringes

Dr. GEORGE MOGEY (Leeds) writes: With reference to the question and answer on the above subject ("Any Questions?" *Journal*, June 27, p. 1459) . . . these syringes have one great advantage which, perhaps because it is so obvious, I have not seen mentioned. It is the simplification of aseptic precautions. The only parts which need to be sterilized by the doctor are the cartridge diaphragm, the needle mount with its prong for piercing this diaphragm, and the needle. The producers say they are considering the issue of a sterile container for about half a dozen needles and mounts: sterilization by boiling could be achieved in the surgery before the round and the needles carried in safety until required. Until the present such equipment has been a luxury, but if, as is claimed, the cartridge costs no more than conventional single-dose ampoules, it is likely to become popular. If the demand becomes great one can expect more and more manufacturers to compete in the sale of both the glass cartridges and the metal holders. Before this happens, may I plead for uniformity in the size of the glass ampoules, so that any cartridge may be used in any holder? The 2-ml. ampoule, already well established in dental practice and for which a number of holders are available, would appear to be the most suitable. Diameter of the cartridge is, however, of greater importance than length or volume from the point of view of standardization.

Peptic Ulcer in Women

Mr. P. A. LANE ROBERTS (London, S.W.15) writes: Dr. T. Csato (*Journal*, July 11, p. 95) contends that the absence or disappearance of peptic ulcer symptoms during pregnancy is the most impressively unequivocal coefficient in the natural history of the condition. One swallow does not make a summer, but at least Dr. Thomas Hodgkin would have had reason to dispute this statement. In his *Lectures on the Morbid Anatomy of the Serous and Mucous Membranes* (1840, Vol. 2, p. 371, London) he described the appearances of a typical lesion, and then cited only one case, which he evidently considered representative: "One well-marked case of ulceration occurred in a young woman whose vomiting commenced on her becoming pregnant and continued uncontrolled till about the fourth month, when she died."

cross-matched for the patient. One pint (568 ml.) of blood was administered during an operation for partial gastrectomy. As the ulcer was adherent to the pancreas the operation was unusually long owing to the difficulty of getting below the ulcer before transecting the duodenum. It was considered, therefore, advisable to give a second pint (568 ml.) of blood post-operatively. When the bottle containing the blood was practically empty, the patient collapsed. He was covered with sweat and his pulse was almost imperceptible. He complained of a pain in his back but there was no blood in the urine. Dextran was substituted for blood. The following morning he was jaundiced, although the stools retained their normal colour. He had double vision, was completely unconscious of his surroundings, and was very restless. His physical condition, however, was much better. Dextran was continued for another 12 hours. After that the patient was able to take water and glucose drinks by mouth. He remained disorientated and restless for several days. His jaundice has now completely disappeared and his mental condition and vision are restored to normal.

Two points are well worth noting—the recovery of the patient in spite of the large amount of blood administered, and the presence of cerebral phenomena, which were absent in the cases quoted by previous correspondents on this tremendously important subject.—I am, etc.,

Kildare.

D. J. CANNON.

Frame for Standard Blood Bottle

SIR,—The accompanying photographs show a wire frame made to my design by my technician, Mr. R. T. Miller, to accommodate the standard bottle of blood.

The ordinary loop which clips on to the bottom of the bottle is seldom sent to the operating theatre, and the clips kept in the theatre break very quickly where they are bent over. The frame illustrated is made of brass wire, which has some spring in it, and the bottle simply needs pushing into this frame, which can be hung on to the drip

stand. It can easily be made by the technician on the spot at the cost of a shilling or two, and should save the transfusion service a considerable amount of money in clips.

The photographs were taken by Mr. E. J. Pamey, the hospital photographer.—I am, etc.,

Northampton.

F. F. WADDY.

Eosinophil Content of Spleen in Addison's Disease

SIR,—The role of the spleen in the removal of eosinophils from the blood stream is being investigated in this laboratory, and I would like to know more about the content of eosinophils in the spleens of patients who died from Addison's disease of the adrenals.

As such necropsy material is becoming uncommon, I would appeal to my fellow pathologists who possess tissues from cases of Addison's disease to send me a small piece of spleen in fixative. Relevant details would be appreciated, including the age and sex of the patient, interval between death and necropsy, cause and duration of the disease, and whether or not the patient had been treated with cortisone or deoxycortone.—I am, etc.,

Birmingham Accident Hospital,
Bath Row, Birmingham, 15.

S. SEVITT.

Obituary

W. FRANCIS ELLIS, C.M.G., O.B.E., M.R.C.S.

An interesting career, which could be divided roughly into two parts, ended on July 11 with the death at Tangier of Lieutenant-Colonel W. Francis Ellis at the age of 75. William Francis Ellis was born in 1878, the fourth son of the late W. H. Ellis, J.P., of Shipley Hall, Yorkshire, and was educated at Bradford Grammar School and at the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1901. In the following year he entered the R.A.M.C. and immediately saw service in South Africa, gaining the Queen's medal with five clasps.

When war broke out again in 1914 Ellis served successively in France, the Dardanelles, and in Palestine, and was four times mentioned in dispatches. In addition he qualified for two campaign medals as well as the 1914 Star. He was appointed O.B.E. in 1919, when he held the rank of major (acting lieutenant-colonel), and later in the same year he received the brevet of lieutenant-colonel, with which rank he retired from the R.A.M.C. in 1924. During most of the 22 years he was in the Army Colonel Ellis worked as a surgical and ophthalmic specialist.

On retiring from the Service he settled in Tangier, and there he turned to journalism and politics. For many years he was *The Times* correspondent for the territory, and he did much good work as a member of the Tangier Port Commission, and as British vice-president of the International Legislative Assembly from 1925 to 1940 and again from 1945. During the whole of the last war he was press attaché to the British Consulate General, in which capacity his experience as a journalist proved of great value. His services were officially recognized by his appointment as C.M.G. in the 1945 New Year Honours List. Colonel Ellis married three times. He is survived by his widow, a son, and a daughter.

ROBERT GEORGE HOGARTH, C.B.E., F.R.C.S.

We are indebted to Dr. J. WILKIE SCOTT for the following appreciation of the late Mr. R. G. Hogarth, whose obituary notice was printed in the *Journal* of July 4 (p. 47):

Mr. R. G. Hogarth at the time of his death was the doyen of the medical profession in Nottingham. The subject of his presidential address to the Nottingham Medical Society over 30 years ago was "Notable Doctors of Nottinghamshire." Many famous names were included; in any such roll in the future his own will assuredly be given high place.

His career in Nottinghamshire was an outstanding one, and of no one could it be more truly said that he had the ball at his feet from the start. He was accustomed to say that he owed his appointments as house-physician and house-surgeon at St. Bartholomew's to his prowess for the hospital at football, cricket, and athletics. Probably there were more weighty reasons and it may just have been his way of speaking, for Hogarth was ever aware that bare facts were made more piquant by the addition of a little flavour. He certainly had a brilliant record as an athlete. In his last year at Felstead he won the 100 and 220 yards, the quarter mile, and the long and high jumps; at Bart's he was captain of the cricket and football teams and also of United Hospitals; and he played for various first-class football clubs. The trophy he prized most was the medal awarded him for the open amateur long jump in 1890. During a boyhood spent in the Border country he acquired proficiency in fishing and shooting, and he retained a love of these throughout his life.

Despite his love of and skill at sports Hogarth was never deflected from his ambition to attain success in life and in surgery in particular. Indeed, his proficiency on the field of sport helped him on his way, bringing him hosts of friends and even to some extent shaping his future. His appointments as surgeon to the Notts Forest and Notts County football clubs led him to take an increasing interest in the treatment of injuries, fractures, and joint affections, and his services were often required for accidents in the hunting field. He was largely concerned with the inauguration of the Cripples' Guild, from which emerged the now well-known Harlow Wood Orthopaedic Hospital. He did, in fact, develop as a long suit in a general surgical practice what is now known as traumatic surgery.

Success came to him quickly. His reputation as a skilful operator and as one having cautious and careful judgment spread, and before long he had a magnificent surgical practice. In his presidential address to the B.M.A. in 1926 on "The Medical Practitioner and the Public" he showed remarkable foresight of the shape of things to come. He took the opportunity to advocate such measures as the provision of wards for paying patients and the extension of contributory schemes to meet the rising costs of hospitals and so possibly enable them to be preserved on a voluntary basis. It was only after the lapse of some years and in face of opposition that these projects were achieved in the county. He had the rare honour for a provincial surgeon not attached to a teaching hospital of being elected to the Council of the Royal College of Surgeons of England. Other distinctions came his way, and he was frankly appreciative of them. In his book of reminiscences, written in unpretentious vein, he looks back upon a life of very varied interests, and pays tribute to many who were his friends and helped him on his way. It seems strange that one of his greatest friends, from whom he derived much inspiration, Victor Bonney, should have died within a few days of him.

Hogarth—Bob to his friends—was a very human, genial person, with much charm of manner. There was nothing in the least degree thrustful in his demeanour—in conversation he was depreciatory of himself—and yet he was usually the centre of attention in any gathering, even in the presence of more celebrated people. He appeared frequently in the law courts, where he was much in demand in cases arising under the Workmen's Compensation Acts, and was a very able and wily witness. He had a disarming way of belittling his own knowledge and seeming to agree with the opposition—except, perhaps, over just one point, which was often a crucial one. He had always been rather occupied with his health, and for years before this really did decline he was a confirmed and self-confessed valetudinarian, but, as his complaints were interspersed with his natural drolleries, he was never a bore. His final illness was a protracted and a trying one. He was bed-ridden for over 18 months, and it was a relief when the release, for which he longed, came quickly and peacefully at the end.

Medical Notes in Parliament

Treatment of Rheumatism

Mr. J. SNOW on July 16 inquired whether the Minister of Health had considered the publication entitled "Rheumatic Complaints in an Urban Population" (Kellgren, J. H., *et al.*, *Ann. rheum. Dis.* 1953, 12, 5; and see leading article at p. 194 of this *Journal*), and whether, in view of this evidence of lack of treatment facilities and public knowledge of possibilities of cure in certain categories, he would have a survey made in small industrial towns.

Mr. IAIN MACLEOD said he was aware of this report, which provided evidence of reluctance to seek medical advice for rheumatic complaints rather than of lack of facilities. Although this exploratory work was of great interest it did

not yet warrant a great dispersion of effort from other research on rheumatic diseases into widespread inquiries of the kind suggested.

Mr. SNOW suggested that the Minister should consider the fact that the rheumatologist was not considered of consultative status by the Ministry of Health. He said physiotherapy departments were congested by cases referred to them by orthopaedic surgeons who had no specialist knowledge of the direct applications recommended by rheumatologists. Mr. MACLEOD replied that he recently received a deputation on consultant rheumatology and thought the Ministry had to some extent satisfied it.

Colonel M. STODDART-SCOTT asked whether Mr. Macleod knew that some regional hospital boards had no specialist facilities for treatment of rheumatism. Would the Minister ensure that throughout the country there were facilities whereby rheumatism could be diagnosed and given appropriate treatment? Mr. MACLEOD said he would like to look into that.

National Service Medical Boards

Colonel M. LIPTON asked the Minister of Labour on July 16 how doctors were selected for the medical examination of National Service recruits; what fees were payable; and what age limit was imposed on the doctors so selected.

Sir WALTER MONCKTON in reply said vacancies on the panels of the National Service Medical Boards were filled on the recommendation of a regional medical officer of the Ministry of Health after consultation with the local medical committee appointed under the National Health Acts. No precise qualifications were laid down, but a minimum of 10 years' professional experience was expected. The majority of practitioners appointed in recent years had had Service experience. Members of National Service Medical Boards were paid £2 12s. 6d. per session, normally of two and a half hours, with an additional half-guinea for the chairman. No age limit was imposed provided the doctor was fully fit and efficient, but, in general, a doctor over 65 years of age would not be nominated for appointment.

Sir WALTER MONCKTON on July 16 told Mr. Gower that he was examining closely the working of the National Service Medical Boards with a view to ensuring that the number of cases where men were not graded correctly according to the standards laid down—which he believed to be proportionately very few—was kept to a minimum. Medical boards were already required to go very fully into the personal and family medical histories of every man and to obtain reports from his medical practitioner or from any hospital by which he had been treated in any case where this appeared likely to help to resolve a doubt as to his fitness. Instructions had been given, and recently repeated, that in cases where there was doubt inquiries ought to be made either of the hospital or of the medical practitioner concerned. If the medical practitioner sent a certificate with the man it was attached to the medical report. Hospitals and consultants were consulted in one in every seven cases.

Prescription Charge

On July 16 Mr. A. BLENKINSOP asked whether the Minister of Health would abolish the 1s. prescription charge in view of the recommendation of the British Medical Association Annual Meeting.

Mr. IAIN MACLEOD answered: No, Sir. He said he had studied what had been said at the British Medical Association and also at the Trade Union Congress, but it had not altered his view that no change should be made at present.

Onchocerciasis in Africa

Mr. LESLIE HALE asked on July 15 what progress had been made with the survey of the incidence of onchocerciasis in the Gold Coast, Cameroons, and Nigeria entrusted to the British Empire Society for the Blind.

Mr. OLIVER LYTTTELTON said the main survey began in the Gold Coast last November. It was hoped to extend it

to Nigeria and the Cameroons early next year. The cost was being borne by the British Empire Society for the Blind, but the local Governments provided medical facilities and accommodation. Although the scheme had proved a heavy drain on the Society's finances, it hoped to be able to complete the survey within the allotted time.

Influenza Trials

Mr. MACLEOD in answer on July 16 to Mr. N. N. DODDS said the results of the trial of a new influenza vaccine carried out last winter had been given preliminary study by a committee of the Medical Research Council. Over 12,000 individuals took part in the trial. Influenza was diagnosed in 3% of the group given the new vaccine and in 4.9% of the group given an older type of vaccine. 6,340 volunteers received the new trial vaccine of the virus A type, and 192 had influenza. 6,370 received an older type, and 309 had influenza. These results were considered to be sufficiently encouraging to justify further research on the vaccine with a view to improving it.

Casualties in Korea

United Kingdom casualties in Korea up to the end of May, 1953, were 4,222 officers and men, of whom 702 were killed or died of wounds.

Hospital Doctors' Remuneration

Mr. GILBERT LONGDEN asked on July 9 what was delaying the review of the remuneration of hospital medical staffs.

Mr. IAIN MACLEOD answered that the matter was before the Medical Whitley Council. It raised difficult issues, but he was sure a decision would not be unnecessarily delayed.

Replying on July 8 to an inquiry by Mr. KENNETH ROBINSON concerning hospital consultants, Mr. MACLEOD circulated the following table:

Regional Hospital Board	At December 31, 1951			At December 31, 1952		
	Total No. in Contract with the Board (2)	Whole-time * (3)	Part-time † (4)	Total No. in Contract with the Board (5)	Whole-time * (6)	Part-time † (7)
Newcastle ..	322	139	183	358	110	248
Leeds ..	311	65	246	313	81	232
Sheffield ..	351	81	270	369	92	277

Liverpool ..	246	48	198	277	50	227

Notes: * The figures in columns (3) and (6) represent in terms of whole-time equivalents the amount of service given to each board by consultants who are whole-time in the National Health Service. Some whole-time consultants give part of their service to a second regional board, or a board of governors. † The figures in columns (4) and (7) are the difference between columns (2) and (3) and columns (5) and (6) respectively and they may not, therefore, correspond exactly with the numbers of individuals.

SCOTTISH HOSPITAL ENDOWMENTS

Commander T. D. GALBRAITH on July 13 moved that the Hospital Endowments (Scotland) Bill be read a third time. He said that the Hospital Endowments Commission, set up under the National Health Service (Scotland) Act, 1947, to inquire into existing endowments and to prepare schemes for their reallocation if necessary, had concluded that the income from the endowments was greater than could usefully be employed in providing additional amenities for Scottish hospitals. The Bill gave effect to the Commission's recommendation that some of this income should be made available for medical research. It provided for the setting up by the Secretary of State for Scotland of a Scottish Hospital Endowments Research Trust, and it would empower the Hospital Endowments Commission to transfer endowments

to that Trust. The Commission intended to transfer a proportion of the £13m. endowments with which it was concerned from the boards of management to the research trust. An amendment had limited the transfer of endowments to such an amount as produced in the year ended March 31, 1952, an income of £120,000. By giving this Bill a third reading the House would make it possible to establish in Scotland a valuable future medical research fund.

Mr. A. WOODBURN said there was no disagreement about the Bill in any part of the House. It sprang from a debate in the Scottish Grand Committee in 1948 which had disclosed that Scotland showed an increased incidence of tuberculosis, which in 1949 was found to be confined to young women and men over 53. It was necessary to investigate the problem further than could be done by collection of statistics. Consultations followed with the Medical Research Council with a view to having the Scientific Advisory Committee of the Secretary of State merged with the body which would undertake guidance of research in Scotland. The work of the Medical Research Council would not be interfered with, and it would be represented on the Scottish research body. Research should be an essential part of the training of students. The new body would have the opportunity of finding the people who were capable of research and giving them tasks to undertake.

Mr. JAMES MCINNES said he was glad the Secretary of State had eliminated the fears which existed in many hospitals in Scotland about the administration of these endowment funds.

The Bill was then read a third time without a division.

Universities of St. Andrews and Dundee

Mr. JAMES STUART on July 13 moved the third reading of the University of St. Andrews Bill, which had already passed the House of Lords. An amendment proposing that the University should have the title of the University of St. Andrews and Dundee was not selected by the Speaker. Mr. Stuart hoped that the new organs of government in the University would begin to function this autumn.

Lieutenant-Colonel WALTER ELLIOT remarked that many of the schools which had been developed in St. Andrews were in future to be developed in Dundee, notably the flourishing school of preclinical medicine.

Mr. HENDERSON STEWART said a new Dundee college was to be established, including not only the University College and the School of Economics, but also the advanced medical and dental schools.

The Bill was then read a third time.

INDUSTRIAL INJURIES BENEFIT

The report stage of National Insurance (Industrial Injuries) (No. 2) Bill was taken in the House of Commons on July 13. Mr. JOHN MCKAY moved to amend the section of the principal Act dealing with benefits for widows, in order to place the industrial widow in the same position as the widow who drew benefit under the National Insurance Act. In ordinary industrial occupations there were nearly 2,000 fatal casualties every year. Dr. H. MORGAN seconded the amendment.

Mr. OSBERT PEAKE said the amendment was acceptable to the Government. It brought the two Acts into line and ensured that the widow under the Industrial Injuries Act got the higher rate of widows' pension if she was over 40 when she ceased to be entitled to the widowed mother's allowance. The House agreed the amendment.

Mr. R. H. TURTON then moved that the Bill be read a third time. He said that by relaxation of conditions 8,000 claimants a year could qualify for disablement benefit, and perhaps 2,000 would qualify for special hardship allowance. The Government hoped the Bill would receive the Royal Assent before the recess and that the appointed day would be towards the end of August. Changes then would include provision of modified hospital treatment for men whose assessment was below 20% and who had a disablement gratuity.

Dr. BARNET STROSS was glad that men who had been recently rejected because they only had a small loss of faculty could now have their cases reopened.

Mr. TOM BROWN, speaking on the appointment of medical boards, said that many medical men and women who sat on these boards, particularly in the mining areas, had no knowledge of working conditions. It was essential that these boards should consist of persons who knew something of the conditions under which men and women sustained accidents.

The Bill was then read a third time.

M.O.s at Singapore.—There are 344 medical officers on the establishment in the Federation of Singapore. Seven of them are over 55 years of age. In addition 58 medical officers are employed on a month-to-month contract. There are 104 vacancies.

Cost of Ambulances.—The ambulance service, which cost £4,114,000 in 1948-9, is estimated to cost £9,593,000 in 1952-3.

Consultant Appointments.—The Minister of Health states that no consultant appointments proposed by regional hospital boards since January 1, 1953, have been rejected by him. A number of proposals, including 12 from the Newcastle Regional Hospital Board, are under consideration and discussion with the board.

B.C.G. Manufacture.—Any manufacturer may apply for a manufacturing licence for production of B.C.G. vaccine under the Therapeutic Substances Act, 1925. The conditions which an applicant would need to fulfil are laid down in the Therapeutic Substances Regulations, 1952.

Insurance Bill.—The National Insurance Bill was read a third time in the House of Lords on July 9.

Analgesia.—Gas-and-air machines available to domiciliary midwives in England and Wales were 4,098 in 1948, 5,430 in 1949, 6,051 in 1950, 6,156 in 1951, and 6,264 in 1952. In practice at present the analgesics which midwives may administer are pethidine or gas-and-air.

Royal Assent.—In the House of Lords on July 14 the Royal Assent was signified to the Births and Deaths Registration Act, the National Insurance Act, the Army and Air Force Annual Act, and the Therapeutic Substances (Prevention of Misuse) Act.

Medico-Legal

COMMANDING OFFICER ACQUITTED

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

On July 16, 1953, Lieutenant-Colonel Alfred Gleave, R.A.M.C., the officer commanding Moston Hall Military Hospital, was acquitted by a Chester court martial of the two charges brought against him. These were that between April 1 and May 19, 1953, knowing that allegations had been made that Private Harrison had been ill-treated in hospital, he failed to report the matter to his superiors or make a proper investigation; and that on May 18 he improperly agreed the terms of a statement to the Press that he had made full inquiry into the allegations of ill-treatment, knowing the statement to be false.

On June 16 a statement was made in the House of Commons by the Secretary for War on the subject of Private Harrison's death, and it was said that the commanding officer of the hospital would be called to account for his conduct and would be tried by court martial. At the trial it was not suggested by the prosecution that Lieutenant-Colonel Gleave was party to any ill-treatment of Private Harrison, or knew or indeed before April 1 should have known that any ill-treatment was taking place.

Private Harrison was admitted to Moston Hall on March 26. On arrival he was examined by the admitting officer, Captain Lyle, in the presence of Lieutenant Moran. They observed that he walked in an extremely bizarre way but with no regular fault in his gait. He said he had no pain. A provisional diagnosis of hysteria was recorded and Private Harrison was assigned to Ward M 4/5, which at that time was in charge of Major Hobson. Next day because his moaning in the night had disturbed the other patients he

was moved to a side ward. On the night of March 27 Lieutenant Mary Parry Jones saw the other patients standing round Harrison, who was sitting on the floor, jeering at him. On March 30 he was transferred from Ward M 4/5 to a ward used as a mental and detention ward, where he came under the care of the psychiatrist, Captain Whiteley, who examined him twice and on April 1 thought he might be well enough to travel to Netley for specialist psychiatric treatment.

On that same evening the deputy matron, Major Maudsley, saw him on her rounds and thought he looked so ill that she at once sent for Captain Hamilton, the orderly medical officer, who examined him and could feel a growth in his liver. He was then taken to a private room and put on the dangerously ill list. He died on April 5.

Upon Private Harrison's name being put on the dangerously ill list, which was kept in Colonel Gleave's room, Captain Hamilton saw Colonel Gleave and told him the prognosis was hopeless, and Major Hobson came to him on April 2 in what he described as rather a flutter and said that Harrison's case had not been completely diagnosed and that they had missed his enlarged liver, which was probably malignant, and that the hysterical symptoms had rather overshadowed it. Colonel Gleave as a result issued orders that future examinations must be carefully carried out.

On April 10 one of the patients who had been in Ward M 4/5 when Private Harrison was there, a Private Nicholson, went absent, and when brought before Colonel Gleave elected trial by court martial. At his trial on May 17 both he and Private Rosser, who had been the night nurse in Ward M 4/5, made allegations that Private Harrison had been ill-treated.

On hearing these allegations, which came as a complete surprise to him, Colonel Gleave asked Captain Hamilton, Deputy Matron Maudsley, Major Serjeant (the administrative officer, and the chief wardmaster W/O Gillies if they had heard of any such thing taking place. He did not speak to the sister in charge of Ward M 4/5 because she was away on sick leave, nor to Major Hobson, who had left the Service. He discussed the allegations on the telephone with the A.D.M.S. Western Command, Lieutenant-Colonel Orr. He did not make inquiries in the wards or ask patients in Ward M 4/5 about the allegations, which he thought were fantastic. He did not think it desirable to send for Private Rosser and two other witnesses who gave evidence at Private Nicholson's court martial, because he thought them unqualified and biased.

When on the evening of May 18 Major Borthwick, the Command senior information officer, spoke to Colonel Gleave on the telephone, Colonel Gleave authorized a press statement to the effect that he had made full inquiry and was satisfied that there was no truth in the allegations that there had been ill-treatment of patients.

After a retirement by the court of 34 minutes the Judge Advocate announced that Colonel Gleave had been found not guilty of the first charge, and not guilty and honourably acquitted of the second.

Universities and Colleges

UNIVERSITY OF BIRMINGHAM

Professor F. A. R. Stammers has been appointed representative of the University on the Standing Joint Committee of the University, the United Birmingham Hospitals, and the Birmingham Regional Hospital Board; Professor A. B. MacGregor has been appointed a representative of the University on the Central Counties Dental Postgraduate Committee, Dr. J. M. Malins a representative of the University at the King Charles I School, Kidderminster, and Dr. K. A. Bisset a representative of the University on the International Congress of Microbiology, Rome, September, 1953. Dr. K. A. Bisset has been reappointed a representative of the University on the Public Health Classes Advisory Committee.

The title of Reader in Social Medicine has been conferred upon Dr. R. G. Record, Lecturer in Social Medicine. The title of Honorary Lecturer in Radiology in the Department of Surgery has been conferred upon Dr. C. G. Teall, University Clinical Lecturer in Radiology. The title of University Research Fellow has been conferred upon Dr. W. Taylor, part-time Lecturer in Medical Statistics, during his tenure of a fellowship financed by the Rockefeller Foundation. The title of University Clinical Lecturer has been conferred upon Dr. J. F. K. Hutton (Radiology). The title of Reader in Systematic Bacteriology has been conferred upon Dr. K. A. Bisset, Lecturer in Bacteriology.

Professor C. H. Pae, Department of Pharmacology, University of Taegu, South Korea, will work in the Department of Pharmacology for a year from October 1, 1953.

Professor J. W. Orr, Professor of Pathology and Director of Cancer Research, has been granted leave of absence for one month during the Autumn Term, 1953, to act as External Examiner and adviser in Pathological Studies at Makerere College, Uganda.

The Barling Scholarship for postgraduate work in Surgery has been awarded for 1953 to Mr. J. M. Small, University Clinical Lecturer in Neurosurgery.

UNIVERSITY OF LEEDS

At a meeting of the Council on June 17, a Rockefeller Travelling Fellowship for 1953-4 was awarded to Geoffrey Watkinson, M.D., M.R.C.P., Lecturer in the Department of Medicine.

The following appointments were announced: M. Ellis, M.B., F.R.C.S., as Clinical Lecturer in Surgery, and J. B. Farquhar, M.B., F.R.C.S., M.R.C.O.G., as Clinical Lecturer in Obstetrics and Gynaecology.

C. J. E. Wright, M.Sc., M.D., Lecturer in Pathology, has been granted leave of absence for one year, to enable him to take up a British Empire Cancer Campaign Travelling Fellowship in the U.S.A.

At a congregation for the conferment of honorary degrees held on June 25, on the occasion of the meeting in Leeds of the British Association of Urological Surgeons, the honorary degree of D.Sc. was conferred on Professor Charles B. Huggins and Mr. R. Ogier Ward.

UNIVERSITY OF BRISTOL

The following candidates have been approved at the examinations indicated:

FINAL M.B., Ch.B.—¹Winifred J. Coates, ²Ruth J. Grose, D. L. Archer, A. M. Bain, ³Isabel K. E. Brister, T. A. V. Brooks, J. G. Cook, A. J. Coppen, R. Crossley, K. D. Davies, P. W. E. Downes, Dorcas Edwards, M. B. Gee, W. E. L. Gordon, J. D. Jefferies, R. D. Laloo, A. J. Macdonald, Doreen E. McConnell, ⁴P. O. Nicholas, Marguerite E. Pennefather, J. H. Perry, H. Price, M. J. Ree, T. D. Richards, Beryl M. Shipton, Ruth L. Skrine, W. B. Spry, Audrey B. Stevenson, Margaret G. Taylor, J. W. Ware, A. J. Webb. In Group II, completing the examination: Elizabeth M. James. In Group II only: J. A. Beel, J. P. Bishop, Christine F. Boulter, Margaret V. Brown, M. J. Page, J. Roynance, Catherine M. Stephen.

DIPLOMA IN PUBLIC HEALTH.—Part II: M. C. O'Connor, G. D. Teague.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—Part II: E. G. W. Cross, J. D. Orme.

DIPLOMA IN MEDICAL RADIODIAGNOSIS.—Part II: A. Bednarski.

The following candidates have been approved at the examination indicated:

M.D.—D. H. Johnson (with distinction), R. Maggs, R. H. Owen.

¹With second-class honours. ²With distinction in medicine. ³With distinction in child health. ⁴With distinction in public health.

FACULTY OF OPHTHALMOLOGISTS

Mr. A. B. Nutt (Sheffield) has been co-opted to the Council of the Royal College of Surgeons of England for 1953-4 as the representative of Ophthalmology.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates, having completed the final examination, have been granted the Diploma of the Society, enabling them (upon complying with the requirements of the Medical Acts) to practise medicine, surgery, and midwifery: A. Booth, G. I. Taylor, H. A. Whitehouse, G. J. John, J. G. Cooper, V. R. Jones, R. G. Jones, G. R. Vesey, C. M. Stevenson, J. D. Spouge, J. W. S. Webb, D. J. Waller, G. L. Haworth, L. Chapman,

C. L. Smith, W. G. Rhys-Jones, D. Porter, E. W. Fowler, T. C. Ryan, E. R. Lester, E. McK. Sycamore, R. A. Cooper, W. G. Nethery, B. Lewis, J. A. Scanlon.

CONJOINT BOARD IN IRELAND

The following candidates were successful at the recent post-graduate examinations:

DIPLOMA IN ANAESTHETICS.—P. R. Mesham, T. W. Vanniasingham, N. H. Jafry, Mary L. Mackay, Evelyn M. Gallagher, J. R. McCarthy, M. F. McGrath, E. A. Vaughan, J. D. Carstens, Nora M. Kelleher, A. A. Alvarez, J. D. Twomey, P. M. F. McGarry.

DIPLOMA IN CHILD HEALTH.—J. K. Heskin, Joan M. MacCarthy, J. F. O'Halloran, H. Z. G. O. Senanayake, Hirarani Thakur, T. J. Mahon, T. J. M. Lydon, Geeta S. Mehta.

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY.—Dr. H. J. Scott.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in England and Wales in the week ending July 11 (No. 27) were as follows: paralytic 118 (85) non-paralytic 65 (41), total 183 (126). This is an increase of 57 compared with the previous week, the figures for which are in parentheses. Up to and including the twenty-seventh week the following numbers of cases were reported in the years shown: 1947, 487; 1948, 708; 1949, 631; 1950, 1,447; 1951, 907; 1952, 895; 1953, 1,200.

Week Ending July 11

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,072, whooping-cough 4,407, diphtheria 17, measles 5,504, acute poliomyelitis 183, dysentery 525, paratyphoid fever 3, and typhoid fever 6.

Infectious Diseases

During the week ending July 4 the largest falls in the number of notifications in England and Wales were 267 for scarlet fever, from 1,333 to 1,066, 261 for measles, from 6,871 to 6,610, 200 for dysentery, from 676 to 476, while the only large rise was 574 for whooping-cough, from 4,116 to 4,690.

The largest increases in the number of notifications of whooping-cough were 64 in Devonshire, from 114 to 178, and 60 in Essex, from 288 to 348. The largest declines in the incidence of scarlet fever were 52 in Lancashire, from 193 to 141, and 32 in London, from 87 to 55. The largest falls in the number of notifications of measles were 115 in Gloucestershire, from 318 to 203, 92 in Yorkshire West Riding, from 734 to 642, 83 in Cornwall, from 223 to 140, while the only large rise was 64 in Wiltshire, from 140 to 204. 14 cases of diphtheria were notified, being 4 fewer than in the preceding week.

126 cases of acute poliomyelitis were notified during the week, and these cases were 36 more for paralytic and 30 more for non-paralytic cases than in the preceding week. The southern section of the country still continues to be the most affected, and during the week the number of cases increased from 43 to 94, compared with 17 to 32 in the remainder of the country. The largest returns during the week were Essex 24 (Southend-on-Sea C.B. 5, Chelmsford M.B. 4, Ilford M.B. 3), Middlesex 17 (Ruislip Northwood U.D. 3), Kent 9 (Chislehurst and Sidcup U.D. 2), Surrey 7, London 6, and Southampton 6 (Farnborough U.D. 2).

The largest returns of dysentery were London 85 (Deptford 13, Westminster 13, Islington 12), Lancashire 50 (Liverpool C.B. 15, Preston C.B. 12), Yorkshire West Riding 39 (Barnsley C.B. 10), Bedfordshire 34 (Luton M.B. 25), Surrey 31 (Banstead U.D. 10), Middlesex 31, Essex 21, Norfolk 20 (King's Lynn M.B. 14), Durham 20 (Stanley U.D. 8), and Staffordshire 19 (Brierley Hill U.D. 14).

144 of the 475 cases of food-poisoning were notified in Easington R.D., Durham. 93 further cases were reported from Lancashire, where the cases were spread over 20 administrative areas.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending July 4 (No. 26) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1953					1952

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

First World Conference on Medical Education.—Details of the programme of this Conference (August 22-24) were published in the *Journal* of July 4 (p. 32). All those wishing to attend are advised to register as soon as possible by applying to the secretary of the Local Arrangements Committee, Dr. E. Grey Turner, B.M.A. House, Tavistock Square, London, W.C.1. To help to meet the expenses of the Conference, which are considerable, a registration fee of £4 is payable. Anyone interested in the work of the Conference may register, and registration confers the right to attend all meetings, excursions, and receptions. There will be a reception (6.30 p.m.) at B.M.A. House on August 22, and an excursion to Cambridge (10.30 a.m.) on August 23. On Monday, August 24, the Presidential Address on "The Challenge to Medical Education in the Second Half of the Twentieth Century" will be given by Sir Lionel Whitby in the morning, and the following addresses, also given in plenary session, will be delivered on Monday afternoon: "What is Education?" by Sir Richard Livingstone; "The History of Medical Education," by Professor John F. Fulton; and "Medicine—a Technology or a Profession?" by Colonel S. M. K. Mallick.

Medical Periodicals of the World.—This week, in London, medical librarians from all over the world have been attending the first international congress on medical librarianship, under the presidency of Sir Cecil Wakeley, P.R.C.S. On Monday, the day before the official inauguration of the congress, an exhibition of world medical journals was opened in the Old Library at B.M.A. House. The exhibition, which was arranged by Mr. L. T. Morton, information officer of the *Journal*, is probably the most complete and representative collection of current medical journals ever assembled. It contains over 2,000 journals from 68 different countries. The exhibition underlines the rapid trend towards specialization in modern medicine, and its impact on librarian, editor, and reader cannot but be healthily sobering. The delegates to the congress were entertained to tea at B.M.A. House before the opening of the exhibition, and Dr. Angus Macrae welcomed them on behalf of the Council of the British Medical Association. The exhibition was then declared open by Sir Francis Fraser in a speech of great felicity. He recalled his early debt to a librarian who had shown him how to use a medical library—"A gate to one of the great joys of my life." After describing what would be found in the exhibition, Sir Francis appealed to the assembled librarians not to grudge their personal help and instruction to the beginner in the use of a medical library. "You have something to give—something almost priceless."

Psychiatric Research.—The Rockefeller Foundation of New York has made a grant of £28,800 to the Department of Experimental Psychiatry, University of Birmingham, for research in psychiatry and in the biochemistry and pharmacology of the nervous system. The work will be under the direction of Professor J. Elkes. The department was founded in 1951. Its aim is the application of experimental methods to problems of clinical psychiatry. The problems under investigation at present are essentially neurochemical and neuro-pharmacological. It is, however, hoped to develop systematic studies into the preventive and social aspects of psychiatry as well. An early treatment centre, comprising in-patient, day-patient, and out-patient facilities, is being planned, and this should provide a suitable setting for studies of this kind.

Other Rockefeller Awards.—Two other Rockefeller grants to support scientific projects in British universities are announced this quarter. About £14,000 is being provided for neurohistological and neuro-anatomical research at the Department of Human Anatomy, Oxford, under the direction of Dr. A. G. M. Weddell. University College, London, is

receiving £8,000 for research in mammalian genetics under the direction of Dr. H. Grüneberg. The work will be done in the Department of Eugenics, Biometry, and Genetics over a period of five years. Grants to enable British workers to visit laboratories and research institutions in the United States and Canada go to Dr. W. F. Floyd, of the department of physiology, Middlesex Hospital Medical School, Dr. J. F. Goodwin, lecturer in medicine at the Postgraduate Medical School of London, Professor R. A. Gregory, professor of physiology at Liverpool University, and Professor C. F. W. Illingworth, Regius Professor of Surgery at Glasgow University.

University of London Model Welfare Centre.—A building licence has now been issued for the model child welfare centre and school clinic which is the first part of the development plan of the Institute of Child Health. The building is made possible by a magnificent gift received some years ago from the South African "Aid to Britain Fund." The project is being financed by the "Natal Gift," a sum originally of £106,000 which was raised in the Province of Natal. A site has been purchased at the corner of Guilford Place and Guilford Street. The new building will provide on the ground floor facilities for normal maternity and child welfare centre work, and on the first floor for school clinic work. The London County Council will be responsible for a substantial portion of the running costs. The centre will be used for demonstration purposes for the postgraduate students of the Institute, and for the study of the healthy child. Plans for the building are at an advanced stage and preparation of the site is to start forthwith.

Heberden Society.—Meetings of the Heberden Society were held in Manchester and Buxton on July 10 and 11. Lord Horder, the president of the Society, presided. The annual Heberden Round was conducted by Dr. J. H. Kellgren, director of the Rheumatism Research Department at Manchester. He took as his theme the subject of osteoarthritis, and showed cases illustrating the variations in the condition from the monarticular type to the newly defined syndrome of "primary generalized osteoarthritis," which Dr. Kellgren and Dr. R. Moore described recently in the *British Medical Journal* (January 26, 1952, p. 181). This was followed by demonstrations of the research into the chemical and physical aspects of collagen tissue which are being carried out in the new laboratories of the department. After tea communications were given by Dr. H. G. B. Slack on "Isotope Studies of Collagen Metabolism," by Mr. D. S. Jackson on "Chemical Studies of Connective Tissue Stability," and by Dr. J. Ball on "Fatal Complications of Rheumatoid Arthritis." Sir Harry Platt was the chief guest at the Society's dinner at the Senate House of the University of Manchester. Next day the meeting was continued at the Royal Devonshire Hospital, Buxton, where Dr. R. Harris demonstrated methods of rehabilitation in the chronic rheumatic diseases, Mr. J. C. Cregan presented cases showing the results of acrylic arthroplasty of the hip in traumatic and osteoarthritic disease, and Dr. H. S. Barber presented a number of cases for discussion.

Polar Medals.—Among the members of the Falkland Islands Dependencies Survey who have been awarded the Polar Medal in Silver for "good services in Antarctic expeditions between the years 1944-50" are eight doctors. They are: Surgeon Captain E. W. Bingham, Dr. J. D. Andrew, Surgeon Lieutenant-Commander E. H. Back, Dr. A. R. C. Butson, Surgeon Lieutenant D. G. Dalglish, Dr. J. M. Roberts, Dr. W. J. L. Sladen, and Dr. R. S. Slessor.

COMING EVENTS

Ophthalmology Congress.—The 17th International Congress of Ophthalmology will take place at the Waldorf Astoria Hotel, New York City, from September 12 to 17, 1954. The president is Dr. Bernard Samuels, New York. The main topics for discussion at the congress will be primary glaucoma and the aetiology of uveitis. Original

papers should be submitted to the secretary-general not later than January 1, 1954. Further information about the arrangements for the congress may be obtained from the secretary-general, 17th International Congress of Ophthalmology, 100, First Avenue Building, Rochester, Minnesota, U.S.A.

International Society for the Study of Biological Rhythms.—The fourth meeting of this Society will take place at Basle on September 18 and 19. Speakers include Professor C. P. Richter, from the Johns Hopkins Hospital, Baltimore, Dr. G. P. Wells and Professor H. Kalmus, from University College, London, and Dr. J. N. Mills and Dr. S. W. Stanbury from the University of Manchester. Further information may be obtained from Professor F. Georgi, Neurologische Universitäts-Poliklinik, Basle, Socinstrasse 55.

Electroencephalography and Clinical Neurophysiology.—The Third International Congress of Electroencephalography and Clinical Neurophysiology will be held at Boston, Massachusetts, from August 17 to 22. Further details may be obtained from Dr. Robert S. Schwab, secretary general of the congress, Massachusetts General Hospital, Boston 14, Massachusetts, U.S.A.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, July 27

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., three-dimensional surgical film in colour: Mediastinal Tumours.

Tuesday, July 28

INSTITUTE OF NEUROLOGY.—5 p.m., Professor Kurt Goldstein (U.S.A.): On Aphasia.

APPOINTMENTS

CARRICK, GORDON S., M.B., Ch.B., D.P.H., D.I.H., Medical Officer of Health and Port Medical Officer for the Burgh of Greenock.
DUNLOP, META L., M.B., B.Ch., D.P.H., Medical Officer of Health, Borough of Gillingham, Kent; continuing also as Assistant County Medical Officer of Health (half-time).

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—A. H. C. Couch, M.D., M.R.C.P., Consultant Chest Physician in the East Norfolk Area; M. F. Bethell, M.B., B.Chir., Senior Registrar in Psychiatry in the Ipswich Area; N. Vincenti, M.D., Ear, Nose, and Throat Registrar, East Suffolk and Ipswich Hospital and Ipswich Borough General Hospital; M. E. Johnston, M.R.C.S., L.R.C.P., Ear, Nose, and Throat Registrar, Peterborough Memorial Hospital.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—G. G. Wylie, F.R.C.S., Surgical Registrar; J. G. Stewart, M.R.C.S., L.R.C.P., Part-time Ophthalmic Registrar; D. O'Brien, M.B., B.Chir., D.C.H., House-physician; J. R. F. Ingall, M.B., B.S., House Surgeon to Ear, Nose, and Throat Department; G. Fleet, M.B., B.S., House-surgeon.

RITCHIE, DAVID A. R., M.B., Ch.B., D.M.R.D., Senior Registrar in Radiodiagnosis, Western Infirmary, Glasgow.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—J. Scott Brown, M.D., D.T.M.&H., D.M.R.E., Consultant Radiologist to South Somerset Clinical Area; H. V. Wingfield, F.R.C.S.Ed., Consultant Thoracic Surgeon to Devon and Cornwall Area.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Fletcher.—On July 13, 1953, in Manchester, to Nans Trefflys (formerly Jones), wife of Frank Fletcher, M.D., a son.

Jones.—On July 12, 1953, at University College Hospital, London, W.C., to Monica (formerly Cogman), M.B., B.S., wife of Peter Jones, M.V.O., F.R.C.S., a daughter.

Jordan.—On July 18, 1953, at Cardiff, to Dr. Patricia (formerly Arnold), wife of Dr. J. Warren Jordan, a daughter.

Laidlaw.—On July 9, 1953, at 40, Sherbrooke Avenue, Glasgow, S., to Caroline, wife of Dr. Stuart Laidlaw, a son—Ian Maxwell Stuart.

Mace.—On July 12, 1953, at the Lewisham Hospital, London, S.E., to Josephine (formerly Bruce), wife of Dr. B. E. W. Mace, a sister for Peter James.

Rogers.—On July 14, 1953, at Cardiff Royal Infirmary, to Barbara, wife of Lambert Rogers, V.R.D., F.R.C.S., a daughter.

Sherburn.—On July 4, 1953, at Fairfield Nursing Home, Doncaster, Yorks, to Margaret Beryl (formerly Shepherd), wife of Dr. Vincent E. Sherburn, of 87, Alderson Drive, Doncaster, a daughter—Patricia Anne.

DEATHS

Gater.—On July 10, 1953, at Oakfield, Salisbury Road, Fordingbridge, Hants, Arthur William Gater, M.R.C.S., L.R.C.P., Lieutenant-Colonel, R.A.M.C., retired.

James.—On July 5, 1953, at North Charlton, Alnwick, Northumberland, Margaret Helen James (formerly Morton), M.B., B.S.

Liley.—On July 8, 1953, at Tripoli, North Africa, James Arthur Liley, M.C., M.R.C.S., L.R.C.P.

Manifold.—On July 6, 1953, the result of an accident, Ronald Hector Cameron Manifold, M.R.C.S., L.R.C.P., D.M.R.D.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Penicillin and Sulphonamide Tablets

Q.—Is there any special advantage in the combination of penicillin with two sulphonamides in one tablet?

A.—There is no proved synergistic action between penicillin and the sulphonamides, though of course their use in combination does cover a wider range of organisms. Oral penicillin, though particularly useful in children, is a most expensive form of treatment, and should not be encouraged for conditions where the sulphonamides alone would act equally well. There would thus seem to be little justification for combining these two agents in one tablet.

P.A.S. for Arthritis

Q.—Australian workers have claimed good results from the treatment of rheumatoid arthritis and osteoarthritis with sodium para-aminosalicylate. Has this treatment been tried in Britain, and, if so, with what results?

A.—The natural history of rheumatoid arthritis is characterized by recurrent exacerbations and remissions, and this fluctuating course has led to many therapeutic claims which have not been upheld by further experience. In generalized osteoarthritis affected joints often pass through a more or less acute, disabling, painful stage, which is followed by a partial recovery of function although the anatomical changes in the joints tend to increase. Therapeutic claims in these diseases should therefore be viewed with great caution, particularly if they are not supported by very carefully controlled trials.

Para-aminosalicylic acid was given a careful small-scale trial¹ in the Edinburgh University unit for the treatment of chronic rheumatic diseases. These workers failed to demonstrate any therapeutic effect in patients with rheumatoid arthritis, even when the drug was given in high enough dosage to produce toxic side-effects.

Boric Acid Poisoning

Q.—A 63-year-old woman patient of mine has been taking a teaspoonful of boric acid powder for four weeks, mistaking the container for one which used to contain Epsom salts. Thus she took, daily, four times the maximal dose of an allegedly cumulative drug without any ill-effects whatever. Large amounts of boric acid are said to produce albuminuria, malnutrition, insomnia, headache, dimness of vision, depression, feeble pulse, ecchymoses, lumbar pain, nausea, vomiting, diarrhoea, collapse, and death. Could pharmacologists have based their information on one or two isolated cases? What is the explanation of my patient's lack of symptoms?

A.—It is generally agreed that amounts of boric acid above 2 grammes daily may be harmful, but the variation in susceptibility of different persons is very great. For many substances there is a tenfold variation. Thus one person may need ten times as much of a substance as another to produce a certain effect whether medicinal or toxic. The B.P. dose is an average dose. Excretion of boric acid requires several days, though it reaches maximum rate in two hours. Ross and Conway¹ quote 27 cases of poisoning,

20 of which were fatal. More than half of these were infants, in whom 1 to 3 grammes was often fatal. A number of adults are reported to have died after the application of boric acid to wounds and ulcers. Others survived the injection of 15, 20, and 28 grammes respectively. Only one case of accidental ingestion by an adult is reported. This was fatal; one and a half ounces (45 grammes) of borax was found in the stomach. Watson² considers that boric acid is almost entirely ineffective as a drug and at the same time dangerous, and that it should be removed from general use as rapidly as possible.

Syringes in General Practice

Q.—We are intending to replenish our stock of syringes for our general practice. What varieties are available, and which type of mount is recommended? How should the syringes be sterilized and transported?

A.—The following types of syringe are available: Glass and metal (stainless steel) syringes, with metal plungers; glass and metal syringes, with ceramic plungers; glass syringes, with glass plungers but with metal needle mounts; and all-glass syringes. The first three types of syringe generally have Record mounts. Although there are no particular disadvantages in using syringes having Luer or S.I.M.A. mounts, it should be borne in mind that in this country the needle most readily available is that with the Record mount. All-glass syringes are generally produced with a Luer mount, as this is less liable to fracture than the lighter Record mount. A Luer to Record adapter is available so that needles with a Record mount can be used on all-glass syringes.

Boiling is still the most convenient method of sterilizing all these types of syringes, care being taken to keep barrel and plunger separate if the plunger is made of metal. All-glass syringes may be sterilized by the hot-air method, at a temperature of 150° to 170° C. (see *Med. Res. Coun. Mem. No. 15, H.M.S.O.*). After boiling, or other method of sterilization, the syringes may be kept in 75% alcohol. This solution can conveniently be prepared by adding 5 oz. (140 ml.) of sterile distilled water to a pint 570 ml.) of industrial methylated spirit, the alcohol content of which is about 95%.

Metal spirit-proof cases are available for carrying syringes (up to 20 ml.) in the bag. These cases contain either the syringe and one needle or the syringe and six needles. However, to prevent contamination of the spirit by blood-borne viruses, such as that of infective hepatitis, needles that have been used should not be returned to the container before being boiled; and when blood or other fluid has been withdrawn into the barrel of the syringe (as just before an intravenous injection), the syringe itself should be sterilized before being returned to the spirit. Once a week the whole container should be sterilized by boiling and refilled with fresh spirit.

Vaccination in Pregnancy

Q.—Are there any specific dangers to mother and foetus in primary vaccination during pregnancy?

A.—There is some indication from an investigation carried out in Glasgow that pregnant women who are vaccinated in the first three months of pregnancy are more likely to abort than are unvaccinated women. There is no positive evidence about the occurrence of developmental abnormalities in the foetus if it lives until full term. The risk of abortion does not seem to extend beyond the first trimester, but obviously a severe primary vaccinia, like any acute infection in a pregnant woman, may endanger the life of the foetus at any stage of its development. Primary vaccination in pregnancy should not therefore be recommended unless there are compelling reasons for it.

Height and Weight Tables

Q.—Height and weight tables for both children and adults seem nowadays on the low side. Most of these tables were compiled many years ago. Could up-to-date figures be given?

A.—Height and weight tables for adults generally give the "normal" weight for different heights and ages; they give no information about the "normal" or average height. The best tables that are available are those published by the Metropolitan Life Insurance Company of New York, but a comparison of these with older tables gives no indication whether American adults are taller now than they used to be, but only whether they are heavier at a given height and age.

Unfortunately, there are no up-to-date tables for the heights and weights of British adults or children which are sufficiently comprehensive to be recommended for general use, but there seems to be no doubt that present-day children are both taller and heavier than children of similar ages 30 or 40 years ago. Until measurements of large numbers of British children are available the figures published in 1941 by O'Brien, Girshick, and Hunt¹ are recommended. These tables were compiled from the average measurements of 147,000 American children from various walks of life and living in 17 different States; the measurements were made between 1937 and 1939 for the purpose of designing patterns for children's garments.

Beryllium-containing Alloys

Q.—I am medical officer to a company of electrical and electronic component manufacturers. During the process of manufacturing, a compound bronze, containing 0.25% of beryllium, is used in sheet and strip form. Does the beryllium content in the compound render the bronze any more poisonous? If so, what sort of precautions should be taken in the treatment of cuts and abrasions acquired by the workers during the handling of this material?

A.—Chronic berylliosis has been recorded following exposure to beryllium in the manufacture of beryllium-containing alloys, but up to the present time no cases are known to have occurred when exposure to beryllium has been limited to the handling of the finished alloy. It is unlikely that granulomata of the skin would result from cuts and abrasions acquired by workers handling the compound bronze described.

Transfusion Technique in Agranulocytosis and Thrombocytopenia

Q.—If it is decided to give fresh blood to patients with agranulocytosis or thrombocytopenia, what transfusion technique is recommended? If the blood is citrated, the leucocytes and platelets are rapidly destroyed.

A.—In cases of agranulocytosis or thrombocytopenia it should theoretically be best if the blood is given by the direct syringe method; but in practice it is found quite satisfactory if citrated blood is used, the donor being bled immediately before the transfusion is given. In agranulocytosis the blood is of value not particularly for supplying leucocytes but for supplying fresh complement and probably other unknown factors. Transfusions of blood from cases of chronic myeloid leukaemia or polycythaemia with a high leucocyte count do not appear to be more beneficial than transfusions of normal blood. In thrombocytopenia methods for preparation of suspensions of blood platelets for transfusion have been devised,¹ and these have been reported to be effective.

NOTES AND COMMENTS

Psoralens and Vitiligo.—Dr. H. GRUEBEL LEE (Johannesburg) writes: I read with interest under "Any Questions?" (*Journal*, June 13, p. 1344) the item concerning the place of psoralens in the treatment of vitiligo. In the 1952 *Year Book of Dermatology and Syphilology* (p. 65) mention is made of the treatment of this disability by topical application, or oral treatment in tablet form, or a combination of the two, with two crystalline extracts, ammoidin and ammidin, isolated from the annual umbelliferous plant well known in Egypt, *Ammi majus* lin. (Edwin Sidi and J. Bourgeois Gavardin, of the St. Louis Hospital, Paris). At the same time actinotherapy resulting in erythematous-vesiculation was given, sunlight appearing more effective than ultra-violet irradiation. Only six cases were treated, two with topical application alone, one only receiving the drugs in tablet form, and the remaining three being treated by a combination of both. The results appeared encouraging, in that repigmentation was established in some of the patients treated. It is obvious that the number of cases dealt with is too small to draw conclusions from. Further, one has seen vitiliginous lesions where pigmentation has re-established itself spontaneously, and finally a small proportion of cases appear to clear by the empirical exhibition of vitamins, if continued for a sufficient length of time. Parenteral treatment by gold salts is, I think, on account of their toxicity, unwarranted in a condition that is harmless apart from the possible psychological stress conditioned by its cosmetic imperfection. I have long held the opinion that in vitiligo the melanin-forming mechanism is in a state of inhibition rather than that of permanent impairment. In 1946, through the courtesy of Dr. I. Muende, I showed at a meeting of the Royal Society of Medicine a case of dermatitis bullosa striata pratensis, an occupational pigmentary dermatosis caused by contact with parsnips or other plants, with subsequent exposure to sunlight. Incidentally in the skin-patch testing of this one case more definite positive tests were elicited with the stem than with the parsnip itself. It occurred to me later that such aetiological factors might be used as a basis for therapy in vitiligo; and accordingly I subjected in 1949 and onwards about a dozen cases to such. Unfortunately this was done in the absence of scientific criteria—namely, the parsnip solution was prepared the night before use as an aqueous solution containing a hypersaturation of vegetable and stem, finely grated, and filtered the following morning before use. It was painted on as three coats on the lesions, allowed to dry, and these were subjected to suberythema doses of ultra-violet radiation. At the same time these patients received twice daily vitamin-B complex and 50 mg. of ascorbic acid, together with 100 mg. of para-aminobenzoic acid three times a day. Treatment was given twice weekly, and lasted several months. Roughly half the cases improved, the first two completely; but, as appears to be usual in any new treatment, particularly when not subject to adequate control, the later cases failed to react. One's initial enthusiasm consequently waned. It is of interest that the first case who exhibited a multiplicity of lesions on the face, neck, chest, and back completely cleared, although several lesions—for example, behind the ears and on the back—received no treatment, and lagged behind the others in their resolution. Initially when such lesions clear they are manifest by pigmented stippling.

CHRONIC BRONCHITIS: AN INTRODUCTORY EXAMINATION OF EXISTING DATA*

BY

N. GOODMAN, B.Sc.

R. E. LANE, M.D., F.R.C.P.

AND

S. B. RAMPLING, M.D., M.R.C.P.†

(From the Nuffield Department of Occupational Health, University of Manchester)

During 1950 a survey was made of the registered disabled persons in four areas of Great Britain. Particular attention was paid to the causes of disablement and to the effects of disability on employment. In all four areas chronic respiratory disease was an important cause of disability; in the north-western area it was the largest single disease group among registered disabled persons and accounted for more unemployment than any other physical condition. This led to an examination of the data available on death and sickness resulting from chronic respiratory disease among the general population. These data are summarized here.

I. MORTALITY

In much of what follows the Registrar-General's figures are used. It is first of all necessary to understand what is implied by "chronic bronchitis" when used as a cause of death on death certificates. It is likely to cover a wide range of conditions from bronchiectasis or chronic bronchitis and emphysema to the degenerative conditions, often primarily cardiovascular, of the older age groups. The Registrar-General has often indicated that there is an overlap between bronchitis and pneumonia as the primary cause of death, and also a similar overlap between deaths caused by respiratory and heart diseases at older age groups. Indeed, as long ago as 1848, William Farr pointed out that "bronchitis and other inflammations or congestions of the chest were . . . the causes of many deaths, particularly among persons afflicted with asthma and heart disease."

If a large proportion of deaths are assigned indifferently to respiratory or myocardial causes, a study of the respiratory deaths alone may give a misleading impression. For this reason, where possible, deaths from bronchopneumonia and from the group of deaths termed "myocardial degeneration" are considered in parallel with those from bronchitis.

The change in 1939 of the Registrar-General's method of selecting the primary cause of death from certificates

*A précis of some of the main points formed a contribution to a symposium on chronic bronchitis at the Annual General Meeting of the Association of Physicians of Great Britain and Ireland in May, 1952.

†Working on a Medical Research Council grant.

with multiple causes has greatly affected the respiratory group of deaths. Under the rules prevailing before 1939 any heart disease was chosen as the primary cause of death in preference to a respiratory disease when both were mentioned together. From 1939 the deaths have been classified according to the primary cause given by the doctor signing the death certificate. The effect of this change can be judged by the fact that the 1938-9 bronchitis mortality figures would show a "100% increase at all ages for each sex, the effect being smallest at ages under 5 and greatest at ages between 55 and 75" (Registrar-General, 1947). Thus, in general, the figures of respiratory deaths before and after 1939 cannot be compared other than for the crude total rate for which the Registrar-General gives conversion factors.

As mortality from bronchitis is negligible below the age of 50, it is unlikely that the mortality rates will be affected very much by the exclusion of those in the armed Forces during the war years.

Sex and Age Differences

When used for comparing groups such as men and women inaccuracies in classification are likely to affect both sexes equally and comparison can be informative.

Fig. 1 gives the age specific death rates from bronchitis for men and women separately. The rates for men are three to four times those for women of the same age; the mortality of men of each age group is, in fact, very similar to the mortality of women 10 years older. (A similar difference between the rates for men and women is found in the Scottish figures, although the rates are in fact lower.) Examination shows that this is not due to more women than men being certified as dying of heart disease.†

†A difference of three times in the respiratory rates would mean that nearly all the female deaths attributed to "myocardial degeneration" would have had to be misdiagnosed in this way. This is very unlikely, especially as the male rate from this cause is already about one and a half times that of the female. Moreover, the male/female ratio for death rates from myocardial degeneration has remained constant throughout this period. The group of bronchitis deaths which also had myocardial disease mentioned on the certificate as a contributory or secondary cause of death were tabulated by the Registrar-General up to and including 1945 and formed about 30% of all bronchitis deaths for both sexes at 45-54, 37% at 55-64, and about 40% at 65-74 years.

That men have a higher death rate than women for all causes is a well-known feature of the past 100 years, and during this period the male excess has steadily increased (Martin, 1951). The rates from bronchitis, however, show a greater male excess than for all causes, the male/female ratio for bronchitis being more than

FIG. 1.—Bronchitis and bronchopneumonia death rates, 1939-50. A=Men aged 65-74. B=Women aged 65-74. C=Men aged 55-64. D=Women aged 55-64. E=Men aged 45-54. F=Women aged 45-54.

TABLE I.—Ratio of Male to Female Death Rates in Age Groups

Year	Bronchitis			Broncho-pneumonia			Myocardial Degeneration			All Causes		
	45-54	55-64	65-74	45-54	55-64	65-74	45-54	55-64	65-74	45-54	55-64	65-74
1939	3.5	2.5	1.6	1.9	1.6	1.3	1.4	1.4	1.2	1.5	1.5	1.4
1940	3.6	2.6	1.5	2.0	1.6	1.3	1.5	1.5	1.3	1.6	1.6	1.4
1941	3.3	3.1	1.6	1.9	1.9	1.2	1.4	1.5	1.3	1.5	1.6	1.4
1942	3.8	3.6	1.9	1.9	1.9	1.4	1.3	1.7	1.3	1.5	1.6	1.4
1943	3.8	3.2	1.7	1.9	1.8	1.4	1.5	1.6	1.3	1.5	1.6	1.4
1944	3.8	4.0	2.1	2.4	2.1	1.5	1.6	1.6	1.3	1.5	1.7	1.5
1945	3.8	3.5	2.1	2.1	2.2	1.5	1.4	1.5	1.3	1.5	1.7	1.4
1946	4.1	3.9	2.1	1.9	1.6	1.6	1.5	1.6	1.3	1.6	1.7	1.5
1947	3.6	4.1	2.3	1.9	1.6	1.6	1.5	1.6	1.3	1.5	1.8	1.5
1948	3.9	4.7	2.8	1.8	2.2	1.6	1.5	1.6	1.3	1.5	1.8	1.5
1949	3.6	4.1	2.4	1.7	1.8	1.4	1.3	1.6	1.3	1.6	1.8	1.5
1950	4.4	4.4	2.7	1.5	1.6	1.5	1.3	1.4	1.3	1.6	1.8	1.5

twice that for deaths from all causes in age groups 45-54 and 55-64, while for the 65-74 age group the male/female ratio was in excess to a smaller degree. The myocardial degeneration group of deaths and deaths from bronchopneumonia, however, shows a male excess much nearer the excess for all deaths (Table I).

Social Class

The most recent data on social class mortality are for the triennium 1930-2, when there was an inverse relationship between the death rate from respiratory disease and the

social class. The mortality from bronchitis (Fig. 2, Tables II and III) in social class V (unskilled workers) for both men and women was about five times as great as that for social class I (professional classes). For myocardial disease the correlation with social class is also similar, but the gradient is less steep. Sutherland (1947) has pointed out that each social class consists of a conglomeration of occupations which show a wide range of mortality rates within each class. He examined the variation between these classes compared with that within each class. This has been done here for both bronchitis and myocardial diseases, and the observed gradient with social class was statistically significant for both of these disease groups.†

FIG. 2.—Distribution of deaths from bronchitis and myocardial disease according to social class, 1930-2. Ages 20-65 years. The mortality for all men (black columns) or all married women (open columns) is represented by 100.

TABLE II.—Bronchitis Deaths, 1930-2. Standardized Mortality Rates

Social Class	Men		Married Women 35-65	Single Women 35-65
	20-65	35-65		
I	31	31	27	87*
II	57	57	57	58
III	91	92	99	58
IV	124	126	121	78
V	156	157	156	78
All social classes, including unoccupied	100	100	100	100

* Including unoccupied single women.

One of the striking features of Fig. 2 is that, although the actual rates for men were higher than for women, the ratio of deaths between the various social classes was similar for the two sexes. It would appear, therefore, that in 1930-2 some at least of the factors which determined this ratio affected men and women equally, and these would more likely be of a general environmental rather than of an exclusively occupational nature.

To see if the association between social class and chronic bronchitis still exists in spite of changed conditions, a more up-to-date measure is available. Wilkins (1952) found that a useful measure of the socio-economic status of towns is the percentage of households in which the chief wage earner has a basic wage exceeding £7 10s. a week. He estimated this percentage for the county boroughs of

†As in Sutherland's paper, the analysis of variance was applied to the logarithms of the standardized mortality ratios, as these unlike the ratios themselves, were normally distributed. The ratio of the between to within variances were for bronchitis 7 ($P < 0.001$) and for myocardial diseases 5.8 ($0.01 > P > 0.001$).

TABLE III.—Bronchitis Deaths, 1930-2. Comparative Incidence of Social Class Mortalities. (Rate for all Social Classes, Including Unoccupied in Each Age Group=100). (From Registrar-General's Decennial Supplement, 1931)

Social Class	Men					Married Women					Single Women				
	20-	25-	35-	45-	55-65	20-	25-	35-	45-	55-65	20-	25-	35-	45-	55-65
I	—	D	D	32	33	—	D	D	D	D	—	—	—	D	47
II	D	67	53	55	59	—	D	44	67	55	—	—	D	100	117
III	88	79	86	90	94	D	106	98	99	98	59	58	82	—	170
IV	D	113	129	122	127	—	92	114	111	126	—	—	—	—	—

Unoccupied	E	737	E	E	45	—	—	—	—	—	—	—	—	—	—

D and E indicate deficit or excess when there are fewer than 20 deaths recorded.

England and Wales for 1949-50. When this was compared with the bronchitis figures there was a significant correlation between it and the bronchitis death rates for men aged 45-64 in county boroughs for 1947-8 ($r = -0.65 \pm 0.12$). Many factors are reflected in this measure, but it does show that there is still at the present time a correlation existing between bronchitis deaths and conditions grouped vaguely as "socio-economic."

Region and Degree of Urbanization

The highest death rates from bronchitis are experienced in the northern and western parts of England and Wales (see Table IV and Fig. 3). The conurbation of South-east

TABLE IV.—Bronchitis Deaths, 1950. Rates per 10,000 per Year

Standard Region	Age 45-54		Age 55-64	
	M	F	M	F
England and Wales	10.8	2.5	43.0	15.8
Northern	13.2	3.2	40.5	18.7
Tyneside conurbation	18.8	3.3	63.8	28.1
Remainder	11.2	3.2	32.3	15.2
E. and W. Riding	13.6	3.3	56.1	18.7
W. Yorkshire conurbation	15.0	4.1	63.3	19.8
Remainder	12.6	2.5	50.8	17.8
North-western	16.4	4.7	61.7	26.0
S.E. Lancs conurbation	20.8	6.2	77.8	34.4
Merseyside	15.7	3.2	64.6	19.6
Remainder	12.9	4.0	47.1	21.5
North Midland	8.6	2.2	42.8	11.2
Midland	12.8	2.2	45.9	18.3
W. Midland conurbation	16.1	3.4	56.2	22.6
Remainder	9.5	2.1	36.6	14.1
Eastern	5.9	1.1	24.4	12.3
London and S.E.	9.0	1.8	40.5	13.8
Greater London	9.9	1.9	46.6	8.6
Remainder	5.9	1.3	24.5	8.7
Southern	5.4	1.3	25.7	10.3
South-western	6.4	1.4	25.9	18.5
Wales	12.2	2.4	46.9	22.2
Wales I	14.0	2.7	51.5	22.2
Wales II	7.6	1.8	37.1	11.4

Lancashire has the highest rate (20.8 per 10,000 men in the 45-54 age group), which is almost four times the rate for the southern region (5.4 per 10,000). How far this difference is attributable to geographical conditions and how far to urbanization it is impossible to say.

Urbanization has repeatedly been shown to influence deaths from chronic bronchitis, and the latest figures confirm previous experience. The highest death rate from bronchitis in both sexes and at all ages is experienced by those living in "conurbations." There is a progressive decline in the death rate with the size of the towns, and the lowest figures are found in the rural areas (Table V, Fig. 4).

TABLE V.—Bronchitis and Degenerative Heart Diseases, 1950. Death Rates per 10,000. (Age 45-54)

	Bronchitis		Degenerative Heart Disease	
	M	F	M	F
England and Wales	10.8	2.5	7.4	5.2
All conurbations	13.7	3.1	6.9	4.3
All conurbations excluding Greater London	17.5	4.4	9.1	6.1
Urban areas with population of 100,000 and over	12.2	2.7	7.8	5.7
50,000 and under 100,000	10.6	2.6	8.9	5.7
Under 50,000	9.5	2.3	8.3	6.1
Rural areas	5.5	1.3	6.8	5.3

The ratio of male to female death rates does not appear to vary much for the varying degrees of urbanization, but does differ between the different standard regions, the north-western having the lowest ratio 3.5, for age 45-64, with North Midlands very near (3.8), and, at the other end of the scale, London and Wales each with a ratio of 5.1 and the eastern region with 5.4.

"Degenerative heart diseases" do not show such a consistent fall in rates with a decrease in size of town, but those living in conurbations (excluding Greater London) have the highest risk and rural areas the lowest risk of dying from these causes (Table V).

Atmospheric Pollution

Stocks (1947) drew attention to the inverse relation that existed between hours of sunshine and bronchitis death rates. He pointed out that smokiness of atmospheres, the shorter day, and the excess of cloud are all cumulative and affect northern towns particularly. Attention has been drawn to the relationship between atmospheric pollution and death rates from respiratory causes in many papers, such as those by Mills and Mills-Porter (1948) and Herring-ton and Moriama (1939), but in all these studies the areas with the worst pollution are also those with lower social and economic standards.

There is ample evidence that atmospheric pollution may be responsible for the deaths of many who suffer from

FIG. 3.—Bronchitis death rates in regions, 1950. Men aged 45-64 years.

FIG. 4.—Distribution of deaths from bronchitis and degenerative heart diseases according to degree of urbanization, 1950. Men aged 45–64 years. A=Conurbation. B=Urban districts. C=Rural districts. ("Industrial" conurbations are: S.E. Lancs, Merseyside, Tyneside, W. Yorkshire, and W. Midlands.)

chronic respiratory and heart disease. The Meuse disaster in 1930 and the Donora Valley incident of 1948 are widely quoted. The extensive official report of the Donora episode shows that over 40% of a population of 14,000 were in some way affected, but that all but 1.7% were quite well within a week of the fog lifting. It was those who suffered from long-standing respiratory disease who were more likely to be killed or incapacitated for long periods. London has long provided examples of the results of the lethal nature of severe fogs, which may give a death rate of the same order as that experienced in the severest epidemics (*British Medical Journal*, 1953). The recent London fog was responsible for 6,000 deaths, most of which were in the age groups above 45.

It may well be that exposure to continuous but much less severe atmospheric pollution, such as is experienced in many of our large towns, contributes to the high death rate from chronic bronchitis of those who live in industrial towns, but no evidence is available which makes it possible to be certain of this point.

At the other end of the scale, the Scandinavian countries, with a dry atmosphere little polluted by smoke, record very few deaths from bronchitis. For example, in 1948 the death rates per 10,000 from bronchitis in these countries for the age group 50–60 years were:

	Males	Females
Norway	0.2 (5)	0.4 (7)
Sweden	0.4 (25)	0.2 (12)
England and Wales	17.8	4.5

The actual numbers of deaths in the Scandinavian countries are given in parentheses.

The actual number of deaths were small in the Scandinavian countries, but when all respiratory deaths (excluding tuberculosis and carcinoma of the bronchus) were considered together there was still very little difference between Norway and Sweden or between men and women in these countries, whereas this country's rates were much higher (Table VI).

TABLE VI.—All Respiratory Deaths (Excluding Tuberculosis). Rate per 10,000

Age	Norway		Sweden		England and Wales	
	Men	Women	Men	Women	Men	Women
40–49	1.8	1.9	1.1	1.1	5.2	2.4
50–59	4.4	3.3	3.6	2.1	17.4	5.4
60–69	11.9	9.3	8.1	7.1	46.0	14.3
70–79	39.5	44.3	26.0	30.6	80.3	43.0

It is possible that deaths from chronic respiratory disease were certified as cardiac deaths in Scandinavian countries. Examination of the figures shows this cannot affect the relative positions to any large extent, as the rates for death from heart disease are lower in Norway and Sweden than in this country.

Occupation

(The latest figures are for 1930–2—that is, when there was some overlap between respiratory and myocardial causes of death. There is a significant correlation between the standardized mortality ratios for bronchitis and for myocardial disease for the different occupations, $r=0.68$; $P<0.0001$.)

TABLE VII.—Occupational Distribution of Bronchitis Deaths, 1930–2. Males Aged 20–65. (All Males=100)

Social Class III		Social Class IV		Social Class V	
Ratio		Ratio		Ratio	
Coal hewers and getters	170	Metal grinders	222	Costermongers, newspaper sellers	230
Metal moulders and diecasters	169	Road transport—horse-drivers	205	Messengers, porters, etc.	203
Furnacemen, rollers, etc.	163	Iron and steel foundry furnace-men and labourers	179	Water transport, dock labourers	199
Masons, stone-cutters	147	Coal workers, above ground	172	General labourers, etc.	187
Cotton-spinners	132	Coal—others below ground	143	General unskilled workers, etc.	176
Warehousemen, storekeepers	118	Textile dyers	140		
Salesmen of meat, greens, etc.	117	Coal—conveying to shaft	135		
Paper-hangers, painters, etc.	111	Sawyers and wood turners	128		
Boiler-makers, etc.	108	Coal workers below ground	126		
Hairdressers, etc.	107				
Boot factory workers (skilled)	103				
Boot-makers and repairers	102				
Tailors, etc.	100				
Cotton-weavers	97				
Bricklayers	94				
Smiths and skilled forge-workers	92				
Total of all in Social Class III	91	Total of all in Social Class IV	124	Total of all in Social Class V	156
Stationary engine drivers	89	Fitters' labourers, etc.	123	Builders' labourers, etc.	133
Filters, mechanics, etc.	81	Metal machinists	111	Railway porters	117
Postmen and sorters	80	Coal workers—roadways	102	Other workers, navvies, in building	74
Domestic servants (indoors)	73	Boiler firemen and stokers	93	Agricultural labourers	52
Typists and other clerks	71	Platelayers	90		
Bakers and pastry-cooks	67				
Carpenters	65				
Road transport—motor-drivers	64				
Railway engine drivers, etc.	60				
Civil Service typists and clerks	54				
Gardeners, nursery-men, etc.	51				

The standardized mortality ratios for bronchitis for different occupations are given in Table VII. Owing to the great differences between social classes the occupations have been grouped into their respective classes. Dusty trades were high on each list, and the figures for 1930–2 almost certainly will include cases of pneumoconiosis, which were not at that time diagnosed with the same accuracy as to-day.

Predominantly outdoor work does not seem to have an adverse effect. Gardeners, agricultural labourers, railway porters, builders' labourers are all below their own social class averages. Sutherland (1947) reached a similar conclusion. It must, however, be remembered that these figures are based on the occupation as given on the death certificate, which may not be the predominant occupation of the individual's working life. This was especially likely to apply in the 1930's. Moreover, the existence of chronic bronchitis may have driven men from work involving heavy physical labour either to lighter work or, more usually, to no work at all. The very high death rate from this cause among unoccupied males probably reflects this result of the disease.

II. SICKNESS

Little information is available on the incidence of sickness from chronic bronchitis. Inquiries made by the Social Survey in 1951 suggested that 16.5% of the total days lost from sickness by those aged 21 and over resulted from respiratory complaints* (this excluded 23% due to colds and influenza) (Table VIII).

TABLE VIII.—Social Survey—Survey of Sickness, 1951. Total Days Lost Each Month. Age 21 Years and Over (4,000 Persons Interviewed Each Month)

Month†	Males			Females		
	All Illnesses	Colds and Influenza	Respiratory Diseases‡	All Illnesses	Colds and Influenza	Respiratory Diseases‡
January	8,384	3,764	1,336	11,333	6,267	2,078
February	6,546	2,671	1,137	7,669	3,038	1,635

		20	17		26	16

† Based on interviews in the two following months except for August and September, when, owing to the General Election, there were no interviews in October.

‡ For list of diseases included, see footnote on this page.

In a survey of illness in general practice Pemberton (1949) found that in Sheffield bronchitis was the commonest cause for which a doctor's advice was sought. In the eight practices examined it accounted for 13% of consultations in a week in winter and 7.6% in a summer week. Pemberton (1952) reported that in three Sheffield steel-works employing 9,970 men bronchitis accounted for 13% of all medically certified illness over the period January–June, 1949. In a factory in the Manchester area employing some 1,700 employees this percentage was 14.5. Using data from Raffle (1951), we estimated that 13,000 man years are lost annually in England and Wales from bronchitis.

Sex Differences

What little information there is suggests that the male mortality excess from this disease may not reflect its true sex incidence. In fact the Social Survey found in 1951 that of all days lost during the years through illness the women lost more through respiratory complaints than the men (Table VIII). The women seemed to have shorter and more frequent attacks than the men. For women not going to work the criterion of "days lost" is taken to mean the number of days on which they were prevented by the illness from going out of doors. These figures are open to criticism, since they are based on interviews in which information was sought about the illnesses and days of incapacity experienced during the preceding two months and the cause of such illness is that given by the informant.

In the Statistical Report of the Health of the Army 1943–5 (1948) it was found that in 1943–4 the percentage of A.T.S. admitted to hospital for bronchitis, when standardized for age, was higher than that for soldiers, whereas the percentage of cases requiring discharge from the Army was much higher for men than for women. This report dealt, of course, with a highly selected group of both men and women, but it comments: "This difference between

*Acute sinusitis; laryngitis and tracheitis; acute upper respiratory infection of multiple or unspecified sites; pneumonia; bronchitis; other respiratory diseases (excluding hypertrophy of tonsils and adenoids).

discharge and morbidity sex differentials suggests that (a) the incidence of the more serious type of bronchitis—namely, cases leading to discharge—is higher among men, and (b) the reverse is true of the milder cases that do not involve discharge." Of all military discharges (category E) for 1943–4, 50% were due to bronchitis.

In a survey of respiratory illness in Corby in 1949, Sutherland and Wilson (1950) concluded that "the incidence of respiratory illness among women aged 15 to 44 was double that reported by men."

There is very little information on sickness among women over 45 years of age. Firms keeping records of certified sickness absence for men and women doing similar work find that women have from two to three times the men's rate, age being comparable, for absence due to bronchitis as well as that due to all certified sickness. It must be remembered that this is a comparison of sickness absence, and that economic and social conditions may make absence from work more necessary or perhaps easier for a woman than a man. It is difficult, however, to believe that these factors would change a two to three times male excess, as seen in the mortality figures, into a two to three times female excess for sickness.

Occupation

There is very little information on the effect of occupation on sickness due to bronchitis. Bradford Hill (1929) examined the sickness experience of printers from 1921 to 1925 as given by the records of approved societies, and in the next year he also examined similar figures for operatives in Lancashire cotton-mills for 1923–7, which was repeated 10 years later by Harvey (1939). The number of days' sickness per person per year from respiratory causes (excluding colds and respiratory tuberculosis) are shown in Fig. 5. This chart also gives the recent post-war experience

FIG. 5.—Sickness from bronchitis and other respiratory disease (excluding respiratory tuberculosis, colds, etc.) in males. Number of days' sickness per person per year. Printers and cotton workers from Bradford Hill (1929, 1930), transport workers from Raffle (1951).

of a group of transport workers (Raffle, 1951). It will be seen that those exposed to cotton dust (strippers and grinders) begin to show an increase in lost time from respiratory causes at a much earlier age than those not exposed to dust. It must be pointed out, however, that cotton dust is known to be irritating. Figures are not available to show the effect upon sickness rates of bland or inert dusts, though it has long been held that "dust which impairs the vitality of the lungs predisposes to tuberculous infection . . . and . . . to other respiratory disease" (Collis, 1923).

Disablement

The survey of registered disabled persons to which reference has already been made was carried out in four regions—London, Midlands, North-west England, and Scotland. In the north-western region not only was bronchitis the largest single disease group encountered (with the possible exception of skeletal conditions) but it accounted for more unemployment at all ages and social levels than did any other physical condition. In the sample of 1,184 drawn from this area there were 124 patients with chronic bronchitis of whom 24 (20%) were unemployed. The prospects of employment for men who were severely disabled by bronchitis did not appear to be influenced by the possession of manual skill—this was in marked contrast to general experience. Those with bronchitis who were unemployed at the time of the interview had often undergone a steady decline in social status since becoming disabled. The frequent winter exacerbations of their disease and the necessary long absences from work made them very uncertain employees. It was estimated that 42% of those with bronchitis were severely incapacitated for any type of work, whereas only 23% of the rest of the sample were disabled to a similar extent.

DISCUSSION

While the facts given above are of interest the reasons for them still remain obscure, and much of what follows is but surmise.

Sex Difference

The reason for the male mortality excess from chronic bronchitis is not clear, and is made more difficult to understand by the apparent excess of respiratory sickness among women. The observation that chronic bronchitis takes a more serious course in men is confirmed by Fulton (1953), who has found that in a series of deaths from cor pulmonale in a Manchester hospital over 90% were in men. This sex difference in bronchitis may be due to hormonal or other constitutional differences, so resembling rheumatoid arthritis and coronary disease in its predilection for a particular sex. The fact, however, that this difference is not observed in the Scandinavian countries may be an argument against such an explanation. It might, however, be explained by the different work habits of men and women. Comparatively few women work for long periods in cold, rain, fog, and dust. Nor is there the same economic urge for them to return too early to such conditions following acute respiratory infection. Physical effort carried out during or immediately after an acute respiratory infection may also be a factor in the different sex incidence. For the most part men of social classes III, IV, and V do heavier physical work than women. It is likely that this heavy exercise and the heavy breathing it induces may produce excessive stretching in lung tissue still abnormal as the result of recent infection. The fact that those conurbations where it is the custom for married women to go out to work show a lower sex difference than in those where most married women stay at home supports this hypothesis.

Smoking may also be a factor in producing this sex difference. In a series of 50 male patients with chronic bronchitis seen clinically in the north-western region almost all had been cigarette smokers. A number regard the pre-dyspnoeic stage of their bronchitis as a "smoker's cough." Most of them had continued to smoke except during the more acute exacerbations of their disease, and many had ultimately to cut it down or give it up completely.

If these surmises are in fact correct, one might look for a narrowing of the gap between male and female deaths from chronic bronchitis in the next 20 years, first, because of the reduction in physical work required of the modern workman on account of increased mechanization; and, second, because the smoking habits of the sexes have undergone a change.

Social and Economic Factors

Many writers have emphasized the importance of social factors in the aetiology of chronic bronchitis. Overcrowd-

ing and cross-infection, malnutrition, and inability to treat early respiratory infections with enough care may all play a part. In most working-class homes it is impossible to treat a serious respiratory infection with the respect it deserves, and the cross-infection and re-infection that ensue among many of these families is familiar to most general practitioners. Douglas (1951) found that lower respiratory tract infection in the first six months of life was four times as great in the infants of manual workers as in those of professional and salaried classes, and he attributes this to "the general pattern of their living as well as their home conditions."

The greatly improved nutrition of the children of social classes IV and V, and the remarkable reduction in overcrowding reported by the Registrar-General (1952) in all our slum areas, may do something to reduce the excess of this disease among these social classes in the future.

Urbanization and Location

It is difficult to separate the effects of socio-economic factors and those due to urbanization and location. Living in a town involves more opportunities for cross-infection during entertainment and travel. It is not unlikely that pollution of the atmosphere from small amounts of coal dust and sulphur dioxide has an irritating effect on the respiratory tract. There is no doubt at all that smoke associated with fog has a serious effect on the elderly and the chronic bronchitic in precipitating a mortal bronchopneumonia. Part of the excess of deaths in the poorer classes may be accounted for by their living in a more heavily smoke-polluted atmosphere.

It is not easy to be sure of the importance of location, because the industrial towns, with their crowding and heavy atmospheric pollution, happen to be situated very largely in the north and west. It is true that the rural areas of the north and west show higher figures than the rural areas of the south and east, but this may be due to contamination from nearby industrial areas. It seems probable, however, that the humidity of these parts, particularly when it is accompanied by smoke, has a bearing on the incidence and course of chronic bronchitis in the north-west. The strikingly low mortality rate from this disease in the Scandinavian countries, where a much drier as well as cleaner atmosphere is enjoyed, supports this view.

Disablement

The serious nature of this disease is shown by the high incidence of disablement among its victims. At a comparatively early stage they may become incapable of heavy physical effort, and winter exacerbations make them unreliable workers throughout the winter months.

Little can be done to help the patient with established emphysema, and any hope lies in prevention. While the social and occupational factors are slowly being mitigated it would seem that the general practitioner has an important part to play in reducing this disablement. The modern range of antibiotics have provided him with a means of giving effective treatment for the acute respiratory infections, and the National Health Service has made the full treatment of these conditions freely available to everyone. It would also seem to be important to persuade the man whose job involves heavy physical effort or exposes him to fog, cold, or dust to delay his return to work until his chest has fully recovered from acute pulmonary infection. By such measures fewer bronchitics may pass into the chronic stage and their deterioration may be retarded.

CONCLUSION

For many years this crippling disease has been complacently accepted, and the "cough bottle" has been one of our national institutions. The problem is one of great complexity. A logically planned attack upon it cannot be made until more is known of the weight to be given to various aetiological factors. Further investi-

gations planned to throw light on the different incidence of the disease in the two sexes might give a useful lead in such a study. Long-term studies of the natural history of the disease are already in progress and are likely to give information on the importance of certain occupational factors.

It is certain, however, that the problem is too difficult to be solved by a piecemeal approach. What is needed is a well-planned and co-ordinated attack by experts from various fields. Quite apart from humanitarian consideration, the economic loss resulting from this disease calls for immediate action.

THE PLACE OF THE HOSPITAL IN A NATIONAL HEALTH SERVICE*

BY

Sir ALLEN DALEY, M.D., F.R.C.P., D.P.H.

Administrative Areas

Our next problem in a combined service is the areas to be covered and the populations to be served. Many think that there are too few regional hospital boards and that the original conception of between 30 and 40 would have been better. This might have avoided the expensive administrative set-up of hospital management committees and also have avoided the friction which tends to develop between the boards and the management committees. There are, however, obvious advantages in linking hospital boards with teaching hospitals, though some may say that the disadvantages outweigh them. The location of the university medical schools, placed where they are for entirely different reasons than to be the nucleus of a national health service, certainly caused grave difficulty when the boundaries of the 14 regional boards were being settled. It is clear that if there were a combined service a much larger number of areas than 14 would be needed. There are 145 local health authorities and about the same number of executive councils. In any organization of a combined service, the hospital areas would have to coincide with those of local authorities, many of which would have to be associated with their neighbours for the purpose of making an adequate area for hospital planning—generally regarded as one

*The second of the Croonian Lectures delivered before the Royal College of Physicians of London on July 9.

to serve at least one million people. This coincidence of boundaries of responsibility would in itself greatly facilitate co-operation between the hospital services and those of local government.

It is the dream of many to restore hospital provision to local government. With salaries and conditions of service for hospital staffs fixed centrally and specific regulations made concerning the method of appointment of consultants, the main objections to this are not nearly so strong as in the past, but, without ruling it out, I will not discuss it further, as it hinges on the relationship between the finances of central and local government and on a complete reform of the boundaries of local government areas, involving inevitably the disappearance of many of the smaller local authorities. The emotional reaction to any such proposal is infinitely greater even than that evoked when it is proposed to close a small hospital. Parliament is unlikely, in the foreseeable future, to tackle such a thorny and controversial subject.

My conclusion, therefore, on the questions of a combined service, and whether it should be administered by nominated or elected bodies, is that the practical difficulties of making any radical change, particularly at this stage, are insuperable, but it is not beyond the realm of realism to go back to the "Willink" proposals so far as the number of hospital boards is concerned, and this would ensure a much closer association with the other two branches of the service—the local authorities and the executive councils.

Why Does the State Charge Itself with the Cost of Hospitals?

In the meantime, it behoves us to look again at the administrative structure as it exists to-day and try to determine what is the proper function of a hospital in a national health service. In the first place, we must remind ourselves that Governments do not pour out vast sums of money because they are sorry for sick people. They do so because there is a national insurance scheme which pays out money to people who cannot work because of ill-health and to the dependants of those who die, and also because the Government needs for the well-being of the nation, in peace or in war, the productive capacity of all its nationals who are able to work.

The first National Health Insurance Scheme provided from 1913 a general-practitioner service for insured persons. It was for the dual purpose of providing treatment so as to get the insured persons off the funds and back to work again as soon as possible and also to provide responsible certifying officers for sickness and disablement benefit. Sir William Beveridge, as he then was, said in effect in his report of 1942 (Beveridge, 1942) that if his scheme, which provided larger benefits, was to be successful a comprehensive medical service available to all, free at the time the service was needed, was essential. The link, again, is with the payment of cash benefits.

The objectives of the Service are, primarily, to maintain the health of the community, to prevent disease, and to restore to good health as soon as possible all those who fall ill. That the Service also relieves suffering and prolongs the life of the aged is incidental, as, collectively, whatever their private feelings, Governments, as such, are not sentimental.

Prevention of Illness and Speedy Restoration to Good Health

The insistence on prevention of illness and a speedy restoration to good health of those who fall sick as a major responsibility of a national health service is no new idea of my own. It is the thread running through the recent book

of Sir James Ross (1952). Even in the training of nurses the Working Party reporting in 1947 (Nurses, 1947) stressed the need for giving more attention during training to "modern ideas of social and preventive medicine." The British Medical Association (1930) in its proposals for a general medical service for the nation gave as the first of its fundamental principles "that a satisfactory system of medical service must be directed to the prevention of disease no less than to the relief of individual sufferers."

Owing, no doubt, to the inadequate attention paid in the past to the importance of preventive medicine in the training of the medical undergraduate, there is a tendency among many workers in the clinical field to take little or no interest in preventive medicine or, if they think about it at all, to leave it to "the public health people." I shall endeavour to show that it is the bounden duty of every doctor, particularly those working in a national health service, himself to participate in the practice of preventive medicine so far as it relates to his own patients, and that without the close co-operation of those whose major interest is curative medicine the preventive medicine specialists cannot do their job properly.

Hospitals and Preventive Medicine

There is a considerable body of support, particularly in the U.S.A., for hospitals taking a more active part in preventive work. Dr. Stanhope Bayne-Jones (1949) said "hospitals should become increasingly houses of prevention instead of houses of pity." He quotes the report of the Committee of the New York Academy of Medicine on "Medicine and the Changing Order," published in 1947, to the effect that "the whole perspective of hospital care should be enlarged to include preventive as well as curative care." He lists a number of special activities of a preventive nature which hospitals should provide. They include diagnostic and consultation clinics available to all, clinics for periodic health examinations, and child welfare and child development clinics. He also quotes Corwin, who wrote in 1946: "Hospitals and their out-patient departments are increasingly being looked upon as strategic centers for all health service activities."

The late Viscount Dawson wrote in an American book (Bachmeyer and Hartman, 1948) on hospitals: "For 25 years or more the idea has been spreading that the practice of medicine should be occupied not only with those disabled by sickness or accident but also, if not primarily, with the building up of health, and that for the extended purpose our medical services have become too haphazard and inco-ordinate in their arrangement. In other words, organization has not kept pace with ideas."

Writing in the same volume, Dr. James A. Hamilton, the then President of the American Hospital Association, says of his own country: "This disjointed conglomeration of health agencies is uneconomic, duplicating, and wasteful. The high quality of medical care cannot be maintained and the volume of health services cannot be adequately extended to the great mass of the people if such isolationism is allowed to continue in its present form"; and Dr. I. S. Falk, after pointing out that, with our present lack of knowledge, most sicknesses and most deaths cannot be controlled in the sense of preventing their occurrence, says: "These diseases which we cannot wholly prevent need early detection and accurate diagnosis and the patients need prompt and comprehensive care. . . . The principal import of these contentions is that medical care must be regarded as an integral part of a broad programme of public health."

Boudreau (1934) says: "It is in the out-patient department that the closest approach is made to incipient disease, and it is here that the somewhat arbitrary distinction between curative and preventive medicine loses its force." But he adds that "a hospital cannot function properly as an instrument of prevention unless its staff knows, lives, and breathes in an atmosphere of prevention," and "the hospital must be integrated with all the other health services of the community, which should fit together and be adapted and regu-

lated to each other like the wheels of a watch. . . . It must be fitted into the community; the community cannot be changed to suit the hospital."

Sir Arthur Newsholme (1932) says: "The history of hospitals is one first of care for the sick, then with advances in medicine and surgery, of increasing care, and lastly of prevention. The last stage now overlaps with the needed care and cure."

A more recent writer, Professor H. W. C. Vines (1952) says: "Apart from the curative treatment of the already ill, the acute hospital, as part of the local community, should now be developing a functional part in the prevention of disease as in the more distant future its activities may have to be considerable." At the recent International Hospital Congress he developed this theme and said: "The real future of the hospital service may well come to lie not in the wards but in the polyclinics, and it is these which must gradually become the major centres of practical preventive medicine."

Dr. Malcolm T. MacEachern (1935) lists the four primary functions of a hospital as: (1) care of the sick and injured; (2) education of physicians, nurses, and other personnel; (3) prevention of disease and promotion of health; and (4) advancement of research in scientific medicine. He adds, "In the out-patient department especially, there is an extensive field for the teaching of hygiene, an opportunity which should not be neglected. The hospital should take leadership in educating the public individually and *en masse*." Dr. Edwin Crosby puts number three rather differently when he says (International Hospital Federation, 1953) that one of the functions of a hospital is "to foster and promote the public health and preventive medicine programs of the community."

The Commission on Hospital Care in the U.S.A. (1947) reported that "general hospitals should co-ordinate their efforts with those of other community agents concerned with the prevention and treatment of disease, and, when conditions permit, the general hospital should serve as the focal point through which the health service of the community is integrated. . . . Hospitals should participate in community-wide educational programs, thereby assisting the public to obtain a full understanding of the importance and methods of obtaining a high level of health. . . . Hospitals and health departments should co-ordinate their efforts and integrate their functions. . . . There should be a close relationship between hospitals and public health departments so that the educational activities can include training in public health work. . . . However, the gap between curative and preventive medicine is constantly narrowing. It appears important for the physician to give more and more of his attention to preventive measures and to the maintenance of the health of his clients. . . . The public health department is the logical agency to direct such programs. . . . But, physicians, hospitals, and public health departments should pool their efforts by integrating the functions of preventive and curative medicine in order to serve more effectively the health needs of the whole population."

It is striking that these expressions of opinion come mainly from the U.S.A., where the provision of medical care is still regarded as a matter for the private individual and not, as here, a public responsibility.

Interest in the Subject

It is an indication of the great interest now being taken in this subject that, at the Eighth International Hospital Congress just held in London and attended by representatives of over forty nations and from whose transactions I have already quoted, the central theme was "preventive medicine as a major function of the hospital and its implications."

The above quotations may lead some to the thought that the hospital should become the centre of gravity of the preventive health services, and it is well, therefore, to note

some opinions to the contrary. For example, Dr. Van den Berg, a representative of the World Health Organization, said (International Hospital Federation, 1949): "Hospitals should concern themselves with the treatment of patients and it is difficult to combine this with the direction of preventive measures as a whole. . . . But, preventive and curative medicine are connected. . . . They blend in fact. . . . Much curative treatment is . . . a part of secondary prevention: that is to say, in which the object is not to prevent disease but to ensure that an existing disease is not aggravated and does not cause permanent illness or mental incapacity. . . . Hospitals play an important part in this extensive field of secondary prevention and, although, in my opinion, they cannot form the centre of the health organization on the one hand, on the other, they cannot lose their touch with it entirely." At the same congress Dr. Charles Maitland (England) said: "We must not regard hospitals as institutions that can be expanded indefinitely. We must ask, Why are people in hospitals and need they be there?"

Again, Miss Florence Nightingale (Cook, 1913) is recorded as saying "that hospitals are, at best, only a necessary evil: a necessity, as someone has said, in an intermediate stage of civilization. The secret of national health is to be found in the homes of the people."

Finally, Sir Andrew Davidson (1952) said: "My considered opinion is that the emphasis must be on the domiciliary health services through the co-operation of the family doctor and the health service of the local authority. The rising cost of hospital care—if nothing more—is forcing more attention to be paid to the preventive health services." Dr. G. E. Godber (International Hospital Federation, 1953) said: "It is not the specialized hospital services which should control the others, rather it is the needs of the others which should largely determine the form which hospital services should take." And, he added, "The medical officer of health, who is the most valuable co-ordinating influence in the whole health service, should be confident that in the hospital he has an ally, second only to the family doctor."

The above quotations, and they are but examples of many more, have been introduced to make it clear that during the past few years many people both here and in America have been thinking about the future of hospitals and the part they should play in promoting good health and preventing serious disease.

Hospital Costs

With the increase in scientific aids to diagnosis and advances in techniques of treatment, hospitals require more staff of all grades, and hospital maintenance costs, as already mentioned, are rising. Staff salaries tend to increase and hours of duty to decrease. In the U.S.A. and in Australia nurses now work 40 hours a week. In considering the place of the hospital in a national health service the question of the actual cost of the hospital section of the service and its relation to the total cost of the whole service become important. The last figures published for the whole service are for the financial year 1950-1 (Ministry of Health, 1952). I have rounded the figures to the nearest thousand.

	Thousands	% of Total
Hospitals: capital ..	11,123	2.9
maintenance ..	213,483	55.0
General medical services ..	42,072	10.8
Pharmaceutical ..	34,810	9.0
Dental ..	40,337	10.4
Ophthalmic ..	19,572	5.0
Local health authority services (50% grant) ..	15,621	4.0
Other ..	11,261	2.9
	388,279	100

The actual costs for some of the services for 1951-2 are now available (Accounts, 1951-2). The expenditure on hospitals, on both capital and maintenance, is slightly lower than in the previous year. Pharmaceutical costs rose by

over £10,000,000; those on dentistry fell by nearly £9,000,000, and on ophthalmic services by nearly £11,000,000. Medical services cost the same, but the Danckwerts award of some £10,000,000 a year, apart from arrears, had not been implemented until after the financial year. In 1950-1 the local health authority services cost public funds double the figure given above, which is the cost to Government funds. The other half is found from the local rates. I am confident that argument will never cease on whether or not the allocation of the total budget is in the best interest of the community, and I do not propose to enter the lists, though many will, no doubt, soon be jousting before the Guillebaud Committee. But perhaps I might add the words of the cynic, "Extravagance is other people's expenditure."

Other Preventive Activities of Local Authorities

For the reasons set out earlier it is impossible to calculate an accurate figure showing the proportion of the total bill for the National Health Service which is devoted directly and entirely to the prevention of disease, but there is no doubt that it is small compared with the total cost of the Service. It must also be mentioned that many quite costly services provided by local authorities under the Public Health, Housing, and Education Acts are important contributions to preventive medicine and are not contained in the accounts of the National Health Service. These other services include sewerage and drainage, provision of healthy homes, pure water, collection and disposal of household refuse, open spaces and playing-fields, pure food, safe milk, prevention of atmospheric pollution, health education, the school health service, and the work of sanitary inspectors in connexion with the control of infectious diseases. Expansion of the services for promoting the health of factory, shop, and office workers would also not be a charge on the National Health Service, but would undoubtedly pay dividends in promoting community health. The effect on health of full employment and better national nutrition must also be mentioned.

Function of the Hospital

We are now in a position to examine more closely what hospitals do, what they ought to do, and their exact place in a national health service. I think it will be agreed that their primary function is to diagnose and treat the sick. But some provisos are needed even here. They should not usurp the position of the general medical practitioner. They should be consultative for him, and patients should not be asked, or even allowed to continue, to attend an out-patient department or be admitted for in-patient treatment if the treatment can be given at home by the family doctor and the home circumstances are suitable.

Training.—But hospitals have other important functions, including the training of doctors, nurses, midwives, and medical auxiliaries of all kinds. Teaching hospitals for medical students are in a special position with regard to the admission and retention of patients, as students must be taught the ailments, both common and serious, met with in general practice. Maybe the best way to do this is to include during the undergraduate training a short period of preceptorship with an approved general practitioner. This is probably better than admitting patients who need only general-practitioner care to teaching hospitals, but undoubtedly the range of patients dealt with in a teaching hospital in both the out-patient and in-patient departments must for these reasons be much wider than if the need for hospital, as distinct from family doctor, care were the only consideration. There is an increasing tendency both in this country and in the U.S.A. to devise better methods for preparing medical undergraduates for general practice.

Care of the Sick.—I have been considering up to now the acute general hospital, whose primary concern is, and always will be, the care of those who are seriously ill, though, as discussed earlier, it has important preventive functions. But the majority of the hospital beds in this country are not in acute general hospitals but in special hospitals of all types.

Planning Hospital Services

The regional hospital boards are the planning authorities for all types of hospital, except teaching hospitals, and general practitioners and public health officers, because of their special interest in, and knowledge of, the problems concerning those whose needs are best met in special hospitals, should be more closely associated than in the past with these planning functions. These classes of patient include not only those whose admission to hospital is needed because of their home conditions and not because they are in need of specialist care, but also the chronic sick, the "fever" case, the tuberculous, the long-stay cases in children, the mentally defective, and the mentally disordered, including the mental observation ward case, to mention only some examples. Only by associating at the planning stage those vitally concerned in the other two branches of the Service can full integration be achieved and the needs of all sick people met.

Integration with General Practice

With lessened house room, more women working in industry, and perhaps a greater reluctance of young people to care for their aged relatives at home, more accommodation is needed, so that general practitioners can admit patients to hospitals where they will continue to be under their own care; and some of these hospitals should be used for the instruction of medical students. Hospitals, too, have a responsibility for providing the means by which the knowledge of general practitioners can be kept up to date. There are various ways by which this may be done, and it involves not only close co-operation by reports sent to hospital with patients and the prompt dispatch from the hospital of notes on his discharge, but making the general practitioner feel that he is a welcome and essential member of the combined team of doctors, some working inside and some outside the hospital, engaged in caring for the sick of the district.

This leads to a regret that the former "district" hospital with direct responsibility for the sick of their defined district is disappearing, with the result that the patients who are less interesting from the purely medical point of view have more difficulty than in the past in obtaining a bed. It is all to the good that no meticulous inquiry about where he lives need now be made before a patient is admitted; but when patients, whose need of admission to a hospital is clear, are refused at their local hospital and that hospital takes no step to secure their admission elsewhere, the pendulum has swung too far.

Before 1948 the publicly maintained hospitals each had a definite district for which they were responsible, and if they could not themselves make a bed for an urgent case it was the duty of an officer of that hospital to find one himself in another public hospital. It is a disconcerting fact that in some 10 to 15% of the applications for beds made to the London Emergency Bed Service a bed cannot be found immediately, and the name must go on a waiting-list, sometimes for a considerable time, and occasionally the patient is dead before a bed can be offered. When a bed is offered it is sometimes miles away from the patient's home, involving extra ambulance costs, and cost and inconvenience to the patient's relatives. This type of waiting-list is apart from the waiting-lists to which we have become accustomed for "cold surgery" and for non-urgent medical cases to which the same objection cannot be taken, though complacency about this and taking the easy road that we cannot do anything about it unless we open or build more beds is to be deplored. One would ask what steps are taken to divert them to a hospital where the waiting list is shorter. Do we not, instead, take a pride in the length of our waiting-list as a tribute to our skill and popularity?

The hopes of those who maintain that the future of general practice lies in group practice from the health centres envisaged in the National Health Service Act and in the

report of the Medical Planning Commission sponsored by the British Medical Association (Medical Planning, 1942) are not being realized because so few centres are available. The idea is still in the experimental stage, and it would be of great value if two or three such centres were placed each within the curtilage of, or immediately adjoining, a general hospital. By this method, the prospect of bringing together hospital, general practitioner, and public health clinic services might really be achieved for that locality.

The Chronic Sick

Questions concerning the chronic sick and the aged and infirm loom large in any national health service. It was given close attention by the local authorities when they were responsible for the public hospitals. Fortunately, many leaders of the profession are now also becoming interested in the problem (British Medical Association, 1947, 1948). It is realized that much can be done to prevent deformities, to restore the bedfast to ambulation and, in some cases, to their homes. The day of the large hospital for the "chronics" has, I hope, passed. All general hospitals, including teaching hospitals, should use a proportion of their beds for the more chronic type of patient "for thorough examination, and whenever possible they should provide treatment with a view to the patient's return to a useful life." The last few words are a quotation from the Goodenough Report on Medical Education (Medical Schools, 1944). When further active treatment is likely to be unavailing there should be an adequate number of "half-way" houses or "rest homes."

Again, there should be a closer association between the homes for the aged, administered by the welfare departments, and the geriatric departments of the hospitals. The geriatrician who has worked hard to restore a patient to ambulation should continue to supervise that patient even after transfer to a home for the aged. This need not interfere with the responsibilities of the general practitioner on whose list the patient is.

The senile patient who is confused in mind presents a special problem. He should not be relegated, as a certified patient, to a mental hospital but dealt with, as recommended by the Ministry of Health in a recent circular (Ministry of Health, 1950), in accommodation specially provided for this type of patient. The basis is for the patient to be investigated in a short-stay psychiatric unit in a geriatric department. For many the subsequent destination will be a long-stay annexe. Some of these may be detached buildings in existing mental hospitals but with a distinctive name and a separate entrance. They would no longer be a part of the mental hospital proper, and procedure under the Lunacy and Mental Treatment Acts would be unnecessary.

Special Hospitals

The needs of special hospitals are apt to be overlooked in the more spectacular and in many ways more satisfying work of the acute general hospitals. Mental hospitals and institutions for the mentally defective form the largest number. Though these hospitals and institutions, because of their size, the need for extensive grounds, and the statutory requirements for safeguarding the liberty of the subject, must be separated physically from other hospitals and must be, for all purposes, under medical control, yet the isolation of their staffs from the stream of current medical thought, which was common a generation ago, must be removed. A satisfactory feature of the new scheme is that it brings mental and general hospitals, and their staffs, more closely together. The increasing extent to which the staffs of mental hospitals act as consulting psychiatrists to the in-patients of general hospitals and take psychiatric clinics there and, in return, the consulting staff of the linked hospital or hospitals visit the mental hospital to advise on special cases of physical ailments, is a welcome development.

The objective should be for the same team of psychiatrists to be responsible in the linked hospitals for (1) con-

sultative work in the general hospitals, including psychiatric clinics; (2) mental observation ward work; and (3) work in the mental hospital itself.

There is little to be said about institutions for the mentally defective. It is open to argument whether there should be classification by institutions or within institutions. In the very large service with which I was formerly associated it was found to be advisable to have separate institutions for the higher-grade defective, but this is not possible everywhere. As a result of the deplorable lack of institutional accommodation many defective children have to wait long periods for a bed, with devastating consequences on the other members of the family. Mental illness is a great burden on the community, and little progress has been made in devising means for preventing mental ill-health, dealing satisfactorily with the incipient case, or preventing relapse. When sound methods are found, their application will no doubt involve close co-operation with the local health authorities.

There are many sanatoria and hospitals for the tuberculous. Though the death rate from tuberculosis is happily now declining, these special institutions are likely to remain in use for many years as more and earlier cases are being discovered. There is also an increase in the length of treatment required for the established case. There is no doubt that, when the glad day comes that all the beds available are no longer needed for the tuberculous, good use will be made of the accommodation. It is important that each physician in charge of a chest clinic should have beds at his own disposal and not simply be an out-patients physician. These beds should be in local, or district hospitals.

The incidence of the acute infectious diseases has fallen spectacularly in recent years. We cannot, however, be certain that this will continue. The virulence of the streptococcus, which was low in the days of Sydenham, high at the end of the last century and the beginning of this, and low again now, may be enhanced, and, though modern therapeutics are now available, more beds may some day be needed for scarlet fever. Many more beds are required now for acute poliomyelitis than was the case before 1947, and no one knows what new communicable diseases may appear. But, at least for the moment, the beds in the large fever hospitals cannot be filled. The small independent fever hospital cannot be justified as a separate entity. The present trend is to use large fever hospitals for other purposes but to retain a small section in single-bedded cubicle wards for such acute communicable diseases as arise. If well managed, there is, with one exception, no reason to fear the spread of infection to other wards. The exception is smallpox, for which special provision is essential. The earmarked accommodation must always be ready to be opened and a well-vaccinated staff be on call.

With increased facilities for air-borne travel, Oriental smallpox of a virulent type is an ever-present menace. The greatest danger is the patient with the disease highly modified by previous vaccination and with an immunity which is just fading. It is not creditable to the hospital service that within the last three years eleven members of hospital staffs have died of smallpox (Glasgow, 1950; Parker, 1952). That such unfortunate events can be prevented is shown by the experience of the Metropolitan Asylums Board and the London County Council, which dealt with thousands in cases of this disease, sometimes in epidemics, sometimes in sporadic cases, without any of the hospital staff ever being infected. But disaster is averted only by constant vigilance.

A Statutory Duty

Looking at the infectious diseases problem as a whole, there is a statutory duty to notify such cases to the medical officer of health, and he must take such steps as are practicable to control the spread of these diseases. Clearly he cannot act without knowledge of the cases, and it is highly unsatisfactory that, in a sufficient number of cases to be alarming, individual hospitals fail to bring in the local medical officer of health when there is infectious disease

among patients or staff (Ministry of Health, 1953). As recommended by the Central Health Services Council and the Ministry of Health, the local medical officer of health should be a standing member of the committee, which every hospital is asked to set up, on cross-infection. Not only will this be of great value to the hospitals but it will ensure, by collaboration with the hospital staff, that his own knowledge of infectious conditions is kept up to date. This is specially important now that so many medical officers of health who were in charge of fever hospitals have been displaced.

Other special hospitals do not present the same problems of relationship to the other branches of the National Health Service, but there is the question of their relationship to the hospital service as a whole. In hospital centres, with many general hospitals, there is a place for the large special hospital—for example, for children, neurology, urology, eye diseases, ear, nose, and throat diseases, skin diseases, etc.—to which the specialists concerned from the units of the general hospitals are also attached. Such a hospital can be a centre for the training of specialists and a spearhead for research; apart from that, it is probably better not to have small special hospitals, but to have adequately staffed and equipped departments in the general hospitals, where all the laboratory and other resources are available and where consultants in all other specialties are to be found. If we could start *de novo* the ideal would be to have a large general teaching hospital with the various special hospitals grouped around it and with the "hotel-keeping" and business side under the same general administration.

Maternity

The provision of maternity beds presents a special problem. As explained previously, all three branches of the National Health Service are intimately concerned in maternity work. The trend is for women to prefer institutional to domiciliary confinement, and in one American city it is reported that 99% of the confinements occur in hospital and the other 1% in taxicabs. But in this country we are far from the stage when a bed in a maternity unit is available for every woman who would like to have her confinement there. If such beds were there, and used, the practice of the domiciliary midwife would disappear, and unless general practitioners were given access to a much higher proportion of maternity beds than at present there would be little midwifery for him to do.

A solution might be to reserve the beds in units or hospitals, staffed by specialists, for the abnormal case and for those normal cases required for the training of medical undergraduates and pupil midwives, and to deal with the other normal cases either at home where the domestic circumstances are suitable or in hospitals or homes where women could be attended by general-practitioner obstetricians or general practitioners of their choice. There would still be a place for the municipal clinic for intermediate antenatal supervision and for group instruction, including antenatal exercises.

The Clinic Doctor.—Speaking of clinics, the hospitals, so long as whole-time local health authority medical officers continue to take clinics, should make provision for antenatal clinic doctors to take some part in the work of the hospital so that their knowledge will be kept up to date. Similarly, the doctors who take infant welfare centres and work in the school health service should exchange duties with hospital staff to their mutual benefit. In several London hospitals, senior registrars from paediatric departments take infant welfare clinics while the clinic doctor attends at the hospital to do his work. Thus there is a real marriage of preventive and curative work.

Children's Long-stay Units

Another instance of the need for co-operation of the hospital service with other authorities occurs in the case of children whose stay in hospital is likely to be prolonged.

It is a great misfortune for a child to have a serious illness, but it is doubly unfortunate if, as a result of a long stay in a hospital, he is further handicapped by loss of education. It is therefore most important that arrangements be made with the appropriate education authority for teachers to be provided for all children whose convalescence, or even treatment, is likely to be prolonged. A similar problem exists in the adolescent or young adult who is preparing for an examination. Correspondence courses can often be arranged. For others, diversional or occupational therapy is increasingly supplied and should be encouraged.

Pathology and Radiology

There is little to be said about pathological and radiological aids to diagnosis. It is, however, interesting to recall that these were the great lacks when the L.C.C. took over the municipal hospitals in 1930; and I understand that the same was noticed when hospitals throughout the country, and in the small voluntary as well as the municipal, were used during the war as part of the Emergency Hospital Service.

For the smaller hospitals it is probably better to cover their laboratory needs by including them in a group with a group pathologist in charge and having on his staff experts in the subgroups—morbid anatomy and histology, haematology, bacteriology, and biochemistry—rather than expecting one man to cope with all the requirements. But the importance of close association between the clinician and the pathologist cannot be overstressed. If staff and money were available there should be an all-rounder primarily responsible for each small hospital with experts from a group or reference laboratory available.

Radiodiagnosis is not yet so highly departmentalized as pathology now that radiotherapy has separated from radiodiagnosis. The question has arisen whether or not radiodiagnosis should be provided in health centres for group practice, and general agreement has been reached that, provided there is a hospital with good radiodiagnostic facilities reasonably near, there is no need to provide it actually in the health centre.

These two departments, laboratory and x-ray, concern intimately another branch of the National Health Service—namely, the general-practitioner service. They are essential to his work. An increasing number of hospitals now allow direct access of general practitioners to these departments without requiring their patients to attend the out-patient department and be examined by one of their consulting staff. The fears that the departments would be flooded out and unnecessary examinations called for have in most cases proved to be unfounded.

Special Units

In a national hospital service, as distinct from a number of independent hospitals, special units are needed. Examples are plastic surgery, neurosurgery, thoracic (including cardiac) surgery, and radiotherapy. Here, again, it is necessary to break down isolationism and induce the staffs of the hospitals in the "gathering ground" to send their patients. This is often a slow educative process and can be done best by demonstrations at the special units and by staff visits to the outlying hospitals.

A Hospital Service

And this, perhaps, is the place to emphasize what I regard as my main theme in these lectures, which is that we are now supposed to have a hospital service. It has collective responsibility for providing a casualty service, an out-patient service, and an in-patient service for all who need them. As a unit in that service each hospital has a responsibility to all who apply to it, provided that, apart from emergencies and casualties, they are sent by their general practitioners. It is not compatible with that responsibility to decline a patient and to take no further interest in him. If, for any good reason, a hospital is unable to provide for his particu-

lar needs, it should be regarded as a duty of the hospital to which he applies or more generally to which his doctor applies on his behalf, and which represents to the applicant the National Hospital Service as a whole, to take trouble to ensure that his needs are met within the hospital service of which they are a part, and not to leave it to "somebody else"—the general practitioner, the patient himself, the M.O.H., or the Emergency Bed Service—to find a place where his needs can be met. *Per contra*, local patriotism and the belief that one's own hospital is the best in the country are grand things, but they should not run, as they have been known to do, to the extent of declining to send a patient, however "interesting" and however much he would like to stay, to another hospital where there is a special unit for such cases. This is another aspect of the "service" conception.

Then there is the relationship of the hospital service as a whole and of its individual units to the other two branches of the Service. From what has been said before, I hope that it will be agreed that there would be many advantages if all three branches were under the same administration and if the areas and populations covered by all three were the same, but there is no immediate prospect of this. Moreover, it would involve two-tier administration and control: one covering the whole area for large-scale planning and probably for financial control, and the others with suitable readily accessible local headquarters for day-by-day administration. As the day for this is in my opinion far distant, it is a challenge to those working in the Service to try to overcome the weaknesses inherent in the present administrative structure.

The committee of the Central Health Services Council, already referred to, struggled for months with this problem of the proper integration of the three components of the Service, but had to be content with general advice about the formation at local level of committees representative of the three branches. A primary duty of any administration is to consider, like the doctor prescribing a new and potent drug, the side-effects of any action about to be taken. This Service is new and potent, and many of its side-effects were not realized at the time the dose was prescribed. There are, in fact, few hospital activities which do not affect at least one of the other two branches: often they repercuss on both. Obvious examples are the opening of maternity beds or the provision of a geriatric unit, of a convalescent home or a child-guidance clinic or more beds for the mentally defective. So the first essential is free trade in information and the giving of advance information to others likely to be concerned before definitive action is taken. And this applies not only to the hospital side but to the other two as well. Formal meetings are, however, not essential for this type of co-operation. It can be done quite well on the telephone, between the three or four people concerned, and they, in turn, can consult with those in their own administration who ought to be told and would have useful advice to give. In only a small proportion of the matters under consideration will a formal meeting and discussion be needed.

One handicap to this method of ensuring smooth working is the size of the areas covered by the regional boards and, in consequence, the large number of local authorities and executive councils covered, wholly or partly, by most of them. At hospital management committee level the difficulties are not so great except in the cases of hospitals and sanatoria taking patients from a large number of separate health authorities, but even there they could be overcome.

Research

Before I close there are three other matters I would like to mention. The first is research. When I had responsibility for a hospital service I attached great importance to this, and appointed two committees—one on the general hospital and the other on the mental hospital side but with cross-representation—to encourage research in every possible way, to give advice to those who sought it, and to provide

statistical help and equipment. The members were appointed by their colleagues, and among other things were able to collate the experience of different hospitals and compare the results of different methods of treatment of the same condition. It is to be hoped that, as time goes on, a similar type of organization will develop in the present hospital system. Now that the public purse has assumed responsibility for medical treatment, the State and everyone who contributes to its upkeep has an interest in reducing the size of the bill. This means that more and more attention must be given to the reasons why people need hospital treatment. This necessitates a real interest in the matter and the making of observations which can be pieced together.

Cholera was looked upon as an "act of God," and would probably have remained as such until the germ theory was enunciated but for the famous observations Dr. John Snow made a hundred years ago. His implication of the Golden Square pump and his deduction that cholera was spread by drinking contaminated water was the direct result of careful observation, and saved thousands of lives. The keeping and collation of adequate records is essential if isolated "observations" are to bear fruit. Also, it is important to know which diseases make the greatest calls on hospital services. It will be found in the case of many such diseases that we do not know, within present knowledge, how to reduce their incidence or even to catch the patients in the early stages of the disease, when, presumably, the prospect of shorter and more successful treatment is better.

Investigations of community health in different localities in the hope that the differences will point to the aetiological factors involved is possible in a national health service, and the opportunity should not be neglected. It involves close co-operation between clinicians, statisticians, and public health workers.

Rehabilitation and Convalescence

The two remaining points have much in common. They are the importance of rehabilitation and aftercare and of medico-social work.

The days are gone when a hospital ceased its interest in a patient when he was discharged and when the physician or surgeon who sought information about the health of his patients two or three years after discharge and published it was regarded as unusually enterprising. As mentioned earlier, the State is not concerned primarily with hospitals in their humanitarian aspects but because they are the machinery by which members of the State can be restored to working capacity and so reduce the cost to the State of supporting them in hospital or at home as non-working members of the community.

Rehabilitation or reablement schemes are therefore being developed, and training in new employments when this is needed. Here, also, is yet another illustration of the need for a hospital to co-ordinate its work with that of another body—in this case the Ministry of Labour.

The question of convalescent homes and of recuperative holidays needs to be re-examined. At present, convalescent homes, of which there are not enough, are the responsibility of the regional hospital boards and no charge is made to the patient. Recuperative holidays are provided by the local health authorities, who are required by law to make a charge. In practice, there is little difference in the clinical condition of those recommended. If the doctor, either hospital or general practitioner, thinks that a convalescent case will be admitted earlier through the local authority, he will be admitted earlier through the local authority, he recommends a "recuperative holiday" unless active medical supervision and nursing care are essential. This artificial distinction should be eliminated and either hospitals or local authorities be charged with the duty of providing for both categories. A definite link, preferably under the same management, should be forged between specific hospitals and specific convalescent homes so that there may be close contact between the two staffs. Further, it should be made easier for general practitioners to get their patients away for convalescence.

Medico-Social Work

Lastly, there is the important question of medico-social work. Hospital almoners, as already mentioned, do excellent work. There is also a wide range of medico-social work done by health visitors and almoners of the local health authorities. By statute, local authorities are responsible for the provision of "aftercare" and for home nursing, and have the power, which most authorities exercise, to provide a home-help service. Through their various powers and duties, particularly in the maternity and child welfare and school health services, the local authorities possess a great store of information about economic and domestic conditions which can be placed freely and gladly at the disposal of hospital almoners. When hospital staffs and general practitioners really know the nature of the assistance which can be given by health visitors they find it invaluable and use it increasingly. The almoning and health-visiting staffs are complementary to each other, and great good can result from their acting as a team.

Summary

It is impossible to divide medicine into two compartments, preventive and curative. The interlocking is far too great.

The hospital is an essential part of a national health service, not only for the diagnosis, cure, and relief of illness, but for the prevention of illness. But the hospital is not the centre of gravity of the service any more than the general-practitioner service or the public health service is the centre of gravity.

The other two branches are equally essential, and any of the three will make a more effective contribution to the health of the nation if they work together as closely as possible, centrally, regionally, and locally; avoid any tendency to competition, rivalry, or isolationism; and listen sympathetically to suggestions, requests, or even criticisms which come from workers in the other branches.

There is only one National Health Service, not three independent components of it. It should, as a service, be founded on the basic need of preventing ill-health and reducing the number of people for whom in-patient care is essential. The ideal would be to administer the Service through one, and only one, local body, nominated or elected or a mixture of both, but the difficulties appear to be insuperable without a change in the boundaries of local government.

The individual hospitals must remember that they are part of a national hospital service with a collective responsibility for the institutional care of the sick.

The acute general hospitals are only part of the hospital service. The various special hospitals, including the mental hospitals, far outnumber in beds the acute general hospitals. The special hospitals perform functions which are absolutely essential to the welfare of the community and must receive their due share of money, staff, and prestige. The provision of hospital beds where general practitioners can attend their own patients must not be neglected.

Hospitals are primarily for the diagnosis and treatment of the sick, and for many illnesses they only can provide the necessary service. Their rising costs are a matter of grave concern. It is more important than ever before to ensure that they are used to the best advantage, that they play their part in the preventive services, and supply the "needs" of the other two branches of the Service.

The out-patient consultative departments, or polyclinics as they may be called, will probably play an increasing part in the development of the Health Service.

The hospitals, particularly those with attached medical schools and research institutions, are the spearheads of research, but a plea is made for associating with certain types of research the local medical officer of health, who is anxious to know the amount and nature of the sickness among the community which he serves. By observing "associations," as did Dr. John Snow, the causes, now unknown to us, of many diseases may be revealed.

Hospitals are the training-grounds for doctors, nurses, and medical auxiliaries. Though the training of doctors is a responsibility of the universities, and not of the National Health Service, the training given in hospitals should emphasize, by the work going on there, the interdependence of the three branches of the Service and how they work together.

I am most grateful to the College for giving me this opportunity of expressing my views on a subject which I regard as of paramount importance to the future of the National Health Service, a service which, if it does what is expected of it, will make a substantial contribution to the happiness and prosperity of the nation. I am grateful, also, to my listeners for giving me so much of their time; and to the many, too numerous to mention individually, who have helped me with advice and suggestions. I must, however, specially thank Mr. C. C. Barnard, Librarian of the London School of Hygiene, for invaluable help in looking out references.

RELATIONSHIP OF ALIMENTARY
LIPAEMIA TO BLOOD
COAGULABILITY

BY

H. W. FULLERTON, M.D., F.R.C.P.

W. J. A. DAVIE, M.B., Ch.B.

AND

G. ANASTASOPOULOS, M.D.

(From the Department of Medicine, University of Aberdeen)

It has been clearly shown that a factor of lipid nature is essential for the normal process of blood coagulation, although its precise character has not been finally determined (Macfarlane *et al.*, 1941). This finding led us to undertake experiments designed to discover whether the coagulability of blood is altered during the lipaemia which follows the ingestion of fat. The work is conveniently divided into two parts: (1) the influence of alimentary lipaemia on prothrombin times ("accelerated clotting times"); and (2) the effect of such lipaemia on the coagulability of blood estimated in silicone-coated tubes.

1. Influence on Accelerated Clotting Time

The technique adopted was the usual one-stage method of determining the prothrombin time (Fullerton, 1940). For a reason which is referred to later, Russell-viper venom ("stypven") was used as the thromboplastin in the test. The observations may be divided into three groups.

(a) In a group of eight patients taking the ordinary ward diet, blood was removed at intervals after meals and the accelerated clotting times were determined. The fat content of these meals varied from 12 to 30 g. The accelerated clotting times showed no significant variation throughout the day.

(b) A group of five patients were given a breakfast containing 65 g. of fat (bacon, eggs, bread, and butter). The results are shown in Table I. It is seen that in each case a significantly shorter time was found at the height of the lipaemia, with an average reduction of 4.9 seconds.

TABLE I.—Accelerated Clotting Times after Fat Intake of 65 g.

Case	Fasting* (Seconds)	Time† (Hours)	Shortest Reading‡ (Seconds)	Differences (Seconds)
1	22.5	3	15.4	7.1
2	23.7	3½	19.7	4.0
3	23.0	2½	19.8	3.2
4	25.1	3	20.2	4.9
5	25.8	3	20.6	5.2
Means	24.0		19.1	4.9

TABLE II.—Accelerated Clotting Times After Fat Intake of 85 g.

Case	Fasting* (Seconds)	Time† (Hours)	Shortest Reading‡ (Seconds)	Differences§ (Seconds)
1	24.5	5	10.9	13.6
2	22.3	4½	13.4	8.9
3	23.0	3	12.8	10.2
4	24.3	2½	17.5	6.8
5	22.3	3½	14.8	7.5
6	24.7	3½	13.1	11.6
Means	23.5		13.7	9.8

* Accelerated clotting times with the patients fasting.
† Time interval at which the shortest accelerated clotting time was reached during the lipaemia.
‡ Actual reading obtained.
§ Differences between the fasting and the shortest times.

(c) In a group of six patients similar observations were made following a meal containing 85 g. of fat (two eggs, 2½ oz. (70 g.) of bacon, 1 to 1½ oz. (28 to 42 g.) of butter, bread, tea with milk and sugar). The results are shown in Table II. Again in each case a marked reduction in the accelerated clotting time is evident during the lipaemia, and its degree is much greater than with a fat intake of 65 g. The effect is probably due to an increase in the essential lipid factor during lipaemia. The other forms of thromboplastin ordinarily used in the accelerated clotting test—for example, acetone-dried extracts of rabbit brain (Quick, 1938) and viper venom plus ovolecithin (Witts and Hobson, 1940)—do not reveal this reduction during alimentary lipaemia. Presumably this is because these thromboplastins contain large amounts of lipid, so that alterations in the plasma content of lipid are obscured (Fullerton and Anastasopoulos, 1949).

It was realized that the findings set out in Tables I and II could not be interpreted as indicating that a real increase in coagulability occurs during lipaemia. The inference that naturally occurring thromboplastin is influenced by lipaemia in a manner similar to viper venom is not justified. Accordingly, similar experiments were performed using the clotting time in silicone-treated tubes as a measure of the coagulability of blood.

2. Influence on Clotting Time Measured in Silicone-coated Tubes

Method

"Teddol," a silicone-like material, was used. It reacts vigorously with water, yielding hydrochloric acid with heat evolution and a solid silicone formed by the intercondensation of the resulting hydrolysis product. Tubes measuring 3 by ½ in. (7.5 by 1 cm.) were filled with "teddol," and after ten minutes the solution was poured off and the tubes were inverted and allowed to drain for two minutes. They were then washed thoroughly in five changes of distilled water and were dried at room temperature. In estimating the clotting time with these tubes a needle, without a syringe, was inserted into a vein at the elbow and the first few millilitres of blood was run into a tube containing oxalate solution. This sample was later centrifuged, and the degree of lipaemia was estimated macroscopically. The first sample presumably contained any thromboplastin resulting from the trauma of the venepuncture. Then approximately 2 ml. was run into each of two teddol-coated tubes, and immediately these tubes were placed in a water-bath at 37° C.

Each tube was examined by tilting every five minutes, and the end-point taken was the time at which the tube could be inverted without flow of the blood. The object of using two tubes was to assess possible variations due to different degrees of silicone coating. Occasionally, if clotting appeared to be almost but not quite complete at any reading, another examination was made before the next interval of five minutes had elapsed. It may be pointed out here that the difference in the readings given by the two tubes did not exceed five minutes in any case.

Results

(a) With this technique the changes in the clotting time of whole blood were observed during the phase of lipaemia following the ingestion of a meal rich in fat (80-85 g.) composed of bacon, eggs, bread, and butter. Table III shows the preliminary results in four normal subjects. It is seen

TABLE III

Case	Fasting	3 Hours	Difference
1	mins. 25, 25	mins. 15, 15	mins. 10
2	30, 30	15, 20	13
3	30, 30	10, 15	18
4	25, 25	15, 20	8

that in each case the clotting time three hours after the meal was considerably shorter than the fasting time. Macroscopic lipaemia was present at three hours in each case.

(b) The experiment was then expanded to include readings at 3, 3½, and 4 hours after the meal in 11 subjects. The results are presented in Table IV. It is seen that in Cases 1-9 much shorter clotting times occurred following the high-fat meal. The maximal reduction varies from five to fifteen minutes and averages ten minutes. In Cases 1-9 macroscopic lipaemia was present following the meal. In Cases 10 and 11 a significant reduction in clotting time did not occur; in neither of these cases was macroscopic lipaemia observed at 3, 3½, and 4 hours after the meal.

9	20, 20	10, 15	10, 10	10, 15	10

(c) As a control, observations were made in nine patients before and after the ordinary ward breakfast (fat content 12-30 g.). The results (Table V) show that, with the possible exception of Case 4, a significant reduction occurred in only one case (No. 9). In Cases 1-8 no macroscopic lipaemia was observed at 3, 3½, and 4 hours after the meal; in Case 9 macroscopic lipaemia was present at these times and was absent in the fasting sample.

Comment.—The results in Tables III, IV, and V show that the coagulability of blood as measured by this technique increases markedly after a high-fat intake if this produces macroscopic lipaemia. Conversely, meals low in fat have no influence on the clotting time unless macroscopic lipaemia develops. These results would seem to have greater significance than those given in section 1, since they demonstrate that clotting induced by naturally occurring thromboplastin is accelerated by lipaemia. Whether this effect is due to an increase of the essential lipid factor or to an alteration in the physical state of the plasma dependent upon its high content of chylomicrons during lipaemia has not been determined, and in any event the distinction does not influence the significance of the findings. We have discovered only one reference to observations similar to those described above. Duncan and Waldron (1949), using collodion-lined tubes, demonstrated a shortening of the clotting time in dogs and in humans, after the ingestion of cream. The implications of the results were not discussed.

Discussion

Lipaemia and Thrombosis

The results of these experiments seem striking enough to justify speculation regarding the pathogenesis of thrombosis, both arterial and venous.

Lipaemia is common in diabetes mellitus (Bloor, 1921; Joslin, 1927), pregnancy (Boyd, 1934), leukaemia (Pernokis

and Freeland, 1941), and after ether anaesthesia (Boyd, 1936) and acute blood loss (Boyd, 1934; Horiuchi, 1920). In all these circumstances thrombosis is frequent, although, of course, additional factors must be borne in mind; for example, the arterial degeneration in diabetes, venous stasis produced by the gravid uterus in pregnancy, the increased viscosity of blood in leukaemia, and immobilization after anaesthesia and blood loss. Nevertheless it seems possible, in view of the results described above, that the increased coagulability produced by lipaemia may be a factor responsible for the frequency of thrombosis in the conditions mentioned. It is known that coronary thrombosis not infrequently follows ingestion of a large meal (Master *et al.*, 1940; Smith *et al.*, 1942; Boas, 1942). It is impossible, however, on the evidence available, to determine whether this association is due to the decrease in coronary blood flow accompanying gastric distension (Gilbert *et al.*, 1940) or to the increased coagulability of blood which we have shown follows the ingestion of meals rich in fat.

Perhaps stronger evidence in favour of our thesis is given by the numerous observations which relate thrombosis to the dietary intake of fat. For example, Dock (1946) has noted that diets rich in eggs, cream, and butter are particularly common in men who are neither diabetic nor hypertensive, but who develop myocardial infarction. Malmros (1949) also considers that excessive consumption of eggs, butter, and other foods rich in fat may be the cause of the large numbers of cases of myocardial infarction now being observed. He points out that in Denmark the consumption of fat has been high for a long time and did not decrease in the second world war, whereas in Norway the consumption of fat and eggs was very low during the war. He thinks that this may explain why there was a fall in the incidence of myocardial infarction in Norway but not in Denmark during that period. Closs and Dedichen (1949) showed a similar fluctuation in the incidence of thrombo-embolic disease in general during the war in Norway.

Lipaemia and Atherosclerosis

Although the pathogenesis of atherosclerosis remains obscure despite intensive investigations for many years, some recent work has tended to discount the view of Virchow that the essential lesion is a primary degeneration in the arterial wall and has lent support to the earlier work of Rokitsky. This point of view has been emphasized in recent years by Duguid (1949, 1952), who holds that the lesion in atherosclerosis does not arise initially within the arterial wall but follows the incorporation into the vessel wall of fibrin deposits which are covered by vascular endothelium and later show hyaline and fatty change. If this conception be correct then it follows that any factor which leads to intravascular fibrin formation may be of importance in the pathogenesis of atherosclerosis. The results of our experimental work have led us to consider whether alimentary lipaemia may be a factor of importance in this process.

A large volume of work indicates that the level of the serum cholesterol probably bears some significant relationship to the development of atherosclerosis (Boas *et al.*, 1948; Gubner and Ungerleider, 1949; Duff and McMillan, 1951; Gould, 1951; Keys, 1951a, 1951b; and Katz, 1952). Numerous investigations on these lines have been carried out since Anitschkow (1933) showed that arterial lesions similar to atheroma followed cholesterol feeding in rabbits. As Keys *et al.* (1952) have pointed out, this finding cannot be applied directly to the problem of atherosclerosis in humans, since the amount of cholesterol needed to produce the lesions in rabbits is fantastically high in comparison with the cholesterol content of the diet in man. He concludes that "from the animal experiments alone the most reasonable conclusion would be that the cholesterol content of human diets is unimportant in human atherosclerosis." In any event, it is now clear that in man there is no relationship between the serum cholesterol level and the habitual dietary intake of cholesterol (Keys, 1949; Keys *et al.*, 1950;

and Gertler *et al.*, 1950) but marked changes in the cholesterol level occur when the intake of fat is altered (Keys *et al.*, 1950; Hildreth *et al.*, 1951; and Keys, 1952). It is thus apparent that the large amount of evidence which links high serum cholesterol levels with the development of atherosclerosis may simply mean that a high-fat intake is related to atherosclerosis, and it is our suggestion that the high-fat intake acts by inducing increased coagulability of blood during phases of lipaemia.

Any theory of the pathogenesis of thrombosis and atherosclerosis must account for the notable variation in the age of onset and also for the tendency for the lesions to increase with age. Therefore it would be necessary, if our theory is to withstand criticism, to adduce evidence that the degree of lipaemia following ingestion of fat shows considerable individual variation and that in general it tends to be greater in the elderly than in the young. It is not difficult to find experimental work which supports both these suggestions (Neches *et al.*, 1949; Morrison *et al.*, 1949; and Moreton, 1950). In our own studies we have noted great variation from case to case in the macroscopic degree of lipaemia following the standard high-fat breakfast, and Morrison and his co-workers (1949) devised a fat-tolerance test which showed that the rise in the serum lipid constituents following a high-fat meal varied within wide limits and was particularly high in 25 patients with recent coronary thrombosis. Neches *et al.* (1949), by a study of the chylomicron counts after the ingestion of fat, found that this measure of lipaemia was altered much more in elderly individuals than in the young.

We suggest, therefore, that the pathogenesis of atherosclerosis may not be so obscure as it has appeared in the past. The conception that lipaemia, by leading to increased coagulability, produces fibrin deposits which are incorporated into the arterial wall accords well with our experimental findings and with a large amount of circumstantial evidence relating atherosclerosis to fat intake and serum cholesterol levels. It does not of course explain the apparent increase of atherosclerosis in the coronary arterial tree, but it is important not to let this particular aspect overshadow the general problem. We know of no convincing evidence that the overall incidence of atherosclerosis is increasing to a greater extent than can be accounted for by the general increase in longevity; the cause of its frequent and early localization in the coronary arteries may well be a problem separate from that of atherosclerosis in general.

It should be pointed out that our findings suggest that it is the occasional high intake of fat that is likely to be important rather than the average daily intake, since we found that the normal ward breakfast was followed by an increase in coagulability in only one case. If further work supports the theory set out above, studies of fat tolerance will become of increasing importance. In this way it might be possible to use the information thus obtained to determine which individuals are likely to develop atherosclerosis if a high dietary intake of fat is continued.

Summary

Alimentary lipaemia increases the coagulability of blood as measured by the "accelerated clotting time" and the clotting time in silicone-coated tubes.

The possible relationship of this finding to the pathogenesis of thrombosis and atherosclerosis is discussed.

ASSOCIATION BETWEEN PERIOD OF GESTATION AND LENGTH OF MENSTRUAL CYCLE

BY

THOMAS McKEOWN, M.D., Ph.D., M.R.C.P.

J. R. GIBSON, Ph.D., M.B., D.P.H.

AND

T. DOUGRAY, M.B., M.R.C.O.G.

(From the Department of Social Medicine, University of Birmingham, and St. Chad's Hospital, Birmingham)

It has often been stated that the period of gestation may be a multiple of the length of the menstrual cycle. This possibility is suggested by evidence, in experimental animals and in man, of cyclic activity in the ovary during pregnancy, and by a supposed association between the length of the cycle and the duration of pregnancy. The association can by no means be said to be established in man, the lack of good data being due largely to the difficulty of establishing the length of the menstrual cycle. In the course of an inquiry in which pregnant women were investigated from the first antenatal attendance until two years after the birth of the

child, we have recorded both the period of amenorrhoea and the length of the cycle for 1,227 mothers of single births, and the data are here used in an examination of the association between the two variables.

(a) *Period of Gestation*.—Our only indication of the period of gestation is the duration of amenorrhoea. The date of onset of the last menstrual period was recorded at the first antenatal attendance,* and the date of birth was extracted from the records of notification of birth submitted to the public health department.

(b) *Length of Menstrual Cycle*.—Either on leaving hospital or at the first home visit of a health visitor, mothers were given a calendar on which they were asked to cross off each day of bleeding during the year after the birth of the child. This calendar was printed on a child's record card, on which were entered other items of more interest to the mother (such as the weight of the child). Mothers were subsequently interviewed at a welfare centre or at home within two weeks of each quarter during the year following birth, at which time the record card was inspected and the menstrual history copied on to another document. These documents provided the data used in the analysis which follows.

As a means of excluding some pregnancies of abnormal length, the examination is restricted to the 1,227 mothers of single births whose children survived to the end of the first year. (For example, this device excludes several pregnancies whose duration is influenced by the presence of a malformed foetus.) For 362 of the 1,227 mothers the data were considered incomplete, either because the period of amenorrhoea was not reliable or because fewer than three menstrual cycles were recorded in the year after birth.

Of the 865 cases in which the data were thought to be complete enough, 149 were excluded because the menstrual history was irregular. It is not possible to give any precise indication of what constituted an irregular history, except to say that two observers inspected the data independently, and with few exceptions decided upon exclusion of the same cases.

Table I shows the association between the length of the cycle and the period of amenorrhoea for the 716 women who had at least three regular cycles, and for whom the period of amenorrhoea was recorded unequivocally. The shortest mean length of cycle was 23 days (six women) and the longest 45 days (one woman).

The data suggest that the period of amenorrhoea increases slightly with the length of the cycle. The association is, however, somewhat irregular. This irregularity is attributable largely to the fact that the mean length of cycle for each woman has been calculated from all cycles during the year. Inspection of the records indicates that many women whose menstrual cycles are in general quite regular have one or two cycles which are grossly inconsistent with the others, and whose inclusion must make the mean less

TABLE I.—Period of Amenorrhoea Related to Length of Cycle. Length of Cycle is Given as a Crude Mean

Mean Length of Cycle (Days):	23	24	25	26	27	28	29	30	31	32	33	34	35	36	37	38	Over 38	Total

child, we have recorded both the period of amenorrhoea and the length of the cycle for 1,227 mothers of single births, and the data are here used in an examination of the association between the two variables.

Period of Amenorrhoea Related to Length of Cycle

We have attempted to collect fairly extensive data in respect of pregnancies of all mothers domiciled in the County Borough of Smethwick whose children were born

accurate. We have therefore recalculated the mean length of cycle for each of the 716 women, after excluding cycles whose lengths were judged to be inconsistent with the other observations. Table II gives the number of recorded cycles upon which the adjusted means are based: thus for 37 women the mean is based on three cycles, and for 34 on four.

*70% of the mothers were supervised during the antenatal period by one of us (T. D.).

TABLE II.—Number of Cycles upon which Adjusted Mean Length of Cycle is Based

No. of Cycles	No. of Women	No. of Cycles	No. of Women
3	37	8	105
4	34	9	137
5	56	10	129
6	70	11	60
7	88		716

In Table III the adjusted means are used to relate the period of amenorrhoea to the length of the cycle. The chart shows a straight line* fitted to the observations, and the means have also been plotted. The data indicate that the period of amenorrhoea increases by about a day for each additional day on the length of the cycle.

† See text for method of adjustment. ‡ Means have been calculated from the ungrouped data.

Chart showing mean period of amenorrhoea related to mean length of cycle.

*The regression of mean period of amenorrhoea on mean length of cycle was estimated by the method of least squares from the data given in Table III. The equation of the fitted line is $y = 253.39 + 0.95x$.

Before accepting these results we should consider the possible objection that a menstrual history recorded in the year after the birth of a child may not be typical. It is difficult to know what could be regarded as a typical menstrual history of parous women. We have, however, excluded grossly abnormal cycles, as indicated above, and we have satisfied ourselves that the results are not substantially affected by variation associated with birth order or maternal age.

Discussion

The possibility that the period of gestation may be a multiple of the length of the menstrual or oestrous cycle, and that the time of onset of labour coincides with an estimated time of reappearance of the cycle, is suggested by three kinds of evidence.

1. It is well established that all cyclic activity of the ovary does not cease during pregnancy. As a rule this activity consists in ripening of fresh follicles without ovulation, a phenomenon observed in several species by Loeb (1923) and Evans and Swezy (1931). But occasionally overt manifestations of cyclic activity have been noted; for example, by Nelson (1929) in the rat, and by Tinklepaugh (1933) and Elder and Yerkes (1936) in the chimpanzee. Hartman (1932) referred to two reports (by Saint Hilaire and Cuvier, and by Allesch and Fox) of menstrual bleeding throughout pregnancy in women, and Wintz (1925) described two interesting cases of periodic bleeding from the empty horn of a bicornuate uterus.

2. The fact that in a few species the mean duration of gestation is approximately a multiple of the mean length of cycle has been considered significant (Shaw, 1926; Snyder, 1938). In animals such as the rat and mouse the association is scarcely surprising, since the duration of pregnancy (20-21 days) would be a multiple of any cycle of less than six days. But in man the observation that the mean period of amenorrhoea (280 days) is ten times the mean length of the menstrual cycle (28 days) is more suggestive.

3. In man, the length of the cycle and the duration of gestation are said to be correlated. Jolly (1928) recorded histories of five women with regular 24-day cycles whose pregnancies were 265 days, when estimated from the middle day of the last menstruation to birth, and corresponded roughly to 11 cycles. Results on women with longer cycles were inconsistent. More extensive data published by Wahl (1936, 1937) undoubtedly suggest that the duration of gestation increases with the length of the cycle, although the increments are too small to be consistent with the view that the one is a multiple of the other.

In the present communication it is shown that among women with regular cycles the mean duration of amenorrhoea (from onset of menstruation to birth) increases by about a day for each additional day in the mean length of the menstrual cycle. This also suggests that the period of gestation is not a multiple of the length of the cycle. A more plausible explanation of the association between the two variables is as follows.

There is good reason to believe that the length of the post-ovulatory phase is fairly constant, being about 14 days, and that variation in the length of the cycle is due mainly to variation in the pre-ovulatory phase (Zuckerman, 1937; Latz and Reiner, 1942; Corner, Hartman, and Bartelmez, 1945; Rock and Hertig, 1948; and Krohn, 1949). The period of amenorrhoea might therefore be expected to increase by one day for each additional day in the length of the cycle, even if the time between ovulation and birth were constant. In Table IV the period between ovulation and birth has been estimated by subtracting the interval between

TABLE IV.—Period Between Ovulation and Birth Related to Length of Cycle

Mean Length of Cycle (Days)	Period of Amenorrhoea (Days)	Assumed Interval between Onset of Menstruation and Ovulation (Days)	Estimated Period between Ovulation and Birth (Days)
23	274.8	9	265.8
24	274.0	10	264.0

32	281.8	18	263.8
33	281.7	19	262.7
34	285.8	20	265.8
35	285.1	21	264.1

the onset of menstruation and ovulation (assumed to be 14 days for women with 28-day cycles, and adjusted according to length of cycle) from the periods of amenorrhoea recorded in Table III. The estimated periods between ovulation and birth obtained in this way are all reasonably close to the mean of 266 days, based on 716 births.

It is concluded that variation in the period of amenorrhoea according to the length of the menstrual cycle is probably determined by variation in the interval between the onset of menstruation and ovulation. If this is so, the period between ovulation and birth seems to be independent of the length of the cycle.

It is perhaps necessary to stress that the observation that the period of amenorrhoea increases by about a day for each additional day in the length of the cycle is based on mean values derived from a large number of cases. The mean duration of gestation is of course associated with many other variables, and it seems unlikely that its association with the mean length of cycle can be used in individual cases to give an estimate of the expected date of delivery more accurate than the conventional one.

Summary

The association between the period of gestation and the length of the menstrual cycle has been investigated in 1,227 women whose menstrual history was recorded for one year after the birth of a child. The data were considered adequate for 716 women with regular cycles.

It is shown that the period of amenorrhoea (from the onset of menstruation to birth) increases by about a day for each additional day in the length of the cycle.

It is suggested that variation in the period of amenorrhoea according to the length of the menstrual cycle is determined by variation in the interval between the onset of menstruation and ovulation. If this is so, the period between ovulation and birth seems to be independent of the length of the cycle.

We are indebted to Dr. Hugh Paul and to the midwives and health visitors of the Public Health Department, Smethwick, for their assistance in this inquiry. The nursing staff of St. Chad's Hospital assisted in the completion of the antenatal and birth records.

"Anoxia not only stops the machine, but wrecks the machinery."—HALDANE.

A good deal has been written on the subject of hypoxia, and great stress has been laid upon its deleterious effects on certain systems and organs, and on the organism as a whole. All authors stress the importance of avoiding hypoxia and of promptly terminating it should it occur.

Courville (1939) has examined the pathological findings associated with acute hypoxia in nitrous oxide anaesthesia. Although it is more than 10 years old his classification of the pathological findings, based on the severity of the hypoxic episode and the length of survival time, retains as much of its value to-day as it did when it was first published.

Many conditions, both medical and surgical, may be accompanied by hypoxia, but the surgeon encounters it in its most dramatic form—that is, as acute cardiac failure, arrest, or standstill. It is generally recognized that in these cases the immediate concern is to re-establish efficient pulmonary ventilation by artificial respiration combined with oxygen, and to restore the circulation to the vital centres by manual systole. Efficient manual systole must be accomplished within four minutes from the time that heart action has ceased, and more quickly if possible. If chronic hypoxia has preceded the acute episode, then the period within which circulation to the vital centres must be restored may be very much shorter than four minutes. There are many cases on record in which recovery has followed cardiac arrest lasting longer than four minutes, but as the minutes pass the chances of full, and later of partial,

*Published with approval of the Chief Medical Director, Veterans Administration. The statements and conclusions recorded are the result of our own studies and do not necessarily reflect the opinion or policy of the Veterans Administration.

recovery become progressively less. Once the circulation has been restored, the various manœuvres designed to induce spontaneous resumption of cardiac activity may be carried out in a deliberate and somewhat more leisurely way; or else they may not be needed at all, as not infrequently the heart will resume beating under the stimulus of manual systole alone.

Although literature on hypoxia is extensive, there are only scattered and inadequate references to the treatment of the post-hypoxic state. It is generally assumed that irreversible damage to the vital structures, and particularly to the brain and brain stem, occurs at the instant of the hypoxic episode and that treatment is futile on account of the irreversibility of the damage. We believe, and we hope to show in the following discussion, that the passive "wait-and-see" attitude which has hitherto prevailed is not justified, and that active treatment is not only possible but is vitally necessary if we are to save a number of those who in the past would have succumbed. We agree that any destruction of nervous elements at the time of the hypoxic incident is irreversible, but suggest that in many cases such total destruction is only of minor extent and that there are large areas of reversibly damaged tissue which is capable of recovery under suitable management. We believe that much of the fatal hypoxia and extensive cerebral damage occurs in the post-hypoxic period, and can thus be prevented.

The Role of Cerebral Oedema

One of the sequelae of acute hypoxia is the appearance of cerebral oedema. This is only to be expected, as oedema will appear anywhere in the body where oxygen want has interfered with the integrity of the capillary membrane. This oedema interposes a physical barrier between the oxygen-supplying blood capillaries and the cells. In the brain the oedema, affecting as it does a structure enclosed in a rigid bony case, has the further damaging effect of raising intracranial pressure and of thus interfering mechanically with cerebral circulation. Thus the initial hypoxia becomes potentiated, and with it the hypoxic damage mounts, completing a vicious circle of great detriment to the chances of the subject's recovery. It is of little avail at this stage that the original hypoxic episode has been controlled. The vicious cycle will continue even after, say, the heart has been restarted after cardiac arrest and efficient circulation has been re-established. It is necessary to break the vicious cycle—that is, to treat the existing or developing cerebral oedema. We believe that even the pre-terminal hyperpyrexia which is often seen in these cases may in at least some of them be explained on the basis of oedema involving the heat-regulating area. Therefore this sign need not be taken as necessarily pre-terminal, although it often precedes death. We take it to mean only that extensive damage is present which is extending into the hypothalamus.

Dehydration Therapy

With these considerations in mind, we have of late subjected patients who have had an acute hypoxic episode to a regimen of vigorous dehydration. The following case history is presented as an example of the method of treatment, and also because of the extreme severity of the hypoxia, which yet was followed by a quite unexpected return to apparent clinical normality.

A well-nourished man of 43 was to undergo thoracotomy for carcinoma of the left lung. His general condition before operation was good, and apart from his present illness there was no other major disorder. Bronchial obstruction due to the growth made it impossible to collapse the affected lung during operation, and after some manipulations cyanosis began to appear, and continued to increase in intensity. The cyanosis was not relieved by repeated tracheo-bronchial toilet, and only momentary improvement followed whenever a moderate amount of blood and

secretions was aspirated from the dependent lung. The lesion was found to be inoperable and the chest was closed; this was completed two hours and thirty-five minutes after induction. After closure the patient reacted, opened his eyes, but still his colour remained dusky as before. Bronchoscopy was done and much material was aspirated; while this procedure was still in progress cardiac arrest occurred.

The chest was immediately reopened and an asystolic flabby heart was found. Manual systole restored circulation to the extent that a carotid pulse could be felt; soon the heart resumed spontaneous action. An estimated four minutes had elapsed from the time the diagnosis of cardiac arrest had been made to the establishment of manual systole. Oxygen administration through an endotracheal tube had been carried out from the instant the heart had been known to have stopped. After efficient heart action had been observed for some 10 minutes, the chest was closed. The patient was breathing spontaneously and oxygen administration was continued, but he remained in deep coma with widely dilated pupils and all reflexes absent. The colour was improved but by no means satisfactory.

At this stage, half an hour after successful restoration of circulation, 50 ml. of 50% glucose was injected intravenously, and within one minute signs of lightening of the coma were observed, such as roving eyeballs and involuntary incoordinated movements of the extremities. This improvement persisted for a little over half an hour, when coma again deepened without, however, reaching the depth that had obtained prior to the glucose medication. Some four hours later the temperature began to rise rapidly, and the injection of glucose was repeated. This time the patient made attempts at sitting up and even of getting out of bed, but he was still unconscious. Later the coma again deepened, but the level did not reach to where it had been before the second injection. The temperature began to fall and during the night a slow intravenous drip of 1,000 ml. of 25% glucose was given. He remained in light coma during the following day, but regained consciousness on the third post-operative day, and thereafter made an uneventful although slow recovery. He had no residual neurological symptoms and presented no evidence of kidney damage from the hypertonic solution when he was discharged from hospital 10 days later.

This was a case in which total hypoxia of at least four minutes, superimposed as it was upon prolonged severe hypoxia, made it likely that the patient would succumb; yet after vigorous dehydration therapy he recovered with no apparent residual damage. This would indicate that the nervous elements destroyed beyond recovery by the original hypoxia must have been relatively few. It was striking how after each administration of hypertonic glucose the coma markedly lightened and never quite returned to its previous depth, and how by the same measure it was possible to check hyperpyrexia. That the result was not permanent after each administration is not surprising, as we know that oedema recurs after the drug has ceased its dehydrating action. This has been sometimes called "rebound oedema." The improvement observed was not due to the glucose itself, as it has been shown that glucose is ineffective in increasing cortical survival time, at least in rabbits exposed to hypoxia (Noell and Chinn, 1950); nor does it increase resistance to hypoxia in dogs (Snapp, Adler, and Kramer, 1948). The same has incidentally been shown also in rabbits for glutamate, pyruvate, succinate, and fumarate (Noell and Chinn, 1950).

It would appear that concentrated human serum albumin, which has been recommended as a substitute for hypertonic glucose in the control of oedema (Cole, 1951), is also useful in these cases, and it has been employed by one of us in a recent case. Another substance which is worth trying, especially because of its universal availability, is double or quadruple concentrated plasma. This may be obtained by reconstituting dried plasma with half or one-quarter the quantity of water usually employed. On theoretical grounds plasma expanders, such as dextran and polyvinylpyrrolidone would also seem to be indicated, but there is as yet not enough information to allow of their evaluation as dehydration agents. Serum or plasma has proved as effective as hypertonic glucose and may actually be preferable, as the latter, if administered for any length of time, may lead to renal damage. However, this should not be a deterrent to its use in the absence of a more suitable agent, for the con-

dition of the patient is desperate. It may be advantageous to give a diuretic agent at the same time as the hypertonic solutions, in order to maintain kidney function during this critical period. Efficient kidney function is probably a very important factor in the control of the oedema. Recurrence of oedema will be prevented largely by a rigid control of fluid and electrolyte administration, but the effectiveness of such control depends much upon adequate renal function.

Adequate Oxygenation

Oxygen is administered continuously throughout the post-hypoxic period, and a mask or nasopharyngeal catheter is preferred to a tent on account of its greater efficiency. A scrupulously clear air-way is maintained at all times and secretions are often aspirated through an endotracheal tube. A slight head-down tilt of the bed at approximately 7 degrees assists the drainage of secretions without interfering unduly with cardio-respiratory function or causing congestion of the head. There should be no hesitation to perform a tracheotomy in order to ensure an unobstructed air-way or to facilitate the removal of secretions. Tracheotomy is also advisable if coma is prolonged, as it is unwise to keep an endotracheal tube in position for longer than 24 to 36 hours.

While a clear air-way is of the first importance, the adequacy of tidal exchange must not be overlooked. These patients may remain in a state of chronic hypoxia if adequate ventilation is not ensured. If necessary they can be placed in a Drinker respirator or a similar device. We recently observed a case in which post-operative hypoxia occurred when the patient was returned to her bed. Ten hours later she was still unconscious with only leg reflexes remaining; under a regimen of endotracheal tube, Drinker respirator, and concentrated albumin, she revived sufficiently in three hours to respond to instructions. Anaesthetic drugs have no place in the treatment of the post-hypoxic respiratory depression, having been shown in rabbits to be actually harmful (Noell, 1948).

Other Measures

Another problem in these cases which requires mention is that of gastric dilatation. This condition is combated by early passage of a stomach tube; the tube may be left *in situ* to ensure against recurrence of dilatation, and may later be used for feeding purposes if coma is prolonged.

Meanwhile general supportive measures are carried out vigorously. Nutrition of the patient must be ensured, and may be carried out via a stomach tube, as described; intravenous protein hydrolysates are administered if necessary. Vitamins of the B complex and vitamin C are of advantage. Blood is transfused, and in this one must be guided by the actual amount lost. Overtransfusion is very harmful in these cases, but so is any deficiency of the oxygen-carrying elements of the blood. The blood pressure must be maintained, and for this vasopressors are preferred to intravenous fluids over and above the minimum requirements, so as not to interfere with the dehydration regimen. For the same reason electrolytes, particularly sodium, are omitted from such solutions as must be given. It must always be borne in mind, however, that along with the brain the whole body is being dehydrated; this necessitates a careful watch on the patient's electrolyte balance during the period of this therapy. If the blood pressure proves difficult to maintain, vasopressors are administered. Schmidt (1950) has shown that intracranial vessels are relatively insensitive to all drugs that constrict blood vessels elsewhere, and hence any of the innumerable vasopressors available may be employed. We personally prefer noradrenaline in a continuous drip for a period of time, or, failing this, phenylephrine hydrochloride ("neosynephrine").

Antibiotics are administered, and the stir-up regimen is followed—this consisting in turning the patient frequently from one side to the other; and carbon dioxide inhalations for short periods may also be indicated. This not only

improves pulmonary ventilation but also has a potent cerebrovascular dilating effect. The important point to remember is that under no circumstances must these patients be left flat on their back for any length of time. As the coma lightens, they may become very restless. If this occurs the temptation to over-sedate must be resisted, else the central depression and consequently reduced tidal volume will precipitate further hypoxia.

In an attempt to increase cerebral circulation, stellate ganglion block has been recommended and is widely employed, but it is still controversial whether the smaller cerebral vessels possess muscular constricting elements, and no final agreement has been reached on their extrinsic innervation (Schmidt, 1950). However, we are not too much concerned with these small blood vessels, but rather with the larger stems and the named vessels. It may be argued that these too should already be in a state of maximum dilatation; but that they are capable of further dilatation when the stellate ganglion is blocked can be inferred by use of the flicker photometer, and that they actually do dilate under conditions of hypoxia after a stellate block can be observed directly on retinoscopy. In the absence of localizing signs, the ganglion to be blocked is the one opposite to the side of the patient's usual preponderance. If, however, no result is obtained we would not hesitate to carry out a bilateral block despite dangers which have been ascribed to this procedure. We have seen no ill effects from it. Various drugs have also been recommended and tried in order to improve cerebral circulation, but they appear to be of little value.

Conclusion

Our therapeutic resources against the effects of acute hypoxia are few. They must ensure adequate oxygenation of the vital tissues of the body and suppress cerebral oedema with its potentiating effect on the hypoxic damage to the central nervous system. We believe that a dehydration regimen combined with the administration of oxygen, maintenance of an adequate tidal exchange, and general supportive measures afford the best means of achieving these ends. However, even when this line of treatment is adopted, it is still quite impossible to prognosticate on the outcome in individual cases. We have seen patients who immediately after the acute hypoxic episode looked fairly well deteriorate rapidly within a matter of hours, probably owing to rapidly developing and poorly controlled cerebral oedema, while others even after many days of coma regain consciousness without showing residual damage. Hence, we must not abandon hope in even those cases which seem hopeless at the onset; once an acute hypoxic episode has taken place, the patient's chances of recovery depend largely on our acting quickly, thoroughly, and completely.

Summary

A line of treatment is presented to combat the sequelae of acute hypoxia. This is based on the assumption that much of the damage is due to cerebral oedema which supervenes after the acute hypoxia has been relieved. Vigorous dehydration, combined with the administration of oxygen, maintenance of adequate tidal exchange, and general supportive measures are the mainstay of treatment.

We wish to acknowledge with thanks the helpful and constructive suggestions received from Dr. Paul Bucy, professor of neurology and neurological surgery at the University of Illinois.

PYRIMETHAMINE ("DARAPRIM") IN THE TREATMENT OF VIVAX MALARIA

BY

Sir GORDON COVELL, M.D., D.P.H., D.T.M.&H.

P. G. SHUTE, F.R.E.S.

AND

M. MARYON

(From the Malaria Laboratory, Horton Hospital, Epsom)

At a meeting of the Royal Society of Tropical Medicine and Hygiene in July, 1952, it was suggested that pyrimethamine might prove of value in effecting a radical cure of vivax malaria by destroying the late exoerythrocytic forms of the parasite which are presumed to be responsible for relapse. The investigations here recorded were undertaken with the object of testing this theory.

The parasite used was the Madagascar strain of *Plasmodium vivax* which has been maintained at Horton for the routine treatment of neurosyphilis for the past 28 years. A peculiar characteristic of this strain of *P. vivax* is its tendency to give rise to attacks of fever with parasitaemia between the 30th and 40th weeks after mosquito infection. In most cases these attacks represent relapses following a primary attack which has begun 9 to 15 days after infection. In some instances the incidence of the primary attack itself may be delayed until this period.

The subjects of the trial were 12 patients, none of whom had a previous history of malaria. Each of them was subjected to the bites of 10 to 12 mosquitoes from an infected batch of *Anopheles atroparvus* on September 6, 1952. An overt malarial attack developed in each case after an incubation period of 9 to 11 days.

Each patient underwent a course of 50 mg. of pyrimethamine given as a single daily dose over a period of five days (total 250 mg.). Treatment was begun in all cases on the day when parasites were first found in the

peripheral blood. In two cases this was on the day before the first rise of temperature, but in the remainder it was on the first or second day of fever.

Result

In three of the subjects relapses (pyrexia with parasitaemia) occurred 55, 74, and 88 days after the last day of treatment (see Chart). Each relapse was treated, as in the primary attack, with a five-day course of 50 mg. of pyrimethamine daily. The patient who relapsed on the 74th day experienced a second relapse on the 14th day after completing his second five-day course. He was treated for this with a single dose of 50 mg. of pyrimethamine, but relapsed again 22 days later. A fourth subject relapsed on the 99th day. It was thus already clear that treatment of the primary attack with pyrimethamine in full dosage was not an effective method of preventing relapse of this strain of *P. vivax*.

It was now decided to test the effect of a weekly dose of 25 mg. of pyrimethamine given over a period of two months on the incidence of late relapses, which, as noted above, may be expected to occur with this strain of *P. vivax* between the 30th and 40th week after infection. Accordingly, on the 99th day after completion of the first course (the day on which the fourth patient (D) relapsed), the whole group, with the exception of the individual (A) who had already relapsed twice, received a single dose of 25 mg. of pyrimethamine, which was repeated at weekly intervals for the next seven weeks (eight doses in all).

Fifty-nine days after the last weekly dose (32 weeks after the infecting feed) the patient (B) who had relapsed on the 55th day experienced a second relapse. Every other member of the group, without exception, relapsed on one or more occasions between the 32nd and 41st weeks after the infecting feed (see Chart). There was thus no indication that the eight-weeks course of pyrimethamine given from the 17th to the 24th weeks after infection had had any effect on the subsequent relapse rate.

The results afford a striking example of the very high rate of relapse which occurs with this strain of *P. vivax* following early treatment of the primary attack. In patients who are allowed to have a dozen or more peaks of fever with this strain of parasite before the primary attack is terminated (as in the routine treatment of neurosyphilis with malaria therapy) the relapse rate is in the region of 50% only.

Effect of Pyrimethamine on Clinical Attack.—As was to be expected from the experience of other observers, the clinical response to pyrimethamine in the primary attack was slow. Fever persisted for seven days in one case, for six days in three, for five days in five, for four days in two, and for three days in the remaining one. It is clear that pyrimethamine unaided is not a satisfactory drug for the treatment of vivax malaria in a non-immune subject.

Toxicity

One of the patients (F) developed pyrexia on the eighth day after completing the five-day course of 50 mg. of pyrimethamine given for treatment of the primary attack. Fever continued in an irregular fashion for eight days, but no parasites were found at any time in the peripheral blood despite repeated and intensive search of both thick and thin smears. Two days after the onset of fever there was epistaxis over a period of 12 hours. On the following day the red blood cell count was 4,000,000 per c.mm.

LEPROSY: REPORT ON FOUR CASES

BY

JOHN ROGERS, M.B., Ch.B., B.Sc.

AND

DOUGLAS G. ADAMSON, M.D., M.R.C.P.

(From the Departments of Dermatology and Medicine, University of St. Andrews)

Although a temporary increase in the incidence of leprosy in Great Britain was expected following the second world war (Ryrie, 1947), the disease remains relatively uncommon. Compulsory notification was introduced in September, 1951. In England and Wales 48 cases were notified in 1951 and 65 in 1952, but at least 100 of these were existing known cases. In Scotland seven cases had been reported up to the end of 1952.

During the past four years the four cases reported below were encountered in routine hospital practice in one city. It will be seen, however, that not all were due to the aftermath of global war, at least two being attributable to factors peculiar to a jute-manufacturing seaport. Even in this small series the diverse symptomatology and varying clinical types of the disease are well illustrated.

Case 1

The Goanese wife, aged 23, of a British Service man was first seen in May, 1948, with a circinate lesion of the right lower leg of 18 months' duration (Fig. 1). The margin of the lesion was raised and infiltrated, while the central flat area showed marked loss of sensation to light touch and pin-prick. No other skin lesion was present, nor could any thickened nerves be found. Biopsy of the active edge showed a tuberculoid histology; no acid-fast bacilli were demonstrated either here or in a nasal scrape. The lepromin test was positive.

FIG. 1.—Case 1. Circinate lesion of leg before treatment with solapsone.

Twelve patients suffering from primary attacks of mosquito-induced vivax malaria (Madagascar strain) were treated with 50 mg. of pyrimethamine daily for five days. The clinical response to the action of the drug was slow, and for this reason alone we regard it as unsuitable for treatment of the clinical attack in non-immune subjects.

Four of the patients relapsed between the 55th and 99th days after completing the course, one of them on two occasions.

On the 99th day 11 of the group were given a single dose of 25 mg. of pyrimethamine, which was repeated at weekly intervals for the following seven weeks. All of them relapsed on one or more occasions between the 8th and 18th weeks after completing this eight-weeks course.

There is no indication that either of the two courses of pyrimethamine administered in this trial (50 mg. daily for five days during the primary attack and 25 mg. weekly for eight weeks, starting three and a half months later) were of any value in preventing the incidence of relapse, though it is possible that the attacks might have occurred somewhat earlier had the drug not been given.

We wish to express our thanks to Dr. J. H. Watkin, physician-superintendent, and to the staff of Horton Hospital for their co-operation in carrying out this investigation.

The British Standards Institution has issued a sectional list of British standards for hospital equipment. It catalogues standards for medical and surgical apparatus; laboratory glassware and scientific apparatus; furniture and fittings; textiles and clothing; photography and radiography; methods of testing; symbols, tables, and definitions; and electrical equipment. The list also includes a note on what new standards for hospital equipment are now being prepared. The list (P.D. 1644, dated June, 1953) is obtainable from the British Standards Institution (Sales Branch), 24, Victoria Street, London, S.W.1.

Treatment with weekly intradermal injections of "moo-grol" for two months produced no improvement. In December, 1948, solapsone by mouth was started. The maximum tolerated dose of three 0.5-g. tablets was taken intermittently over a long period. When last seen in May, 1951, the leg lesion had almost disappeared and sensation in the area showed considerable improvement.

Case 2

A British man aged 30, who had served in Cyprus, Syria, and India during the second world war, attended in August, 1948, with a generalized non-itchy eruption of brownish-red slightly infiltrated patches over the whole body surface. The Wassermann reaction was negative. A tentative diagnosis of sarcoidosis was not confirmed by biopsy, which showed an infiltrate of mononuclear cells and lymphocytes surrounding sweat ducts and follicles. In view of the possibility of a pre-mycotic eruption x rays and thorium X were applied to selected areas, without clinical benefit.

More lesions appeared, and in April, 1950, the face had become "leonine" (Fig. 2). The following neurological signs were then elicited: impairment of all forms of sensation over the larger plaques on the trunk, with palpable thickening of ulnar and lateral popliteal nerves on both sides. A thick palpable nerve was present on the medial

FIG. 2.—Case 2. Before treatment with thiosemicarbazone.

side of the right knee-joint. Biopsy of a nodule under the chin revealed numerous acid-fast bacilli in "globi" and scattered throughout the dermis. Bacilli were also found in a nasal scrape. The lepromin test was negative.

Treatment with thiosemicarbazone, 150 mg. daily, was started in May. Frequent blood examinations and liver-function tests revealed no deviation from normal and the patient had noted no side-effects. The skin lesions flattened gradually, and the leonine facies disappeared within one year. A nasal scrape was negative in March, 1952, and biopsy at that time revealed scanty and degenerated acid-fast bacilli in the skin. Treatment was continued with a dose of 100 mg. of thiosemicarbazone daily.

Case 3

A British man aged 65, who had retired after 30 years' service in India, was first seen in February, 1950, complaining of numbness and wasting of the right hand for four years, followed a year later by numbness of the left forefinger and of both feet.

Examination revealed scattered areas of depigmentation of the skin on the arms and legs. Weakness of both grips, the right more than the left, was present. There was wasting of the small muscles of the right hand, particularly the three ulnar interossei and the hypothenar muscles, and slight wasting of the left hypothenar muscles. Trophic sores and healed blisters were present on both hands, particularly on the right. The deep reflexes were normal in the arms; the right knee-jerk was diminished, the left normal; both ankle-jerks were absent. The plantar responses were flexor; the abdominal reflexes were present. Scattered areas of sensory loss to light touch, pin-prick, and temperature were present on the arms and legs. Position, vibration, and pain senses were normal. Some thickening of the ulnar nerves behind the medial condyles of the humeri was noted.

Biopsy of the edge of a depigmented area on the leg showed histological changes compatible with a diagnosis of leprosy, but no acid-fast bacilli could be demonstrated. The diagnosis of leprosy was confirmed by Dr. Ryrie. On his recommendation diaminodiphenyl sulphone (D.D.S.) was started in February with an initial dose of 100 mg. daily, later increased to 300 mg. daily. Only slight improvement was noted during treatment with this drug. The grips became stronger but the sensory loss was not appreciably lessened. After six weeks' treatment the drug had to be stopped for 10 days on account of malaise accompanied by slight cyanosis and an increase in urinary urobilinogen. In March, 1951, after 12 months' treatment, the condition had become static. Thiosemicarbazone was then substituted after a rest period of two weeks. The initial dose of

100 mg. daily was quickly increased to 150 mg. daily and this latter dose was maintained for 12 months without toxic effects. The disease seemed to be arrested, though no dramatic change in the condition had occurred.

Case 4

An Indian aged 30, temporarily resident in the city, was first seen in January, 1953, complaining of numbness and tingling of both feet. There was a history of treatment for leprosy in India until August, 1952.

Examination revealed no skin lesion, but a thickened nerve was palpable on the dorsum of the right foot and a similar thickened nerve was found below the right knee. The ulnar nerves also appeared thicker than normal. Areas of partial anaesthesia were found above both wrists; while in the feet hyperaesthesia of the proximal two-thirds was associated with diminished sensation over the distal thirds. A nasal scrape revealed numerous acid-fast bacilli, mainly packed in macrophage cells. Treatment with oral solapsone was started.

Comment

All four patients had contracted the disease in areas where leprosy is endemic. Cases 1 and 2 are connected with the movement of Service men during the war, but Cases 3 and 4 stem from the interchange of personnel between a jute-manufacturing Scottish town and the jute-producing areas of India and Pakistan.

Case 1 illustrates the tuberculoid type of the disease, while Cases 2 and 4 are undoubtedly lepromatous. Case 3 apparently belongs to the uncharacteristic type which cannot be placed in either polar group (Muir, 1948).

Little inference can be drawn from the results of treatment. It is doubtful if the intermittent and inadequate treatment with solapsone by mouth had any influence on the tuberculoid case. In the uncharacteristic case, in which irreversible tissue changes have occurred, therapy could not be expected to show any positive response but the symptoms and signs have certainly not progressed. The response of Case 2 to thiosemicarbazone has been good, and the gratifying absence of toxic side-effects supports Ryrie's (1950) views on the use of this drug. Nevertheless, many years must elapse before the question of "cure" by this or any other chemotherapeutic method can be assessed (Cochrane, 1952).

Summary

Four cases of leprosy occurring in hospital practice in one British city during the past four years are reported. The relatively high incidence is explained by local factors in addition to the expected post-war increase. Results of treatment to date are recorded.

We are indebted to Dr. John Kinnear and to Professor I. G. W. Hill for permission to publish these cases. We gratefully acknowledge the expert assistance of the late Dr. G. A. Ryrie and of Dr. R. G. Cochrane, of the British Empire Leprosy Relief Association.

The Foot Health Educational Bureau has been incorporated in the Central Council for Health Education. The Bureau was founded in 1941 to stimulate public interest in the care of the feet, to effect liaison between the leather and shoe trade on the one hand and the medical profession on the other, to advocate good standards of shoe manufacture and fittings, and to influence the public towards the purchase of the right shoe for the job. It has run conferences and "Foot Health Weeks," and published many booklets and pamphlets. Its advisory services are used by local authorities, hospitals, schools, and the trade.

CASE OF LEPROSY SEEN IN A VENEREAL DISEASE CLINIC IN BRITAIN

BY

J. OLIVER DOYLE, M.D., M.R.C.P.I.

Assistant Venereologist, Sheffield Royal Hospital and
Doncaster Royal Infirmary

Cases of leprosy are infrequently seen in venereal disease clinics in Great Britain. In view of this the following case is interesting enough to merit publication.

Case Report

A married British metal-worker aged 36 attended the medical out-patients department on May 12, 1951, with a history that he had been perfectly well until a month previously, when swelling of the ankles, arms, and hands developed. This was accompanied by a nodular rash on the face, back of the hands, forearms, and dorsal aspects of the feet. He was feeling perfectly well. He was admitted for investigation, and a tentative diagnosis of sarcoidosis was made.

A biopsy report on one of the nodules on the dorsal aspect of the left forearm was very suggestive of sarcoid, but a second biopsy was asked for. Unfortunately at this time he had discharged himself from hospital as he felt so very well. An x-ray film of the chest and finger-joints did not confirm the diagnosis.

In September, 1951, he developed a profuse nasal discharge which was occasionally blood-stained, especially first thing in the morning. This was treated by his own doctor with little success. In April, 1952, he was referred to the oto-rhino-laryngologist, Mr. Petty, who suggested that a Wassermann test be taken; this was found to be positive. The patient was then referred to the Infirmary.

On examination on May 2 a discrete symptomless nodular eruption was present on the face, back of the hands, extensor surface of the forearms, and dorsal aspects of the feet. The nodules measured about $\frac{1}{4}$ by $\frac{1}{4}$ in. (0.3 by 0.3 cm.). A non-irritating squamous erythematous rash was present over the anterior surface of both tibiae. The lesions had remained unchanged during the past twelve months.

The information was elicited that from 1938 to 1943 the patient had served abroad whilst in the armed Forces and had returned to England in the latter year. He had not been out of England since. Whilst abroad he served in India, Iraq, Palestine, Abyssinia, South Africa, and the Libyan Desert, and some of the regiments in which he served had coloured personnel. There was no history of venereal infection or any convincing clinical evidence of venereal disease. Nothing abnormal physically was elicited in the cardiovascular or central nervous system. Blood Wassermann and Kahn tests at this time were negative. Cerebrospinal fluid examination was within normal limits. His wife's Wassermann and Kahn reactions were negative.

A specimen of the patient's blood was forwarded to the Venereal Disease Reference Laboratory, St. Peter's Hospital, Whitechapel, on May 9. The routine Wassermann test was positive, serum diluted 1 in 128; cardiolipin Wassermann reaction positive; routine Kahn test positive; and Price's precipitation reaction negative. Dr. Orpwood Price reported: "In the absence of any history of syphilis, I should like to test another specimen from this patient before expressing an opinion."

On May 23 a routine Wassermann test was positive, serum diluted 1 in 32; a routine Kahn test negative, and Price's precipitation reaction negative. Dr. Orpwood Price reported: "The general pattern of this patient's serology and the history appears to favour the opinion that the positive reactions are non-syphilitic in nature. I therefore suggest that

he be tested at monthly intervals in order to find out the general pattern of his serological reactions." At this stage a tropical non-venereal disease was regarded as a likely cause of the serological reactions.

Further specimens of blood were tested on June 27 and July 17; the reactions of the former were anti-complementary, and the latter sample was reported on as follows: "Routine Wassermann reaction positive, serum diluted 1 in 64; cardiolipin Wassermann reaction positive; routine Kahn reaction negative; Price's precipitation reaction negative."

On July 4 a biopsy of one of the nodules on the right cheek showed a histological picture closely resembling sarcoid. On July 31 a biopsy of one of the nodules on the forehead showed a similar histological picture to the previous sections.

Cutaneous leishmaniasis and sporotrichosis were ruled out.

Sections were then forwarded to Professor R. A. Willis, of Leeds University. He expressed the opinion that the sections showed nothing histologically very distinctive, suggesting leprosy as a remote possibility. Ziehl-Neelsen-stained sections revealed a profusion of intrahistiocytic acid-alcohol-fast bacilli. A nasal swab and ear clippings showed moderate numbers of *Mycobacterium leprae*.

Photograph showing squamous erythematous rash on anterior surface of tibia.

When Dr. Orpwood Price was told that the patient was proved to be suffering from leprosy he suggested that he should perform Nelson's treponemal immobilization test on the patient's serum as a matter of interest; this test gave a clear-cut negative result.

Discussion

When a patient with a positive Wassermann reaction gives no history of venereal disease and no convincing clinical evidence of venereal disease, specimens of blood should be examined at monthly intervals to determine the general pattern of the serology. If it is then concluded that the positive reactions are non-syphilitic in nature and are probably in the nature of biological false-positive reactions, steps must be taken to determine the cause of those reactions. Confirmed (to exclude technical error) positive standard serological reactions occurring in the absence of treponemal infection are biological false-positive reactions. Stokes and James (1949) consider that the biological false-positive may be part of a general-infection reaction mechanism shared by many diseases and forms of injury and more highly developed in some persons than in others.

Moore and Mohr (1952) state that the chronic biological false-positive reaction is not innocuous and not to be discussed lightly, but is often, perhaps usually, a manifestation of serious underlying disease. The chief conditions in which such a reaction may occur are leprosy, the allergic diseases such as disseminated lupus erythematosus, periarthritis nodosa, rheumatoid arthritis, rheumatic fever, and sarcoid. Stokes, Beerman, and Ingraham (1944) state that a biological false-positive Wassermann reaction is found in 60-80% of cases of leprosy.

It is of interest that in the present case Nelson's treponemal immobilization test was negative, as this test is claimed to differentiate between true and biological false-positive Wassermann reactions. Nelson *et al.* (1950) state that the treponemal immobilizing antibody does not occur in the serum of normal persons or of those suffering from non-treponemal diseases. They have shown that of 57 lepers seropositive by standard tests (76% of those tested), 47 were negative with the treponemal immobilizing test. The incidence of positive reactions with the latter test was approximately the expected incidence of syphilis in the social and socio-economic groups from which the lepers were drawn.

It is feasible that our patient contracted leprosy as a result of prolonged contact with coloured troops.

Summary

A case of lepromatous leprosy exhibiting a chronic biologically false-positive Wassermann reaction is presented. The importance of considering the possibility of a biological false-positive Wassermann reaction in the absence of convincing clinical evidence of syphilis is stressed. Steps must be taken to determine the cause of the false-positive reaction. Histologically the lesions somewhat resembled sarcoid.

I am indebted to Dr. Douglas J. Campbell for help and advice in the preparation of this paper; to Dr. I. N. Orpwood Price for his interpretation of the serological reactions; to Professor R. A. Willis for his histological report; to Dr. H. Lederer, pathologist, Doncaster Royal Infirmary, for criticism and advice; and to the Department of Medical Photography, Sheffield Royal Hospital, for the photograph.

Medical Memorandum

Two Cases of Polyarteritis Nodosa with Uraemia

Polyarteritis nodosa is now being diagnosed during life with increasing frequency (Klein, 1949). The following cases manifested general symptoms, particularly kidney involvement with uraemia. The first patient died in a uraemic state, whilst the second apparently recovered.

CASE 1

A house-painter aged 62, the father of three healthy children, was admitted to the surgical department on March 29, with complaints of severe pain and superficial ulcerations in the lower extremities of two months' duration. The family history was irrelevant. He had suffered from bronchial asthma for the past 17 years, and had been using ephedrine to relieve his attacks. Physical examination revealed limited chest excursions with musical rales in both lungs; the heart sounds were muffled, but no murmurs were heard. The blood pressure was 120/70 mm. Hg, and the pulse rate 74. The lower extremities were warm, with small petechiae and small areas of superficial necrosis over the toes and the medial and lateral areas of both legs. The right dorsalis pedis artery was not palpable. The E.S.R. and full blood count were normal, the blood urea was 42 mg. per 100 ml., W.R. and Kahn were negative; a chest radiograph showed increased lung and hilar markings, and the aorta enlarged and elongated.

A tentative diagnosis of thromboangiitis obliterans was made, and periarterial sympathectomy was performed on both femoral arteries (Leriche). At operation the arteries were found to be constricted. The patient made an un-

eventful recovery, the ulceration of both legs improving and after leaving hospital healing completely and never reappearing. He continued to have occasional asthmatic attacks. The pain in the legs recurred three months after operation, but was less severe, and appeared on exposure to cold; he continued thus for about a year and a half, until readmission. Four weeks before this he began to suffer from very severe frontal and occipital headache, accompanied by dizziness, but without vomiting. The headache was severer at night than during the day; analgesics gave relief for a few hours only. He noticed that his legs had become swollen, and two weeks later his face also became swollen, especially around the eyes. On several occasions his urine was red. There was no lumbar pain and no frequency or dysuria. His urine contained albumin, many red cells, and a few white cells and casts. The blood urea was 56 mg. per 100 ml. He looked pale, with slight oedema of the face, especially around the orbits, and of the legs. Physical examination was normal throughout, but there was tenderness on fist percussion over the loins. His blood pressure was 200/120. *Fundi*: Disk boundaries blurred, blood vessels enlarged, arterial reflexes increased, many haemorrhages and cotton-wool exudates.

A few days after admission the patient developed a severe generalized epileptiform seizure, with loss of consciousness and white foam at the mouth. His blood pressure was 250/150. He was given aminophylline intravenously, and the attack subsided. On the sixth day after admission his temperature rose to 102° F. (38.9° C.). He complained of slight pain in the pharynx, but examination revealed no apparent reason for the fever. The white cells numbered 10,800, a few days later increasing to 19,200 per c.mm. The differential count showed a shift to the left, the eosinophils remaining between 2 and 3%. The urine showed no change. Sulphadiazine and penicillin were given with no effect on the temperature. The headaches increased. The blood urea rose to 77-98 mg. per 100 ml. Plasma euglobulin was increased. Cold fraction strongly positive—irreversible at room temperature. On the fourteenth day after admission he developed a slight cough. On physical examination there was slight dullness at the base of the right lung, with many crepitations. An x-ray film of the lungs showed density of the right base. Eye-ground findings showed improvement. The haemorrhages and exudates were absorbed. On the twentieth day the patient complained of abdominal pain; the abdomen was soft and there was no localized tenderness. The white cell count was 20,000 per c.mm., and the urine showed no change.

The protean nature of the complaints—headache, fever, cough, abdominal pain, pain in the extremities, the fluctuating nature of the eye-ground changes, as well as the anaemia, leucocytosis, the increased E.S.R., the blood-protein changes, and the renal insufficiency—suggested polyarteritis nodosa.

During the following week the patient's condition deteriorated. The urinary findings became more pronounced, especially the haematuria. The blood urea increased in a few days from 98 to 262 mg. per 100 ml., and he died on the twenty-sixth day after admission, in a uraemic state.

Typical changes of polyarteritis nodosa in the kidneys, myocardium, liver, spleen, pancreas, and mediastinal fat tissue were seen at necropsy.

CASE 2

A married woman aged 25, with two healthy children, emigrated to Israel from Yemen in 1948. Three years before admission, when she arrived from Yemen at an immigrant transit camp in Aden, she had suffered for a few months from a febrile disease of unknown nature, and apparently recovered. Eighteen months later, a few weeks after arriving in Israel, she started to run a mild fever, fluctuating during the day, accompanied by severe headaches, pain in the neck, shoulders, and abdomen. She vomited three or four times daily. The attending physician suspected pregnancy, since menstruation stopped with the onset of the illness. This condition lasted for a fortnight, after which she felt better, and during the following month

she was able to work in the fields. Every now and then she felt feverish and weak, and suffered from headache and pain in the shoulders and upper abdomen. Albuminuria was found and she was sent to a hospital in town, where she stayed seven months, during which time she had recurrent periods of chilliness, severe headache, abdominal pain, dizziness, nausea, and vomiting. At that time no abnormal findings were detected on physical examination except for an enlarged and tender liver.

During her seven months' stay in the hospital the urine albumin fluctuated between 2 and 4.5%, and the blood urea between 18 and 180 mg. per 100 ml. The sedimentation rate fluctuated, but was always increased. Blood cultures were repeatedly negative, as well as blood examinations for typhoid and brucellosis. Sputum examination for tubercle bacilli was negative. Radiographs of the lungs, spinal column, gastro-intestinal tract, kidneys, and urinary tract did not show any abnormalities. Sternal puncture did not show a deviation from normal. The patient was given penicillin, streptomycin, and aureomycin with no effect on the course of the fever. The general condition continued to deteriorate, the anaemia became severe, and the differential count at one time showed 7% eosinophils. Finally, she was given three blood transfusions, which apparently had a good effect: her temperature became normal and she left the hospital slightly improved and without fever. Erythrocytes numbered 3,000,000 per c.mm.; urine showed albumin ++; blood urea, 40 mg. per 100 ml.

She returned home and felt well for two days, after which she had a new relapse of fever, severe headache, shoulder pain, chills, ringing in the ears, abdominal pain, and vomiting. In addition for the first time she had blurred vision, and also swelling of different parts of the body with itching which lasted for a few hours. A few days later she was readmitted. She was very weak and the state of nutrition was very poor; her skin was pale grey. Physical examination was normal throughout, with blood pressure 130/80, no oedema, and the urine containing albumin 4%; and many red and white cells but no casts. *Blood*: R.B.C., 3,500,000 per c.mm.; Hb 10.5 g.%; W.B.C., 9,700 per c.mm., differential count normal except for 7% eosinophils; reticulocytes 0.9%; thrombocytes, 150,000; bleeding-time, 4 minutes; clotting-time, 3 minutes; sugar, 72 mg. per 100 ml.; urea 52 mg. per 100 ml.; cholesterol, 256 mg. per 100 ml.; Weltmann, 10; total proteins, 7.4 g. (albumin 4 g., globulin 3.4 g.); euglobulin, increased; cold fraction standard urea clearance, 68%. *Sputum*: negative for tubercle bacilli. *Stools*: negative for ova (including schistosomes) and amoebae. *Rectoscopy*: Atrophied mucosa, no ulcers or granulation tissue seen. *Fundi*: Arterial constriction, increased reflexes of the arteries, haemorrhages in all layers of the retina, deep spotted and superficial flame-shaped, some of them being in a stage of reabsorption; multiple cotton-wool exudates. X-ray film of lungs and kidneys showed nothing abnormal. X-ray film of heart: slight left ventricular hypertrophy. E.C.G. normal.

The patient stayed for six weeks in the ward afebrile, while the urine albumin fluctuated between 1.5 and 4%, and the blood urea between 40 and 100 mg. per 100 ml. The eosinophils in the blood increased to 18%; blood cultures were negative several times. Repeated examinations of the fundi showed reabsorption of the haemorrhages and exudates.

A biopsy of the right pectoral muscle was made which, however, was negative for polyarteritis nodosa. Upon further inquiry the pathologist, who had received a biopsy specimen taken before the patient's admission to our hospital, informed us that the specimen showed the typical histological picture of acute periarteritis nodosa—fibrinoid degeneration of the intima and inflammatory changes in and around the arterial wall (see illustration). Decisive proof of the diagnosis was thus obtained.

The patient was in hospital for six weeks, her general condition gradually improving. She gained in weight; the

albuminuria dropped to 0.5%. Blood urea dropped to 39 mg. per 100 ml.; the fundi showed great improvement; and she was discharged in an improved condition. Three and twelve months later she was found to be in good health. The blood count and blood pressure were normal, and the urine contained only traces of albumin. She gained in weight, looked well nourished, had no pain, and was able to perform her household duties and help her husband in the fields.

We were dealing with a disease running for over 10 months with febrile and afebrile periods, severe headache, abdominal and joint pains, normocytic anaemia, slight leukocytosis, and eosinophilia, hyperglobulinaemia with severe and constant involvement of the kidneys, marked rise of blood urea, massive albuminuria, haematuria, severe and

Polyarteritis nodosa. Section through artery of subcutaneous tissue.

rapidly changing eye-ground fundi findings with no hypertension. The fluctuating nature of the kidney manifestations, the febrile episodes, the abdominal pain, as well as the marked leucocytosis with eosinophilia, indicated the presence of a systemic disease leading to severe involvement of the kidney. The absence of skin eruptions and of pathological findings in the heart, and the presence of leucocytosis and eosinophilia, made the diagnosis of Libman-Sachs disease improbable. Subacute bacterial endocarditis was ruled out because of the absence of cardiac involvement, splenomegaly, clubbing of the fingers, and petechiae. The diagnosis of polyarteritis nodosa fitted the clinical picture best.

COMMENT

Prognosis of polyarteritis nodosa has had a better outlook during the past few years. Since the clinical manifestations of the disease are now better known, cases are diagnosed that previously would not have been recognized until necropsy. Our second case, the diagnosis of which was proved by biopsy, manifested clinically severe kidney involvement up to renal insufficiency. This patient made a remarkable recovery, and is now, at least 30 months after the onset of the disease, apparently in good health. The clinical course of this case indicates that prognosis, even when major organs, such as the kidney, are severely involved, need not be fatal.

Acknowledgment is due to Dr. H. Ungar, of the Institute of Pathology of the Hebrew University, Hadassah Medical School, Jerusalem, for the pathological data supplied.

CYTOCHEMISTRY

Cytochemistry: A Critical Approach. By Professor J. F. Danielli. Biological Research Series. (Pp. 139; illustrated. £1 12s.) New York: Wiley and Sons, Inc. London: Chapman and Hall, 1953.

Cytochemistry is a very recent offshoot from the main tree of biological research. As the author of this monograph points out, it has little in common with the essentially morphological approaches of cytology and histology, since the aim of the cytochemist is not to exhibit structure but rather to demonstrate the loci of specific chemical reactions normally taking place within the cell, and, furthermore, to measure their reactions in as quantitative a manner as possible. In this brilliant little book Professor Danielli begins with a general analysis of the possibilities of artifacts arising at various stages in the techniques used; he then proceeds to a description of recent work, a great deal of which is his own, on the localization of phosphatase activity, a form of activity which, to judge by the work cited, would appear to be at the basis of all secretory processes. The Feulgen reaction, which demonstrates the presence of deoxyribose nucleic acid, thereby permitting the staining of chromosomes during mitosis, relies on the conversion of the deoxyribose to an aldehyde; again, aldehyde would appear to be concerned in fat metabolism. Consequently the whole subject of the cytochemistry of aldehydes is of great practical importance, and the author devotes a chapter to this problem.

The relationship between synthesis of protein and nucleic acids is a theme running through most recent cytochemical studies. In the present monograph there is a valuable assessment of the recent work of Brachet and Caspersson among others. According to the author the claim that nucleic acids are concerned in protein synthesis is well grounded, and he puts forward the suggestion that the nucleic acids can influence or determine the folding of the newly synthesized protein chains, thereby imparting their specific characteristics. In a final chapter the future outlook in cytochemistry is briefly reviewed. The author points out that biochemistry, concerned as it is with homogenates, pulped tissues, and tissue extracts, is very indiscriminating in that all cells of an organ are usually treated as equal, whereas the cytochemist is well aware of the wide differences in chemical composition that often exist among cells of apparently the same histological type. He expresses the hope that the combination of the present indiscriminating approach of biochemists, and the more perceptive but undeveloped techniques of the cytologist, will be richly rewarding.

Written by a brilliant investigator, whose original contributions to the science of living matter have carried him into the very front rank of modern biologists, this monograph, by virtue of its critical yet imaginative approach, may justly be regarded as a masterpiece that will guide for years to come present and future investigators in this new branch of biology.

HUGH DAVSON.

INTRODUCTION TO RADIATION BIOLOGY

Radiations and Living Cells. By F. G. Spear, M.D., M.A., D.M.R.E. (Pp. 222; 60 figures. 18s.) London: Chapman and Hall, 1953.

This small volume is a most useful addition to the textbook literature on radiation biology as an introduction to the subject for medical and postgraduate students and for those workers such as physicists in allied branches of biological science. At the end of the book a bibliography suggests future reading of a mixed type to follow this initiation into the subject.

The author has throughout made clear the nature of the tissues and cells to which his descriptions of radiation effects apply, and this to the tyro is of tremendous value. He discusses the effects of radiation on cells generally and

on the various tissues—adult, embryonic, or malignant—and refers to much experimental work and to theories of how radiation acts on cells. The book is well printed on good paper, in a form handy for the pocket. The illustrations are particularly clear and apposite.

Criticism of defects is always distasteful, but there seems to be an error in the labelling of Fig. 6, and it seems an error to refer to any cell divisions taking place in normal meiosis as "highly abnormal" (p. 24). The note about Sr⁹⁰ retention (p. 149) leaves one ignorant of the method of administration. The importance of oxygen tension in connexion with cell sensitivity could profitably be discussed in view of its importance in clinical and experimental work, and it seems wrong to suggest that dose rate dependence is not compatible with the larger hypothesis of radiation (p. 195). The balance of language could be adjusted a little: "to equate the immaturity of normal cells with the anaplasia of malignancy" is on the same page as "what is called the atomic number."

These criticisms should not deter anyone from reading and keeping the book. It will be a great help to all starting an interest in radiobiology, while among radiotherapists and hospital physicists, who all know of Dr. Spear, it will enhance his already excellent reputation.

FRANK ELLIS.

CANCER IN CLINICAL PRACTICE

Basic Principles of Cancer Practice. By Anderson Nettleship, M.D., F.A.C.P. (Pp. 398. £2 14s.) London: Baillière, Tindall and Cox, Ltd. 1952.

In this book a professor of pathology tries "to tell something of what is known about cancers as clinical entities." The book is written primarily for the general practitioner and medical student. He gives a brief general description of the pathology, methods of diagnosis, and main lines of treatment of the various forms of cancer, and follows this with short accounts of cancer as it affects the various organs and regions of the body. There is also a chapter on cancer research and another chiefly on the medico-legal aspects of cancer. The facts are clearly stated and the author speaks with authority on pathological questions, but the clinical part is rather brief and scarcely sufficient for the medical student, who will need to supplement his clinical knowledge of the various cancers from textbooks on surgery.

We were interested to learn that "the improvement of cancer diagnosis by indoctrination of lay audiences has steadily lost its effectiveness," and felt some comfort in the words of a pathologist to the effect that "cancer research is too complex to be well understood even by its disciples." We hope the author is correct in his surmise that "there will probably never be the need for a large group of cancer specialists from whom the patient will first seek treatment," and can endorse his opinion that "it seems wise, therefore, that general practitioners become general oncologists, with a sound approach to the fundamental problems in each field" (the word oncology means the science or the study of tumours). This is an interesting book and there are over a hundred illustrations, but we wish the index were fuller.

ZACHARY COPE.

MENTAL DEFICIENCY

Notes on Mental Deficiency. By J. F. Lyons, L.R.C.P.&S.I., D.P.H., D.P.M., and W. A. Heaton-Ward, M.B., Ch.B., D.P.M. (Pp. 48. 3s. 6d.) Bristol: John Wright and Sons, Ltd. 1953.

The object of this booklet is to provide the newcomer with a practical guide to the administrative aspects of mental deficiency practice and to give a sufficient treatment of clinical and aetiological factors, and of the objects and methods of care and training. In that it gives a simple outline of the subject and is written mainly from the hospital point of view, it will be helpful to nurses training in mental deficiency, and it may also be useful to social workers and duly authorized officers concerned with the community care of the mentally handicapped. The necessary pruning of essentials has, on the whole, been well done, although some

of the space devoted to outworn aetiological theories might better have been devoted to the recent important work on intrauterine and genetic factors. Although it is not easy to explain hereditary influences to the layman in such small compass, an attempt to do so might well have replaced the description of the causes of "vitiation of the germ plasm." On the clinical side, too, the sections devoted to a few arbitrarily chosen rarities such as gargoyism and lenticular degeneration seems to be quite unnecessary and the system of headings in this section is rather confusing.

The need for a handbook of just this size and readability is great, and its appearance will therefore be welcome to lay workers in this field. But it must be said that the interpretation of the working of the Mental Deficiency Acts, and indeed the administrative sections generally, are much clearer and more up to date than the clinical sections.

ALEXANDER KENNEDY.

THORACOSCOPY

Operative Thorakoskopie. By Dr. Stanko Dujmušić. German translation by Dr. Rudolf Herz. (Pp. 222; 204 figures. M. 48.) Vienna-Düsseldorf: Wilhelm Maudrich, 1953.

This volume is a monograph on thoracoscopy and on its use in overcoming the difficulties which may arise in the production of a satisfactory pneumothorax for the treatment of pulmonary tuberculosis. The method was first developed by Jacobaeus, the distinguished Croatian surgeon, whose pupil and successor the author was. Although the subject is a limited field it is one in which experience and fine technique are essential to success, and these it is obvious that the author possesses in an exceptional degree.

The anatomy of the thoracic cavity as seen through the thoracoscope is fully described and illustrated by admirable coloured plates and diagrams, and there follows a discussion of the mode of formation of pleural adhesions and of their physical characters. The division of these adhesions is the chief problem of thoracoscopy, and the whole technique of this procedure is described in great detail, beautifully illustrated in colour. The various difficulties which may arise and their avoidance are discussed, as well as the possible risks. It would be difficult to imagine a more complete and precise treatise on a limited but important subject, and thoracic surgeons will find its perusal well worth while, even if their knowledge of German is limited. It is indeed a mine of accurate information admirably presented.

HENRY SOUTTAR.

LUNG ZONES

Pathologie et Structure Pulmonaires. By Professors H. Warembourg and P. Graux. (Pp. 221; 94 figures and 64 plates. 2,500 francs.) Paris: Masson et Cie. 1953.

The natural division of the lungs into lobes has served well for many purposes, but a new conception of lung structure has been taking shape, and the future specialist in lung diseases may have as much regional anatomy to learn as the neurologist. The modern view is that the lung is a segmented or zoned organ, each zone being self-contained and separated from its neighbours by connective tissue, with or without a fissure as well. This independence of the zones is not only anatomical but also clinical and pathological, and so we may have "zonitis" in many different sites. The final map of the zones has still to be drawn, and the nomenclature has yet to be standardized, but enough progress has been made to warrant the comprehensive survey here provided.

This could well be described as the book of the zone, for its scope is wider than that of the authors' *Pathologie des Zones Pulmonaires*, published in 1947. It opens with a historical introduction describing the evolution of the zone concept, from Ewart's adumbration of it in 1889 to the present day. The first part of the book gives the general anatomy of the bronchial tree, arterial tree, pulmonary veins, bronchial arteries, lymphatic system, and nerves of the lung. The second part deals with the anatomical, clinical, and radiological aspects of the individual zones in

the three lobes of the lung, and ends with sections on the fissures and on the bronchi and bronchoscopy. The third part is devoted to pathology, and covers the main diseases of the lungs and bronchi, including malignancy, the final sections being on angiopneumography and zonectomy. The authors add a substantial and up-to-date bibliography of works in the chief European languages. The illustrations—many of them chest radiographs—are excellent.

The appeal of the book is unusually wide for a specialist work, since the subject is treated from the different viewpoints of the anatomist, radiologist, pathologist, physician, and surgeon. All these could read the whole work with pleasure as well as profit, for the authors' French is concise and easy.

RAYMOND WHITEHEAD.

CONTACT DERMATITIS

Contact Dermatitis. By George L. Waldbott, M.D., F.A.A.A., F.A.C.A., F.I.A.A., F.A.C.P. (Pp. 218; 131 figures. £3 3s.) Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

To play the detective has a great fascination for the physician, and the dermatologist is in a favoured position for this game. The characters and distribution of an eruption may enable him to show a knowledge of the patient's habits and pursuits or of his possessions which suggest the touch of magic. The industrial medical officer may be able to carry these observations to such a point as to know with certainty the exact phase in a particular process which has been responsible for a pattern of skin reaction in a workman. Some years ago under the title of *Occupational Marks* Dr. Ronchese¹ published a book on such industrial stigmata.

Dr. Waldbott, an allergist, has been impressed by the diagnostic significance of the patterns of reaction from external agents and has now written this monograph on the subject. He does not define his title. Some dermatologists include under it all forms of eczematous dermatitis produced by external agents, while others limit its use to those forms dependent on an allergic sensitization to an external contact, excluding primary irritants. It is in the latter sense that Dr. Waldbott uses the term "contact dermatitis." The work is well produced, on excellent paper, with 131 illustrations, most of which are clear and instructive. The author suggests that the work may be studied by the patient with contact dermatitis, to assist him in doing his own detection. This accounts, no doubt, for a semi-popular presentation and a rather unnecessary number of illustrations. It is a novel way of obtaining the patient's co-operation, but it seems to have been attended by some success. The work is interesting and amusing, as well as being instructive, and it will form a useful book of reference for the dermatologist and for the general practitioner who is sure of his diagnosis.

With the increasing complexity of the chemical character of our external contacts, there is a great increase in sensitization dermatitis from such sources. Dermatitis of this type may masquerade as constitutional eczema for years when recognition and removal of the cause would be immediately curative. Yet diagnosis is often fraught with difficulty, and it is dangerous and unwise to depart from fundamental principles and to accept the diagnosis of contact dermatitis without adequate proof. The neglect of history-taking and of necessary investigative procedures is not to be encouraged.

The author illustrates many interesting patterns of contact dermatitis on fingers and hands, some of which seem a little too good to be true and are certainly not as often encountered in practice as could be desired. It is difficult to go all the way with the allergist in his approach to the problem of pruritus ani and pruritus vulvae. The book as a whole is stimulating and concerns a field that is constantly expanding, but it is rather extravagant in size and in price.

ANTIMALARIAL DRUGS

Because of strategic necessity research on antimalarial substances was vigorously pursued during the last war, and there has since been little slackening of the tempo. This is as it should be, for malaria is still probably the greatest killing disease in the world. The important work of Fairley and his colleagues put on a sound basis the therapy of malaria with the drugs in use during the war, but since 1946 experiments as comprehensive as his have not been possible. Thus pyrimethamine was at first thought to be very useful for the treatment of acute attacks of malaria, but this conclusion was reached after therapeutic trials in Africans who were partially immune. It is now known that in non-immune patients the drug acts slowly, and its unaided use in fulminating attacks may be dangerous and ought to be discontinued. Goodwin,¹ however, reported that it is an effective suppressant, and Coatney and his colleagues² showed that when individuals taking suppressive pyrimethamine are bitten by mosquitoes conveying *Plasmodium vivax* the onset of malarial symptoms may be indefinitely delayed. This implies that the drug has an effect on either the pre-erythrocytic or exo-erythrocytic forms of *P. vivax*, and the observation led to the hope that in overt malaria treatment with pyrimethamine would destroy exo-erythrocytic forms in the liver and late relapses would thereby be inhibited. On another page in this issue Sir Gordon Covell and his co-workers have now shown that these relapses are not inhibited, and it is thus clear that the exo-erythrocytic forms of the parasite survive the doses administered. But the possibility remains that the pre-erythrocytic forms may be susceptible to the drug. If this is so the drug still constitutes an important advance in malarial therapy, for when taken in suppressive doses the development of these overt attacks (and all later phases of the parasite) and late relapses would be inhibited.

In a letter at page 285 Lieutenant-Colonel Taylor draws attention to the fact that *P. falciparum* infections may occur among those taking pyrimethamine.

His observations dovetail to some extent with those of Dr. B. M. Nicol reported in last week's *Journal* (page 177). The latter found that attacks of malaria occur, though not with equal frequency, among people taking proguanil, mepacrine, or quinine. When given in correct dosage the complete effectiveness of mepacrine as a suppressant has been proved beyond doubt. In fact during the last war members of the Forces who developed malaria in areas in which mepacrine suppression was in force could be charged with indiscipline for failure to take the drug. In Nicol's series, out of 21 persons who stated that they were taking mepacrine regularly 14 said that while doing so they had had malaria. If the malaria in these 14 patients was correctly diagnosed their statements that they had taken the drug regularly must be considered unreliable. In view of this, the claims of those taking other drugs must be suspect. Nevertheless such studies are useful, for they show how much the drug can accomplish in spite of what is almost certainly irregular dosage.

The absolute capacity of a drug to suppress an infection can be assessed only under strictly controlled conditions. Nicol appreciated this and emphasized that his information was dependent upon such doubtful factors as the patient's memory and knowledge of the method of diagnosis in his or her case. It is, however, clear from his study that in spite of human inconsistency individual prophylaxis with proguanil is highly effective, only 6 out of 203 individuals taking 100 mg. of the drug daily having had proved attacks of malaria. Suppression was much less satisfactory in those taking mepacrine or quinine.

In investigations of the therapeutic efficacy of antimalarial drugs the most important point to determine is the effect of the drug in non-immune persons who, preferably, have not been to the Tropics. If the results of drug treatment are satisfactory in them, then they must also be satisfactory in those in whom its action is assisted by immunity. In asserting that two of his patients required intramuscular quinine Lieutenant-Colonel Taylor raises a matter which was discussed in the correspondence columns of this *Journal* during the latter part of 1951 and early in 1952. The position was summarized at the time in an annotation.³ Sir Philip Manson-Bahr also discusses the use of quinine in his letter at page 284 and inquires why it has of recent years been relegated to obscurity. To this surely the answer is clear. If speed of action is required quinine must give pride of place to chloroquine, while for prophylaxis it is known to be incompletely effective against *P. falciparum* and to engender blackwater fever. It seems that Sir Samuel Gee's utterance needs modifying to "Go on using your

drugs as long as they cure, but don't cling to those that sometimes kill when you have found others to work safely."

For the treatment of acute attacks of malaria chloroquine appears to be the most rapidly acting drug⁴ and for fulminating or cerebral *P. falciparum* infections is best given intravenously in a saline drip. Intramuscular or intravenous mepacrine is probably the most satisfactory alternative to chloroquine, but the use of quinine in these cases is inadvisable in view of the risk of blackwater fever, and pyrimethamine and proguanil should also not be given unaided for such infections, as Sir Gordon Covell has recently emphasized in a letter to this *Journal* (July 4, page 41). For malarial suppression proguanil is the drug of choice, for it combines effectiveness with absence of toxicity, while it is the only drug known to be a true causal prophylactic in *P. falciparum* infections. It may be found that pyrimethamine also has such an effect against this parasite and *P. vivax*. If this is so, it will mean that a drug has at last been found which when taken prophylactically prevents late relapses of benign tertian malaria. Finally, it cannot be too firmly stressed that quinine should not be used for suppression. In maximally tolerated doses it has been found to be ineffective and to lead to latent or to recrudescing infections in the presence of which blackwater fever is liable to develop.⁴ An important result of the introduction of the modern antimalarials is that in communities in which they are used in proper dosages blackwater fever is abolished. This in itself has led to great saving of life.

THE PLACE OF THE HOSPITAL

The administrative structure of the National Health Service has been the subject of much comment and criticism since the Acts creating it were passed, and five years' experience of its working has shown that much of the criticism is justified. In his Croonian lectures published in this and last week's issues of the *Journal* Sir Allen Daley sets out his reflections on some of the problems confronting us in the light of these first five years of the N.H.S., and he maintains, "It is recognized generally that a weakness of the new Service is the division of its administration into three separate compartments." There will be much support for this point of view, but far less support for the solution which he propounds—namely, to go back to the Willink proposals for a number of joint area authorities for hospital services.

Sir Allen surveys the scene as a former medical administrator with a special interest in preventive medicine, and sees "no clear or logical line of

demarcation in the present distribution of function between the three branches of the Service." He considers the tripartite separation of functions between hospitals, general practitioners, and local health authorities as artificial and illogical, and shows how efficiency is impaired by such separation when close integration is so essential—in the prevention and control of infectious disease, in tuberculosis, in the care of the chronic sick, in mental health, and in the maternity services, where the "interlocking of function is most pronounced." Another difficulty he points out is in deciding whether a person is aged and infirm or can be regarded as one of the chronic sick, and he says, "However broad the dividing line, one must be fixed somewhere, as a hospital authority cannot be expected to provide accommodation for the aged and infirm, though when local authorities were responsible for both hospitals and welfare institutions the exact definition was not of great importance." And now there is the further complication that if the hospital authority accepts the patient no charge is made, whereas if the local health or welfare authority does so the patient is assessed for payment. He also sees "a change which is not an improvement and which follows the thesis that hospitals are responsible only for patients for whom treatment is likely to be beneficial, and if no further benefit is likely they become the responsibility of the local health authority."

In view of these difficulties, and the tendency to isolate the general practitioner from the hospital, everyone will agree with Sir Allen's observation that "all who work in it should realize that there is only one National Health Service, and that all proposals for development and change should be discussed with representatives of the other services whose own work in some way or another is likely to be affected." At this point Sir Allen says, "Some may feel that the only logical solution of all these administrative difficulties is to have for each area one, and only one, body responsible for the administration of all three branches." He recognizes, however, that the practical difficulties at this stage are insuperable, but feels that it is not unrealistic to go back to the Willink proposals, which would ensure a much closer association of the hospitals with the other two branches of the Service. This is related to the thorny problem of the reorganization of local government boundaries, which would in itself greatly help co-operation between the hospital services and those of local government. Sir Allen's observations on unifying the administrative structure should be studied very carefully. It is a problem that will sooner or later have to be faced, with the associated problem of whether the unified administrative body should be elected or nominated.

¹ Goodwin, L. G., *British Medical Journal*, 1952, 1, 732.

² Coatney, G. R., et al., *Trans. R. Soc. trop. Med. Hyg.*, 1952, 46, 496.

³ *British Medical Journal*, 1952, 1, 590.

⁴ Fairley, N. H., *ibid.*, 1949, 2, 891.

Meanwhile what is to be done to encourage a greater sense of unity in the Service, and how in particular can the hospitals help? This is a challenge to those working in the Service to try to overcome the weaknesses in the present administrative structure. Any interim solution which multiplies the amount of time spent on paper work and increases the existing plethora of committees is rightly condemned. Formal meetings are not essential for this type of co-operation, and much can be done by personal consultation even on the telephone. The hospitals have an important part to play in this integration, but the "hospital is not the centre of gravity of the Service any more than the general-practitioner service or the public health service is the centre of gravity." The tripartite partnership is one of equality of status.

Observing that hospitals should take a more active part in preventive work—a theme discussed in these columns recently¹—Sir Allen points out that "there can be no clear-cut line of demarcation between the work of hospital and health authorities so far as preventive and curative medicine are concerned." The special hospitals, of which there are many, have a role quite as important as that of the acute hospitals, and, in the planning of hospital facilities for the chronic sick, chest cases, mental defectives, and so on, he pleads for a closer association between the hospital board, general practitioners, and public health officers. By associating at the planning stage, all the partners in the Service will gain in understanding each other's needs. He agrees too with those many critics who have contended that general practitioners should have hospital beds in their charge, that they should have prompt reports, access to pathological and radiological facilities, and be welcomed in the hospitals. Not only is the patient thus benefited, the doctor is helped to keep up to date. Hospitals should also make full use of the services of the medical officer of health in the prevention and control of infectious disease, and should join with him in research into the amount and nature of the sickness in the community. In these and many other ways Sir Allen feels that hospitals should play their part in the preventive services and "supply the needs of the other two branches of the Service."

These lectures should be closely studied by everyone concerned with the running of the Service, for apart from Sir Allen's main thesis, outlined here, he makes many pungent and timely comments obviously intended to be controversial on a variety of topics. As to regional boards, for example, he avers that "many think there are too few, that the original conception of between thirty and forty would have been

better." Discussing the functions of the Ministry of Health, he states that it "undertakes to an increasing extent executive responsibility and issues directives about the management and staffing of hospitals." And he poses, but avoids answering, the question whether this is a more tolerable method of control than the former executive control of local authority hospitals by the local authorities and their officers.

CHRONIC BRONCHITIS

Now that rickets has ceased to be a major problem its characterization as the English disease might well be transferred to chronic bronchitis, which alike appears to be a typical product of the English weather and murky towns. As a cause of death, sickness, and chronic disability it is of primary importance, and it is anomalous that as a subject for research it has until recently been accorded scant attention. The report in our opening pages this week by N. Goodman, R. E. Lane, and S. B. Rampling, from the Nuffield Department of Occupational Health, Manchester, draws attention to those outstanding epidemiological features of the disease which are likely to prove the most fruitful starting-points of a search for methods of prevention.

That the disease is commoner in Britain than in some other parts of the world is shown by comparison, for instance, with Scandinavia. For men aged 50 to 60 the death rate from bronchitis in 1948 was 50 times as high in England and Wales as it was in Norway and Sweden. But the incidence is not equally high in all parts of Britain, nor in all sections of the population. It is two to three times higher in towns than in the countryside, and twice as high in the north and west as in the drier south and east. According to the Registrar-General's occupational mortality statistics the disease is five times as common among both men and married women of the poorest economic class as among members of the professions. The explanation of this may lie in the overcrowding and consequent greater ease of infection associated with poverty. The origins of the disease may perhaps be found in the conditions under which infancy is passed—when, for example, respiratory infections are so common among the children of the poorer-paid citizens. It is striking that, in Britain, the chronic disease appears principally in men, even though morbidity data all agree that the acute condition occurs equally in both sexes, if indeed not more often in women. The difference may, perhaps, be due to constitutional factors, but it is certainly worth inquiring whether alternatively it may not be due to the different work habits of men—the greater physical effort undertaken by some whilst still suffering an acute infection—or to their different smoking habits.

With the experience of last winter's fogs fresh in the memory it cannot be doubted that atmospheric pollution is responsible for aggravating the disease and for hasten-

ing the death of a large number of sufferers. But whether it is responsible for starting the disease is a question on which there is at present no evidence. Until proved otherwise (if it ever is), pollution of the air must be regarded as a likely cause of the first importance. Similarly fresh—often virus—infections are clearly responsible for a high proportion of acute exacerbations, although, to quote Stuart-Harris and his collaborators,¹ "No one has ever found an infective agent which could with confidence be described as an actuating cause." They found that pneumococci were frequent inhabitants of the sputum in all phases of the disease, but that the types came from the whole range of the species, and the distribution resembled that found in the healthy nasopharynx more closely than that in the sputum in cases of pneumonia. In the past it has been suggested that *Haemophilus influenzae* might be of particular importance, and May² has recently confirmed this possibility. He realized that the apparent variation in the predominant organisms in the sputum might be due to irregular distribution, so that the appearance of any particular one might be determined largely by chance in the selection of the portion of sputum for culture. By a system of random sampling of the sputum he found that both those organisms which have seemed to be responsible for the infective element of the disease—*Haemophilus influenzae* and *Pneumococcus*—are those which are distributed most irregularly and so most likely to be missed on occasions. Chemotherapy designed to eliminate them can give much temporary relief of symptoms. But no method has yet been found which will prevent reinfection as soon as the patient returns home and is exposed to the family cold.

DIAGNOSIS OF POLIOMYELITIS

The rising incidence of poliomyelitis, illustrated at present by a graph every week in our Vital Statistics section, means that many family doctors will have the anxiety in the next two months or so of considering whether one of their patients has the disease. The earlier the diagnosis, the more effective can be the measures taken to mitigate the consequences of the infection. The patient's life, indeed, can depend on early treatment.

Two phases of the disease may be distinguished. The first of these is called the minor illness. It represents the body's response to infection and concludes the incubation period of about seven to ten days (or occasionally longer). The symptoms are similar to those of many other acute infections, and commonly include headache, malaise, and shivering. There may also be sore throat and perhaps gastro-intestinal disturbances. Pyrexia may be slight, and together with malaise may be the only manifestation of infection. The inference that the infection is poliomyelitis may sometimes be drawn when a patient is known to have been in contact with a recognized case. The family doctor faced

with such an early case may wonder whether the patient should be isolated at home or sent into hospital, and whether or not the case should be notified. The medical officer of health may be asked to take the responsibility to decide. Many cases end with this phase, the attack then being termed abortive. A few go on to the so-called major illness, when paralysis may or may not occur.

The principal disturbances in the major illness are meningeal. Headache is almost invariably present and is usually supra-orbital and persistent. Vomiting, often repeatedly, is very common. Alertness, apprehensiveness, and sleeplessness are notable rather than drowsiness. Certain signs may be elicited, of which the most important is stiffness of the posterior cervical and back muscles. The neck and back may be poker stiff, but the head is not retracted. Kernig's sign is often present. Neck or back stiffness may be so slight as to be detected only by the patient's inability to kiss his bent knees. Differential diagnosis at this stage is from pyogenic meningitis and, if the cerebrospinal fluid is lymphocytic, tuberculous meningitis; but the possibility of other virus infections of the meninges should also be borne in mind. Epidemic myalgia (Bornholm disease)¹ may be of increasing importance in the differential diagnosis. Meningismus can be misleading; there the C.S.F. is normal, but so it may be occasionally in poliomyelitis. Other common causes of error are local inflammation in glands or tissues of the neck giving rise to an impression of meningeal rigidity. Some patients are found on further observation to have rheumatic conditions.

When paresis or paralysis occurs, it is rarely seen earlier than 48 hours after the first symptoms of the major illness. When gross and asymmetrical, with weak or absent reflexes, there is rarely difficulty in diagnosis. Slight pareses are very easily missed. Paralysis may spread for several days after its first appearance. When paralysis is quite symmetrical and associated with some sensory impairment, a toxic cause should be suspected. Brachial radiculitis is not uncommonly confused with poliomyelitis. In hysterical paralysis the tendon reflexes remain active. Many cases of pseudo-paralysis are also seen—in the immobilization, for example, caused by osteomyelitis or rheumatism.

Apart from the diagnosis of the disease, the early recognition of serious complications may be life-saving. In the bulbar type death often occurs from the patient's inability to keep his airway free from secretions. Speech difficulty and weak cough may indicate the necessity for prompt postural drainage. Weakness of the shoulder girdle may point to respiratory muscle paralysis. This should be carefully investigated, for it may be insidious in onset and later rapidly progressive. An increasing tendency to sleeplessness and apprehension may suggest this complication, and a simple test, such as the patient's incapacity to count far in one breath, may demonstrate it, as also will a feeble cough. Finally, urinary retention due to temporary bladder paralysis is common, especially when the lower extremities are involved, and is apt to be overlooked.

THE KING'S FUND

Apart from its "rich uncle" role, the King Edward's Hospital Fund for London has had a co-ordinating influence on hospital affairs in London and has helped hospitals to find practical solutions to their problems. If the Fund had not been in existence when the hospitals were nationalized some other body would have had to be created, probably on not nearly so good a pattern nor so rich in resources, to stand for the partnership between the State and voluntary service in hospital administration. Although it has made large grants and appropriations—£271,000 under these headings in 1952—the Fund has never been a mere distributor of largesse. Nor has it, since its earliest years, ever entered the field in competition with individual hospitals for subscriptions. Subscriptions are certainly welcomed, but the income from subscriptions and donations last year was only £11,500. From legacies—and there are indications that testators who would formerly have left their money to individual hospitals are now making the Fund their beneficiary—it received £65,000. But its income from investments and properties was more than one-third of a million. The Annual Report for 1952 sets out the various purposes for which grants have been made—purposes which are often designed to make life in hospital more agreeable for the patients. For instance, many hospitals have been helped to improve their gardens, often with the co-operation of the Royal Horticultural Society. The Fund also maintains important services for the benefit of hospitals collectively, such as the Emergency Bed Service, the Hospital Administrative Staff College, and the School of Hospital Catering. New ground was broken last year in the organization of courses in administration for trained nurses. Another new enterprise of the Fund is the setting up under the wing of the hospital service of convalescent homes for the aged sick. A sum of £350,000 has been set aside for this purpose. The plan is for twelve homes, all in the environs of London. Seven are open and three others are being built. All four Metropolitan Regional Hospital Boards have agreed to meet the maintenance costs. Each home is linked with a hospital where the medical staff is actively interested in the care of the elderly. All are managed by voluntary organizations, the lion's share being borne by the British Red Cross Society. The idea is to facilitate the patient's discharge from hospital, rather than to provide beds for the chronic sick. The first of the homes, with 30 beds, admitted 222 old people during the first 22 months of its existence. The capital cost for the first seven homes was £870 for each bed.

The control of hospital expenditure is a subject which has been discussed recently, and the report points out the three alternatives—curtailment of services, reduction of standards of service, reduction of expenditure. No hospital would wish to adopt the first or the second. Whether the third is possible remains to be seen, but the author of this report evidently thinks something can be done to reduce duplication and overlapping, which have wasted capital and greatly increased maintenance costs. The report continues: "Has not the time arrived for a backward swing of the pendulum; the

time to resolve the balance of functions; the time for hospitals to ask not, 'How much more can we get to spend?' but, 'How much can we reduce our demands?'"

EATING BEHAVIOUR

Provision for feeding industrial workers in canteens has made immense strides in recent years, and this has brought with it many problems, of which the most obvious are dietetic and economic. It is surprising that until recently these problems have not been studied in their social context. The significance of the meal as a social occasion as well as a means of refuelling the human machine should have been plain enough to the business man, who could have obtained useful advice on the subject from any group of housewives. But by and large the "industrial caterer" has been content to go his own way and to try to develop an efficient service by studying such relatively simple questions as refrigeration, protein content of various foods, and so on, rather than problems of how to feed A and B, regarded as human beings rather than experimental subjects.

This is simply not good enough, because different kinds of workers take advantage of canteen services in different ways. For instance, Cook and Wyndham,¹ in a report of a recent study of the subject carried out in Australia, point out that administrative staff tended to use canteen services much more often than production staff. As this preference could not be satisfactorily explained in terms of economics, an investigation was made into the circumstances in which the worker feels "at home" in the more intimate moments of feeding, and it was found that they varied greatly from one group of workers to another. The point is an important one, and investigations carried out to discover what domestic arrangements should be made in works canteens may lead us a long way to understanding social phenomena about which we now know much too little. The task thus set may prove to be unexpectedly difficult—and unexpectedly rewarding—for no elaborate psychiatry is needed to show that complaints about canteen food or seating arrangements may be symptoms of much more profound tensions in industrial relationships. The maxims that restful surroundings promote good digestion and that good feeding promotes good work are simple, but their practical application may be intensely complicated.

The Australian report discloses that upholstered seats were reserved in the canteens for administrative workers—a somewhat surprising fact that hardly tallies with the popular conception of Australian social behaviour. We are left in doubt whether this had anything to do with the unpopularity of the service to the industrial workers. The final conclusion appears to be the unsatisfactory one that "it all depends." Even so, grumbling about quite good food is frequent enough in British factories. It is usually taken to be a symptom of bad morale, but the problem is rarely probed at all deeply.

We record with regret the death on July 26 of Dr. Mervyn Gordon, consulting bacteriologist to St. Bartholomew's Hospital. He was 81 years of age.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

CORTISONE AND A.C.T.H.—I

BY

C. L. COPE, D.M., F.R.C.P.

Physician, Postgraduate Medical School of London

The administration of A.C.T.H. or cortisone raises the concentration of adrenal cortical hormone in the circulating blood and presumably also in other body fluids. This may be of very great benefit at certain stages in a variety of disease states, but why this should be so is still by no means clear.

There is abundant evidence that animals and indeed humans without adrenal glands resist the stresses of trauma, infection, toxic substances, and adverse environmental conditions much less well than do those with healthy adrenal tissue. There is also plenty of evidence that the adrenal cortex is very readily stimulated by such stresses to liberate increased amounts of adrenal cortical hormone into the blood stream. Even psychological stress will produce this result: screwing up one's courage, for instance, involves such adrenal cortical stimulation. It would seem that the increased concentration of hormone in the blood helps the cells of the body to resist adverse trends in the internal environment, though how this is achieved is unknown. It may be that the adrenal hormones strengthen the cell membrane or lower its permeability. It has been suggested that the adrenal cortical hormones provide the cells "with an asbestos suit protecting them from the fires of infection." Although such a statement explains nothing, it nevertheless provides a useful working concept of what it is hoped to achieve by therapy with A.C.T.H. or cortisone. Such a concept takes no account of specific diseases; it merely considers disease in general as a damage to the tissues of the body. But this is the proper way to regard the use of cortisone. The results of therapy are quite empirical and little is to be gained from pushing theory further than this simple generalization.

A substance with so fundamental an action brings its own responsibilities: it must not be given indiscriminately. By protecting against disease, it may reduce or eliminate some of the traditional signs or symptoms of disease. Thus the temperature associated with infection may be reduced to normal, even though the infection itself persists or even extends; the malaise of a toxæmia may be eliminated, even though the disease causing it is unaffected; the sedimentation rate, an important clinical sign of disease, may be reduced to normal. With all these improvements in the state of the patient a false sense of security may be produced in those in whom the disease process is not actually under control. Perforation of gastric ulcers and extensive peritonitis have occurred in patients on cortisone, and have remained undiagnosed because the traditional indications of the catastrophe were masked. Because of such dangers, it is of great importance that a complete diagnosis should be made before cortisone or A.C.T.H. therapy is attempted. These drugs should never be given as a last resort to patients with undiagnosed disease who appear to be resistant to the more usual forms of treatment. They must not be regarded as the last refuge of the therapeutically destitute. Cortisone and A.C.T.H. are not known to cure any disease: they only alleviate some of the manifestations;

other aspects of the disease process may remain unaffected, and to these the patient may still succumb, in spite of full cortisone therapy.

As already stated, the essential process in A.C.T.H. or cortisone therapy is to raise the concentration of adrenal cortical hormone in the circulating blood. The hormone concerned is very probably a steroid called compound F (17-hydroxycorticosterone). Its chemical formula is known and it can be manufactured. It can be detected in small amounts in blood or body fluids and occurs in higher concentration in the blood of the adrenal vein. Although cortisone itself, which is a mildly oxidized relative of compound F, is probably absent from circulating blood, it has very much the same physiological actions as the natural hormone. It is likely that cortisone acts by being converted into compound F within the body. When compound F becomes available commercially it will probably prove even more effective than cortisone.

Principles of Therapy

Cortisone is usually supplied either as tablets of acetate to be taken by mouth, or in the form of a suspension of finely divided crystals of cortisone acetate in a saline medium, suitable for intramuscular but not for intravenous injection. It is stored at room temperature.

When cortisone acetate is taken by mouth it is quickly absorbed and the therapeutic effect is rapid, but the amount in the blood falls back in a few hours to its original level. It is therefore best given twice a day or oftener. Cortisone acetate injected intramuscularly behaves differently. It is relatively slowly absorbed and much will often persist at the injection site after 12 or 24 hours. If daily injections are given, more and more will collect at the injection sites, producing a depot of cortisone which is only slowly absorbed. Blood levels will thus rise more slowly than with oral cortisone, and the maximum effect may not be attained until injections have been given for several days. When injections cease, absorption will often continue from these depots for a week or more. Therapeutic effect will thus diminish gradually. The cortisone acetate suspension can be given orally if desired. It is readily taken mixed with a little milk, and is then rapidly absorbed.

When cortisone is administered by either method the patient's own adrenal glands tend to be inhibited and gradually pass into a state of disuse atrophy. This is not a serious matter if cortisone continues to be administered, but if therapy is suddenly stopped the patient may find himself without either administered or self-produced hormones and may pass temporarily into a state like Addison's disease. To avoid this risk the dose should be tailed off gradually so as to give the patient's own adrenals an opportunity to resume normal function. Tailing off is probably the more necessary when cortisone is given orally, because with injected cortisone the depot effect provides for this to some degree.

Adult dosage of cortisone varies according to circumstances from 25 mg. to 200 mg. per day.

A.C.T.H., or adrenocorticotrophic hormone, is a highly purified protein fraction of the anterior pituitary lobe of cattle or other animals which has the unique power of stimulating the adrenal cortex to greatly increased activity, to hypertrophy, and to much augmented production of its

own hormones. It is stable in the dried state and is readily soluble in normal saline or water. Like most protein-type therapeutic substances, it is destroyed by the digestive juices of the stomach and small intestine, and so is inactive when taken by mouth. It must therefore be administered by parenteral injection, either intramuscularly or intravenously.

When A.C.T.H. enters muscle some of it is probably destroyed locally and some enters the blood stream to pass ultimately to the adrenal gland. Circulating A.C.T.H. is unstable and is fairly rapidly destroyed, probably within 15 minutes. It follows that when A.C.T.H. is injected intramuscularly only a small part becomes available for adrenal cortical stimulation: perhaps two-thirds or more of the total is destroyed either locally or in the blood stream. Not only this, but an injected dose is available for only a relatively short time, and adrenal stimulation probably starts to subside an hour or two after the injection. There are several methods for overcoming this difficulty. Injections may be repeated at frequent intervals; for this purpose, four times in the 24 hours is usually recommended. A given daily dose of A.C.T.H. produces considerably greater stimulation when given in divided doses over the day than when given as a single daily injection. A second method of producing more continuous stimulation is by a process analogous to that with zinc protamine insulin. A.C.T.H. can be incorporated in a gelatin base, and the resultant gel, which becomes fluid on gentle warming, is protected from rapid destruction after injection and is liberated slowly from the injection site over a number of hours. With this gel a single daily injection can provide continuous gentle stimulation of the adrenal over the greater part of the 24 hours. The third method is to administer the A.C.T.H., dissolved in saline, as a slow intravenous drip over a period of six to eight hours a day. A prompt response is obtained and the efficacy of a given dose is increased by 5 to 15 times, an important point where supplies are restricted. Though this is a very economical method of administration it clearly has several disadvantages. It is unsuitable except for patients confined to bed and in hospital; it needs constant supervision, is an encumbrance to the patient, and may occasionally lead to venous thrombosis. Although all three methods are still in use, the daily injection of A.C.T.H. gel is generally the method of choice.

Obviously A.C.T.H. will have no clinical effect if the adrenal cortex is diseased, as in Addison's disease, or if for any other reason it is unable to respond. Although in the great majority of patients the adrenal cortex is responsive, yet it is desirable to have some indication that this is so. It is most readily done by carrying out eosinophil counts; if a sufficient output of adrenal hormones has been achieved the eosinophil count will fall practically to zero. A check such as this is of considerable value during A.C.T.H. therapy, since in addition to adrenal unresponsiveness it occasionally happens that the sample of A.C.T.H. is either inactive or of low activity. In suitably equipped hospitals, observation of a rise in output of 17-ketosteroids or of so-called 11-oxysteroids is an additional check on the activity of the A.C.T.H.

When, after a course of injections to which the patient has responded, the A.C.T.H. is stopped abruptly, the hypertrophied and over-acting adrenal cortex is suddenly deprived of its stimulus. It is liable then to become inactive for a few days, and in this period, as with cortisone, adverse withdrawal phenomena may occur. The dose of A.C.T.H. should therefore be tailed off gradually to a low level before finally stopping treatment.

Contraindications to Therapy

Perhaps the most important single contraindication is ambiguity of diagnosis. Great harm may be done by giving these drugs to unsuitable patients. An improvement in well-being and indeed a euphoria, with fall in temperature and sedimentation rate and possibly some gain in weight, may easily give an entirely erroneous impression that the drug is doing good, thus diverting attention from the need

for treatment by more traditional and orthodox methods. Undiagnosed fevers and abdominal disorders of uncertain nature are examples where the drug should in general be avoided.

The second major contraindication is ignorance on the part of the physician of the physiological effects of the drugs. There are certain overdosage effects which should always be watched for, and these are considered below. They are all very real, and more harm than good may be done if any of them are allowed to develop too far unchecked.

In certain clinical states A.C.T.H. or cortisone should be given with special caution, and preferably only by those already experienced in its use and in the dangers of overdosage. Important among such relative contraindications are congestive heart failure with oedema, diabetes mellitus, and hypertension if it is already producing symptoms. Special caution is also necessary in any person who shows or has shown evidence of a psychopathic personality, as this can easily be made worse or a latent abnormality may become manifest.

Since A.C.T.H. is effective only by virtue of its stimulation of the adrenal cortex, it should not be expected to succeed in patients with seriously diseased adrenal glands, as in Addison's disease. Conversely, in states of adrenal hyperactivity, such as Cushing's syndrome, further stimulation with A.C.T.H. will only aggravate the disorder.

Particular caution is necessary in giving the drug to any person with active or latent tuberculosis, as there is considered to be danger of lighting up the activity.

Metabolic and Overdosage Effects

The same general metabolic effects are produced by both cortisone and A.C.T.H., but overdosage phenomena are rather commoner with A.C.T.H. because the response to a given dose of A.C.T.H. varies considerably from person to person. There is a mild but appreciable tendency to sodium and water retention during the first few days. Occasionally this may be sufficient to produce manifest oedema; in persons who are in any way sensitive to sodium retention, such as those with early congestive failure, signs of aggravation such as weight increase or rise in jugular venous pressure must be carefully watched for. If any adverse tendency is detected or even suspected, it will usually be wise to restrict the sodium intake, at least during the period of early therapy.

The drugs also cause a tendency to increased renal loss of potassium. In prolonged intensive therapy this may become sufficient to be of clinical importance. Muscular weakness and electrocardiographic changes may suggest an excessive potassium loss. Since potassium deficiency may be insidious in onset and difficult to detect, it is wise to ensure an adequate intake by supplementing the ordinary diet with 2 or 3 g. of potassium chloride. There may be also an increased calcium excretion in the urine. This is seldom of any clinical significance, but in patients with disturbed calcium metabolism, such as those with the steatorrhoea of non-tropical sprue, attacks of tetany have occasionally been provoked.

Carbohydrate metabolism is profoundly altered by these drugs. Sensitivity to insulin is decreased so that the blood sugar tends to rise, and in the established diabetic insulin requirements may be temporarily but very considerably increased. For this reason it is wise to be very cautious in administering the drugs to known diabetics. Their effect on blood sugar may be sufficiently great in non-diabetics to produce glycosuria. Such glycosuria is not, by itself, adequate reason for lowering or stopping dosage.

Adrenal cortical stimulation also usually involves the increased production of adrenal androgens. This may lead to mild evidence of masculinization in females, with a tendency to acne, amenorrhoea, or even hirsutism. These androgenic effects are usually negligible unless therapy with A.C.T.H. is intensive and prolonged. They are promptly reversed when treatment is stopped, and are not usually reasons for curtailing it.

SUPPLEMENTARY LIST OF APPROVED NAMES

The General Medical Council has authorized the following "approved names" selected by the British Pharmacopoeia Commission. The list supplements the consolidated list of names published in January and the supplementary list printed in the *Journal* of April 18 (p. 882).

Approved Name	Other Names
Bromazine	2 - (4 - Bromodiphenylmethoxy) - ethyldimethylamine. "Ambo-dryl."
Carbimazole	2 - Carbethoxythio - 1 - methylimidazole. "Neo-mercazole."
Cetomacrogol 1,000	Polyethylene glycol 1,000 monocetyl ether.
Chloropromazine	3 - Chloro - 10-(3-dimethylamino-propyl)-phenothiazine. "Larg-actil" is the hydrochloride.
Dextromethorphan	(+) - 3-Methoxy-N-methylmorphinan.
Dextrorphan	(+) - 3-Hydroxy-N-methylmorphinan.
Dihydrallazine	1 : 4 - Dihydrazinophthalazine. "Nepresol."
Dimenhydrinate	8-Chlorotheophylline salt of (2-diphenyl - methoxyethyl)dimethylamine. "Dramamine."
Hydrocortisone	17-Hydroxycorticosterone. "Hydrocortone."
Insulin zinc suspension	Insulin lente.
Insulin zinc suspension (amorphous)	Insulin semilente.
Insulin zinc suspension (crystalline)	Insulin ultralente.
Iproniazid	N - isoNicotinoyl - N' - isopropylhydrazine.
Isophane insulin	NPH insulin.
Levomethorphan	(-) - 3-Methoxy-N-methylmorphinan.
Levorphan	(-) - 3-Hydroxy-N-methylmorphinan. "Dromoran" is the tartrate.
Macrogol 4,000	Polyethylene glycol 4,000.
Macrogol 400	Polyethylene glycol 400.
Methoxamine	β - Hydroxy - 2 : 5-dimethoxy- α -methylphenethylamine. "Vasylax" is the hydrochloride.
Neomycin	An antibiotic produced by a strain of <i>Streptomyces fradiae</i> .
Noradrenaline	(-) - 2-Amino-1-(3:4-dihydroxyphenyl)ethanol. (-)-Noradrenaline. "Levophed."
Oxytetracycline	An antibiotic produced by <i>Streptomyces rimosus</i> . "Terramycin."
Phenylindanedione	2-Phenylindane-1:3-dione. "Dindevan."
Pholcodine	2'-Morpholinoethyl ether of morphine. "Ethnine."
Primidone	5-Ethylhexahydro-5-phenylpyrimidine-4:6-dione. "Mysoline."
Propantheline	2'-Diisopropylaminoethyl xanthen-9-carboxylate. "Pro-banthine" is the methobromide.
Racemethorphan	(±) - 3-Methoxy-N-methylmorphinan.
Racemorphan	(±) - 3-Hydroxy-N-methylmorphinan.
Salicylamide	<i>o</i> -Hydroxybenzamide.
Sodium antimonogluconate	Sodium salt of a trivalent antimony derivative of gluconic acid. "Triostam."
Stibamine glucoside	N-Glucosyl derivative of sodium <i>p</i> -aminophenylstibonate.
Thurfyl nicotine	Tetrahydrofurfuryl nicotine. "Trafuril."
Sodium Stibogluconate	Amendments Sodium salt of a quinquevalent antimony derivative of gluconic acid. "Pentostam."
Ethyl methimazole	This Approved Name is now replaced by Carbimazole (see above).

Less clearly related to the known effects on metabolism are the psychological changes. The improvement produced by the drugs in a susceptible disease such as rheumatoid arthritis is so marked that a dramatic increase in well-being and optimism is to be expected. Yet the mental stimulation and optimism, amounting to frank euphoria, often occur to a degree far in excess of what can be accounted for by such physical improvement. They appear largely to be direct effects of the drugs themselves and may occur even when the disease process has in no way been affected. Thus one scientist patient with advanced myeloid leukaemia was stimulated to plan many new scientific activities although no alleviation of his leukaemia occurred and he was dead within a week. In people of different make-up there may be depression rather than euphoria. This depression, together with insomnia, may become progressively more severe until frank psychotic tendencies become apparent. Though these mental changes are usually reversible, they should call for a careful review of therapy, and in general the dosage should be reduced.

[Part II will appear in our next issue.]

Refresher Course Book.—The first collection of articles of this series (fully revised) are available as a book containing 55 chapters, price 25s. Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

3-D AT CARDIFF

A three-dimensional surgical film in colour was shown at the Annual Meeting in Cardiff, presented by Ethicon Suture Laboratories. Entitled *Mediastinal Tumours*, it was made in Washington and was projected by special equipment lent from America. Each member of the audience was equipped with light polaroid spectacles, and there seemed to be few, if any, complaints of headache or visual discomfort. The film showed the surgical technique for the removal of such tumours in considerable detail, two operations being demonstrated, one for a thymoma by a left approach, the other for a cyst above the right diaphragm. The three-dimensional effect greatly enhanced the film's usefulness, especially as its subject lay within a body cavity. The relations of the various structures were immediately seen, and the highlights reflected from the moist organs were no longer the source of confusion they often were in two-dimensional films.

The film included a good spoken commentary, mostly descriptive of the steps being performed but interspersed with some general observations on the subject, such as the acceptable advice that all patients with mediastinal tumours should be subjected to exploratory thoracotomy, and that aneurysm can most reliably be excluded by angiocardio-graphy.

Advantages of Stereoscopic Effect

The film lasts about 40 minutes, and thus for most purposes is unnecessarily long. The experienced surgeon will learn little from it, for the operations are among the simplest performed within the thorax, and the ordinary doctor would probably have preferred more clinical or pathological facts and less technique. These are minor criticisms, applicable to a great many medical films. No doubt the film is directed especially at the trainee surgeon—a small group for whom it is ideal. Other audiences will probably be more interested in the film itself than in its subject. The stereoscopic effect is a definite advance, making the surgical technique notably easier to understand and visualize. This film, indeed, gives a clearer view than that obtained by most visitors to a crowded operating theatre, and others by the same process, perhaps showing more complex operations, or new ones, will be warmly welcomed—especially if condensed versions, omitting all but essential details, are available for showing to practising surgeons.

MEDICAL LIBRARIANSHIP

FIRST INTERNATIONAL CONGRESS

The first International Congress on Medical Librarianship was held in London from July 21 to 25, and was attended by delegates from over thirty countries as well as by representatives of international organizations. After an inaugural session there were symposia on the role of the medical librarian in the world, on education and training for medical librarianship, on the centralization of medical library resources, and on international co-operation in this field. Other events of the Congress included visits to the medical libraries of London and various exhibitions.

Sir CECIL WAKELEY, in a brief presidential address in the Beveridge Hall of the University, said that in his capacity as President of the Royal College of Surgeons he was closely concerned with one of the largest and most frequented medical libraries in London; as a medical editor he was vitally interested in medical bibliography and documentation; and as a practising surgeon he had long known that "some of the finest consultants available are to be found in medical libraries"—not only in the shape of the volumes on the shelves but of the librarians at the desks. Medical librarianship, he said, was a highly specialized subject and one admirably suited for an international congress. The medical librarian, who was not merely a librarian with some knowledge of medicine or a physician who was fond of books, was now taking his proper place in the world of scientific medicine and research. It was the ever-increasing complexity of modern medicine and the constantly growing bulk and variety of its literature which had given the medical librarian his place. The exhibition of medical periodicals of the world at the headquarters of the British Medical Association (*Journal*, July 25, p. 233) comprised some 2,500 journals, and he was told that there were 1,500 current medical periodicals which it had not been possible to include. For his own part he found this unique array of journals, in all languages and covering every department of medical knowledge, not only impressive but a little frightening.

Some thread by means of which they could find their way in and out of this labyrinth, Sir Cecil Wakeley continued, was provided by the Armed Forces Medical Library at Washington in its *Current List of Medical Literature*; but no single body could be expected to bear such an exclusive responsibility for long, and it was one of the objects of that Congress to hammer out ways of inter-library and international co-operation so as to spread the load. Perhaps a means might be found by which each country would be able to produce rapidly a current index to its own medical literature, and all the national indexes might then be assembled and reissued by one of the great international agencies such as the World Health Organization or Unesco.

In the Congress attention would be paid to the fundamental problem of the recruitment and training of the medical librarian. The curriculum which the librarian now had to pursue and the examinations which he must pass before he was entrusted with a medical library of any importance ensured that his specialty took a fitting place among the other specialties of medicine. The Congress, he said in conclusion, afforded a unique opportunity of serving the medical libraries of the world by planning for co-operation of the libraries on an international scale. The matters to be discussed demanded initiative and enthusiasm; this was no place for the academic formalities of a dead subject.

The vice-presidents of the Congress, who numbered 22 and represented 10 countries, were then presented to the president by Mr. W. R. LeFanu, the chairman of the Congress Committee, and each of them made a brief

response. The British vice-presidents included Sir Zachary Cope (who drew attention to a valuable library not mentioned in the programme, that of the Medical Society of London); Professor E. C. Dodds, Harveian Librarian, Royal College of Physicians; Sir Francis Fraser, Director of the British Postgraduate Medical Federation; Mr. Geoffrey Keynes, Honorary Librarian of the Royal College of Surgeons; Mr. H. J. Seddon, Honorary Librarian of the Royal Society of Medicine; Dr. J. W. Trevan, of the Wellcome Research Institution; Dr. A. L. Goodall, Honorary Librarian of the Royal Faculty in Glasgow, and Mrs. Lilian Lindsay, Honorary Librarian of the British Dental Association.

Medical periodicals from 68 countries on display in the Old Library, B.M.A. House.

The Armed Forces Medical Library

An exhibition to illustrate the services of the Armed Forces Medical Library at Washington was opened later on the same day at the Wellcome Research Institution. The American Ambassador in London was expected to perform the ceremony, but in his unavoidable absence this was done by Colonel EISSLER, of the Embassy, who said that in America they were very proud of the Armed Forces Medical Library. The Library was founded in 1836 and was now the largest collection in the Western Hemisphere and among the five or six largest medical libraries in the world. It was in 1868 that John Shaw Billings became the librarian, and he raised it from a collection of 5,000 volumes until, in 1895 when he left it, the volumes numbered over 100,000, and the great *Index-Catalogue*, which Dr. William Welch, of Johns Hopkins, once called the most important contribution Americans had made to medicine, was begun. Colonel Eissler said that the Americans felt that the Library was held in trust for the advance of medical science and for the use of all men in every country at work on the problems of disease. He was told that the catalogue was valued in Great Britain. Fifty-seven volumes had been published since its inception in 1880, and copies were deposited in many libraries and research institutions throughout the world. The services and resources of the Library, subject only to limitations of time, money, and personnel, were available internationally.

The exhibition was in the form of large panels illustrating the achievements and services of the library, the latter including photo-duplication, reference, translation, and research.

The final session of the congress was held on July 25, with Mr. R. Eriksson (Karolinska Institutet, Sweden) in the chair. Papers on international co-operation were read by Mr. E. Carter (Unesco) and by Mrs. Eileen Cunningham (Vanderbilt University, Nashville, Tennessee). These were followed by general discussion on the possibility of establishing an international medical library association. The following committee was appointed to ensure continuity of international co-operation among medical librarians and to prepare for

second congress after a suitable interval: Dr. J. Anker (Denmark), Mr. W. J. Bishop (U.K.), Dr. S. A. Chitale (India), Mrs. E. R. Cunningham (U.S.A.), Mr. R. Eriksson (Sweden), Dr. A. Hahn (France), Professor K. J. Hartmann (Germany), Dr. A. H. M. C. Kessen (Netherlands), and Mr. W. R. LeFanu (U.K.). Lieutenant-Colonel F. B. Rogers (Armed Forces Medical Library, Washington) expressed the appreciation of the delegates for the excellent organization of the congress and the hospitality accorded them while in London. It was announced that 315 delegates had registered from 32 countries and three international organizations.

SOCIAL MEDICINE CONGRESS IN VIENNA

[FROM A SPECIAL CORRESPONDENT]

An international congress of social medicine* was held in Vienna from May 23 to 25 under the presidency of Professor P. VERGA, director of the Institutes of Pathology and Cancer Research, University of Naples. The congress was attended by about 200 doctors. The three main themes were "Health and Living Conditions," "Effects of War on Physical and Mental Health," and "Medical Measures in the Face of these Problems."

On the first theme, Professor J. GILLMAN (Physiology Department, Witwatersrand University) said that complexes of nutritional and endocrine variations, rather than single factors, might influence the incidence of certain diseases and account for some of the differences between populations. As the diet of a population changed from inadequate to adequate, some diseases, such as pellagra, tuberculosis, and certain liver diseases, might be expected to decrease, and others, including diabetes, cardiovascular disease, and some forms of cancer, to increase. In addition to climate and geography, man determined to some extent his own and economic environment in which he lived. Dr. R. GIRARD (Guadeloupe) presented health statistics from the less developed parts of the French Union, and analysed the achievements and needs of their health services: for the ratio of doctors to inhabitants was 1:30,000 in Afrique Noire; 1:10,000 in Madagascar; 1:5,000 in Algeria; 1:4,000 in Guadeloupe; and 1:1,100 in Metropolitan France.

In the general discussion Dr. ALICE STEWART, Reader in Social Medicine, University of Oxford, summarized the work of her team upon the spread of tuberculosis in factories: this suggested that the risk to a given population was housed in large groups in spacious workrooms might be greater than when divided into small though overcrowded groups. Dr. P. D'ARCY HART, director of the Medical Research Council's Tuberculosis Research Unit, London, spoke on priorities in tuberculosis control and research. In countries with underdeveloped tuberculosis services, present chemotherapy had a much more limited use than in those with advanced technical resources and communications; prevention, particularly by improvements in living conditions, must continue to be the main weapon in control. Even in the more technically advanced countries the continued importance of social conditions in affecting tuberculosis levels should not be forgotten. Dr. Hart gave some examples of this continued relevance in Britain: in spite of sharp declines in tuberculosis rates, differences between better-off and poorer areas were still striking. Professor L. S. BOGOLEPOVA (Central Research Institute for Health Education, U.S.S.R. Ministry of Health) outlined current methods in her field. Much stress was laid on lectures to the public. Lecturers ranged from well-known physicians and medical scientists to final-year students, and the subjects from diet and practical hygiene to the history of medical discoveries and the lives of famous scientists. Similar lectures were given to convalescents and out-patients in hospitals. In addition to articles in the general press, a large volume of popular literature was produced. Organiza-

*Congrès Mondial des Médecins pour l'Etude des Conditions Actuelles de Vie.

tional responsibility lay with local "houses of health education," headed by the Ministry of Health's health education department; the Central Research Institute was responsible for improving educational techniques and for providing training for lecturers.

Effects of War

The opening paper on the second theme of the Congress was by Professor G. FRONTALI, director of the paediatric clinic, University of Rome, on "The Nutritional State of Children in Italy in the Post-war Period," as ascertained by a survey under the National Research Council. Social classes showed great differences in the quality and quantity of nutritional intake. In the higher classes the intake was close to the recommended figures, and was only slightly less in the peasant class. It was considerably lower in adequacy among the children of urban workers. There were also geographical differences, and it was remarkable that owing to poverty vitamin-C consumption was particularly deficient in the south (sufficient to produce haemorrhagic syndromes), even though this region contained the most important centres of production of citrus fruit.

The secretary of the Chinese Medical Association, Peking, Dr. SU CHING-KWAN, described national efforts to institute public health and education methods in China after a period of high rates of infectious diseases, high infant mortality, and malnutrition, exacerbated by long years of war. He described the "Patriotic Health Movement," which aimed at making the whole population actively interested in practical hygiene and living conditions, thus assisting the still very limited qualified personnel. Campaigns for the proper handling of food, for destruction of flies, mosquitoes, and vermin, and for raising the general standard of cleanliness had been highly encouraging. Drs. M. SHIOTSUKI, N. KUSANO, and S. YAMAMOTO (University of Tokyo) gave first-hand experience of the lesions caused by the atomic bomb explosions.

The main report on the third theme was given by Dr. B. WEILL-HALLÉ (Paris), who discussed the Hippocratic Oath and medical ethics in the world as it is. Apart from the meeting in 1949, which revised the 1929 Geneva Convention, a number of conferences had been held on this subject since the war. Among these was the meeting of l'Office International de Documentation de Médecine Militaire at Vichy in 1951, where the doctor's position in the face of the threat of bacteriological warfare was discussed. In 1950 the Medico-Judicial Commission of Monaco, discussing the relationship between the doctor and his country, attempted to differentiate the loyal duty which the citizen owes to his country from the obligations which his specific social function imposes on him. This Commission proposed an international convention for medical practice which, confirming the bans of the Geneva Convention, condemns the use of medicine for destructive purposes, and according to which the doctor retains the right to refuse his collaboration to acts contrary to his conscience. The speaker made a plea for doctors to examine their consciences when asked to undertake work other than the preservation of health and life.

Sir S. S. SOKHEY, of India, late deputy director of World Health Organization, urged that voluntary groups and associations should be set up to further the study of living conditions and health, particularly in countries whose public health services were not yet mature. This suggestion, as well as some of Dr. Weill-Hallé's proposals, was included in recommendations submitted to the closing plenary session of the Congress by its president. It was agreed that the improvements in health which could undoubtedly result from various improvements in living conditions were still inaccurately defined in all countries; that the second world war had brought to the fore new aspects of the consequences of war upon the health of populations; that doctors should again be reminded of their ethical obligations not only to their individual patients but to the community at large; and that to fulfil these obligations and promote health on a world basis, unimpeded exchange of ideas and therapeutic measures was required.

British Medical Association ANNUAL MEETING, CARDIFF, 1953 SUMMARY OF PROCEEDINGS

THE SECTIONS

SECTION OF PREVENTIVE MEDICINE

Wednesday, July 15

The Health Visitor and the Family Doctor

With the president, Dr. J. GREENWOOD WILSON (Cardiff), in the chair, Dr. LLYWELYN ROBERTS (Sheffield) opened a discussion on the health visitor and the family doctor. After giving a short historical review, Dr. Roberts stressed the importance of social as well as medical therapeutics. He felt that the health visitor was the key worker who should co-ordinate all the social agencies. It was still not yet fully appreciated by all doctors that health visitors were highly qualified nurses who, in addition to State registration, had taken at least the first part of the C.M.B. and had also obtained the health visitor's certificate. Health visitors could possibly assist the family doctor with the care of the mother and child, with problem families, with some psychological problems, with domestic emergencies due to ill-health, with the care of the aged in their own homes, with the care of the disabled, and with the care of the mentally deficient and the mentally sick. In many of these situations the health visitor could act as liaison officer between the doctor and whichever statutory or voluntary agency might best be able to give assistance. Dr. Roberts thought that there were far too many home visitors, and that the health visitor, by reason of her specialized training and experience together with her confidential position in the family, might well act as the channel for the economic employment of all the social agencies in any particular case. In order to achieve these aims there must be the closest relationship between family doctors and health visitors in exactly the same way as between general practitioners and district nurses and midwives.

Dr. STANLEY THOMAS (London) spoke as a family doctor of thirty years' experience. Among the important advances in medicine he had seen in his time he now counted the rapidly increasing liaison between general practitioners and the preventive medicine services. He referred to the paramount importance of the assistance of nurses in modern practice and instanced particularly the help received from the district nurse and midwife. He felt that there was similarly an essential need for the assistance of health visitors in unravelling the social problems of patients, particularly in connexion with young mothers and infant feeding, tuberculosis, mental illness, convalescence, problems of the aged, and juvenile delinquency. Doctors must first be convinced of the status and value of health visitors, and it was most important they should realize that she was first and foremost a hospital-trained nurse. In his opinion the health visitor was the key to liaison between the family doctor and the preventive medicine services.

The Cardiff Scheme

Dr. D. A. WILLIAMS (Cardiff) gave the point of view of a consultant physician with close personal experience of working with specialist health visitors. The scheme had started in Cardiff by the allocation of a health visitor to help in the aftercare of diabetic patients who had been admitted to Llandough Hospital. Owing to its success the scheme was extended by the attachment of other health visitors for patients with gastric disorders and with asthma. The health visitor was the ideal type of social worker—being a nurse of the status of ward sister who was also a social worker and an ideal liaison officer. She had a particular part to play in providing sound health education in the

home, where it was most needed and most likely to be heeded. The three diseases of diabetes, peptic ulceration, and asthma all provided home problems which were closely concerned with causation and treatment.

In the subsequent discussion Dr. H. D. CHALKE (London) described a modest scheme in his own area which had been successful in introducing individual health visitors to a number of general practitioners. He agreed that the health visitor should co-ordinate the work of other social workers, and he was particularly impressed by the part which the health visitor could play in the domiciliary care of old people.

Dr. M. L. H. EVANS (Lewisham) expressed the opinion that much antagonism could be broken down by regular meetings between general practitioner and health visitor. If the health visitor could come to such a meeting primed with details of problems presented by some of the doctor's cases, then her value would be likely to be more apparent. Dr. W. E. THOMAS (Glamorgan) spoke of the problems of county councils with large distances to cover. He thought liaison between doctors and health visitors had improved considerably. There was a national shortage of health visitors and it was difficult to make additions to the staff. Dr. MARY ESSLEMONT (Aberdeen), as a general practitioner with previous local authority experience, made a strong plea for direct contact between doctor and health visitor, preferably by telephone. Dr. W. B. QUISENBERRY (Hawaii) also spoke from a background of experience of both general practice and public health. He thought that health nurses were so versatile that doctors might be inclined to expect too much from them. They played an important part in the care of the chronic sick, and the speaker had found them of great value in his scheme for cancer control. In incipient mental illness they could do much good.

Dr. S. S. B. GILDER (World Health Organization, Geneva) thought that health education was the particular sphere of the public health nurse. More and more the importance of sociology in medicine was being recognized, and in certain circumstances, such as in a very backward area, a public health nurse might be able to achieve as much success as a medical officer.

Dr. A. TALBOT ROGERS (Bromley) said that a number of recent inquiries had all revealed a lack of understanding between general practitioners and health visitors. They must get together and realize their common problems. He was critical of too much specializing among health visitors. The all-purpose health visitor was the best person to assist the family doctor. The health visitor should work with the family doctor rather than for him, and he deprecated the argument often put forward that general practitioners were too busy to cope with social problems.

Dr. W. M. FORD-ROBERTSON (Beirut) wondered whether either the family doctor or the health nurse was adequately trained in the psychosomatic aspects of general practice.

CANCER AND THE COMMUNITY

The meeting of the Section continued in the afternoon with a discussion on cancer and the community. Dr. PERCY STOCKS (Rhos-on-Sea) was unable to be present, and his opening paper was read by the president, Dr. J. GREENWOOD WILSON (Cardiff). Dr. Stocks felt that the attitude of the general public to the cancer problem differed from that of the medical profession. The former looked towards prevention while doctors were at the moment more concerned with improvements in treatment. It was time to bring the cancer problem fairly and squarely into the field of preventive medicine. As measured by the estimated loss of working life, cancer deaths were now of greater economic importance than fatalities from respiratory tuberculosis or accidents. The finding of statistical relationships between cancer incidence and environmental factors ought to lead to action now, and not be shelved to await a full understanding of cancer aetiology—which may be long delayed. Researches arising out of such statistical evidence were already proving fruitful in cancer of the lung and stomach.

Medical officers of health could give effective assistance in environmental field studies on these and other forms of cancer. For instance, why was cancer of the stomach commoner in certain large cities and in some rural areas of North Wales? The public should be informed of the statistical evidence implicating environmental factors such as smoking, so that each individual could decide for himself what it amounts to. The responsibility of the medical officer of health for health education should include cancer education.

A Programme for the Control of Cancer

Mr. RONALD W. RAVEN (London), in his opening remarks, pointed out the world-wide challenge of cancer. He gave details of recent national variations in growths of different sites, and dealt briefly with the family and individual problems that can arise as a result of cancer.

Mr. Raven then outlined a five-point programme for the control of cancer. (1) *Research into causation.* Clinicians and laboratory workers must co-operate, and more field research might yield important results. (2) *Prevention.* Cigarette-smoking and atmospheric pollution possibly had something to do with lung cancer, and here there was a place for preventive work, as there was in industry in connexion with carcinogenic mineral oils and tar. Surgery also had a place in the removal of pre-cancerous conditions. (3) *Early diagnosis and treatment.* Cancer is at first always a local disease, and the aim should be to diagnose it before spread has taken place. Progress has been made in treatment by surgery, radiotherapy, and chemotherapy. (4) *Rehabilitation and after-treatment.* There was a need for special convalescent homes for patients who had been treated for cancer. (5) *Care of patients with advanced disease.* This was a big problem at present. Much could be done to relieve pain, and above all else despondency must be averted.

Mr. Raven emphasized that the community had certain responsibilities in such a programme, chiefly in the direction of prevention and early diagnosis. The public must be advised how they can play their full part, and cancer education was therefore necessary. There should be an education plan on a national basis with the object of substituting intelligence and optimism in the place of ignorance and fear. To achieve this the speaker looked to medical officers of health, acting through local cancer education committees. The medical officer of health would be greatly assisted by his field workers, such as the district nurses, health visitors, and midwives. Medical students and student nurses should receive full education in early symptomatology. The methods of teaching would include leaflets, articles in the press, lectures, films, and the use of wireless and television. A very useful series of 12 leaflets had been produced by the Marie Curie Memorial Foundation which gave simple facts about cancer in general and essential information about cancer of certain special sites.

Dr. E. K. MACDONALD (Leicester) said that the size of the cancer problem could be stated in graphic terms by equating the number of sufferers in England and Wales at any one time to the total population of a town the size of Blackpool or Southend-on-Sea. The total number of new cases each year was equivalent to the population of a city like Oxford, while the total cancer deaths each year were equivalent to the complete wiping out of a town the size of Doncaster or Southport. Although some cases were asymptomatic until too far advanced for remedial treatment, and in others the rate of growth was too rapid, nevertheless it was true that many patients had symptoms present for a considerable time before medical advice was sought. It was to such patients that cancer education should be directed. It has been calculated that if all the cases were diagnosed and treated by the best known methods the chances of survival would be more than doubled.

It was the duty of the local health authorities under Section 28 of the National Health Service Act to carry out any type of health education that might better the health of the people. Something was being done towards

cancer education in some areas, but this was not enough. In order to achieve success co-operation was necessary between the medical profession, the health department, and the public. Dr. Macdonald hoped that all those attending the meeting would return to their own areas and see if something more could not be done in the way of cancer education. The Central Council for Health Education would be delighted to help if asked.

Cancer Prevention in Hawaii

In the discussion, Dr. W. B. QUISENBERRY (Hawaii) gave an account of the cancer problem in his own country and how it was being tackled. He showed some interesting slides to emphasize the points he made. The problem in Hawaii had increased as the population had aged, and cancer was now the second commonest cause of death. The stomach was the commonest site of cancer, and there were interesting differences in incidence between the Japanese and Caucasian population. The policy of making every private physician a cancer-detection officer had been adopted. Their cancer education programme had been directed towards getting every citizen to have regular physical examinations, preferably every six months, as well as to report to his doctor any signs which might mean cancer. Pathological material could be sent in to a central laboratory without charge, and material from 11,647 patients had given 112 positive results, including 24 specimens taken from patients with uterine cancer who had been asymptomatic but who had been to a cancer-detection clinic. Dr. Quisenberry concluded that cancer prevention was a field which needed far more attention than it had yet received.

The PRESIDENT, in drawing the discussion to a close, said that at the moment there was a divided medical profession in this country on this point, and it was not easy for the medical officer of health to achieve any success with a cancer education programme unless he had the backing of the local doctors.

SECTION OF DISEASES OF THE CHEST

Friday, July 17

Artificial Pneumothorax in Pulmonary Tuberculosis

With the president, Sir CLEMENT PRICE THOMAS (London), in the chair, Dr. HOWARD NICHOLSON (London) opened the discussion. The continual changes in methods of treatment had made it difficult to assess the value of artificial pneumothorax in pulmonary tuberculosis. Nowadays it was necessary to gauge the effects of pneumothorax in conjunction with chemotherapy and to contrast the results with those of pulmonary resection. It was too early to reach definite conclusions. Nevertheless, the conditions in which it was safe to start pneumothorax were well known. It should not be considered in cases with acute spread or pneumonic consolidation, or when there was active bronchial tuberculosis of the lobar or segmental bronchi. Pneumothorax therapy was still indicated when cavities persisted after streptomycin treatment, when there were scattered foci of infection, and when the disease was progressive in spite of adequate conservative treatment. Pneumothorax had no place in treating disease of the nodular type or tuberculomata.

Dr. C. H. C. TOUSSAINT (London) considered that it was now time to review the value of artificial pneumothorax in the light of the widespread use of antibiotics. It was salutary to recall the time-honoured view that artificial pneumothorax should always be an adjunct to general treatment. Since the advent of antibiotics he had remodelled his opinions on the manner in which artificial pneumothorax should be used. It was best to secure cavity closure before inducing a pneumothorax, which could then be safely used as a method of treatment during the patient's rehabilitation. When used in this way it was not necessary to maintain artificial pneumothorax for prolonged periods.

Mr. R. S. BARCLAY (Newton Mearns, Renfrewshire) thought that pneumothorax would be less used in the future as a method of treatment. Serious complications had always been a drawback to pneumothorax therapy, but results of treatment were often so good that its efficacy should not be underrated. Most complications could be avoided by simultaneous antibiotic treatment. The aims of pneumothorax treatment were relaxation of the lung and cavity closure. Endobronchial disease was a contraindication and should diligently be sought by bronchoscopy and bronchography. Preliminary rest and antibiotics should always be used so that progress could be assessed and future treatment planned. There should be no hesitation in abandoning an ineffective pneumothorax. The alternative treatment by combining antibiotics and surgical resection should always be considered as the best method of getting the patient back to health as quickly as possible.

Dr. C. S. DARKE (Sheffield) said that pneumothorax treatment should aim at restoring full health while incurring least risk of impairing respiratory function. The optimal period for maintaining a pneumothorax was not known. Some physicians had thought that three years was sufficient, whereas others had maintained treatment almost indefinitely. There was always a risk of disabling and dangerous complications developing while a pneumothorax was present. The policy should be to terminate the pneumothorax deliberately as soon as the disease was arrested. The length of time could be greatly reduced by using chemotherapy and postural retension. A pneumothorax which had given adequate pulmonary relaxation could often be abandoned safely after eighteen months or two years.

Dr. PETER W. EDWARDS (Cheshire Joint Sanatorium) thought that one drawback to prolonged early treatment was that it might prejudice the subsequent induction of a pneumothorax. In one series of patients it had been impossible to induce a pneumothorax in one-quarter of the cases after a period of bed rest. Although rest was essential it should be combined with an early pneumothorax when this was indicated. There was also a danger in embarking too hastily on a course of antibiotic treatment. During the initial rest period pneumothorax could safely be started as soon as the temperature and sedimentation rate began to fall. The correct period for maintaining a pneumothorax was about three years. In cases observed for a period of ten years it had been shown that phrenic crush treatment was of great value when combined with pneumothorax, or used alone when pneumothorax induction had proved impossible.

In the discussion which followed, Dr. V. COTTON-CORNWALL (Liverpool) thought that it was too early to decide whether a shortened period of pneumothorax treatment was of lasting benefit to the patient. In reply to Dr. W. S. HAINES (Mombasa), Dr. TOUSSAINT said it was not always necessary to do thoracoscopy in all pneumothorax patients, but Dr. EDWARDS preferred to do routine thoracoscopy.

Constrictive Pericarditis

Professor FREDERICK R. G. HEAF (Cardiff) took the chair when three short papers were read. Mr. O. S. TUBBS (London) gave an account of constrictive pericarditis. In this disease the heart became encased in a thick inelastic fibrous coat which prevented it from expanding and contracting properly. Calcification of the pericardium commonly occurred, but was not an essential feature. Almost all cases had a tuberculous origin. The clinical picture was that of congestive heart failure in the absence of any readily demonstrable cause. Although peripheral venous congestion predominated, breathlessness from pulmonary congestion was often present. The heart remained small, the apex beat did not shift on changing posture, and cardiac irregularities were common. Radiography showed diminished cardiac pulsation and sometimes pericardial calcification. Excision of the pericardium was required when symptoms persisted after simple treatment. A coloured film was shown to demonstrate the appearances of the heart at operation.

Congenital Atresia of the Oesophagus

Mr. R. H. FRANKLIN (London) said that atresia of the oesophagus, although a rare congenital abnormality, was about as common as hare-lip. Five anatomical varieties had been described, but only two were common. Early diagnosis was not difficult if the possibility of the disease was remembered. Affected babies went blue soon after birth and the blueness returned after pharyngeal suction. Diagnosis could be confirmed by passing a soft rubber catheter to the point of obstruction. Radiographical confirmation could be obtained by introducing 0.5 ml. of iodized oil through the catheter. This should only be done under direct observation when the possibility of surgical treatment had been considered. Radical surgical repair gave most satisfactory results.

Radiological Diagnosis of Pneumoconiosis

Dr. ARCHIBALD L. COCHRANE (Cardiff) described a method of analysing the radiological changes in pneumoconiosis. This system had formed the basis of an international classification. Pneumoconiosis was described as "simple" when the radiological shadows were diffuse and as "complicated" when massive fibrosis was seen. Both forms were divided into four grades according to severity. The figures 1 to 4 denoted the severity in the simple form, and the letters A to D in the complicated form. Standard films representing the minimal changes in each category were available. The respiratory disability and the prognosis could be accurately predicted from the radiological appearances alone.

Mr. E. F. CHIN (Southampton), Mr. J. H. PIERRE (Trinidad), and Dr. A. CAPLAN (Penarth, Glam) took part in the discussion which followed these papers.

SECTION OF NEUROLOGY

Friday, July 17

Diagnosis and Treatment of Meningitis

With the president, Dr. W. RITCHIE RUSSELL (Oxford), in the chair, four papers were read. Dr. HONOR M. V. SMITH (Oxford) pointed out that since modern therapy had provided potent remedies, often specific for certain organisms, the need for early and accurate differential diagnosis in meningitis had become urgent. She emphasized that the early institution of appropriate chemotherapy, with access of the remedy in adequate concentration to all sites of infection, was essential. Recognition of the causal organism was necessary, and it was largely early recognition and treatment that had reduced mortality, which remained high despite specific remedies whenever the start of treatment was delayed. The sulphonamides were effective in meningococcal infection, but pneumococcal meningitis, a most fulminating disease, required penicillin by intramuscular and intrathecal injections: the latter route was safe in a dosage of 10,000 to 20,000 units for adults. Streptomycin gave good results with influenzal and coliform organisms and was essential, with or without isoniazid, for tuberculous meningitis. The onset of this disease was insidious, and the family doctor should consider this diagnosis whenever unexplained malaise, irritability, headache, and fever persisted for five to six days in a child or young adult. Dr. Smith outlined a scheme for reducing delay in the start of treatment—urgent admission to hospital of any patient with suspected meningitis, with a preliminary covering dose of sulphonamides and penicillin, and intramuscular injection of barbiturates to guard against epilepsy (a common hazard in purulent meningitis, especially in children, when it had a very adverse effect on prognosis).

Dr. W. HENDERSON (York) raised the problem of recurrent pneumococcal meningitis. Dr. C. PALLIS (Cardiff) asked if preliminary penicillin might not obscure the results of examining the C.S.F. for organisms. Dr. MARGARET EGAN (Manchester) suggested that isoniazid might also have a

special place in tuberculous meningitis. Mr. MURRAY A. FALCONER (London) asked for the incidence of deafness with streptomycin treatment, which Dr. SMITH said was 10%.

Dangers of Bulbar Poliomyelitis

Dr. A. B. KINNIER WILSON (Oxford) said that this form of poliomyelitis was responsible for the great majority of deaths. Severe involvement of respiratory or vasomotor centres was a rare direct cause of death. More commonly defects in swallowing caused inhalation of saliva or food; or respiratory failure came from concomitant involvement of bulbar centres and respiratory muscles. A clear airway was an urgent need, and simple tilting of the patient in the prone position would usually secure this, though additional suction was at times required. Defects of swallowing were often gradual, and vomiting was not usually thought of as due to bulbar irritation. Nevertheless early recognition was important, because with slow seepage of secretions into the lungs and consequent reduced aeration—not of themselves dramatic—a sudden choking attack might be fatal. A stethoscope over the larynx might detect early swallowing difficulty, and a throat microphone which could be left in position and recorded sounds into a loudspeaker allowed respiratory or swallowing defects to be heard at once throughout the ward. The speaker criticized the widespread use of tracheotomy with controlled respiration via an anaesthetic bag, as used in the recent Copenhagen epidemic. It was unnecessary unless respiratory muscles were also involved. It deprived a very ill patient of the comfort of speech, and later closure of the tracheotomy might be difficult. Dr. Kinrier Wilson concluded by demonstrating on himself the sound of normal breathing and swallowing with a throat microphone.

Dr. W. W. MAPLESON, a physicist from the anaesthetic department at Cardiff, described a two-way valve for use with the Oxford inflator, electrically driven, in place of manual inflation. Dr. A. FULLERTON (Batley) was told in reply to a question that recent tonsillectomy seemed to increase the incidence of the bulbar form of poliomyelitis, but it was not clear that the overall incidence of the disease was thus increased.

Surgical Treatment of Intracranial Haemorrhage

Mr. RICHARD T. JOHNSON (Manchester) said that cerebral haemorrhage in generalized arterial disease had as yet no surgical treatment. This had a growing place, however, in leakage from an aneurysm or angioma, which might present as a space-occupying lesion from slow bleeding with clot formation, or more commonly as frank subarachnoid haemorrhage. In investigating the latter, he thought angiography was always desirable, but might be dangerous in unskilled hands. When to transfer an ill patient to a special centre was a problem. Soon after the haemorrhage angiography might worsen the condition and arterial spasm obscure an aneurysm. Patients seen later were better surgical risks because they were selected. However, Mr. Johnson said that when he did see the patients early he used angiography in the hope of defining the problem for later surgery. Treatment of a clot by evacuation was often very successful, though gradual evacuation might be needed if intracranial tension was high in order to avoid reactionary bleeding at the edges of the cavity. For an angioma full excision was best, if possible; clipping of vessels feeding it had been disappointing. Aneurysms could sometimes be approached directly, and hypotensive drugs had been a definite help. Clear angiographic demonstration was essential, and temporary occlusion of the opposite carotid allowed better concentration of the contrast medium. If direct approach was not practicable there was no doubt of the value of carotid ligation. Steady progress was being made in this field of surgery, and figures from the Manchester department of neurosurgery for the last 18 months supported this.

Dr. T. ROWLAND HILL (London) pleaded for a more experimental approach in the apparently hopeless case,

and asked what the exact cause of death was. He felt carotid ligation as an emergency measure even without neurosurgical help was justified at times.

New Trends in the Diagnosis of Spastic Paraplegia

Mr. MURRAY A. FALCONER (London) mentioned the frequency with which intervertebral disk degeneration caused pressure on nerve roots or cord. The mechanism could be by herniation of the disk backwards, by rupture of the annulus fibrosus with extrusion of a part of the nucleus, or by atrophy of the whole disk with secondary changes in vertebrae such as the formation of osteophytes or spurs. The second mechanism produced a picture of spinal block, with manometric changes and raised C.S.F. protein. Myelograms aided the diagnosis, and surgical removal of the soft-tissue protrusion was best. The third mechanism caused a very slowly progressive paraplegia, and straight radiographs as well as myelograms were helpful in diagnosis. Treatment was first by immobilization, but if operation was needed it was best to do a laminectomy and cut the dentate ligament to free the cord from pressure against the bony ridges present. Attempts at removing these had caused further cord damage. This syndrome was common in the cervical region, though it could occur also in the dorsal spine, and the picture of "cervical spondylosis" was becoming more frequently recognized. The neurological signs were patchy, rather than giving a picture of a transverse cord lesion, and the detailed pathology of the condition was still a matter of argument. However, intermittent trauma, in which traction played a part, was certain, and the speaker thought that compression of the anterior spinal artery might also be concerned in the aetiology.

Dr. J. D. SPILLANE (Cardiff) suggested that correlation of the x-ray changes with the presence or absence of signs and symptoms was required. Both he and Professor P. C. P. CLOAKE (Birmingham), who emphasized the value of immobilization in a collar, suggested that pressure arising in the way described was the commonest cause of insidious paraplegia in the elderly—a view with which the chairman agreed.

Friday, July 17

Symposium on Work and Age

With the president, Dr. J. A. L. VAUGHAN JONES (Leeds), in the chair, Dr. W. P. D. LOGAN (London) introduced a symposium on work and age. He described how over the past 80 years or so birth rates and death rates had been falling in this country, thereby materially changing the age distribution of the population. At present there were two people of working age (15 to 64 years) for every one person outside this age range, whether younger or older. This ratio was now higher than it had ever been, but it would decline still further during the next few decades. This meant that a relatively greater number of children and old people would become dependent on a decreasing population of people of working age. At the same time the proportion of old people in the population would continue to increase and by 1991 would be almost as great as the proportion of children.

Age of Retirement

The 1% sample results of the 1951 census had provided some up-to-date information about the numbers of elderly people who were retired or still working. At ages 60 to 64 years 10% of men were retired, but by the age of 70 years this figure had increased to 70%. Employers, managers, and men working on their own account carried on working to a higher age than the largest group—namely, those classified as operatives. The nature of the occupation also had an influence on the time of retirement. Whereas among agricultural workers aged 70 years and over only 59% were retired, the corresponding figures for

rail transport workers and fishermen were 96 and 94% respectively. The figure for miners and quarrymen was 92%, and for all men aged 70 years and over 77%.

The survey of sickness carried out by the Central Office of Information had shown that in an average month of 1950 days of incapacity for work per month averaged 0.69 per man aged 16 to 34 years, and increased steadily to 1.61 at ages 55 to 64 years, after which no further increase was recorded. The significant inference is that time lost on account of sickness does not suddenly rise steeply at a certain age (for example, the present arbitrary age of retirement, 65 years), but probably increases gradually throughout at least the latter half of adult life. Dr. Logan said that in his opinion there was no justification for retiring people at a specified age. Elderly people, however, must be relieved of work load, and efforts to this end should often be applied under the age of 60 years and not deferred until evidence of breakdown occurred.

Sickness in Post Office Workers

Dr. D. D. REID (London) amplified this aspect of the problem. He based his remarks on an intensive epidemiological survey of sickness, retirement on account of invalidity, and premature deaths which had been carried out over a period of four years among the staff of the General Post Office—one of the largest employers of labour in Great Britain. Sickness absence rates among young women were as a rule worse than those of the equivalent group of male workers. However, the rates among women in their fifties compared favourably with those of men of the same age. While older men were less often absent than young male staff, the average duration of absence and the total number of days lost per person were greater. To some extent these differences were attributable to differing patterns of sickness in the separate age groups. Whereas the common cold—a disease of short duration—was frequent in the younger age groups, chronic bronchitis—a cause of prolonged and recurring sickness absence—chiefly affected men over the age of 45 years. Premature "invaliding out" was mainly occasioned by chronic bronchitis, degenerative heart disease and atherosclerosis, and arthritis and rheumatism—all disorders which adversely affect physical rather than mental capacity for work. Outdoor staff were more often and more seriously affected than indoor staff. Dr. Reid concluded that the urgent need was for job modification to lighten the physical load on the older workers.

The Elderly Skilled Worker

Against this background the Rev. A. T. WELFORD (Cambridge), speaking as a research psychologist, summarized the work which he and his colleagues at Cambridge had been conducting into some fundamental problems in this field. The aim of research into this problem in industry should be to find ways of avoiding the drift of older people into light unskilled jobs. So far as possible they should be assisted to continue in the work in which they were skilled, without according them any special consideration. Towards this end the most promising approach seemed to lie in the modification of the demands made by the sort of work which had been shown to be unfavourable to older people. This could be done by improving machines and work design. Recent investigations, both in the laboratory and in industry, had suggested a number of ways in which such adjustments might be made. It had been established that with increase of age the average level of performance or activity tended to fall and the scatter round that average tended to increase.

However successful the policy of adapting work to the capacity of older people might be, there would nevertheless always be some who would have to change their jobs in middle age. This involved the training of older people, a problem about which adequate knowledge and experience are yet lacking. Current research seemed to show that difficulty in acquiring a new skill might often lie in the actual training rather than in the learning process. Finally he advocated an aggressive attitude by industrial medical

officers to influence the design of machine tools and in securing better and more timely training of ageing workmen.

In the final paper Dr. I. M. RICHARDSON (Aberdeen) gave an account of an investigation which he had made into the effects of ageing on working capacity among foundry workers and coal-miners. If the problems of age and work were to be solved it was necessary first to study individuals, then from those studies to formulate the appropriate average policy, and, thirdly, to go back to the individual and decide how best to apply that policy to him. In his experience the average age at which demands for relief from heavy work occurred was somewhere in the middle fifties. He acknowledged that the term light work had been adversely criticized, but he felt it must be retained because it had a definite meaning to the worker. What was really important was not the title but the meaning. For the workman, light, or more accurately lighter, work meant work in which the pace was slower and in particular was under the individual's own control. Whenever feasible this need should be met without a change of job. When this was not practicable the alternative job should permit the opportunity for the exercise of existing skills.

A lively discussion followed, and all the speakers commended the quality of the papers and stressed the vital importance of the subject. Dr. H. R. FREDERICK (Port Talbot) spoke about the problem as it affected South Wales, particularly the tinplate workers. Dr. G. J. ROBERTS (Cardiff) wondered whether the desire of the skilled workman for a change of job represented opposition to modern mass-production methods, including breakdown of jobs and processes. Dr. W. B. QUISENBERRY (Hawaii) raised the question of accident proneness in older workers and the place of sheltered workshops for their employment. Professor R. C. BROWNE (Newcastle-upon-Tyne) asserted that it was the duty of medical teachers constantly to convince their pupils that the prescription of work should be as precise and detailed as the prescription of medicaments. Dr. J. MCG. ROGAN (London) made the important point that the workman himself often realized his diminishing powers and solved his own problem by finding suitable alternative work. This signified that those concerned in this problem should beware of being too "grandmotherly" in their efforts on behalf of every workman.

Occupational Cancer

Dr. J. GWYNNE MORGAN (Clydach) contributed an occasional paper on a series of cases of occupational cancer of the nose (44 cases) and cancer of the lung (110 cases). These had been observed over the last 40 years among workmen engaged in nickel refining. Some of the processes were very dusty and some of the materials contained arsenic as an impurity. Intensive efforts had been made through mechanization, reduction of dustiness, and the use of arsenic-free sulphuric acid to control the hazard. While sporadic cases continued to appear, none has so far occurred among men who had commenced work on the plant during the past 25 years. A noteworthy feature was that not infrequently the disease had not become manifest until several years after the workman had ceased work in the processes.

Dr. Morgan also described and demonstrated a simple test for detecting coproporphyrin in the urine of lead workers.

Ocular Complications of Diabetes

With the president, Mr. J. H. DOGGART (London), in the chair, papers on the ocular complications of diabetes were read by Mr. G. I. SCOTT (Edinburgh) and Dr. LEONARD H. HOWELLS (Cardiff). Mr. SCOTT emphasized that there was now no doubt that diabetic retinopathy was an entity quite distinct from that occurring as a result of hypertension or atherosclerosis. Even in the older patients in his

series of 150 diabetics retinopathy was equally common in patients with or without hypertension. He also noted that the incidence of retinopathy increased very markedly with the duration of the diabetes, although he stated that some 10% of cases showed retinopathy within a year of the condition being diagnosed. In diabetics of twenty years' standing or more the incidence was over 70%. The speaker then described recent pathological work and findings in the retina, and gave a classification of the clinical stages. In the first stage capillary micro-aneurysms were a prominent feature. These were followed first by punctate and later by blot haemorrhages. Subsequently either retinal haemorrhages might progress and exudates develop or there might be haemorrhages into the vitreous followed by retinitis proliferans, proceeding to detachment of the retina and degeneration of the eye. In another smaller group of cases the initial fundus changes consisted in retinal periphlebitis, following which vitreous haemorrhages and retinitis proliferans also occurred. The total incidence of retinitis proliferans in all cases of diabetic retinopathy varied between 9 and 16%. There was some evidence to suggest in Mr. Scott's cases that careful control of the diabetes reduced the incidence of retinopathy, probably through an effect on capillary fragility. He had found rutin to be of no value. Other changes briefly discussed were alterations in the refraction of the eyes, the development of true diabetic cataract in young persons, and the effect of diabetes on the incidence and development of senile cataract.

Dr. HOWELLS began by saying that diabetes was becoming more common and that in this country some 3% of the population suffered from the disease. He stated that there was an undoubted hereditary transmission, and that treatment of the disease, in that it not only increased fertility but made childbirth safer, was bound to lead to increased numbers of surviving patients suffering from the disease. The disease was much commoner in overweight patients, at any rate in the older age groups. With the increasing longevity of diabetics due to modern therapy ocular complications became more common, and some 30% of all diabetics eventually developed retinopathy. He agreed that the incidence was 70% or more in old age, and had observed that in many of the older patients hypertension and renal changes were added to the ocular complications. In treatment he considered it essential in the older overweight patients to reduce weight, preferably by dieting. If this were successful the condition could be adequately controlled clinically without insulin in many patients. It was preferable to reduce weight by diet only, but if this were unsuccessful then there should be no hesitation in using dextro-amphetamine sulphate. In younger patients a diet should be prescribed which would enable them first to regain and then to maintain the standard weight for the patient's age. In a smaller series of patients than that analysed by Mr. Scott he found the incidence of retinopathy varied little according to the duration of the disease, and that it occurred at least as frequently in well-controlled as in partially controlled diabetics.

Mr. A. B. NUTT (Sheffield) considered the problems of cataract operation in diabetes. In his view, the eyes in these patients should not be considered normal and were more liable to complications; convalescence was often stormy. Among the complications he described were delayed wound healing, infection, haemorrhage, and post-operative iridocyclitis.

In the general discussion Dr. HOWELLS stated in reply to Mr. T. S.-B. KELLY (Hereford) that the renal threshold in diabetes was probably higher than is generally realized, and in reply to Mr. J. E. M. AYOUB (London) that although much work had been done there was no knowledge of any other metabolic factor which might be responsible for retinopathy. In reply to Dr. T. A. S. BOYD (Oxford) he said that at present no clinical differentiation in man should be made between diabetes resulting from insulin deficiency and pituitary dysfunction. Mr. NUTT, in reply to Dr. G. J. ROMANES (East Grinstead) said that the use of the methonium compounds during operation, with the idea

of controlling haemorrhage, was probably dangerous in these cases, but suggested that toluidine blue might prove to be of value.

The President of the Association, Mr. J. W. TUDOR THOMAS, attended some part of the meeting, and welcomed members of the Section.

Corneal Grafting

In the second discussion on the scope of corneal grafting, with one of the vice-presidents, Mr. RUPERT J. PARRY (Cardiff) in the chair, the openers were Mr. B. W. RYCROFT (London) and Mr. E. C. ZORAB (Southampton). After a brief historical review of the past 150 years Mr. RYCROFT spoke about the factors which at present influenced the expansion of corneal-graft surgery. Under the heading of "Technique" he considered the fixation of the graft, the type of section, and the problem of total transplantation of the cornea. He also entered briefly into the problems of administration, touching on eye banks, the preservation of graft material, and the training of surgical teams engaged in this type of work.

The major problems of corneal-graft surgery at the present time were in oedema and neovascularization of the cornea, both of which were possible results of an antibody-antigen reaction the precise nature of which was still not determined in spite of much experimental work. In the speaker's view this reaction was the most important problem in corneal-graft surgery to be elucidated.

Mr. ZORAB dealt with the difficulties met with by the surgeon who was relatively inexperienced in this type of work, emphasizing that he must be eclectic in his decisions on choice of case, on when to operate, and that he should start with lamellar grafts in difficult cases. Technical accuracy in this work was extremely important. He made a plea for research into methods of accurate measurement of the corneal thickness, and into the possibility of developing a satisfactory mechanical trephine. He also discussed from his own experience the pitfalls and poor results occurring from errors of technique.

Mr. J. AYOUB (London) also discussed various complications which may follow the operation, particularly prolapse of the graft, post-operative glaucoma, the development of anterior synechiae, and the occurrence of oedema and vascularization of the grafts. He thought that some post-operative complications were probably due to allergy.

Mr. A. G. LEIGH (London) analysed the various factors resulting in post-operative opacification of the graft, dividing these into three groups: incorrect choice of case, faulty operative technique and post-operative treatment, and delayed opacification of the graft due to the formation of fibrous tissue on its posterior surface resulting from causes so far unknown.

In the general discussion, in reply to Mr. A. G. PALIN (Bristol), Mr. RYCROFT stated that he could offer no explanation for the clearing of the cornea which took place in some cases after a delimiting keratotomy.

SECTION OF ORTHOPAEDICS

Friday, July 17

The Injured Hand

With the president, Mr. A. O. PARKER (Cardiff), in the chair, Mr. W. GISSANE (Birmingham) opened a symposium on the injured hand, later acclaimed by several experienced orthopaedic surgeons as the best they had heard at any scientific meeting. Mr. Gissane spoke on major wounds of the hand. He emphasized the need for the expert planning of treatment; in dealing with manual workers, ultimate function was more important than appearance. The doctrine of saving all viable tissues might be dangerous when applied to the hand, because it so often led to the retention of a stiff, painful, and useless portion of that organ and to unnecessary delay in recovery. All workers showed a remarkable ability to make good use of remnants of a hand that

were painless, mobile, and strong. The aim of surgery must be to restore some of the fundamental uses of the human hand. These were: (1) To act as the two sensitive antennae of the body; thus retention of any part of the hand with normal sensation was important. (2) For use as a clamp to hold things down; the retention of the base of the hand alone would suffice for this. (3) To exert a pincer grip; for this function were required a thumb, its remnants, or a surgical replacement, and at least one finger or its remnants; at least one arm of the pincer must be mobile. (4) To serve as a hook to hold and carry; even the little finger would fulfil this purpose. (5) Finally the hand was a vice; for this purpose at least two fingers and the powerful clamping action of an intact thumb were required.

The intact skin of the hand was always covered with a wide variety of pathogenic bacteria. All hand wounds, therefore, were contaminated from the start, and the important factor in preventing infection was the circulatory response within the first few hours of wounding. This emphasized not only the urgency of surgical intervention but also its primary objective—to improve the blood supply to the injured area. Wound cleaning must be gently and thoroughly performed with a non-irritating soap or detergent, and under anaesthesia. Tension must be scrupulously avoided, and the wounded areas covered by some form of skin graft if tension-free suture was impossible. Judged against the likelihood of full restoration of function some common closed injuries of the hand came into the category of major injuries. Bennett's fracture-dislocation of the thumb and some dislocations of the interphalangeal joints of the fingers were best treated by open reduction and suture of the detached capsule.

Mr. R. J. FURLONG (London) confined himself to the problem of the cut flexor tendon. Immediate suture of the tendon was desirable because it kept the tendon in its normal place, which might otherwise become blocked by scar tissue, and because it tended to prevent secondary changes in the muscle and tendon proximal to the division. But primary suture might be undesirable because of contamination or destruction of the skin and other tissues; in that case skin closure alone was indicated, followed by early mobilization of the finger and hand. Secondary procedures such as tendon grafting were apt to fail if the surgeon was inexperienced and particularly if he had the wrong instruments. Primary suture of the profundus tendon distal to the proximal interphalangeal joint might often produce a useful finger, even if the result was a tenodesis. In the no-man's-land between the first interphalangeal joint and the distal palmar crease, primary suture might sometimes succeed if the sublimis tendon were sacrificed, but for injuries here grafting was usually necessary, of course as a secondary procedure. He preferred the palmaris longus with its paratenon for the graft. Judging the length of graft, position for suture, and tension to be exerted were all problems which should be solved by art and experience rather than set rules. The degree of flexion was determined by the position of the resting hand and fingers. The actual method of suture was no longer regarded as important; either silk or stainless-steel wire was a suitable material, although he preferred the latter. It was his practice to close the wound and apply a pressure bandage before removing the tourniquet.

Mr. EMLYN LEWIS (Cardiff) dealt with the problems of skin loss in hand injuries. In the case of some small defects local grafts from the hand itself could be used; sometimes a severely damaged finger could be filleted and used as a flap. When there was wide "degloving," the skin was seldom viable and paring back was better than attempts at primary suture. A free skin graft provided the most useful cover: the full-thickness graft was ideal but technically difficult to use. The split-skin graft was not suitable for direct application to exposed bone or tendon, and in the hand a further drawback was that it did not replace the palmar cushion. Direct flaps could be obtained from the forearm, and the disadvantage of putting both arms

of action could be obviated by suitable positioning. The amount of skin available on the forearm was limited, so that for larger defects he preferred to place the injured hand below the opposite acromion-clavicular joint and take the flap from that site. Abdominal flaps were inclined to be bulky, although they could of course be reduced later. Tube-pedicles provided good skin with an ensured blood supply, but could be used only in the treatment of the late case.

Mr. L. W. PLEWES (Luton) showed a colour film illustrating some of the methods of industrial rehabilitation of the injured hand. Recovery might be delayed by oedema and resulting fibrosis, by a persistent low hand temperature due to post-infective conditions or vasomotor disturbances, and by failure to use the hand at a very early stage for its usual functions. Another, and subtler, complication was extensor spasm, and Mr. Plewes had been able to demonstrate this by means of a specially constructed oscillograph.

Mr. R. G. PULVERTAFT (Derby) introduced the "chirodemon" of the Derbyshire hills in a series of amusing but highly instructive cartoons illustrating the pitfalls and mistakes of hand surgery. He agreed with Mr. Furlong on the importance of using the proper instruments, and said that watchmakers' tools were very suitable. It was his practice to remove the tourniquet before closing the wound, and he had found that bleeding ceased automatically after a few minutes; ligatures were seldom required. Mr. A. L. EYRE-BROOK (Bristol) considered that the tendon slings in the fingers could be divided and would heal when the soft tissues were sutured. He disliked suture of the tendon graft near the distal interphalangeal joint, and preferred to pass it through a tunnel in the phalanx. He had met with necrosis of the graft and later snapping as a complication. Mr. F. C. DURBIN (Exeter) discussed the disadvantages of plaster in the treatment of phalangeal fractures. For some time he had used open reduction and medullary fixation with Kirschner wires. The wires were buried, and were removed after six to eight weeks when body union had occurred. Severe comminution and gross infection were contraindications. Mr. E. MERVYN EVANS (Swansea) made a plea for the wider dissemination of surgeons and facilities for the treatment of hand injuries and indeed of all accidents. It was obvious from the symposium that important surgical decisions had to be taken at the outset of treatment in these injuries, and it was still too often the case that these decisions were being left to house-officers. Mr. R. H. C. ROBINS (Exeter) showed that the post-articular skin would provide very satisfactory grafts for partly amputated finger-tips. Mr. I. LAWSON DICK (Edinburgh) questioned whether it was always necessary to incise the palm along the skin creases, and asked whether pollicization was such a valuable operation as had been suggested elsewhere. In reply Mr. PULVERTAFT agreed that crease incisions were not essential, but they did provide an invisible scar. Mr. EMLYN LEWIS supported the operation of pollicization, and enlarged on the use of the index finger for this purpose in the treatment of congenital deformities.

SECTION OF OTO-RHINO-LARYNGOLOGY

Friday, July 17

Management of Otitis Media

With the president, Mr. R. D. OWEN (Cardiff), in the chair, Mr. I. SIMSON HALL (Edinburgh) opened a discussion on the treatment of otitis media. By means of a chart compiled from the records of cases of acute otitis seen at Edinburgh before and after the introduction of sulphonamides and antibiotics, he showed that the operation for acute mastoiditis had almost disappeared. In his experience the sulphonamides were more effective on their introduction than they now were, so that nowadays they were only

to these drugs was increasing. On the other hand, the number of cases of chronic otitis coming for treatment was increasing, and certainly many more operations for chronic suppurative otitis media were performed at present than in the pre-sulphonamide era.

In the treatment of acute infections the choice of antibiotic depended on the results of bacteriological tests, but as a rule penicillin should be used first, even when no organisms were available for examination. It was much cheaper than the newer drugs, quite as effective in most infections, and rarely gave rise to side-effects. After three days it would be apparent if penicillin was adequate as the sole means of treatment. If not, then in the absence of otorrhoea pus should be aspirated from the middle ear by puncture or myringotomy in order to test for sensitivity. Mr. Simson Hall's next preference was for streptomycin, but the possible damage this might cause to the hearing had to be remembered. When a slight residual discharge was present at the end of treatment of the acute condition, he had found antibiotic drugs of no value. Any apparent improvement was due to the scrupulous cleansing of the ear which was a necessary accompaniment to their use.

Mr. J. I. MUNRO BLACK (Newcastle-upon-Tyne) said that in examining the ear he advised the use of a headlamp and frontal mirror rather than an electric auriscope. The differential diagnosis lay between otitis media, external otitis and boils, mumps, tonsillitis, toothache, or foreign body. Fortunately treatment for otitis media would also cure boils and tonsillitis, so in these conditions a mistake in diagnosis did no harm. The only advantage of the sulphonamides over penicillin was ease of administration, but against this they were less certain in action and might produce side-effects which mimicked complications of otitis. The combined use of the sulphonamides and penicillin should be avoided. The newer antibiotics could be tried if the organisms proved resistant to penicillin. Treatment should be continued till the otitis was better, as shown by cessation of discharge and return of the tympanic membrane to normal.

Failure to maintain improvement might be due to resistant organisms or to some aggravating factor—e.g., enlarged adenoids, sinusitis, or chronic otitis. If the condition worsened or complications developed all treatment should be stopped for 24 hours and the position reassessed. Surgical intervention was now very rarely needed. The decision to operate was determined by the presence of pus or necrotic material which was not absorbing. The prognosis in treated cases was good, most patients being now successfully treated by the general practitioner.

Mr. GEOFFREY H. BATEMAN (London) agreed with the previous speakers that the change in treatment was quite revolutionary. Now the general practitioner had remedies which he could apply with greater advantage in the early stages, he was making an earlier diagnosis with the aid of an electric auriscope. Sulphonamides occasionally masked an infection, but they enabled cases to be watched confidently, and any operation that might be needed could be postponed to the most favourable time, so that post-operative septicaemia had practically disappeared. Penicillin and the other antibiotics had taken us a step further in effective control. But surgery was sometimes necessary, even when the organism was sensitive and the dosage adequate. Because pain disappeared and temperature returned to normal it must not be assumed that the patient was completely cured. In addition the tympanic membrane must have resumed a normal appearance and the hearing have been fully restored. The basis of treatment should be early diagnosis, adequate dosage of penicillin, myringotomy when pus was present in the middle ear, and careful observation of the ear until it and the hearing were normal. Any unsatisfactory feature persisting more than two weeks should call for an otologist's opinion.

In the subsequent discussion Dr. A. J. MACLEOD (North Uist) asked how it was possible to make a satisfactory aural examination in infants and very young children. Mr. MUNRO BLACK replied that in many cases it was impossible. Dr.

ELSIE WARREN (London) asked how the general practitioners could be sure that there was no otitis media when boils blocked the external auditory meatus. Mr. MUNRO BLACK said the same answer applied, though if the infection in the meatus was recurrent the tympanic membrane might be visible in the quiescent periods. Replying to a question about the effectiveness of oral penicillin in children, Mr. Munro Black stated that the evidence was incomplete, but oral penicillin was worth trying. Mr. S. W. ALLINSON (Boston) asked if it would not be most beneficial if parents trained their children to breathe properly. Mr. SIMSON HALL in reply, agreed that this would be so, and was a step in keeping with the modern tendency to stress prevention rather than cure. Dr. M. L. H. EVANS (London) asked if condemnation of the self-illuminating auriscope was advisable, since in his opinion this apparatus had prior place to the clinical thermometer and stethoscope. Mr. SIMSON HALL replied that the auriscope was very useful, but the head mirror was still needed for examination of the nose and throat. Dr. J. T. REES (London) asked Mr. Bateman what advice a school medical officer should give in a case of recurrent otitis with every cold, and should aural drops be used. Mr. BATEMAN replied that the patient should be examined by a specialist to determine the underlying cause, and that aural drops alone were not of proved value. Dr. G. HOYLE (Tamworth) asked whether the general practitioner should perform Eustachian catheterization when the drums were retracted after successful treatment with penicillin. Mr. BATEMAN replied that retracted drums in a child would probably be due to adenoids, which should be removed. Politzer bag inflation was preferable to catheterization. In reply to Dr. A. LAMONT (Inverness) who asked if there was any contraindication to the use of chloramphenicol locally plus systemic penicillin, Mr. BATEMAN replied that chloramphenicol was better avoided, as it commonly caused local reactions, especially in a repeat course. Dr. E. NOEL REES (Llanelli) asked whether the local application of penicillin was indicated. Mr. BATEMAN replied that local treatment was of no value before the drum had ruptured.

Upper Respiratory Tract Infections in Allergic Children

Mr. C. GILL-CAREY (London), a vice-president, then took the chair, and Mr. J. ANGELL JAMES (Bristol) opened a discussion on the diagnosis and treatment of upper respiratory tract infection in allergic children. In a series of 1,208 children he had seen recently 114 suffered from allergy. Examination was difficult because of the highly strung temperament not only of the child but often also of the parents. Further, the allergic reaction masked the appearance due to inflammation, and vice versa. Constrictor sprays might help in nasal examination, but often the nasopharynx could not be examined without a general anaesthetic. When allergy complicated infection swelling might interfere with sinus drainage, so delaying resolution. In chronic allergy the presence of infection was most difficult to recognize, because of infiltration and fibrosis due to the repeated allergic attacks. There was a strong tendency to lymphoid hypertrophy in allergic children. Recurrence of adenoids after operation was particularly common in such children. In investigation of the sinuses it was important to decide if there was pure allergy, pure infection, or a mixture of the two. Symptoms alone might lead to confusion, and skiagrams were very helpful. Histological examination showed that in uncomplicated allergic conditions there was, typically, an irregular swelling of the mucosa with no fluid collection. Proof punctures were not always reliable.

In the treatment of sinusitis conservative measures were sufficient in almost every case, vigorous anti-allergic treatment being employed at the time and continued after the infection had resolved. Surgery in these cases was hazardous. In conclusion Mr. James pleaded for the closest collaboration between paediatrician, allergist, and rhinologist.

Dr. T. A. BRAND (Newport, Mon) held the view that, in children suffering from allergy and infection, operations on

the upper respiratory tract sometimes aggravated the existing allergy or induced a fresh allergy. The paediatrician was of course more likely to see the failures after operation than was the surgeon. Great caution was needed before surgery was undertaken in allergic subjects. A history of recurrent and prolonged colds suggested the possibility of allergy plus infection. In addition to the more commonly recognized symptoms of allergy, a persistent, unproductive cough, worse at night than in the day and not responding to the ordinary remedies, was often complained of. Skin tests were, on the whole, disappointing, as also was specific desensitization based on such tests, though occasionally a dramatic cure might be obtained. Swabs of the posterior nares, allowed to remain *in situ* for at least a minute, often showed the presence of eosinophilia. Radiological examination could be most helpful.

Treatment should, so far as possible, be conservative. Besides avoidance of contact with the offending allergen, non-specific desensitization might be useful. Antihistamines were disappointing, except for promethazine hydrochloride, in seasonal rhinorrhoea. Theophylline with small doses of phenobarbitone sometimes helped. In combined sinusitis and allergy postural instillations of decongestants were sometimes useful, especially when combined with antibiotics in the early stages and with physiotherapy. Surgery should be undertaken only when recurrent severe upper respiratory tract infections had proved a serious handicap to the child's physical and educational development. The parents should always have possible sequelae explained to them, and rehabilitation exercises should always follow the operation.

Dr. J. PEPYS (London) described three ways in which allergy and infection might be associated—infection leading to the development of bacterial allergy (a view not generally accepted); infection predisposing to the onset of allergy by lowering the clinical threshold; and allergy complicated by infection, a common condition in which disturbed nasal physiology due to allergic mucosal swelling was the determining factor. Hence control of the allergy was essential if lasting results were to be achieved by treatment of the infection. In the diagnosis of nasal allergy a history of frequently recurring colds, lacking the usual sequelae, was important, in addition to sneezing and rhinorrhoea. Nasal itching was characteristic. Continuity of care over long periods was necessary, as the allergic state was apt to persist throughout life, though the nature of the allergen might change. From early infancy up to 4 to 5 years of age food allergens—for example, milk, eggs, chocolate, and nuts—were important, but in later years these were largely supplanted by inhaled irritants. In older children desensitization to inhaled irritants could help, but must be done for long periods. Ephedrine or antihistamines by mouth could be most useful, though prolonged administration might lead to anorexia and depression. Local nasal vasoconstrictors should be used with care, lest "rhinitis medicamentosa" developed. The potentially allergic infant should be recognized early, as this might well lead to a reduction in the incidence of allergic disorders.

The main speakers then answered a number of questions. In reply to Mr. R. G. MACBETH (Oxford), who asked, "Was the pneumococcus the commonest organism found in infection associated with allergy?" Mr. ANGELL JAMES stated that he had found the staphylococcus, streptococcus, and pneumococcus in that order of frequency. Mr. I. SIMSON HALL (Edinburgh) asked what decongestant was advisable, ephedrine or the longer-acting ones: to which Mr. ANGELL JAMES replied that ephedrine was used most, "prvine" and "neophryn" occasionally. Mr. F. C. W. CAPPS (London) asked if it was often advisable to remove the allergic child from its parents for a time. Dr. BRAND replied that the child did very well, but on return home almost invariably relapsed. A long period of absence was necessary—say, two or three weeks in hospital, followed by a long convalescence, preferably not at the seaside. Dr. C. EISINGER (London) and Mr. A. MACKENZIE ROSS also contributed to the discussion.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Treatment of Acute Malaria

SIR,—In his letter (*Journal*, July 4, p. 41) Sir Gordon Covell, possibly unconsciously, has thrown a spanner into the therapeutics of malaria. As a sincere student of malariology may I be pardoned for asking, "Quo vadis?" And if a specialist in this subject finds himself in a quandary regarding the effective drug treatment of malaria, what must be the state of mind of the practitioner in the Tropics, and, more so, that of the unfortunate student who has to be examined on this subject?

Is the object of his letter a proposal of "back to Methuselah," which in this case indicates a return to quinine as adumbrated by his expression of a "more rapidly acting schizonticide"? If this should be the case then it is permissible to inquire why our old friend quinine has been so persistently relegated to obscurity in recent years. It has even been stated in an annotation (*Journal*, March 15, 1952, p. 590) that the use of quinine in the treatment of chronic *Plasmodium falciparum* infections should be discontinued altogether. If any other evidence were required of the present medley regarding the most effective treatments of malaria, it is to be found in the *Journal* of January 20, 1951 (p. 149), where a puzzling complex combination of drugs is suggested for the various forms of this fever.

A long procession of antimalarial drugs has been witnessed in recent years. Hardly has there been time to assess the merits of one before another, allegedly more powerful, synthetic makes its appearance. It is useful to reiterate at this juncture what Sir Samuel Gee is reported to have said: "Gentlemen, go on using your drugs just as long as they cure."

The difficulties of understanding the present situation commenced with the introduction of pamaquin ("plasmoquin") in 1926 by W. Roehl.¹ Up to this time nobody had had the temerity to suggest that any other drug could supersede quinine in the treatment of malaria. Unfortunately, it proved too toxic in routine use for man. Then came mepacrine in 1931, introduced by W. Kikuth,² and this had properties which appeared to outrival those of quinine. Although at first most doctors in Africa and in this country were disposed to despise it, yet mepacrine maintained its position until the outbreak of the second world war. Nobody ever suggested that its schizonticidal action was as rapid as that of quinine, though the combination of the two proved most efficacious in the treatment of acute subtertian malaria. The official Army view in 1939 was that mepacrine was too poisonous for mass administration to troops in spite of the fact that its prophylactic value had already been proved in Yugoslavia, U.S.A., and E. Africa.³⁻⁵ Here these properties were not rated high at that time, so that it was not until 1942 and the fall of Java that the shortage of quinine forced the attention of malariologists to the potentialities of mepacrine as a prophylactic as well as a curative drug, with the result that malaria was banished as a dominating factor in the war in the Far East. All this is now a matter of history, but we have reached the stage when the virtues of quinine as a powerful schizonticide have already been forgotten by many of the present generation of doctors. The end of the war (1945) saw the introduction of proguanil,⁶ which was the result of intensive research and represented an achievement of great scientific value. The first reports from Liverpool (1945-6) on the treatment of both subtertian and benign tertian malaria were so favourable that they made a very wide impression. To commence with, the doses were so small as to suggest an almost ultra-optimistic attitude. Similar claims were made for its prophylactic properties, the dose for which was stated to be 100 mg. once a week. As the years rolled on the fallacies of this appraisal have become apparent and *passu* the doses of proguanil have been stepped up, so that its advocates now suggest as a curative dose for subtertian malaria 12 times that advocated in 1945. But at the present moment, as Sir Gordon states, its value as a powerful schizonticide in this disease is more than doubtful as its action is far too slow, even

in these large doses. Furthermore, another difficulty in the mass treatment of malaria has arisen in the facility with which resistance to this drug is acquired, and this has led to a further increase in the prophylactic dose of proguanil. In order to counteract this tendency some modern workers have been led to advise the combination of quinine with proguanil to increase its effective action. This suggestion begs the question of why one should employ proguanil at all under these circumstances, since it is considered to play such a minor part in extirpating the malaria parasites. Now we have pyrimethamine, which is the latest comer on the stage. In this case, as related in recent issues of the *Journal*, the story appears to be following the proguanil model. At first minute doses were advocated, 25 mg. a day; then, after a few months' delay, papers are published portraying optimistic results, especially in subtertian malaria, and then others follow which appear to give the opposite impression,⁷⁻¹⁰ but Sir Gordon writes that, as in the case of proguanil, in subtertian malaria pyrimethamine should not be used unless in combination with a more powerful schizonticide. One principle seems to emerge from this conflicting mass of evidence—namely, that when the 8-aminoquinolines, such as pamaquin, were introduced, the therapeutic dose was too large, and the longer the drug remained in use the more consistently was it reduced. In this case it was from 0.12-0.03 g. daily. In mepacrine, which at first was thought to have no side-effects, the reverse has happened and it has risen from 0.3-0.6 g. daily, or even higher, with the result that patients are made actually ill; but in the less toxic compounds, such as proguanil and pyrimethamine, the therapeutic doses become increasingly bigger and bigger as time goes on, and even then, as Sir Gordon states, they do not appear to be powerful enough to halt a subtertian attack.

This letter is not to be taken as a disparagement of these antimalarials which have been forged as a weapon in the fight against malaria, nor is it asserted that the disappearance of malaria from great tracts has not been, in some measure, due to their mass application, but I would like to stress the danger of discarding old friends for new without due consideration. It takes a long time to digest all this new information, and it also takes many years for an antimalarial drug to establish a permanent and lasting reputation, so I am glad to see that this question is so fairly and adequately handled in the newly published book *Clinical Tropical Diseases*, by A. R. D. Adams and B. G. Maegraith. —I am, etc.,

PHILIP MANSON-BAHR.

Experiences with Pyrimethamine in Kenya

SIR,—The results obtained by Sir Gordon Covell with pyrimethamine ("daraprim") in preventing non-immune subjects from developing malaria (*Journal*, May 16, p. 1081) are of special interest to practitioners working in malarious areas, such as the Kenya Highlands, where the disease is encountered very often among non-immune Europeans.

Our malaria is almost entirely sub-tertian, and this season it has been exceptionally severe. Numbers of settlers have been using pyrimethamine for prophylaxis, in the manner recommended by the manufacturers. The results which I have personally encountered have not borne out the claims made for this drug, though many have been satisfied by a factorily protected and therefore have not been seen by a doctor. But the fact that there have been fairly frequent failures is of sufficient importance to put on record, as most of the cases occurring after the use of pyrimethamine have been severe, and one, my own child, was nearly fatal.

I have recently treated three cases of malaria in children under 3 years old who had taken their half-tablet of pyrimethamine in the week before the attack. All these commenced with convulsions and the one noted above was an exceptionally severe case. All required intramuscular quinine and sedatives; one of these

cases had a positive blood slide. Two other cases in children under 2, both with positive blood slides, had diarrhoea or vomiting. Two adult men whose slides were negative had severe attacks. Thus there were seven cases, all severe, all of whom so far as could be ascertained had used pyrimethamine as a prophylactic. One other case serves to illustrate a characteristic of this drug which also can be dangerous or fatal. A boy aged 20 months swallowed about 15 tablets while in apparent perfect health. He developed convulsions in about three quarters of an hour which resisted all treatment, and he died two hours later. Necropsy showed cerebral congestion. Histological section did not confirm this, but did show congestion of both kidneys. Chemical examination of the stomach contents showed in various tests a substance which gave identical results to pyrimethamine. This was done to exclude the presence of any other poisonous substance. Two other cases of children consuming up to about 15 pyrimethamine tablets have occurred recently in this area, but the results were not severe. These cases underline the fact that the drug has a relatively attractive taste, and therefore needs to be carefully locked up.

Returning to the prevention of clinical cases of malaria, I would like to suggest that when research is carried out on a new antimalarial drug it should be tested not only on volunteers in Europe, or on the indigenous inhabitants of malarious areas, who probably have a high degree of immunity, and on whom pyrimethamine, at least, works exceedingly well, but also on Europeans living under normal conditions of life in the Tropics. These might well be subdivided into (a) infants, (b) children, (c) adults recently arrived in the Tropics, (d) adults with a long residence and history of many attacks of malaria, and (e) adults with long residence and few or no such attacks. Infants and children could be subdivided into those born in malarious regions and those entering at an early age from abroad. The clinical cases of malaria which are used in the experiments or trials also need careful definition into the various well-known types and grades of severity. It is not enough to say that malaria is prevented or attacks are controlled by a given dosage of a particular drug. The practitioner wants to know whether he can rely on a drug both to treat and prevent pernicious attacks of subtertian malaria, and the milder relapsing types in all cases and under all circumstances. Furthermore, malaria has strange variations in virulence in the same district which require consideration.

It may be that if the records of private practitioners in tropical countries could be made accessible to research workers, they would find much information of the nature indicated, and which would act as a useful check on their own highly controlled experiments.—I am, etc.,

Eldoret, Kenya.

R. Y. TAYLOR.

Post-inoculation Poliomyelitis

SIR,—Dr. James Grant, in his article on post-inoculation poliomyelitis (*Journal*, July 11, p. 66) describes eight cases which occurred in South Tyneside during 1952. Of these, four are shown as having followed the use of combined diphtheria and pertussis prophylactic, but I cannot gather from the text whether the diphtheria portion of this was alum-precipitated or not. He merely describes the material as combined diphtheria toxoid and pertussis vaccine.

I should be glad to know whether the diphtheria component of this material did contain aluminium hydroxide or not, as I think it is a matter of some importance. Admittedly pertussis vaccine alone is apt to be irritant, but there is no doubt that the combined prophylactic containing alum is even more so. To this end I devised a combined prophylactic of pertussis vaccine containing purified fluid diphtheria toxoid without mineral carrier, which I have been using subcutaneously for the best part of three years. This produces no more local reaction at the seat of inoculation than does the same pertussis vaccine when given alone. The Schick-conversion of this material, given as three injections at monthly intervals, is just a fraction under 100%, on observation of over a thousand cases three months after the final injection. The same applies to purified fluid toxoid (Holt) given as three-monthly subcutaneous injections of 0.5 ml. (30 Lf), and for primary immunizations in young children it will be found to cause virtually no reaction at all. It should not be used for boosting doses in older children. The Schick-conversion rate here is also near-optimal three months after the last injection.

Thus I think that the last point of Dr. Grant's summary, that "manufacturers of prophylactics should aim at the production of antigens which will be satisfactory in every way, when given by subcutaneous injection," is already answered. A combined prophylactic, to my original formula, is available from Messrs. Parke, Davis & Co., as W.D.P. (Red), and similar preparations are now marketed by Messrs. Burroughs, Wellcome & Co., and Messrs. Glaxo. The plain fluid toxoid, for use when there is any risk of poliomyelitis in an area, is also available from Messrs. Parke, Davis & Co., and I believe also from Messrs. Burroughs, Wellcome & Co.

I have used nothing but subcutaneous injections ever since I felt that this route might be better for avoiding paralysis.—I am, etc.,

London, S.E.5.

G. BOUSFIELD.

Clinical Research in the N.H.S.

SIR,—In the otherwise encouraging White Paper on this subject¹ it was disappointing to find in paragraph 6 a tacit assumption that "systematic investigations undertaken deliberately and often over long periods" were somehow not within the province of general practitioners but only of "... whole-time clinical professors and clinical research workers ... university professorial units ... research units of the M.R.C. and ... private research foundations." It might not be out of place to remind your readers of the "systematic investigations undertaken deliberately and ... over long periods" by Sir James Mackenzie, whom you mention in your editorial,² by Dr. W. N. Pickles, and by others.

The same assumption seems to underlie the omission of executive councils from among those local bodies which would be authorized to control decentralized Exchequer funds.

It would be unfortunate if the new impetus given to research in general practice by recent events was impeded by any organizational defects that were unwittingly allowed to creep into this otherwise admirable proposal to enrich the life-blood of clinical research throughout the Health Service.—I am, etc.,

Peaslake, Surrey.

A Human Chimera

SIR,—A report in the lay press describes the case of Mrs. McK. (see *Journal*, July 11, p. 81), who is stated to have been "the first human being in medical history with a double set of blood groups." Sir, I beg to differ. In 1943 I joined the Royal Air Force for aircrew duties, and when they typed my blood it was found to be OA. I left England in 1947 for Canada, and the next time I had my blood typed was in 1949 for the blood bank up there. After testing they told me they did not think it necessary for me to donate any. They found it the same, OA. In the Air Force I never came across anyone else with the same group, which fact got me a little worried. However, no matter how many medical officers or laboratory technicians I asked about it, they either would not, or could not, tell me anything, except that I was as healthy as anyone else.

Like the lady mentioned I, too, am a twin. My twin brother still lives in England, and neither of us have had one day's real sickness in about forty years—we are 43 years old. I have a son, 20 years old, who has just got his commission as a fighter pilot in the Canadian Air Force, and my brother has a son and a daughter who are as healthy as the rest of us.

Whether this information will be of any use to you I do not know, but at least I have at last got a definite explanation of what my blood group, OA, stands for.—I am, etc.,

California, U.S.A.

S. BARON.

The Doctor in the Witness-box

SIR,—Viscount Simon in his interesting Cavendish Lecture on the doctor in the witness-box (*Journal*, July 4, p. 1) makes the important observation that the case of the mother who destroys her child is hard to fit into the M'Naghten Rules, but in practice a verdict would be returned which recognized the defence of insanity. I was in a case some years ago where a mother killed her child on learning he was a mental defective—first trying gas then strangulation—because she so dreaded the suffering she imagined in store for him. She was in a highly strung emotional state, but not psychotic, when she performed the act. The case was taken by a very serious judge who asked the jury whether it "really thought she knew what she was doing was wrong?" The jury returned a verdict of guilty but insane in conformity with humanity and common sense, as Viscount Simon supposes.

But since then the Court of Criminal Appeal has ruled that "not knowing the act was wrong" only means not knowing it was contrary to the law. If this is strictly applied in murder, then it virtually excludes every case; only those who were so confused at the time that they did not know the nature of the act, or are so mad as to be unfit to plead, or are idiots, can be said not to know that it is illegal to kill.

One of the defences in favour of the M'Naghten Rules put forward to date is that they have worked, and most of us would agree. But, as Dr. Hobson has remarked, this is not so much due to their intrinsic merit as to the way judges have applied them. But this decision of the Court of Appeal surely rules out a verdict such as in the case cited? For it also stipulated that for the prisoner merely to have thought the act justified was not enough. Yet this is the essence of the case with depressives. They are so depressed that they become suicidal and do not want to leave their loved ones behind, or so deluded that they want to spare others the supposed miseries of this world. Clearly in both cases their judgment is completely unbalanced, and they feel their act justified morally, but they are not so bereft of reason that they do not know that to kill is against the law. Yet the Court of Appeal's ruling makes this the only criterion.

I am not writing this from the motives of supposed sentimentality of the psychiatrist, but because crimes committed as a result of genuine depressive states are those where not only the public but judges, and indeed Viscount Simon himself, feel the criminal should be treated (in an institution of course) yet should not pay the supreme penalty. But if the M'Naghten Rules are to be applied without any flexibility how can they work in these cases? I am not a lawyer, and I would be exceedingly interested to know Viscount Simon's views.—I am, etc.,

London, W.1.

W. LINDESAY NEUSTATTER.

Intravenous Barbiturates for Drunkenness

SIR,—Dr. A. M. Bartley's letter (*Journal*, July 11, p. 95) dealing with my criticisms of his treatment for obstreperous cases of drunkenness is, I believe, based upon certain assumptions which could lead to serious mishaps were they widely accepted by casualty officers or by any practitioners whose duty involved treating cases of this kind.

I am not advocating routine stomach wash-out as a preliminary to thiopentone administration to those cases of violent drunken disorientation, but stand by my original condemnation of this therapy. I have indeed attempted to wash out the stomachs of obstreperous drunks amidst a flurry of fists and to the accompaniment of much choking and retching. It is the difficulty of this traumatic procedure, and the uncertain degree of success obtained in thoroughly removing the contents of the overloaded stomach, which would make me loath to administer an intravenous barbiturate to these individuals. Moreover, the performance of this manoeuvre has often demonstrated that the stomach

has by no means been emptied even by the spontaneous vomiting which has occurred during the stage of obstreperous behaviour.

Certainly the dangers of "silent regurgitation" and glottic spasm are every bit as great in certain types of emergency surgical cases—particularly cases of intestinal obstruction. It is for that very reason that many anaesthetists in these cases avoid a thiopentone induction at all costs and induce anaesthesia by a slower, safer inhalation technique, at least until the airway has been safeguarded by some means such as cuffed endotracheal intubation. If in such cases thiopentone induction is used, then it is established practice among many anaesthetists to lessen the risk of regurgitation by placing the patient in a slight reverse Trendelenburg tilt prior to injection and, in any case, by performing the induction with a sucker ready at hand for immediate use.

In conclusion, I feel that if thiopentone were widely used as a means of quieting unruly drunks, desirable though this end may be, without the facilities of an anaesthetic-room available, there would be introduced a far graver hazard to life than if intramuscular paraldehyde or apomorphine were substituted.—I am, etc.,

London, W.2.

PETER NOBES.

Phenylbutazone

SIR,—The toxic reactions after phenylbutazone ("butazolidin") therapy given for various arthritic conditions are well known, and include anorexia, nausea, vomiting, diarrhoea, dermatitis, palpitations, and, finally, agranulocytosis and sometimes complete aplasia of the bone marrow. The importance of these reactions has been stressed in many recent articles and in particular by Drs. J. R. Nassim and Thomas Pilkington¹ and by Dr. J. C. Leonard.²

I have taken 28 consecutive cases of rheumatoid arthritis, 20 of osteoarthritis, and two of gout which have been treated with this drug. The majority had 0.2 g. three times a day, reducing the dose in many instances to 0.2 g. once a day. Seven received intramuscular injections of 1 g. twice a week, reduced to 1 g. once a week after one month. The majority of the patients have been treated in this way for nine months and none for less than three months. All those with severe symptoms were admitted into hospital and the effect of the initial doses of phenylbutazone carefully assessed. After discharge from the wards they joined the others attending the out-patient department at intervals varying between one and three weeks. The possibility of toxic symptoms occurring was explained to each one, and they were told to stop the drug immediately if this happened and to report back to the clinic the following week.

All the toxic reactions which I have experienced have been mild and have either responded to a reduction in the dose or disappeared spontaneously without any interference. There was only one exception. Severe vomiting in this instance caused the drug to be stopped. The toxic symptoms encountered in this series of 50 people were: palpitations, 1, conjunctivitis 1, nausea 9, vomiting 5, swelling of eyes 2, pruritus 1, diarrhoea 2, dermatitis 4, ulcerated gums (without agranulocytosis) 2.

Twenty-seven of the 50 patients, therefore, experienced some unpleasant symptoms, and this was higher than reported by Nassim and Pilkington (46 out of 109), is about the same as that reported by Cudkowicz and Jacobs,³ but higher than the average of 22% quoted by Leonard after a review of the literature. My results have differed from those of Nassim and Pilkington in one important respect: it was only necessary to stop the drug once, whereas they had to withdraw the drug in 46 out of 109 patients.

Out of the 28 patients suffering from rheumatoid arthritis, 21 had a very good result, three a moderate result, and one was made worse. Out of the 20 cases suffering from osteoarthritis, a very good result was obtained in 13, moderate in three, and a complete failure in four. Both those suffering from gout were almost cured. Forty-two out of the 50 cases have derived considerable benefit from this drug: this figure is much higher than that quoted by Nassim and Pilkington (59 were greatly improved out of a total of 109).

The only other treatment for rheumatoid arthritis which has gained any popularity is that with injection of gold salts, and favourable results with this therapy have been few and troublesome complications due to dermatitis, liver and kidney damage, etc., have been frequent. Furthermore, there is no other drug known which will effectively alleviate the pain in osteoarthritis. The treatment of gout with

colchicum, cinchopen, or salicylates is uncertain. These facts must be taken into account before too much emphasis is placed on the toxic side-reactions of phenylbutazone.—I am, etc.,

Birmingham, 18.

Bornholm Disease

SIR,—The numerous excellent descriptions of the 1951 epidemic of Bornholm disease, or, as our Norwegian colleagues prefer, epidemic pleurodynia (*Journal*, June 20, p. 1345), and the letters from readers indicate a widespread interest among British physicians in the events of that late summer. Laboratory studies provide evidence of the responsibility of Group B Coxsackie viruses, as pointed out in your leading article (p. 1379). Type B3 apparently was prevalent. It also accounted for epidemics in the U.S.A. in 1950 and 1951, and was identified in Australia the same year. It may have been responsible for the epidemic on the Continent as well. We must wait for more information from the laboratories. Meanwhile it is worth noting that while B3 has now been repeatedly implicated, another type, B1, which has not appeared for some years, was the aetiological agent of the American cases in 1948 which led Dr. Curnen to suggest that Coxsackie viruses might be the cause of Bornholm disease.¹

The virologists can be relied upon to solve the question of how many types cause Bornholm disease by comparing their strains and identifying them in terms of a common terminology. Meantime a second point which may have more general interest seems to have attracted little attention in Great Britain. It is whether poliomyelitis and Bornholm disease ever occur simultaneously. The records indicate that 1951 was a relatively light poliomyelitis year in England and Wales, but I find no comment regarding the concurrence or competition of the two diseases. This has attracted attention in the past.

The first statement to come to my attention was that of Gsell,² who described a 1940 epidemic of Bornholm disease in Canton Appenzell and mentioned that an epidemic of poliomyelitis did not occur in 1940 and that "not a single case of infantile paralysis appeared during that summer and fall in Gais and Teufen." Linberg,³ I have since found, made a similar comment regarding a Norwegian outbreak in 1934. There are others. Lazarus,⁴ describing the epidemic in the State of Washington in 1950, the first association of type B3 with Bornholm disease, wrote, "... only one case of paralytic poliomyelitis occurred in Hoquiam during the 1950-1 season, when the pleurodynia epidemic took place. The incidence of poliomyelitis in Grays Harbor County during the same season was about 15 per 100,000 population. Preliminary data indicate that the same thing is happening this year, with cases of pleurodynia again appearing and paralytic poliomyelitis being at a low level." Gabinus, Gard, Johnsson, and Pöldre⁵ investigated an outbreak in south central Sweden in 1950. They mention, "No cases of paralytic poliomyelitis appeared in this region."

During 1951 the disease was widespread in southern Germany. Gärtner⁶ wrote, "In no place where Bornholm disease occurred was a single case of paralytic poliomyelitis recognized." And from Stuttgart, Windorfer and Born⁷ reported, "Interestingly in the same period only one definite case of paralytic poliomyelitis occurred in Stuttgart."

Dr. R. L. Huebner tells me there was not a single case of poliomyelitis in the Texas counties in which pleurodynia was prevalent during 1951, but there was little or no poliomyelitis the following summer as well. He established a type B3 virus as responsible for the outbreak. On the other hand, a type B3 virus appears to have caused widespread disease in Sydney, Australia, late in 1951, and Dr. Stanley⁸ was greatly impressed by the coincidental disappearance of poliomyelitis. It had been prevalent the previous year and returned in force in 1952. Most recently I find a description of an epidemic in Reykjavik, Iceland,⁹ and the comment, "In this period no cases of anterior acute poliomyelitis or aseptic meningitis were reported."

I mention these observations in the hope that readers of the *Journal* may have evidence that bears on the point.

Proof of an interference between the two in nature may be difficult to establish. Certainly all we have so far is merely suggestive. But the evident interest of your readers in the epidemic leads me to think they may have confirmation, and I would be grateful to them for their comment.—I am, etc.,

Albany, New York.

Prognosis in Diabetic Pregnancy

SIR,—In his interesting article (*Journal*, June 27, p. 1413) on the prognosis in diabetic pregnancy Dr. Wilfrid Oakley states that his results fail to confirm the existence of any direct relationship between age of onset of maternal diabetes and foetal loss. As mentioned in the article, this relationship was found by me,¹ but in a series of babies weighing 2,500 g. or more from patients without adiposity. Dr. Oakley uses for his study of this point his total King's College Hospital series (267 of 275 babies), and this may be the reason why the relationship was not found by him.

To get a clearer concept of the causes of the high foetal mortality and of what might be accomplished by a certain treatment, one has to know something of the "natural" prognosis in different groups of patients. The two most important factors seem to be parity of the mother and age of onset of diabetes,^{2,3} which cannot be influenced by any treatment. To use a total material for analysis without classifying may obscure everything but the gross mortality.

In his section on foetal hypoglycaemia, Dr. Oakley concludes that this problem clearly needs further study. I am inclined to draw the opposite conclusion. From what Dr. Oakley tells us it is evident that no relationship exists between foetal hypoglycaemia and neonatal death. In my rather extensive work⁴ on this topic I came to the same result. Since 1946 the newborn infants have not received glucose at the lying-in department B of Rigshospitalet, Copenhagen. It is a characteristic feature of the newborn young of mammals that they can stand a low blood sugar.—I am, etc.,

Copenhagen.

Tropical Diseases in Britain

SIR,—May I be allowed to draw attention to the following points raised in your annotation, "Tropical Diseases in Britain" (*Journal*, May 16, p. 1096)? I entirely agree with Professor W. Melville Arnott's insistence in his letter (*Journal*, May 30, p. 1219) that time must not be lost in starting therapy in cases of malignant tertian malaria, and that in the seriously ill patient intravenous quinine is the most effective treatment.

The writer of the annotation claims that "true hookworm disease occurs only in debilitated populations suffering from heavy infestations superimposed on malnutrition and the avitaminoses; it is not seen in the well-nourished." In the last year I have seen many Europeans carrying ankylostoma ova who were not suffering from "true hookworm disease," but I have also attended two senior officers who were suffering from ankylostomiasis, the clinical features including the rash, pulmonary symptoms and signs, and a heavy intestinal load of parasites, resulting in both cases in severe debility. Both these officers were harassed, frustrated, and overworked, but neither was, or had been, malnourished nor presented any feature of the "avitaminoses."

The other statement in the annotation with which I cannot agree is that "emetine . . . should find no place in the diagnosis" of amoebic dysentery. In my experience the patient who suffers from dysentery which does not respond to phenylsulphathiazole in adequate dosage, and in whom *Entamoeba histolytica* or its cysts cannot be found on examination of several stool specimens, very frequently produces amoebae or cysts in the stools after one dose of 1 gr. (65 mg.) emetine. Further, the case of "pyrexia of unknown origin" in the Tropics may be due to amoebiasis, and if it has been impossible to find a cause for the illness, it is worth trying a course of emetine as a diagnostic measure.

In this part of the world a doctor or a laboratory technician is not expected to be an "experienced pathologist" in order to be able to detect the presence of *E. histolytica* or its cysts in a specimen of faeces, or to be able to differentiate such protozoa from the free forms or cysts of entamoebae which are at present considered to be of little pathological importance.—I am, etc.,

Kaduna, Northern Nigeria.

BRUCE NICOL.

Medical Auxiliaries

SIR,—The letter from Dr. A. P. Cawadias (*Journal*, July 11, p. 96) appeals on somewhat emotional grounds for "equal rights" under the N.H.S. for the three associations of physiotherapists he mentions. The Ministry's only interest in this matter should be in the standard to which medical ancillary bodies shall be required to attain before their members are accepted for employment in the N.H.S., and the absence of any reference to such standards in the Ministry's recent proposed regulations is a cause of considerable concern to many members of the medical profession.

Most of us have in the past relied upon members of the Chartered Society of Physiotherapy, because we know that they have undergone a full-time three-year training at one of the recognized hospital training schools. The published report of the evidence given before the Cope Committee gives little evidence of similar standards of training being required by the other associations mentioned by Dr. Cawadias. It was possibly for this reason that the Cope Committee felt it could not recommend the acceptance of the certificates of these associations for employment under the N.H.S. It may be, however, that further information is now available regarding the training syllabus of these bodies, and where it is carried out; if so this would be of considerable interest in view of Dr. Cawadias's plea.—I am, etc.,

London, W.1.

W. S. C. COPEMAN.

POINTS FROM LETTERS

Cord Traction

Dr. JAMES T. BURROWES (Jamaica) writes: May I be allowed to record my support of Dr. F. C. R. Picton (*Journal*, April 18, p. 887) and the Brandt-Andrews method of placental extraction? This method gives such good results that the routine use of ergometrine intravenously before the commencement of the third stage would appear to be unnecessary.

Treatment of Herpes Simplex

Dr. GORDON J. C. HERD (Elstree, Herts) writes: During the past year I have treated a number of cases of herpes simplex by the application of 10% chloramphenicol in propylene glycol. The eruption in most cases was confined to the lips, the first manifestation having presented some 12 to 24 hours previously. The area involved is washed with soap and water and then painted with the solution, which is left to "dry in." Treatment is repeated twice daily (morning and evening) for about three days. Following the initial application, local discomfort is alleviated, no further extension of the lesions occurring. Within 36 hours there is a marked diminution in the size of the vesicles. These generally break down by the third or fourth day, leaving small areas of granulations which subsequently heal. The only disadvantage I have observed is the unpleasant taste of the preparation should it find its way into the mouth. This effect, however, is evanescent.

Obituary

GERALD SHEEHAN, M.B., Ch.B.

The sudden death on July 11 of Dr. Gerald Sheehan at the age of 54 has removed from the civic and medical life of Carlisle one who had been an outstanding personality in his native city for over 30 years.

Born on June 6, 1899, the eldest of a family of 13, Gerald Sheehan graduated from Manchester University at about the time of his 21st birthday by taking the degrees of M.B., Ch.B. in 1920. He then took over the large general practice established by his father, Dr. Patrick Sheehan, who in his day was also a notable figure in Carlisle and who died the year before his son qualified in medicine. It was a considerable responsibility for a young man to bear, as in addition to the rough-and-tumble of general practice he had to consider the education of a large family, some of his brothers and sisters being already students of medicine. In all, seven members of the family became doctors. In this task Dr. Sheehan had the support of his mother and the benefit of her counsel and advice.

In 1930 he was elected to the Carlisle city council, and six years later he became chairman of its health committee. In 1949 he was unanimously voted to the mayoral chair. His professional and civic attainments made him admirably suited for the chairmanship of the Carlisle Executive Council, an office he held at the time of his death. He was also chairman of the local medical committee.

A kindly and friendly man, Gerald Sheehan had no enemies and was a good colleague, always willing to lend a hand. In time of stress or difficulty no fellow practitioner ever appealed to him in vain. In his professional duties he was ably supported by his sister, Dr. Kathleen Gillow, who carries on the practice. A devout Roman Catholic, he served his Church in many ways. For these services the Pope appointed him a Knight of the Order of St. Gregory. To his widow, formerly Miss Dorothy Johnson, and his three children and to his mother and the other members of the family the heartfelt sympathy of his colleagues is extended.—W. F.

R. J. W. MAWHINNY, C.B., L.R.C.P.&S.I.

Colonel R. J. W. Mawhinny died at Nottingham on July 16 at the age of 85. Robert John Watt Mawhinny was born on December 4, 1867, the youngest child of the late Dr. Thomas Mawhinny, of Mount Nugent, Co. Cavan, Ireland. As a young man he distinguished himself as a student and as a sportsman. He was awarded the gold medal for operative surgery at the Carmichael School of Medicine, Dublin, where he qualified L.R.C.P.&S.I. in 1888 at the early age of 20, and in the same year he won the Ormonde Cup for Ireland as a swimmer.

In 1890 he entered the R.A.M.C. and thus began a notable career in the Army which was to last 34 years, nearly all of which were spent in service abroad, 23 of them in India. During the South African War he took part in the defence of Ladysmith and was present at the engagement of Nicholson's Nek. He was mentioned in dispatches and received the Queen's medal with six clasps.

Earlier he saw service with the Isazai expedition of 1892, the Chitral expedition in 1895, and on the Punjab frontier in 1897–8, receiving the medal and clasp. In 1907 he took the D.P.H. of the Irish Royal Colleges. Promoted to lieutenant-colonel in 1912, he returned to India on the outbreak of war in 1914 after a short period of duty in Ireland. For his active service on the North-west Frontier with the Mohmand expedition in 1915, as A.D.M.S., Peshawar Division, he was mentioned in dispatches, and in the following year he was appointed C.B. By that time he was in Mesopotamia as A.D.M.S., Lines of Communication, Indian Expeditionary Force "D," and distinguished himself further by evacuating casualties by river in very difficult circumstances. He was invalided back to India and appointed A.D.M.S. to the Mari Field Force "B," for which service he received a further mention in dispatches. His promotion to colonel in 1921 was antedated to 1918, and in 1922 he held the appointment of D.D.M.S., Southern Command, India.

After his retirement from the Army in 1924 he went to live at Exeter, where he was in medical charge of troops from 1926 to 1932. Re-employed as an Army medical officer from 1939 to 1944, he was thus able to continue a happy association with the Devonshire Regiment which began when he was a young regimental medical officer during the South African War. Next to medicine his great interest was sport, for all forms of which he was naturally gifted. Apart from his prowess as a swimmer, he was a good swordsman, an excellent horseman, and a first-class shot. His life-long hobby, however, was fishing with the dry fly, preferably one he had tied himself. He married Miss Kathleen S. McEntire and there was one daughter of the marriage. Mrs. Mawhinny died in 1950.

F. V. NANKA-BRUCE, O.B.E., M.B., Ch.B.

Dr. F. V. Nanka-Bruce, a general practitioner well known on the Gold Coast, died on July 13 at the age of 74. He was president of the Gold Coast Branch of the British Medical Association.

Frederick Victor Nanka-Bruce received his early education first at the Government Boys' School, Accra, and then at Queen's College, Lagos, Nigeria. On his return to the Gold Coast he entered Government service as a dispenser and was attached to the expedition which went to Kumasi in 1900—an event which precipitated the last Ashanti War—and with the Governor of the Gold Coast, Sir F. Hodgson, and his party he was besieged in Kumasi Fort until the expedition managed to escape through the Ashanti lines to the coast. Shortly afterwards Nanka-Bruce was sent to Edinburgh University to study medicine, and he duly graduated M.B., Ch.B. in 1907. He then returned to Accra, being the second African to practise medicine in the Colony.

He built up a practice which, at the time of his death, had assumed very large proportions. His name in that part of West Africa came to be regarded as synonymous with scientific medicine and for the efficient treatment of disease sympathetically carried out. Dr. Nanka-Bruce had a very full life. He represented the best type of general practitioner, and he had a high regard for the standing of his profession. The old and the poor were always assured of an understanding reception at his hands, and he gave free treatment and financial assistance to many of the poor of Accra, among whom he spent most of his life. Apart from medicine, which remained his main interest up to the time of his death,

Dr. Nanka-Bruce served his country in a variety of ways. He was a member of the Legislative Assembly from 1931 to 1935 and again in 1946. In 1935 he was appointed O.B.E., and in 1937 he was a representative of the Gold Coast at the Coronation of King George VI. For many years he was a member of the Accra town council, and in 1949 he served on the Coussey Commission which drafted the present Constitution. In 1918 he founded the Independent Press, which produces the *Accra Daily Echo*, and of which he was managing director up to the time of his death. He was also a founder member of the Accra Turf Club, and was chairman of the board of stewards from 1943 to 1944, being himself the owner of racehorses.

Deeply interested in education, Dr. Nanka-Bruce served on the Achimota College Council and was manager of the Accra Royal School and chairman of the board of the Accra Academy. The confidence and esteem in which he was held by his fellow practitioners were shown by his election to the presidency of the Gold Coast Branch of the British Medical Association last February. His death leaves a gap in the public life of Accra which will not be easily filled. He was a good doctor and a good man whose counsels were respected and opinions valued.—H. B. L. R.

Medical Notes in Parliament

Cost of Social Services

During the debate in the House of Lords on July 21 on the motion for the second reading of the Finance Bill Lord SHEPHERD said there had not been a very great increase in the last few years in expenditure on the social services. The cost of these in 1938-9 represented 9.2% of the then national income. In 1950-1 the cost was 11.7%, and in 1951-2 it became 11.5%. If the conditions of the population in 1938-9 had been the same as in 1951, from £50m. to £80m. would have had to be added to the cost of the social services, bringing the proportion of expenditure from the national income for 1938 to the level of last year.

The Bill was read a second time and subsequently passed.

Payment of Scientists

During a debate on July 20 on science and productivity Sir HUGH LINSTADT said the House of Commons had to face the problem of the proper payment of scientific teaching personnel in universities. The same problem had been faced and overcome in medicine. When consultants in the full-time employ of the National Health Service were able to get £5,000 a year from the State, it was no longer possible to employ professors of medicine in the universities at, say, £2,500 a year if men of the right calibre were needed. The universities therefore had to upgrade the status and pay of professors of medicine. The same problem had to be tackled in relation to professors of engineering.

Replying to the debate, Sir WALTER MONCKTON said a programme of research was being launched under the auspices of two committees set up by the Department of Scientific and Industrial Research and the Medical Research Council. Leading industrialists would sit down with professors to think out what could be done to improve the position.

Cost of Prescribing

Colonel STODDART-SCOTT on July 23 asked the Minister of Health what immediate steps he proposed to take to encourage doctors to reduce the present high cost of prescribing and so release funds for improvement elsewhere in the National Health Service.

Mr. IAIN MACLEOD replied that, without prejudice to their right to prescribe whatever they thought necessary in an individual case, he had recently invited all doctors to re-examine the cost of their prescribing. They had been supplied with lists of proprietary preparations classified by the Joint Committee on Prescribing. He had suggested to doctors that they should not prescribe other proprietary preparations without first comparing the cost with that of equivalent or similar standard preparations; and had reminded them of the need for proper economy when prescribing standard products. He had been assured of the co-operation of the medical profession in the efforts to keep the cost of prescribing within proper limits.

Peptic Ulcer

On July 23 Dr. BARNET SIROSS asked the Minister of Health what estimate he had of the numbers of citizens suffering from duodenitis and from gastric and duodenal ulcers. He also asked how far liquid milk was still advised by his department in treating these conditions.

Mr. MACLEOD replied that no figures were available for duodenitis, but it was estimated that about 1 person in 100 in England and Wales suffered from gastric or duodenal ulcer. There was no evidence of any material change in total numbers in recent years, but the number of deaths from duodenal ulcer had increased and that from gastric ulcer had fallen. Responsibility for the treatment of patients must rest with the doctors in charge. His department did not issue advice in these matters.

Unfilled House Appointments

Mr. W. NALLY asked the Minister of Health on July 23 what advice he had given, or what assistance he proposed to render to, the Wolverhampton Hospital Management Committee, which, as a consequence of being unable to fill house posts in the Royal Hospital, Wolverhampton, had been compelled to circularize all industrial first-aid posts in the area asking them to avoid sending patients other than urgent cases to this hospital.

Mr. MACLEOD said he was having an inquiry made. The shortage of junior medical staff in hospitals was general in the region.

Anaesthesia for Childbirth

Miss PAT HORNSBY-SMITH said on July 23 that, while Mr. Macleod had seen a number of allegations about inadequate provision of anaesthesia or analgesia for childbirth, he had only two complaints from mothers in the last two years. In areas where the administration of gas-and-air by midwives was below average the local health authorities were aware of the position. The proportion of administrations was steadily increasing from year to year.

Air Pollution

Replying on July 21 to Mr. SOMERVILLE HASTINGS, Mr. A. E. MARPLES said a committee was being appointed jointly by Mr. James Stuart and Mr. Geoffrey Lloyd to "examine the nature, causes, and effects of air pollution and the efficacy of present preventive measures, to consider what further preventive measures are practicable, and to make recommendations." Medical men on the committee are Dr. J. L. Burn, medical officer of health, Salford County Borough Council, and Professor T. Ferguson, professor of public health and social medicine, Glasgow University.

Health Service Charges

Mr. H. MARQUAND asked the Minister of Health on July 23 whether he would present a White Paper reviewing the effects of the charges for appliances and treatment in the hospital and general-practitioners' services imposed in 1951 and 1952.

Mr. MACLEOD replied: No, Sir. This information could best be given by Parliamentary question and answer.

Mr. MARQUAND asked whether the Minister's attention had been drawn to a statement by Dr. A. J. Macleod

(*Supplement*, July 18, p. 40) to the effect that a recent speech by the Minister of Health suggested that he was anything but confident about the 1s. charge? Were they not entitled to more information?

Mr. MACLEOD said he was delighted to see this additional proof of the slow conversion of the Opposition to the point of view of those called Macleod, who came from the Western Isles.

Mr. BLENKINSOP asked whether the Minister did not recognize that the House welcomed the conversion of the British Medical Association to the point of view expressed always from this (the Labour) side?

National Service Boards

Replying on July 23 to questions by Mr. N. N. DODDS and Mr. J. SNOW, Sir WALTER MONCKTON said he was engaged in consultations with chairmen of medical boards. He had already arranged for the boards to be reminded of the importance of making a full inquiry into the candidate's medical history and of paying full attention to consultants' reports. He was amending the forms sent with the summonses to medical examination so as to draw attention to the fact that medical certificates or reports brought to the examination would be fully considered. Mr. H. Watkinson, the Parliamentary Secretary, had already started personal visits to medical boards. He proposed to do the same after the House rose. The most fruitful course would be to complete the steps which were already in hand and the examination of the individual cases brought to his notice. He also proposed to make a further investigation, with the co-operation of the Services and the Ministry of Pensions, into all cases of men discharged during a recent period shortly after entry with a view to determining the present extent of error and whether it appeared to arise most commonly in certain types of cases or districts.

Replying to Mrs. E. BRADDOCK on July 23, Sir WALTER MONCKTON said no instructions had been given that medical boards must not turn down more than a certain percentage of men in each of the categories. In answer to Mr. SNOW Sir WALTER MONCKTON said on the same date that about half the cases rejected by medical boards were psychiatric cases.

Mr. H. WATKINSON had said on July 21 that 25 chairmen of medical boards were over 70 years of age.

Strawberry Jam.—The average vitamin-C content of strawberry jam is 16 mg. per lb. (35 mg. per kg.). The corresponding value for the fresh strawberries used in the preparation of a pound of jam is 96 mg.

Medico-Legal

THE CHANGING LAW

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Few Englishmen really understand how the English constitution works unless they are professionally concerned, either as politicians or as lawyers, in helping to work it. In *The Changing Law*,* a collection of addresses given to English universities, Lord Justice Denning sets out to draw a picture of the changes by which the law is adapting itself to the social and constitutional revolution of our time. In doing so he provides the ordinary man with a vivid insight into the genius of the constitution, and shows how English law has developed, and is developing, to hold the balance between man and the State and between man and man.

Doctors will find much in the book of direct interest to them. They will see how one of the living masters of the Common Law treats the problems which have been discussed recently in the medico-legal columns of the *Journal*, and among the cases with which the theme is illustrated they

*Published by Stevens and Sons, London, 1953, pp. 122, 10s.

will meet some old friends that have been reported there. They will see how actions for negligence against hospitals have served in the maintenance and development of the rule of law in the Welfare State and in the law of master and servant. They will find what Lord Justice Denning thinks of the M'Naghten Rules and the criminal responsibility of the insane in the situation pointed by the cases of Straffen and Miles Giffard.

Some of Lord Justice Denning's views upon the law do not command universal acceptance. Few, however, who read his book will fail to be glad that he has written it.

Universities and Colleges

UNIVERSITY OF ST. ANDREWS

The degree of M.D. has been conferred on J. Stephen Law.

The following candidates have been approved at the examination indicated:

FINAL M.B., CH.B.—Ann C. Alabaster, W. G. G. Brand, Florence M. Danjoux, A. M. Dick, A. A. Lakeru, J. A. Lawrie, C. S. Leithhead, R. Markham, F. D. Marples (with commendation), C. A. H. Marr, Margaret A. H. Ness, R. G. M. Poston, J. Smart (with commendation), E. Sweeney, Mary E. C. Wright.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the College held on July 21 with the President, Dr. W. A. Alexander, in the chair, it was announced that the following distinguished members of the medical profession had accepted Honorary Fellowship of the College: Professor Charles Herbert Best, F.R.S., professor of physiology and director of the Banting and Best Department of Medical Research in the University of Toronto; Sir Walter Russell Brain, President of the Royal College of Physicians of London; Sir Frank Macfarlane Burnet, F.R.S., director of the Walter and Eliza Hall Institute, Melbourne, Australia; Sir Charles Ernest Hercus, professor of bacteriology and public health in the University of Otago and dean of the Medical Faculty; Sir Gordon Morgan Holmes, F.R.S., consulting physician to Charing Cross Hospital and to the National Hospital for Nervous Diseases; Sir Robert Muir, F.R.S., emeritus professor of pathology in the University of Glasgow; Sir John Parkinson, consulting physician to the Cardiac Department of the London Hospital and to the National Heart Hospital.

The following were elected Members of the College: J. R. Bailey, W. A. Murray, M. A. Wafa, T. J. Danaraj, H. Foster, E. L. Davis, M. Macleod, R. S. Norton, M. Scott-Gray, G. J. V. Perera, D. E. P. Forbes, A. V. A. Vethanayagam, C. H. Gurd, H. P. Vaishnava, D. J. Gudex, Ata-Ul Haq, K. R. Tyler, R. W. H. Simmons, A. Pines, E. O. L. Hoskins, S. G. F. Wilson, S. I. Kuper, P. A. Rechnitzer, G. W. Allan, A. Nestadt, H. D. Jacobs, K. S. Husain, R. Kilpatrick.

SOCIETY OF APOTHECARIES OF LONDON

Sir Wilson Jameson, Master, presided at recent meetings of the Court of Assistants of the Society. Dr. C. F. White, Mr. A. M. A. Moore, and Sir Lionel Whitby were elected to seats on the Court. Dr. Frank Howitt was re-elected as the Society's representative on the British Postgraduate Medical Federation and Dr. G. Hamilton Hogben was appointed representative of the Society on the Central Council for District Nursing in London.

The Honorary Mastery of Midwifery was bestowed upon Sir William Gilliatt in recognition of his eminence in this field, and the Society's Gold Medal in Therapeutics was presented to Sir Charles Harington, F.R.S., in commemoration of his work which led to the synthesis of thyroxine. The presentations were followed by a soiree at which the Society's plate and other treasures were exhibited.

The Society's records from 1617 to approximately 1850 have been deposited in the Guildhall library.

The following candidates, having completed the final examination, have been granted the Diploma of the Society, enabling them (upon complying with the requirements of the Medical Acts) to practise medicine, surgery, and midwifery: T. P. Oliver, R. G. Orr, T. F. Stoye, P. Jensen, S. T. Guest, J. Cottam, E. P. James, W. F. T. Davies, J. R. Croning, R. H. Morgan.

The following candidates were successful in the recent examination for the Diploma in Industrial Health: C. P. Chivers, K. B. Roy, R. Whitelaw.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending July 11 (No. 27) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included). London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in the week ending July 18 (28th week of the year) were as follows: paralytic, 147 (118); non-paralytic, 76 (65); total, 223 (183). This is an increase of 40 compared with the previous week, the figures for which are in parentheses. Districts which have notified 15 or more cases in the year to July 18, with incidences per 100,000 in parentheses, are as follows: Southend-on-Sea C.B., 24 (15.84); Liverpool C.B., 17 (2.15); Hendon M.B., 15 (9.63); Birmingham C.B., 35 (3.15); Coventry C.B., 38 (14.72); and Pewsey R.D.C., 16 (87.77).

The momentum of the seasonal rise was unchanged during the 28th week. The number of notifications was greater than in the corresponding week of any previous year. A further increase must be expected, and the outlook is not favourable. The ratio of notified paralytic to non-paralytic cases remained constant at about 2:1. New cases were scattered widely, and apart from the outbreak in Pewsey R.D., which appears to be ending, there is no focus of unusual size.

England and Wales Second Quarter

The birth rate, stillbirth rate, and infant mortality rate in England and Wales were slightly higher in the second quarter of this year than in the second quarter of last year. There were 179,464 births, giving a rate of 16.4 per 1,000 population. Stillbirths numbered 4,200, giving a rate of 22.9 per 1,000 total births; and there were 4,441 deaths of infants aged under 1 year, giving a rate of 25.6 per 1,000 related live births. The general death rate was 10.5 per 1,000 population, and there were 114,538 deaths.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus ————, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The returns of infectious diseases in England and Wales during the week ending July 11 showed a decrease of 1,106 for measles, from 6,610 to 5,504, and 283 for whooping-cough, from 4,690 to 4,407, and a rise of 57 for acute poliomyelitis, from 126 to 183, and 49 for dysentery, from 476 to 525.

The largest falls in the number of notifications of measles were 225 in Lancashire, from 1,274 to 1,049, 219 in Yorkshire West Riding, from 642 to 423, and 108 in Yorkshire East Riding, from 366 to 258. The largest variations in the returns for whooping-cough were falls of 65 in Warwickshire, from 312 to 247, 63 in Devonshire, from 178 to 115, 59 in Yorkshire West Riding, from 356 to 297, 57 in Staffordshire, from 207 to 150, and rises of 45 in Essex, from 348 to 393, and 42 in Lancashire, from 358 to 400. 1,072 cases of scarlet fever were notified, 6 more than in the preceding week, and no large variation occurred in the local trends. 17 cases of diphtheria were notified, an increase of 3 on the total of the preceding week.

The notifications of acute poliomyelitis were 33 more for paralytic and 24 more for non-paralytic cases than in the preceding week. Half of the increase was contributed by two counties—Warwickshire with a rise of 17 and Lancashire with a rise of 10. The largest returns were Warwickshire 20 (Coventry C.B. 3, Nuneaton M.B. 3, Atherstone R.D. 3), London 19 (Greenwich 3, St. Pancras 3), Essex 19 (Southend-on-Sea C.B. 4), Middlesex 17 (Hornsey M.B. 4, Ruislip Northwood 4), Lancashire 10 (Lytham St. Annes M.B. 4, Blackpool C.B. 3), and Sussex 10 (Worthing M.B. 3).

The largest centres of dysentery were London 109 (Deptford 10, Paddington 11, St. Pancras 28; the remaining 60 cases were scattered through 19 boroughs), Lancashire 100 (Liverpool C.B. 23, Preston C.B. 20, Manchester C.B. 14), Yorkshire West Riding 67 (Heckmondwike U.D. 24, Wakefield C.B. 10), Surrey 45 (Richmond M.B. 24), Norfolk 25 (King's Lynn M.B. 15), Middlesex 24, and Durham 19. 12 further cases were notified in the outbreak in Bedfordshire, Luton M.B., where 251 cases have been notified in the preceding weeks.

Two large outbreaks of food-poisoning were notified during the week—124 notifications in Islington, London,

and 69 notifications in Easington R.D., Durham. 72 further cases were recorded from the outbreak in Lancashire; these cases were spread over 19 administrative areas.

Week Ending July 18

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,018, whooping-cough 4,218, diphtheria 18, measles 4,795, dysentery 380, paratyphoid fever 5, and typhoid fever 4.

Quarterly Return for Eire

The birth rate for the March quarter of 1953 was 21.3 per 1,000 of the population and was 0.5 below the rate for the preceding first quarter. Infant mortality rate was 44 per 1,000 registered births and was the lowest rate ever recorded in a first quarter, being 11 below the rate for the March quarter of 1952. The general death rate was 14.3 per 1,000 and was 0.1 below the rate for the preceding first quarter. 294 deaths were attributed to respiratory tuberculosis and 74 to other forms of tuberculosis; these were 108 and 25, respectively, below the totals for the preceding first quarter. Deaths from infectious diseases included 252 from influenza, 18 from whooping-cough, 8 from measles, and 7 from acute poliomyelitis. Only one death was due to diphtheria. Gastro-enteritis was responsible for the deaths of 51 children under the age of 2 years.

Medical News

College of General Practitioners.—The first annual general meeting of the College of General Practitioners will be held on Saturday, November 14, at 2 p.m. in the Hall of the Society of Apothecaries, 14, Black Friars Lane, London, E.C.4.

First World Conference on Medical Education.—Details of the programme of this Conference (August 22-24) were published in the *Journal* of July 4 (p. 32). All those wishing to attend are advised to register as soon as possible by applying to the secretary of the Local Arrangements Committee, Dr. E. Grey Turner, B.M.A. House, Tavistock Square, London, W.C.1. To help to meet the expenses of the Conference, which are considerable, a registration fee of £4 is payable. Anyone interested in the work of the Conference may register, and registration confers the right to attend all meetings, excursions, and receptions. There will be a reception (6.30 p.m.) at B.M.A. House on August 22, and an excursion to Cambridge (10.30 a.m.) on August 23. On Monday, August 24, the Presidential Address on "The Challenge to Medical Education in the Second Half of the Twentieth Century" will be given by Sir Lionel Whitby in the morning, and the following addresses, also given in plenary session, will be delivered on Monday afternoon: "What is Education?" by Sir Richard Livingstone; "The History of Medical Education," by Professor John F. Fulton; and "Medicine—a Technology or a Profession?" by Colonel S. M. K. Mallick.

The Minister and the Dental Profession.—The Minister of Health, Mr. Iain Macleod, was the principal guest and proposer of the toast of "The Faculty" at the sixth anniversary dinner of the Faculty of Dental Surgery, Royal College of Surgeons of England, on July 17. When he became Minister, he said, one of the things that most needed doing was to improve the personal relationship between the Department, and more particularly the Minister, and the professions concerned with the Health Service. "I am not completely satisfied with the present position in relation to myself and the dental profession," Mr. Macleod went on to urge the best men not to be backward in playing their part in negotiations for the improvement of their profession. "It matters enormously that those whom I meet as representing the professions should be the leaders of those professions." Mr. Macleod declared that he looked forward to the estab-

lishment of a General Dental Council, but one of the difficulties was to find Parliamentary time for the necessary Bill. He ended his speech with a warm tribute to the Dean of the Faculty, Sir William Kelsey Fry. Among the other guests were Sir Cecil Wakeley, P.R.C.S., Sir John Charles, Dame Lillian Penson, and Dr. Bernard Johnson.

Commonwealth Bursaries.—The Royal Society and the Nuffield Foundation are jointly instituting a series of Commonwealth bursaries. Their object is to increase the efficiency of investigators of proved worth by enabling them to pursue research, learn techniques, or follow other forms of study wherever in the Commonwealth the environment is particularly favourable. The bursaries differ from ordinary research fellowships, the main emphasis being on improving the recipients' capabilities rather than on obtaining the solution of a particular research problem. Each bursary will provide for cost of travel and maintenance, but not for a salary as such; bursaries will be tenable for from two to twelve months. For the first five years the scheme will be on an experimental basis. During this period the Nuffield Foundation will contribute £5,000 a year, and the Royal Society will make an initial contribution of £2,500. Later it is hoped that funds may be obtained from other sources, particularly from overseas, to make possible the full development of the scheme. A joint Commonwealth Bursaries Committee has been set up under the chairmanship of Sir Edward Salisbury, F.R.S. It includes two medical members: Sir John Stopford, F.R.S., and Professor G. R. Cameron, F.R.S. Bursaries will be awarded biennially, and application forms (obtainable, with further details, from the assistant secretary, the Royal Society, Burlington House, Piccadilly, London, W.1) must be submitted not later than March 15 and September 15 each year. The bursaries are open to both United Kingdom and other Commonwealth scientists. The first applications will be considered early next year.

Foulerton Research Fellows.—Two physiologists have been appointed by the Council of the Royal Society to Foulerton Research Fellowships. Mrs. P. M. Holton, D.Phil., is to carry out work at the Physiological Laboratory, Cambridge, on chemical transmission in the nervous system. Mr. J. E. Falk, Ph.D., of University College Hospital Medical School, is to investigate the biochemical mechanisms involved in the production of porphyrins and haemoglobin.

School of Medical Photography.—A school of medical photography, provisionally designated the London School of Medical Photography, is being formed as a non-profit-making organization through the co-operation of eight London teaching hospitals. Its aim is to prepare students for the final examination of the Institute of British Photographers in medical photography. The institutions concerned are Guy's Hospital Medical School; St. Mary's Hospital Medical School; the Middlesex Hospital; The Hospital for Sick Children, Great Ormond Street; the Institute of Ophthalmology; the Institute of Orthopaedics; the Postgraduate Medical School of London; and St. Bartholomew's Hospital. Students must have passed the intermediate examination of the Institute of British Photographers; they should be ready for the final examination at the end of four terms. The school opens in October. Inquiries should be addressed to the honorary secretary, Mr. N. K. Harrison, Department of Medical Photography, St. Bartholomew's Hospital, West Smithfield, London, E.C.1.

Rabbits.—The present success of the virus of myxomatosis in controlling rabbits in Australia—it is estimated that in the last three years 80% of the rabbits have been destroyed—has led landowners there to raise a fund in honour of Dr. Jean McNamara, of Melbourne, in appreciation of her long campaign for its use. Dr. McNamara is well known for her work on poliomyelitis, for which she was made D.B.E. in 1935, and it was while working in the United States on a Rockefeller scholarship that she first conceived the idea of using myxomatosis virus for rabbit control. A less happy experience is that of a French doctor who used the virus

to exterminate rabbits on his walled property. According to the *Manchester Guardian*, the doctor is now threatened with prosecution by the State, because the disease is rapidly spreading far beyond the walls of his estate. This is hardly surprising, as the virus is carried by mosquitoes.

"Family Doctor."—The August issue of *Family Doctor* has holiday topics well to the fore. There are articles on swimming, the hazards of picnicking, holiday housekeeping, and "How Hot Can You Get?"—the last giving some account of current research on climatic conditions and working efficiency. James Laver, writing on fashion and health, depicts some formidable corsets and even a machine for tightening their laces. In the Medicine and Health Section, Dr. T. Traherne discusses the causes of suicide, Miss Theodora Alcock advises on left-handedness and mirror writing, Dr. W. Edwards explodes some nature cures, and Dr. Doris Odum tells parents how to bring up their babies the modern way. Constipation, stitch, baldness, and fat children are the subjects of other notes. For the profile, the work of the almoner has been chosen.

Mr. Arthur A. Gemmell was re-elected President of the Royal College of Obstetricians and Gynaecologists on July 25.

Mr. John Foster, senior clinical lecturer in ophthalmology in the University of Leeds, has been invited to deliver the Charles H. May Memorial Lecture before the New York Academy of Medicine in April, 1954.

NEW ISSUES

British Journal of Ophthalmology.—The next issue (Vol. 37, No. 8) will be available in a week's time. Issued monthly; annual subscription £4 4s., single copy 8s. 6d.

British Journal of Preventive and Social Medicine.—The next issue will be available in a week's time. Issued quarterly; annual subscription £2 2s., single copy 12s. 6d.

These journals are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked *. Applications should be made first to the institution concerned.

Monday, August 3

EDINBURGH UNIVERSITY: FACULTY OF MEDICINE.—At West Lecture Theatre, University New Buildings, Teviot Place (Door 4), 5 p.m., Professor Shields Warren (Harvard): Pathologic Consequences of Total Body Irradiation.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Clarke-Williams.—On July 16, 1953, at Catterick Military Hospital: to Shirley (formerly Hinton), wife of Michael Clarke-Williams, M.B., M.R.C.S., a daughter—Marion Anne.

Cliff.—On July 16, 1953, at County Hospital, Hereford, to Margaret, wife of Dr. Philip Cliff, of Colley Horn, Mordiford, Hereford, a daughter—Pauline.

Dakin.—On July 10, 1953, at Grappenhall Maternity Home, Warrington, to Marjorie (formerly Pennington), wife of E. T. Dakin, M.R.C.S., L.R.C.P., a daughter—Julie Karen.

Edwards.—On July 22, 1953, at Argyll Nursing Home, Darlington, to Laurie, wife of Dr. D. R. Edwards, a son.

Gretton-Watson.—On July 16, 1953, at Chester, to Concetta, wife of Dr. B. G. Gretton-Watson, a daughter—Clare Lilian.

Holden.—On July 22, 1953, at King's College Hospital, Denmark Hill, London, S.E., to Ursula (formerly Stanley), M.R.C.S., wife of Surgeon-Lieutenant P. H. Holden, R.N., a daughter.

Laidlaw.—On July 25, 1953, to Greta (formerly Mair), wife of Dr. Allan J. Laidlaw, Barbourne Road, Worcester, a daughter.

Park.—On July 19, 1953, at 40, Wilbury Road, Hove, to Dr. Emily Park (formerly Smith), wife of Harold Park, F.R.C.S., a daughter.

DEATHS

Mason.—On July 5, 1953, at 14, Gainsborough Gardens, Hampstead, London, N.W., Francis Courtenay Mason, M.S., F.R.C.S.

Morris.—On July 7, 1953, at 19, Oak Road, Woolston, Southampton, Hans, the home of his son, Luther Morris, M.D., of Ashgrove, Brisbane, Australia.

Pringle.—On July 12, 1953, John Pringle, M.D., D.P.H., of Hawkbarrrow, Gosforth, Cumberland, formerly of Whalley Range, Manchester, Lancs.

Riley.—On July 8, 1953, at Nordale, Ben Rhydding, near Ilkley, Yorks. Donald Riley, M.B., B.Ch., aged 52.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Treatment of Congenital Cataract

Q.—A child has greatly impaired vision owing to bilateral congenital cataract, one eye being more severely affected than the other. An operation on the worse eye has been suggested. What is the best age at which to do it? What results may be expected? If unsuccessful, is there any risk to the better eye?

A.—When a child has bilateral cataract dense enough to create a serious obstacle to vision, the sooner operation is done the better. Useful vision is obtainable in a majority of cases, but it is impossible with a dense cataract to give a certain prognosis, because the fundus of the eye cannot be seen in detail until a clear gap is fashioned through the opaque pupil. The risk of damage being done to the other eye by operation on the first eye is only slight. There is some risk of sympathetic inflammation in the second eye whenever any intraocular operation is performed or whenever any perforating injury is sustained. Such a risk is negligible in the face of the alternative—namely, the sight permanently obstructed by cataracts.

Pregnancy after Cancer of the Breast Treated with X Rays

Q.—Three years ago a patient was given x-ray therapy following a radical mastectomy for cancer of the breast (3,600 r to the chest wall and 2,700 r to the axilla). She is now two months' pregnant. Is there an increased chance that the foetus will be deformed?

A.—It is difficult to believe that the ovaries can have received a significant dose of x rays, and it can be confidently stated that the previous disease and its treatment do not increase the risk of malformation of the foetus. A more important consideration in a case of this kind is the question whether pregnancy will activate any remaining cancer cells and precipitate a recurrence of growth. The evidence on this is equivocal, and opinions are divided. Nevertheless, some authorities would regard the risk as being so real as to justify terminating the pregnancy.

Gout in a Boy

Q.—How decisive is the finding of a raised blood uric acid in the diagnosis of gout? A boy of 13 has for the last four years suffered intermittently from a polyarthritides until now presumed to be rheumatoid arthritis. However, three consecutive blood uric acid estimations have been 7.1 mg.%, 8.8 mg.%, and 7.3 mg.%. No tophi are to be seen, and there is no family history of gout. Are we justified, on the basis of these high blood uric acid estimations alone, in regarding this as a case of gout, and, if so, what treatment would be indicated in a boy of this age?

A.—The blood uric acid may be raised in renal failure or when there is excessive nuclear destruction as in leukaemia, but if these conditions are excluded a blood uric acid of over 6 mg. is very strong evidence in favour of gout; it is not unknown for this disease to start in childhood, and to present as a polyarthritides. The onset of chronic symptoms at such an early age would indicate unusually severe disease with a poor prognosis.

If there are acute symptoms, treatment should start with colchicine, 0.5 mg. two-hourly, until there is some relief or until diarrhoea or vomiting supervenes (this may be expected after 3–6 doses). The dosage should then be reduced to 0.5 mg. six-hourly and gradually tailed off during the next

six days. After the first few days, and when the gastrointestinal symptoms have subsided, sodium salicylate should be given four-hourly and the dosage gradually increased to the maximum that can be tolerated. This is likely to be in the region of 3 to 6 g. per day. If the treatment is successful there will be an obvious increase in uric acid excretion, and the blood uric acid should fall to normal levels in a few weeks. The salicylate therapy should then be continued indefinitely, and the colchicine may be repeated if there are further acute episodes. If this treatment is without effect other uricosurics such as probenecid ("benemid") may be tried. Dietary restrictions are of minor importance, though foods with a high purine content, such as liver, kidneys, sweetbreads, and sardines, should be avoided.

A Mouth Like a Parrot's Cage

Q.—What is the reason for thirst and apparent dehydration after the ingestion of alcohol?

A.—There is no satisfactory evidence that alcohol is a diuretic: the diuretic effect of alcoholic beverages is due almost entirely to the water which they contain. Some alcoholic drinks—for example, gin—do, of course, contain volatile oils (such as oil of juniper) which are diuretics, and these will cause a greater output of urine than if an equivalent amount of absolute alcohol had been taken.

The consumption of alcohol is followed by an increase in extracellular fluid over and above that due to the water in the drink; this extra fluid can only have come from intracellular water. A loss of intracellular water is probably the fundamental change which produces thirst, whether it results from reduced water intake, diuresis, sweating, haemorrhage, or the ingestion of alcohol. It gives rise to a cessation of salivary flow, dryness of the mouth, and a consequent craving for fluid.

Lotion for Cleaning Eye Sockets

Q.—In a mission school for blind children in India a number of the pupils have had their eyes enucleated, and the sockets tend to become easily infected. What lotion is recommended for regular use to keep the sockets healthy?

A.—The simplest lotion for eye sockets is normal saline solution. When a socket is slightly inflamed oxyecyanide of mercury lotion in a strength of 1 in 10,000 is often beneficial. The disappearance of inflammation is usually expedited if the patient leaves off wearing an artificial eye for a few days.

Does Atmospheric Pollution Cause Sinusitis?

Q.—Is there any evidence that dirt or fumes in the atmosphere are an aetiological factor in the production of sinusitis? I practise in a colliery district and must have seen some 50 cases of sinusitis last winter, many with a polyp in the antrum. Are certain districts more prone to this affection than others? What preventive measures can be taken to reduce the incidence of sinusitis?

A.—There is no evidence to suggest that pollution of the atmosphere has any great bearing on the incidence of sinusitis. Infective sinusitis starts as a head cold which settles in one or other sinus because either the drainage from the sinus into the nose is not effective or the ciliated epithelium lining the sinus is unable to cope with the inflamed products of the mucous membrane. Sinusitis is prevalent in temperate zones where there are frequent temperature changes, and it is believed that such changes play an important part in the production of head colds. Upper respiratory infections are probably equally prevalent throughout the British Isles, and the main preventive measure in reducing the incidence of sinusitis is prevention of the causal upper respiratory infection. In some subjects obvious defects of nasal architecture, such as a badly deflected septum or unusually large middle turbinates, will require correction.

Cyanides in Industry

Q.—In a factory laboratory one worker is constantly handling a sodium and potassium cyanide powder. What are the risks, and what precautions are advised? Would the wearing of a mask be advisable?

A.—Sodium and potassium cyanide are widely used in industry and, handled with care, are relatively non-toxic. Danger arises when they are heated or acted upon by acids or moisture with the resulting evolution of hydrocyanic acid. They are poisonous, of course, if they find their way to the stomach. In the laboratory, where these substances can be properly stored and where the necessary precautions can be maintained, their handling should not be accompanied by any such risk. They should, of course, be properly labelled to prevent accidental ingestion.

The use of a dust respirator is not indicated, since it would be of no avail against hydrocyanic acid if this were present, and might give a false sense of security which could be dangerous.

Beeswax

Q.—Is the wax from honeycombs harmless to eat? Is it absorbed, and, if so, in what form?

A.—Honeycombs which have been made naturally by bees contain about 4.6% of wax. The wax consists mainly of esters of higher aliphatic alcohols with chains of 26 or more carbon atoms. From the high melting-points of these alcohols, and of their esters, it seems unlikely that they can be absorbed from the intestines when honeycomb is eaten upon bread in the usual way. The experience of bee-keepers confirms this view, and the wax is said to be mildly laxative. There would seem to be more chance of absorption, however, if the honey were used to make biscuits, cakes, or sweets under conditions which would cause the wax to become finely emulsified. From the lack of reports of harm resulting from eating comb honey it seems safe to conclude that the practice is quite safe. Common sense would suggest, however, that it is inadvisable to swallow large amounts of indigestible wax from which most of the honey has drained away. If the wax is absorbed at all it probably passes through the intestinal walls in the form of droplets of unhydrolysed wax; the esters of the higher alcohols are more difficult to hydrolyse than the triglycerides which are the main components of dietary fats. In modern bee-keeping the insects are often encouraged to start making honey promptly by providing them with combs made with paraffin wax. This material would be equally resistant to absorption, but again it might be partially absorbed if emulsified by cooking.

Eggs and Delirium

Q.—A man with acute bronchitis was given nine eggs in milk in 18 hours. He became delirious and walked out of doors in his sleep. He has no known allergy to eggs. Could the delirium be ascribed to the ingestion of so many eggs?

A.—It seems unlikely that the eggs were responsible for the delirium and sleepwalking. This number of eggs was frequently given to patients suffering from a gastric ulcer, and nothing untoward happened. It seems more likely that the acute bronchitis was due to a pneumococcal infection, or may have obscured a consolidation of the lung. It is well known that patients with pneumonia, when very ill and near the crisis, become delirious and may try to get out of bed. They may do some injury to themselves and try to jump out of the window. It is for this reason that the lower half of the windows can be opened only 10 inches (25 cm.) or so in many hospital wards. Nurses are taught that patients with pneumonia must be carefully watched and any attempt to get out of bed prevented, if possible.

Vasomotor Rhinitis and Antituberculous Therapy

Q.—Is vasomotor rhinitis a recognized sequel to combined P.A.S. and streptomycin therapy? It developed four days after the start of a two months' course, and has persisted. What treatment is recommended?

A.—Although sensitivity reactions, particularly in the form of skin rashes, are frequent during combined P.A.S. (para-aminosalicylic acid) and streptomycin treatment, vasomotor rhinitis has not been reported with significant frequency. It would be unusual for any sensitivity reaction to develop as soon as four days after the start of a course of treatment unless, of course, the patient had previously received either of the drugs. Whether or not any unusual symptoms and signs are due to either or both of the drugs can be quite easily determined. As soon as it is clear that the symptoms are persistent, both drugs should be stopped. If the symptoms do not clear up, then they are unlikely to have been due to a sensitivity reaction. If, on the other hand, the symptoms cease, then each of the drugs should be started in turn. In this way the drug responsible for the symptoms can be determined. In nearly every instance it is possible to desensitize the patient to the causative drug by administering first a dose too small to give rise to symptoms, and then progressively increasing this dose day by day until a full dose is being given. Of course, if the test of discontinuing the drugs shows that the vasomotor rhinitis is not due to either P.A.S. or streptomycin, the usual symptomatic treatment should be given. Antihistamine drugs such as mepyramine maleate, 50–100 mg. three times a day, should be used. Even if the condition appears to be caused by one of the drugs, it might be found that the symptoms of vasomotor rhinitis are so well controlled by the administration of a suitable antihistamine drug that the simplest procedure would be to continue with the course of streptomycin and P.A.S. together with the antihistamine.

Multiple Cervical Glands in Children

Q.—What is the cause of the multiple small discrete glands in the posterior cervical region which are so commonly found in rather poorly developed children?

A.—The cause is nearly always infection in the nasopharynx, particularly in the adenoids.

Reactionary Haemorrhage after Antrostomy

Q.—What is the best treatment for dealing with a severe reactionary haemorrhage following an antrostomy?

A.—Severe recurrent haemorrhage following an intranasal antrostomy usually comes from the large blood vessel about half-way along the naso-antral wall, and this is implicated as a rule only when the antral opening has been made rather far back. When the blood vessel causes trouble some hours after operation, the inside of the antral cavity should be cleared of clots by suction, and the antral opening plugged with fibrin foam or gelatin sponge. On top of this it may also be necessary to pack some ribbon gauze around the antral opening, and also in the antral cavity. This is almost certain to stop any recurrence of haemorrhage.

Correction.—It is regretted that Crohn's disease was misspelt in the Refresher Course article on "Indigestion in Childhood" (July 25, p. 197).

THE EVOLUTION OF BINOCULAR AND STEREOSCOPIC VISION IN MAN AND OTHER ANIMALS*

BY

WILFRED HARRIS, M.D., F.R.C.P.

Consultant Physician, St. Mary's Hospital, London

Many years ago, on leaving the National Hospital in Queen Square, where I had been house-physician for two years, I began a series of experimental work in Sir Victor Horsley's laboratory in University College on various animals, birds, and reptiles to study the subject of binocular vision and the path of the pupil reflex fibres to light. My results after two years were given in a paper to a special meeting of the Neurological Society in December, 1899, where I showed my microscopical sections of the chiasma in the chameleon, toad, pigeon, owl, rabbit, and cat, demonstrating the Marchi degeneration in the chiasma and optic tracts of the pigeon and rabbit, and in the optic lobes of the pigeon and the pons of the cat, after enucleation of one eye under anaesthesia. In addition, the course of the pupil fibres was suggested by the partial posterior decussation of Meynert's fountain decussation, following wounds of the anterior corpus quadrigeminum. Later on, this work was published (Harris, 1904). I developed the view that the successive improvements in accuracy of vision by binocularity, and finally by stereoscopic vision, were correlated with the importance, indeed the necessity, for certain groups of animals and birds, which live by hunting and chasing other living creatures for food, to acquire good vision.

Thus the shrikes and swallows, the hawks, owls, and eagles required and developed the greatest acuity and accuracy of vision, largely binocular, and amongst mammals the Carnivora developed almost perfect frontal position of the eyes and commencing stereoscopic vision. In the highest group, primates and man improved greatly the scope and accuracy of focusing by stereoscopic vision, but no longer for the purpose of hunting food or escaping from enemies, but in association with the development of the hand—in the monkey and apes mainly for inspection of objects of food seized by the hand; and, finally, in man there was the much greater development of the thumb and the resulting use of the hand in association with good stereoscopic vision for every kind of manual and artistic work. Indeed, foveal acuity of vision has probably diminished in the most civilized races of mankind, though some—the Hottentots, some Indian natives, and the Tierra del Fuegians—are credited with far keener vision than the average white races. Yet the cerebral development of macular vision in man, both in area of cortex and stereoscopic power of brain reception and perception, has without doubt greatly increased.

*A "birthday" lecture given at St. Mary's Hospital Medical School on December 5, 1952.

Stained sections of the chiasma in the chameleon, toad, owl, and pigeon demonstrated that there was total decussation of the optic nerves, while Marchi specimens of pigeon chiasma showed conclusively that the decussation of all the fibres was complete. Similar Marchi specimens of rabbit's chiasma showed that a very few fibres did turn back into the optic tract of the same side, but practically the decussation was total. Neither of the owls survived the operation of enucleation long enough to obtain the osmic acid staining for Marchi degeneration, but the appearance of the cut sections showed that there could be no doubt that the decussation in the owl was as complete as in the pigeon. There was good contraction of the pupils in the pigeon and owl to light shone directly on one eye, but no trace of consensual contraction in the other eye. Birds have voluntary power of contraction of the pupil, so a little care must be taken in testing their pupil's reaction to light, but after doing the test several times the bird gets accustomed to it.

I had a grey African parrot as a pet in those days, and its pupil was much easier to test, owing to the light coloured background. I remember trying to dilate its pupil with a drop of atropine, as I wanted to look at the retina and pecten, but the only result was that it stopped talking for a week. Birds' voluntary power of contracting the pupil is due to their having striated muscle in the iris which is unaffected by atropine. Marchi degeneration in the cat's chiasma showed much more semi-decussation than in the rabbit's, about one-third of the fibres turning back into the optic tract of the same side. In man the proportion of fibres decussating is said to be about seven to five. Consensual contraction of the pupil in the cat is well marked, but is absent in the rabbit owing to the almost total decussation.

Panoramic versus Binocular Vision

Vision in the rabbit and hare is completely panoramic, with no vision directly forwards, and they may even run forwards towards the gun when trying to escape. Several fish and reptiles and many varieties of birds have good binocular vision, though in all of them the decussation of the optic nerves in the chiasma is complete, and in none is there any consensual reaction of the pupil to light, even in the most frontally placed eyes of the owl, which may subtend an angle as wide as 150 degrees in the barn owl, compared with the human parallel optic axes, with the corneae in a horizontal line.

Although the chameleon has complete decussation of the optic nerves, yet it has the power of the most complete convergence of the eyes, with perfect binocular vision when seizing a fly or mealworm. Its eyes are stalked and covered with horny skin except for a small opening in front, at the bottom of which the small black pupil can be seen. When the animal is lively enough in the spring its eyes may be seen to move about quite independently in slow jerky motion, like searchlights; one eye may be pointed directly forwards and the other backwards at an angle of 180 degrees or 90 degrees vertically. If one eye catches sight of a fly or mealworm within range at a distance of a few inches, the eye remains fixed on it, while the other eye is brought round slowly until the two eyes are fixed on the morsel in perfect convergence. Then the mouth slowly opens and the sticky tongue appears; this is then flashed out, taking the grub unerringly, and withdrawn into the mouth. The tongue is not hinged at the front of the lower jaw as it is in the toad, which throws its tongue forward in an arc, as though on a hinge, and the fly or cockroach is gone in a flash, even quicker than in the chameleon's act.

In 1942 a remarkable book was published in America by G. L. Walls on the vertebrate eye, which by his permission I quote from freely in this paper. He states that associated with the perfect convergence of the chameleon's eyes is the highly developed retina, with a central fovea and yellow spot macula, the only animal besides the primates which has a macula; it has 756,000 cones per mm.² in its fovea, which is deeper and even more developed than the human. Walls devotes five pages to the evolution of binocular vision, and these are entirely given up to the question of the fusion of images and the perception of distance, though elsewhere he says, "The hunters tend towards frontality so as to have the best vision of the prey they are pursuing, while the hunted tend to retain laterality of eye position so as to be able to detect an enemy coming from any direction." He does not stress the idea that it is the carnivorous habits of certain reptiles, birds, and animals which have led to the evolution of binocular vision, or that stereoscopic vision has been perfected in the primates, and especially in man, in association with the development of dexterity of the hand for intricate work. In all other respects Walls's book is a mine of information, and my references to types of retinae and foveae are almost entirely quoted from it. I feel so sure, however, that the view of evolution of binocular and stereoscopic vision which I put forward nearly fifty years ago is correct, that I am venturing to discuss it once again.

Acuity of Vision

The marmots, or prairie dogs, have strongly lateral eyes like the rabbit, with little power of lateral movement and with panoramic vision, and for similar reasons, being vegetarian and requiring to avoid their enemies from both sides at the same time. Yet their acuity of vision compares in accuracy with human sight, for their retina, without foveae and containing only cones and no rods, compares in resolving power over its whole area with that of the human fovea. They have yellow lenses, which must mitigate the intensity of full daylight on the cones. On the whole, diurnal animals have a majority of cones in the retina, and pure cones only in the fovea or area centralis, while nocturnal animals have mostly rods; the owl's cones have become much more slender and rod-like in appearance, and the bird has no central fovea, only a temporal one. Many birds have two foveae, central and temporal. Diurnal birds, such as finches,

have mostly cones and comparatively few rods, and in hawks and eagles, and even in the common sparrow, cones are packed very closely in the fovea—400,000 per mm.² in the sparrow—while in the hawk, *Buteo*, no fewer than 1,000,000 cones per mm.² are found. This hawk's retina, with an eye as large as the human, has nearly twice the resolving power of the human fovea, while the visual acuity of some hawks and eagles is at least eight times that of man.

The sharp sight of vultures is well known, because of the great distances from which they can recognize a dying animal. Being carrion feeders on the ground, unlike hawks and eagles, which chase and capture their prey, often on the wing, vultures have no temporal fovea and do not require highly developed binocular vision. Even the shrike, or butcher bird, has much more acute vision than man. A falconer in the Middle Ages used to carry on his saddle a caged shrike which, after the hawk was loosed, would remain excited and fearful as long as the small bird could see the hawk, though long out of sight of the falconer.

A curious structure in the bird's eye is known as the pecten, a comb-like rugose outgrowth from the edge of the optic disk, very vascular and pigmented, but containing no nerve fibres. It is smaller in nocturnal birds, but its function is quite unknown.

Vision may be defined as the reaction to light of certain cells known as visual cells in the retina, which is a cup-shaped structure pushed out from the optic lobe in the brain on each side, consisting of visual cells backing on to an external limiting membrane and a pigment layer, supported externally by a tough fibrous envelope known as the sclera. This is enormously thickened in the whales, so as to make the eye almost immovable. The visual cells consist of rods and cones, the latter being particularly useful in focusing, and are found especially in the area centralis or macula and the fovea, or central vision point in the retina. The fovea in all animals and birds possessing one is avascular, no capillaries intervening between the layer of optic nerve fibres in front and the visual cells at the back of the retina; otherwise the focused image on the fovea would be blurred.

Sphenodon, a New Zealand lizard with nocturnal habits, is the only terrestrial vertebrate with a pure rod retina. Such vision is called scotopic, and cone vision photopic. Rods are more sensitive to light than cones, are distributed especially in the external parts of the retina, and are more useful than cones in dim light. They are bathed on the outside in the visual purple, derived from the pigment layer, which is known as rhodopsin. The retina may be more or less bleached by exposure to strong light for several minutes, but the rhodopsin is gradually reaccumulated on the rods within about half an hour. Vitamin A is a valuable aid to such reaccumulation, and during the late war was made use of in readapting the vision of night-fighters by the administration of halibut oil.

Rays and Vision

The light which strikes the outer layer of visual cells through the inner transparent layers of the retina may be direct light vibrations from a source of light such as the sun, an electric lamp, or a candle. These vibrations of radiant energy are electro-magnetic in nature and have a speed *in vacuo* of about 186,000 miles per second whatever their source. Those vibrations which we call visible light are restricted to a band whose wavelengths vary from about 1/3,000 of an inch at the red end of the spectrum to 1/6,250 of an inch at the violet end. Those rays on the longer side of the red end are the infra-red or heat rays; and still further and with increasing wavelengths are the Hertzian waves of wireless telegraphy which are up to 10,000 metres, or about six miles, in length. Beyond the shorter violet rays are the still shorter ultra-violet rays, with chemical action, and further still come the shorter x rays, gamma rays from radium or from atomic explosions, and finally the cosmic rays, whose wavelengths may be as short as 1/6,000,000,000 of an inch. They have enormous penetrating power, and have been shown to pierce several feet of

lead. All these rays travel at the same speed, and astronomers and physicists assert that nothing can travel faster than light *in vacuo*.

Long wireless waves are constantly travelling all round the world, being reflected downwards by the Heaviside layer in the upper atmosphere and passing perhaps through our bodies without our being conscious of them, but the shorter bands of heat and light rays are arrested by material objects, while the still shorter ultra-violet rays can in quantity damage us, and the still shorter x and gamma rays may be useful in destroying cancer cells but at the same time may be very dangerous. The shortest rays of all, the cosmic rays, we know little about, but it is believed that they reach our galaxy from the almost infinitely distant nebulae. In the upper atmosphere they ionize the air, producing ozone from the oxygen, which shields us from the destructive excess of ultra-violet rays in sunlight. Sir Spencer Jones, Astronomer Royal, in his foreword to a book recently published, *Across the Space Frontier*, comments on the risk from the destructive ultra-violet rays in the unfiltered sunlight that space travellers would encounter.

So it is just one small band, less than an octave, of medium short waves, which have the power of producing light when they strike a solid object and are then reflected into our eyes and retinae, that enable us to see the world around us. These rays entering our eyes are focused by the cornea and especially by the lens to form an inverted image of the object upon the fovea, the central point of vision in the retina. Traversing the transparent layers of optic nerve fibres and ganglion cells and nuclear layers, the rays impinge on the cones in the fovea and on the rods and cones around the macula and the peripheral parts of the retina, and start electric currents. These pass inwards to the layer of nerve fibres and then along the optic nerves, decussating at the chiasma, so that rather less than half turn back into the optic tract on the same side, while the larger remainder cross over to the opposite side, the stimuli in each case reaching the two external geniculate bodies, where the impressions from both retinae are laid over each other alternately, thus laying the foundation of stereoscopic vision. Thence the optic radiations carry the stimuli to the visual cortex in the two occipital lobes on the inner side around the calcarine fissure; lower retina to lower cortex, and upper retina to upper cortex. Thus the upper halves of our total visual field are perceived by the lower half of our visual cortex, and the lower visual field by the upper visual cortex. That this is so is proved by the fact that a lesion of the upper lip of the calcarine cortex and the cuneus above produces a blind area or scotoma in the lower visual field, and a lesion of the lower calcarine area and lingual lobe causes a scotoma in the upper half of the visual field.

Now comes the difficulty. We know from the optics of the eye that the image of any object seen is inverted on the retina. Why then do we see objects in their correct position, and not upside down? There is no known anatomical explanation of this, and so we must assume that there is some psychological reversal of the visual impression after it has reached the visual cortex. This reversal of the retinal inverted image is not a monopoly of the human brain, but must apply to all the lower animals, birds, reptiles, and mammals whose lenses focus on the retina in the same way as ours. It has been suggested that the baby gradually learns from experience, but a day-old foal will nuzzle his mother in the correct manner from the start without any teaching or experience, so it must see its mother the right way up.

A few instances have been reported of young children aged about 6 who, after an illness such as measles, or a head injury, or even after atropine has been put in the eye, may for several weeks see all test letters upside down and may draw objects such as houses and people in the inverted position. Mirror writing, which comes naturally to some children, is due to a somewhat similar process of psychological inversion.

Evolution of Retina

The most primitive light receptor is a spot of black pigment as is found in a unicellular microscopic animal, *Pouchetia cornuta*, or in the pigment in the surface epithelium of the earthworm, where light may cause chemical changes. The first approach to an actual eye is probably that of the limpet, *Patella*, in which a special layer of cells line the bottom of a depression in the skin. A further advance is the pin-hole camera type of eye in the nautilus; then, more elaborate and with focusing lens, the ocellus of the scorpion; then the snail, *Murex*, with a covering cuticle or cornea; and, lastly, the most highly organized of the pre-vertebrate eyes, that of the octopus and decapods, such as *Sepia* and *Loligo*, the cuttle fish, which have retina, vitreous, and spherical lens, with focusing power of moving the lens forwards or backward from the cornea, but very little, if any, binocular vision. These cuttle fish require highly organized and rapid variations of focus as they travel at speed over varying coloured backgrounds of sea-bed, so as to co-ordinate by their nervous reflexes the changing colours of the skin. Though these molluscs have such a highly developed eye, comparable to that of the higher mammals and human beings, the structure of their optic nerves and their central connexions show no evidence of binocular or stereoscopic vision, and there is no decussation of the optic nerves, which pass direct into the lobes of the supra-oesophageal ganglia, a primitive brain.

In passing, I might comment on the fact that the squid and the octopus have anticipated Sir Frank Whittle by many millions of years in their discovery of jet propulsion, with the difference that their method of movement is backwards, or retropulsion. At the same time they have the power of hiding from an enemy by ejecting from the ink sac into the jet a cloud of dark brown pigment, hence the name *Sepia*, or, as the fishermen call it, the pen-and-ink fish. They are, by the way, extremely good eating. It is remarkable that the order Mollusca includes one of the most primitive eyes in the limpet and one of the most highly developed in the cuttle fish.

Varieties of Retina

The vision of all vertebrates may be classed as either diurnal or nocturnal. The latter will have retinae rich in rods, which are more sensitive to dim light than cones. Diurnal vision requires numerous cones, which give clarity of images with focusing in good light, so the foveae of diurnal vertebrates are pure cone. It is not only in relative numbers but also the relative amount of rod or cone substance that is important. This is brought about by an actual increase in size of the eyes, as in hawks, eagles, owls, the larger mammalia, primates, and man. Most birds, being active by day, have retinae rich in cones, but many animals require retinae of a mixed type and rich in rods—such as the Carnivora, wolves, lions, tigers, leopards, and foxes, as many a country farmer has reason to regret on finding his hen-roosts depleted in the morning. Large eyes in the Ungulata (horses and oxen), apes, and man allow of great numbers of rods to be interspersed among the cones without diminishing diurnal vision, while increasing their nocturnal powers in twilight and moonlight; thus man and the Carnivora especially are able to stay up and pursue their gangster business after the birds have gone to bed.

The cone is said to be the older of the two visual cells, and is of special value for focusing and sharp definition, though less sensitive in dim light than the rods. The human fovea is pure cone, but outside the macula rods outnumber the cones by 20 to 1. This greater sensitivity of the rods is demonstrable when looking at a faint star. If you look directly at it the star seems to disappear, but reappears on looking just to one side of it. The belt of Orion is a good test for this point. Or try the brightest star in the Pleiades, Alcyone, who with her six sisters, daughters of Atlas, were chased for five years by the hunter Orion and his dog Sirius, the brightest star in our sky, until Zeus saved them by translating them all to the heavens above.

Teleostean, or bony fishes, are peculiar in having very variable thicknesses of retinae, with twin cones as well as single ones. The eel has 3,000,000 rods per mm.² which is surprising, for its habitat in adult life in fresh-water lakes and canals would not seem to call for a very sensitive retina. The life story of this fish is altogether remarkable. When the adult after some years feels the urge to migrate its eyes grow enormously in size, the fish becomes silvery, makes its way down the streams to the sea, and thence across the ocean to the clear Sargasso Sea in the West Indies. Here they breed, and the adults then die, while the young elvers grow to a few inches in length and then slowly make their way back across the ocean to the estuaries and rivers whence their parents came, and ultimately grow to adult form in the ditches, lakes, and canals whence their parents migrated.

Vision in Deep-sea Fish

The more numerous the rods are in a retina the more sensitive is it to light, and the rods become greatly elongated and slimmer, so that greater numbers can be packed in the same space. This is found in the retinae of deep-sea fish, which dwell at the depth of a mile or more and live in Cimmerian darkness. They never see anything but the photophores or phosphorescent lamps carried by friends or enemies. This luminescence of deep-sea fish is produced by bacteria in tiny tubules in the skin, and this light the fish can conceal at will. About 96.5% of all deep-sea creatures are luminous. It has been claimed that some of them have as many as 25,000,000 rods per mm.² of retina. Some have tubular eyes, fixed in their sockets and immovable, as in the owl, but placed parallel for good binocular vision, others have the eyes fixed for upward vision.

Some freshwater fish have partial binocular vision, for a trout can take a fly quickly on the surface of the pool. It is, however, but an amateur at the job compared with the archer-fish, *Toxotes jaculator*, which can spit a thin stream of water from beneath the surface to hit and bring down a fly in the air several inches above the water. It has a narrow binocular field, but no fovea. As Walls remarks, "If his shooting depends on his sight of the fly in air when seen from under the surface, he must have a truly trigonometric range-finder in his brain to cope with the ever varying distortion of angles, size and distances." If the water is smooth a fish can see out of the water anything subtended by an angle of slightly greater than a right angle with his eye. A person on the bank would look like a tiny doll, which would enlarge the nearer it approached the surface.

Dryophis, the East Indian long-nosed snake, has good binocular vision, due to its having a temporal fovea. It is one of the only two genera that have a fovea, has the sharpest sight of all snakes, and is a most accurate judge of distance. Its pupil is shaped like a keyhole and is placed very laterally on the head, which slopes sharply forwards to its pointed nose, making its view quite unobstructed for good binocular vision.

Carnivorous Birds

Though many birds have two foveae, central and temporal, the owl has only a temporal fovea. The barn owl has the most frontally placed eyes of all birds, with a visual angle of about 150 degrees, compared with the human parallel eyes at 180 degrees. Its retina, being adapted for nocturnal vision, has comparatively few cones but mostly rods, except in its temporal foveae, with which its marked binocular vision enables it to focus and seize the little voles and field mice that are its usual prey. Owing to the owl's nocturnally adapted vision, if it is caught out in the open daylight it is partly blinded by the strong light and is apt to lose its way, and may get mobbed by small birds. Its eye is partly tubular in shape and is quite immovable in its socket, but to compensate for loss of ocular movement the owl has the extraordinary power of rotating its head on its neck to an angle of 270 degrees, or three-quarters of a circle.

Fish-eating Birds

The cormorant, *Phalacrocorax*, has the most powerful accommodation of all birds for compressing the lens by the ciliary muscle. Its lens, which is as soft as the turtle's, can be compressed into a pear shape giving an accommodation power of 40 to 50 dioptries, so essential in following his prey under the water. The gannet, *Sula bassana*, has only central foveae, and so cannot focus its distance when diving from a height into the sea after a fish. This has been proved by fastening a fish on a floating board, when the bird has been seen to transfix the board with its beak. The kingfisher has both central and temporal foveae. It generally dives into a stream from a perch above a pool, having focused a fish beneath the water with its central fovea, but the moment its head is beneath the water it must change its focus to its very external temporal fovea, using good binocular vision in this way as it spears the fish with its pointed bill. The swallow too requires the greatest accuracy in focusing power for catching flies and chafers at speed on the wing.

Many insects, especially the dragon-fly, and some Crustacea have round or oval protruding compound eyes, built up of conical-shaped lenses fixed with their bases against a smooth membrane or cornea, so that vision of objects behind the fly or lobster is possible. Anyone who has tried to stalk a fly from behind must often have noticed this point for himself.

Colour Vision

Colour vision has been demonstrated in fish, reptiles, and birds by training them to take food from different coloured containers. Coloured objects reflect only those coloured rays which we see, absorbing all the rest of the rays of the spectrum. Many street lamps, though excellent illuminants, are very poor in red rays, though rich in green and blue; consequently at night our hands and faces will appear corpse-like in hue, as there are no red rays in the light that illuminates them.

For many years the Young-Helmholtz trichromatic theory—red, yellow, and blue, or red, green, and violet—disputed pre-eminence with Hering's view of three colour substances in the retina, white-black, red-green, and yellow-blue. There are seven primary colours in the spectrum—red, orange, yellow, green, blue, ultramarine-indigo, and violet—and Granit has suggested that there are seven different receptors in the retina, one for each primary colour. This theory has been further developed by Hartridge as a polychromatic theory, which seems likely to oust the older theories, neither of which explains various forms of colour-blindness, which can be satisfactorily explained by the polychromatic theory.

Some brilliant effects of colour, such as the vivid green of some beetles' wings and the coloured eyes of peacocks' feathers and of butterflies' wings, are due to excrescences on the material of the wings acting like a diffraction grating, a piece of plate-glass engraved by a diamond with very close parallel lines, over 12,000 to the inch. These fine lines at their edges break up white light into its spectral colours, and it would be just as useless to try to extract coloured substances from the peacocks' feathers or butterflies' wings as it would be to do so from a rainbow.

Conclusions

Hitherto we have traced the development and value of binocular vision as an assistance to carnivorous fish, reptiles, amphibia, and birds in catching their prey. When we examine the vision of mammals the same and increasing value of binocular vision and frontal placing of the eyes is seen in the Carnivora as compared with the browsing and grass-eating animals, which have panoramic vision and almost total decussation of the optic nerves. The semi-decussation of the nerves in the

Felidae and other Carnivora now introduces an additional element of value—namely, stereoscopic vision, by which I mean that the images from both eyes are now beginning to be laid over one another alternately in the visual centres, first, in the external geniculate bodies, and thence via the optic radiations in the calcarine and neighbouring cortex. This factor doubtless increases the accuracy of fusion of images in depth.

Development of the Hand and Thumb in Co-ordination with Stereoscopic Vision

In the higher mammalian group of primates and man the importance of catching living food has disappeared, as apes and monkeys are mostly fruit eating, and man also is largely fruit eating and agricultural. There is now a more important reason for the development of stereoscopic vision of the highest type, in the increasing importance of the hand in seizing objects for inspection, and for important manual work of all descriptions requiring accurate vision. No one could watch the monkeys in the outdoor cages at the Zoo without noticing how they use the hand and vision in co-ordination for receiving and inspecting the morsels offered to them. Though improvement in vision for hunting animal food is no longer necessary, the human hand is an immense improvement on that of the monkey, chimpanzee, or gorilla—in the development of the thumb and thenar muscles in proportionate strength and the power of opposition of the thumb to the other fingers. By this improvement the value of the hand as a working tool acquires much greater delicacy of movement and co-ordination with vision in its manifold uses of building and of manufacturing tools, objects of vertu, and works of art of every description, as exemplified by a Michelangelo or a Raphael in sculpture and painting, or a Cellini in gem making. In these arts the closest co-ordination of eye and hand is essential, but with musical instruments vision plays little part in the marvellous execution of a Paganini or an Abbé Liszt. Here the ear and memory, and the intensity of practice, take the place of vision.

The monkeys and apes have concentrated on developing all four limbs with four hands, as *Quadrupana*, and the South American monkeys have added even a fifth "hand" in their prehensile tail, thus making an ideal machine for tree-climbing and swinging from branch to branch, and enabling them to travel long distances along the upper regions of the primeval forests without danger from carnivorous enemies on the ground. The offshoot, man, has concentrated on his fore-limb only, and by hand and vision combined—with increasing brain development, the acquisition of speech, and the discovery of fire, of agriculture, firearms, steam power, electricity, the telephone, the internal combustion motor, and, lastly, the means of flying, in ever-hastening speed of invention—has gradually developed from his doubtful position as a cave man to his present supremacy in the living world.

We have yet to see whether the most recent and most powerful invention, atomic fission, will be harnessed for peaceful production of power for all the nations, when all the coal and oil have been used up, or whether it will lead to the greatest means of destruction of civilization in history.

Surgeon, Royal Eye Hospital

The place of the sulphonamides and of penicillin in ocular infections mainly due to Gram-positive organisms, and of streptomycin in infections mainly due to Gram-negative organisms, is now well established. None of these agents has, however, proved of much use in virus infections, except that the sulphonamides are valuable in the treatment of trachoma and in inclusion blennorrhoea, with penicillin almost as effective in the latter infection. The newer antibiotics with their alleged efficacy over a wider range of viruses offer the possibility of therapeutic agents in ocular infections which are due to viruses and are not readily controlled. Outstanding among these are dendritic ulcer, disciform keratitis, epidemic keratoconjunctivitis, and herpes ophthalmicus. Dendritic ulcer of the cornea, a not uncommon condition, shows varying severity and a tendency to frequent relapses. Disciform keratitis, with its dense interstitial infiltration, generally leads to much loss of vision from the resultant interstitial fibrosis. Ocular complications of herpes ophthalmicus, which include a variety of corneal reactions, iridocyclitis, both active and quiescent, and episcleritis, as well as destructive corneal ulceration, are serious considerations. Epidemic keratoconjunctivitis is the least significant from the point of view of resultant damage, but its prolonged course, marked symptoms, and occasional sequels of dendritic ulceration and disciform keratitis, as also the frequency with which it occurs during epidemic periods, present problems of some magnitude. Evidence for the virus origin of these affections is best in herpes ophthalmicus, and almost as definite in dendritic ulceration and in disciform keratitis; the virus origin of epidemic keratoconjunctivitis is less definitely established. Whilst there is little doubt that the first three of these affections are due to a virus of the herpes group, such little as is known of the morphology of the virus of epidemic keratoconjunctivitis suggests that it has some affinity to the virus of trachoma. The assumption that viruses are responsible for a variety of other nondescript corneal and iris reactions has as yet little support.

In the present study an attempt has been made to assess, experimentally and clinically, the value of the different modes of administration of aureomycin, chloramphenicol, and terramycin. The difficulties in establishing experimental virus lesions in animals on which these agents could be tested have precluded any experimental assessment of these drugs. We have had to rely instead on clinical observations.

Aureomycin

Experimental Studies

Intraocular Levels on Systemic and on Subconjunctival Administration.—Preliminary findings in the rabbit gave the following tentative results. (1) Intramuscular injection (100 mg.): No aureomycin could be demonstrated in the aqueous, vitreous, and cornea after two and four hours, except for one reading of 0.8 µg./ml. in the aqueous of one rabbit. (The blood level was adequate at two hours.) (2) Subconjunctival injection (10 mg.): At one and a half and two and a half hours there were tangible levels in the aqueous (2 and 1.25 µg./ml. respectively) and in the cornea (10 and 20 µg./g. respectively). The levels in the vitreous were lower (0 and 0.5 µg./ml. respectively).

Using a plate diffusion method, with *B. subtilis* as the test organism, the results recorded in Table I were obtained. It will be seen that levels reached with aureomycin when

TABLE I.—Aureomycin Hydrochloride: Concentrations in the Aqueous, Vitreous, and Cornea of the Rabbit Reached by Different Dosages and Methods of Administration (Test Organism: *B. subtilis*)

Mode of Administration	Time in Hours	Aureomycin Levels (µg./g. of Tissue)

	4	<0.1	<0.4	<0.3	5.0

given intramuscularly, or orally, were considerably higher in the blood than in the aqueous, vitreous, or cornea. It would therefore seem that the systemic use of aureomycin encounters the same difficulties as were observed with penicillin and streptomycin. The subconjunctival route, which proved so effective in the older antibiotics, has, however, distinct limitations with aureomycin, for the drug is highly insoluble—some 0.02 mg./ml., and this is not increased substantially even if the solution is buffered with sodium bicarbonate. As micronized crystalline aureomycin was available an attempt was made to inject larger quantities of the agent in fine suspension subconjunctivally, and a fairly easily injected suspension containing 20 or even 50 mg. per ml. can be prepared. But such suspensions brought difficulties of their own. In the first place, even when buffered these suspensions are inclined to be irritating, and in the experimental rabbit the more concentrated suspensions tended to produce transient corneal haze and other symptoms of irritation. Secondly, and more significantly, these suspensions were not apparently absorbed into the eye but tended to form a cheese-like deposit subconjunctivally with necrosis of the overlying conjunctiva, so that even after eight days most of the suspension could be scraped away mechanically. As can be seen from Table I, even these extreme measures led to disappointing levels of concentration in the aqueous and vitreous. In fact, there is some suggestion that the smaller, and presumably less irritating, doses give rather better intraocular levels.

The use of aureomycin is therefore beset by two considerable difficulties: systemic administration gives low intraocular levels, while subconjunctival injections are limited to small doses, with resultant low levels of intraocular concentration.

Clinical Studies

Aureomycin, given as subconjunctival injections of 10 mg., was used in 15 cases: in seven fresh cases of disciform keratitis and two cases of dendritic ulcer it was given twice at intervals of five days, in four cases of "superficial punctate keratitis" and two cases of epidemic keratoconjunctivitis it was given once. Ointment of 0.1%, generally at two-hourly intervals, was used in 10 cases—two being of dendritic ulcer, two of herpes ophthalmicus with corneal involvement, five of epidemic keratoconjunctivitis, and one of chronic blepharitis in a patient sensitive to nearly all treatment. The results were almost consistently poor. The promise of a good result obtained in the first case of disciform keratitis treated by subconjunctival injection was not fulfilled in further observations. The only positive results in this series were symptomatic relief within three to five days in cases of epidemic keratoconjunctivitis treated by ointment, though the corneal staining persisted; and a fairly good response to blepharitis in a patient who had proved intolerant to other forms of treatment.

We have no experience of the use of aureomycin in trachoma and inclusion blennorrhoea: the poor results obtained with the herpes group of ocular infections and the equivocal results with epidemic keratoconjunctivitis do not exclude the possibility of good results with the large-sized viruses responsible for trachoma and inclusion blennorrhoea, or in infections due to bacteria insensitive to sulphonamides and penicillin.

Chloramphenicol

Experimental Studies

With a plate diffusion method, using *Shigella sonnei* as the test organism for assay of the antibiotic concentration in the tissues, trials gave the following results in the rabbit. (1) Intramuscular injection of 250 mg./kg. body weight: the levels in both the blood and ocular tissues at two and four hours were nil or negligible. (2) Oral administration of 375 mg./kg. body weight: the blood levels at two hours in two animals were adequate (10 and 20 µg./ml.). The levels in the cornea were nil; in the aqueous 5 and 15 µg./ml., in the two animals respectively; and 0 and 10 µg./ml. in the vitreous. At four hours all levels were nil.

As intramuscular injection looked unpromising, fuller studies were confined to assessing the relative value of oral administration and subconjunctival injection. The results are shown in Table II. The first section of this table shows that the intraocular levels of concentration of chloramphenicol compare unfavourably with those reached in the blood when 500 mg. of the drug is administered orally to the rabbit. These results suggest that the oral use of chloramphenicol is not likely to give adequate concentrations in the eye. Subconjunctival injections of chloramphenicol met with the same initial difficulty as in the case of aureomycin. Chloramphenicol, too, is highly insoluble (2.5 mg./ml.), but it has the advantage over aureomycin that it did not prove irritating when 50 mg. was injected subconjunctivally as a suspension. There were not the same irritative reactions in the cornea, nor any necrosis at the conjunctiva. Particles of chloramphenicol were, however, too large for a suspension to be readily injected, and again micronized chloramphenicol proved better. Several types of micronized suspensions were obtained, and it was found that the 15% chloramphenicol suspension in 1:10,000 benzmethonium chloride ("phemeride") could fairly readily be injected in quantities up to 1 ml. without irritation. The intraocular levels obtained in the rabbit with 1 ml. of such suspension injected subconjunctivally are shown in the second section of Table II. It will be seen that the aqueous levels in particular are much higher than those obtained from oral administration of 500 mg. The effect of adrenaline on these levels is seen in the third section of the table. The injection of the suspension in 0.1% adrenaline leads to

TABLE II.—Chloramphenicol: Concentrations in the Ocular Tissues of the Rabbit Reached by Different Dosages and Methods of Administration (Test Organism: *Shigella sonnei*)

higher and more consistent levels—a finding reminiscent of the observations with penicillin and streptomycin.

Apart from subconjunctival injections, chloramphenicol was also available in the form of drops 0.5% and ointment %, both of which were well tolerated by the experimental rabbit.

Clinical Studies

Chloramphenicol was used in 72 cases, distributed over the following groups: (1) 29 cases treated with ointment %, generally at two-hourly intervals—9 being disciform keratitis, 6 "superficial punctate keratitis," 2 neuroparalytic keratitis with hypopyon, 3 "chronic follicular conjunctivitis" with acute subjective symptoms, and 9 epidemic keratoconjunctivitis; (2) 28 cases treated with drops 0.5%, generally at two-hourly intervals—2 being "superficial punctate keratitis," 8 dendritic ulcer, 1 neuroparalytic keratitis with hypopyon, and 17 epidemic keratoconjunctivitis; (3) nine cases treated with subconjunctival injections of 15% suspension, generally 0.5 ml. with adrenaline—3 being disciform keratitis and 6 dendritic ulcer.

In addition four cases of herpes ophthalmicus and one case of dendritic ulcer were treated by oral administration combined with the use of ointment locally, and one case of post-operative infection was treated intensively by different methods as indicated below.

Apart from the striking exception of epidemic keratoconjunctivitis, the results with drops or ointment were almost consistently poor for disciform keratitis, dendritic ulcer, and the other presumed virus infections. The diagnosis of epidemic keratoconjunctivitis was not made unless the typical picture of hyperaemic conjunctiva, watery discharge, enlarged preauricular nodes, and superficial punctate staining of the cornea were all present. All the 26 cases treated responded well to either ointment or drops; among these were eight cases that had previously been treated unsuccessfully by other methods. Cases of "superficial punctate keratitis" without the other components of epidemic keratoconjunctivitis did almost uniformly badly.

The disappointing results from drops and ointment in dendritic ulcer and disciform keratitis led to the use of subconjunctival injections in six cases of dendritic ulcer and three of disciform keratitis. The subconjunctival injections were generally 0.5 ml., or rather more, at daily intervals for three or four days. No improvement was obtained.

That subconjunctival injections of chloramphenicol may, however, have a definite, even if limited, place in ophthal-

mology is suggested by the isolated case of post-operative infection treated by this method.

A woman aged 81 was found to have an infected wound with the beginning of a hypopyon at the first dressing 48 hours after a cataract extraction. Subconjunctival injection of 500,000 units of penicillin and a similar dose intramuscularly were given, and a smear for bacteriological examination was taken. This treatment was continued for three days, the eye steadily becoming worse. The bacteriological report showed the presence of pneumococci which were resistant to sulphonamides, penicillin, and streptomycin but sensitive to aureomycin and chloramphenicol, and *Micrococcus tetragenus* which was sensitive to streptomycin and chloramphenicol. Chloramphenicol in ointment form was given three-hourly for three days without result. It was then supplemented by oral administration for two days more. At this stage the hypopyon had increased to almost three-quarters of the anterior chamber, and subconjunctival injection of chloramphenicol with the addition of 2 minims (0.12 ml.) of adrenaline was instituted. A marked improvement had occurred by the following day, and within another 24 hours the hypopyon was barely visible. In all, four injections were given at 24-hourly intervals, with chloramphenicol ointment 1% four-hourly. A fairly good red reflex could be obtained ophthalmoscopically on the third day, and the subsequent course was uneventful. Six months later vision with correction was 6/12.

Terramycin

Experimental Studies

Terramycin, like the other two agents, is largely insoluble in water, the maximum solubility of the terramycin base being 0.25 mg. per ml. Micronized terramycin is not readily taken up in suspension. Subconjunctival injections containing a suspension of more than 20 mg. are not tolerated, as there is marked injection of the eye and opacification of the cornea.

Administration by the subconjunctival route is therefore of limited value. As can be seen from Table III, the intraocular levels of concentration reached by various routes were disappointing.

(a) **Oral Administration.**—With doses of 100 mg., the serum and intraocular levels were poor at one and at three hours.

(b) **Intravenous Injection.**—With the same dose the serum level was high, but the intraocular levels, though better than on oral administration, were low.

(c) **Intramuscular Injection.**—Whether terramycin hydrochloride or micronized terramycin was used, doses of 100 mg. once more gave low intraocular levels.

TABLE III.—*Terramycin: Concentration in Ocular Tissues of the Rabbit reached by Different Dosages and Methods of Administration (Test Organism: B. subtilis)*

Mode of Administration	Time in Hours	Terramycin Levels ($\mu\text{g./g.}$ of Tissue)						
		Blood	Aqueous	Vitreous	Cornea	Lens	Ant. Tissues	Post. Tissues
Intramuscular: Terramycin HCl, 100 mg. in 1 ml.	1	2.1 0.89	3.2 2.3	<0.5 <0.5	<2.5 <2.5	<1.5 <1.5	<2.5 <2.5	<2.5 <2.5

	2	1.44 1.12	<0.48 <0.48	<0.5 <0.5	6.00 <1.5	<1.5 <1.5	8.69 1.50	2.18 <1.5
Oral: Terramycin HCl solution aq., 100 mg. in 5 ml.	1	<0.5 <0.5	2.83 1.37	<0.5 <0.5	<1.5 <1.5	<1.5 <1.5	<1.5 <1.5	<1.5 <1.5
	3	<0.5 <0.5	<0.5 <0.5	<0.5 <0.5	<1.5 <1.5	<1.5 <1.5	<1.5 <1.5	<1.5 <1.5
Intravenous: Terramycin HCl buffered, 100 mg. in 1 ml. water	1	37.9 35.6	<2.5 <2.5	<2.5 <2.5	<2.5 2.50	<2.5 <2.5	5.68 9.76	10.0 5.01
	2	47.7 37.7	<2.5 <2.5	<2.5 <2.5	3.36 4.82	<2.5 <2.5	5.52 7.32	4.78 10.2
Subconjunctival: Terramycin micronized base, 100 mg. in 1 ml. suspension	1	<0.4 <0.4	3.14 1.04	1.5 <0.4	<2.0 <2.0	<1.2 <1.2	6.56 12.3	23.8 10.5
	2	<0.4 <0.4	4.4 1.39	<0.4 <0.4	<2.0 <2.0	<1.2 <1.2	7.4 <1.2	7.9 <2.0
	4	<0.4 <0.4	<0.4 <0.4	<0.4 <0.4	<1.0 <1.0	<1.2 <1.2	2.0 1.3	3.5 1.11

(d) *Subconjunctival Injection*.—Suspensions of 100 mg. of the micronized base were both poorly tolerated and unproductive of any adequate intraocular levels. Most of the terramycin remained at the site of injection as an irritating mass that could be removed four days later.

These results suggest that with clinical doses administered systemically little penetration into the eye is to be expected, and the subconjunctival injection does not overcome this difficulty.

Clinical Studies

These were confined to the use of terramycin ointment (crystalline terramycin hydrochloride 0.5%) at two-hourly intervals. There was no result in five cases of dendritic ulcer nor in three cases of disciform keratitis. The results in five cases of epidemic keratoconjunctivitis were of the same order as those obtained with chloramphenicol.

Summary

Aureomycin, chloramphenicol, and terramycin administered systemically do not penetrate readily into the eye, so that adequate intraocular therapeutic levels are not obtained by such administration.

The poor solubility of these agents limits their use as subconjunctival injections. Even in the micronized form, both aureomycin and terramycin cannot be given in suspension, for any substantial concentration produces marked irritative reactions. Chloramphenicol, however, can be fairly readily administered as a 15% suspension; it is well tolerated, and gives adequate intraocular levels; these levels can be both increased and maintained for a longer time if the suspension contains 0.1% of adrenaline.

In the absence of suitable techniques for the experimental study of virus infection of the eye, clinical assessments were made of the value of these agents in several ocular infections assumed to be due to viruses.

(a) Aureomycin in the form of ointment 1% or subconjunctival injection of 10 mg. did not improve dendritic ulcer, disciform keratitis, herpes ophthalmicus with corneal involvement, and in a nondescript group of corneal lesions with superficial punctate staining. In five cases of epidemic keratoconjunctivitis there was symptomatic relief to ointment, but no effect on the superficial corneal staining.

(b) Terramycin ointment 0.5% did not improve dendritic ulcer and disciform keratitis. There was a gratifying response in five cases of epidemic keratoconjunctivitis, the condition clearing up within two to seven days.

(c) Chloramphenicol, in the form of 1% ointment or drops 0.5%, or subconjunctival injection of 0.5 ml. of 15% solution, did not improve dendritic ulcer and disciform keratitis. There was also no improvement with any of these methods, or with oral administration, in four cases of herpes ophthalmicus and in one case of sympathetic ophthalmia. The results were likewise negative in neuroparalytic keratitis, "chronic follicular conjunctivitis," and "superficial punctate keratitis." Gratifying results were obtained in 26 cases of epidemic keratoconjunctivitis treated either by 1% ointment or by drops of 0.5%. A good result was also obtained by repeated subconjunctival injection of the 15% suspension in a case of post-operative infection of the eye caused by a pneumococcus insensitive to penicillin and the sulphonamides.

It may be concluded that, of the newer antibiotics, aureomycin is of little value in ophthalmology; terramycin is useful in ointment form for epidemic keratoconjunctivitis; and chloramphenicol gives results as good as or better than terramycin in epidemic keratoconjunctivitis. Of these three antibiotics, chloramphenicol is the only one which can be given in a relatively high concentration subconjunctivally; it may be of value in the occasional cases of intraocular infection due to organisms sensitive to chloramphenicol but insensitive to the sulphonamides, to penicillin, or to streptomycin.

Apart from the control of epidemic keratoconjunctivitis—a presumed virus infection—by both terramycin and chloramphenicol, the virus diseases of the eye still remain a therapeutic problem.

Our thanks are due to Cyanamid Products, Ltd. (Lederle Laboratories Division), Parke, Davis & Co., Ltd., and Chas. Pfizer & Co., Inc., for generous supplies of aureomycin, chloramphenicol, and terramycin respectively. Aureomycin was also obtained from the Medical Research Council. Dr. Joan Farrar and Mr. I. W. Payne helped with the clinical assessments on cases referred to us by the staff of the Royal Eye Hospital. Dr. P. Muggleton and Mr. B. I. Helliwell, of Glaxo Laboratories, assisted in the experimental work. We are also indebted to Sister Thorogood and Sister Altenberger for their loyal co-operation in the care of patients admitted to the eye unit at Lambeth Hospital.

BREAST-FEEDING IN THE OXFORD CHILD HEALTH SURVEY

PART II—COMPARISON OF BOTTLE- AND BREAST-FED BABIES

BY

ALICE STEWART, M.D., F.R.C.P.

AND

CELIA WESTROPP, D.M., M.R.C.P., D.C.H.

(From the Social Medicine Unit, Oxford University)

In a recent paper some of the social and biological factors which influenced the breast-feeding habits of mothers in the Oxford Child Health Survey were discussed (Westropp, 1953). It remains to discover what special advantages, if any, were enjoyed by the breast-fed babies.

In the following account the change-over from breast-feeding to artificial feeding is referred to as the weaning period. In a few cases complete breast-feeding was never established, but for most of the babies three distinct modes of feeding were represented in the first year: (1) Complete breast-feeding or pre-weaning period: during this phase the only additions to a diet of breast milk were vitamin concentrates. (2) Mixed feeding or weaning period: during this phase the babies were receiving breast milk and other liquid or solid foods. (3) "Other" feeding or post-weaning period: this phase began when the baby ceased to have any breast milk.

Growth and Development

For 142 of the 580 babies who remained in the Survey for a year, weaning began during the first month (group 1), and for 235 it was postponed for at least five months (group 4). In addition, there were 84 babies who began to be weaned in the second or third month (group 2) and 119 in the fourth or fifth month (group 3). The composition of these four feeding groups in respect of sex, parity, birth-weight, and parents' weights is shown in Table I. These

TABLE I.—*Sex, Parity, Birth Weight, and Parental Weights of Four Groups of Babies Defined by Duration of Complete Breast-feeding*

Feeding Group	Age in Months at Onset of Weaning Period	No. of Babies	% Boys	% First-born	Average Birth Weight (lb.)	Average Weight (lb.) of	
						Fathers*	Mothers†
1	0–	142	53.5	41.2	7.53	158.8	131.8
2	1–	84	50.0	51.0	7.33	161.0	132.9
3	3–	119	57.1	55.5	7.66	161.5	131.8
4	5+	235	47.8	41.6	7.54	156.3	132.1
Total		580	51.2	46.0	7.52	158.6	132.1

* Based on 456 records.
† Based on 530 records.

characteristics have been displayed because they are known to have influenced weight gain during the first year (Parfit, 1951; Hewitt and Stewart, 1952).

Body Weight.—According to Table I there was so little difference between the four feeding groups for the factors mentioned that, had the rate of growth been the same for both breast- and bottle-fed babies, each should have gained approximately the same amount of weight. It is therefore significant that by the end of six months there was a definite weight gradient (see Table II); at this age the babies who had been bottle-fed longest were, on average, 12½ oz. (355 g.) heavier than the babies who were breast-fed longest. By the end of the year the average weights of the three groups

TABLE II.—*Increase in Body Weight from 0 to 6 Months and from 6 to 12 Months. Comparison of Four Feeding Groups*

Feeding Group	Average Increment (in lb.)		Average Weight (in lb.) at 1 Year
	0–6 Months	6–12 Months	
1	9.77	5.12	22.42
2	9.47	5.61	22.41
3	9.25	5.25	22.16
4	8.99	4.92	21.45
Total	9.29	5.14	21.95

weaned before the age of 5 months were roughly the same, but these babies were still appreciably heavier than the babies who continued to receive nothing but breast milk for longer periods.

Development of Bones and Teeth.—In Table III the bones and teeth of the babies in the four feeding groups are compared. The comparison, which was made at the age of 12 months, is in terms of the number of carpal and epiphyseal bone centres visible in radiographs of the left wrist, the patency of the fontanelle, and the number of erupted teeth. It will be seen that the division of the babies by duration of complete breast-feeding cuts unevenly across

TABLE III.—*Development of Bones and Teeth. Comparison of Four Feeding Groups in respect of Skeletal Maturity, Patency of Fontanelle, and Number of Teeth at 12 Months*

Feeding Group	No. of Babies	Radiological Data			Fontanelle Closed	No. of Teeth per Child
		Distal Radial Epiphysis	No. of Carpal Bone Centres per Radiograph	No. of Babies Not Examined		
1	142	65.4%	2.24	6	30.3%	6.82
2	84	54.9%	2.34	2	41.7%	6.62
3	119	60.7%	2.18	2	31.1%	6.24
4	235	61.8%	2.24	7	26.0%	6.04
Total	580	61.4%	2.25	17	30.3%	6.35

the dates at which the fontanelle closed and the distal radial epiphysis appeared, and leaves the average number of bone centres in the carpus roughly the same for each group. There is, however, nothing to indicate a systematic difference between the breast- and bottle-fed babies in respect of these three characteristics. On the other hand, the analysis of teeth shows a slight but distinct feeding gradient, with the highest average number among the babies who were weaned earliest.

Other Milestones.—Table IV summarizes the available data for the crawling and walking habits of the babies. In both respects the four feeding groups were very much alike, but the babies who dispensed with the crawling stage tended to be concentrated among those who were weaned earliest, and at 14 months the babies who were breast-fed longest were very slightly "less mobile" than the others.

To sum up, by the criteria chosen to demonstrate growth and development there were more resemblances than differences between the breast- and bottle-fed babies. Such differences as have appeared suggest that bottle-feeding, as practised by the mothers of healthy babies in the Oxford Child Health Survey, tended, very slightly, to accelerate growth.

TABLE IV.—*Other Milestones. Comparison of the Number of Babies (Expressed as a Percentage) who were Crawling at 10 Months and Walking at 14 Months in the Four Feeding Groups*

Feeding Group	Crawling		Walking at 14 Months
	At 10 Months	Never	
1	61.8	13.1	67.7
2	69.6	6.0	71.3
3	71.7	5.0	66.7
4	60.2	6.5	63.9
Total	64.4	8.4	66.5

To discover whether this "acceleration" was attended by any increased risk of ill-health, the sickness dossiers of the babies were examined.

Infections

Very few of the babies were under 2 months old when first seen, and the enrolment procedure effectively excluded babies who were seriously ill at or before this age (Thwaites, 1950; Stewart and Russell, 1952). For this reason all incidence rates in the following account will be for the period two to twelve months and not for the whole of the first year. In the case of head colds it was often impossible to identify the precise mode of feeding at the time of the illness, but the more serious infections have been studied in relation to the diet at the time of falling ill, to the total period of complete breast-feeding, and to one another.

To obtain a fair distribution of the illnesses in relation to the pre-weaning, weaning, and post-weaning periods the survey aggregates for three modes of feeding were calculated for each successive month of life (see Table V). This revealed that for 2,094 months, or 30% of the

TABLE V.—Aggregate Months of Exposure to Three Modes of Feeding During the First Year of Life

% of consolidated first year	30.09	17.20	52.71	100

consolidated first year, the babies were exposed to breast milk only; for 3,669 months, or just over half the year, they had no breast milk, and for 1,197 months (17% of the period) they were exposed to mixed feeding.

In Table VI the first two months of life have been excluded and the exposure periods for the rest of the year calculated for nine groups of babies defined by the duration of the pre-weaning period. Thus the 142 babies who were weaned in the first month were exposed to mixed feeding for 88½ months and to "other" feeding for 1,331½

TABLE VI.—Aggregate Months of Exposure to Three Modes of Feeding Between the Ages of 2 Months and 1 Year for Nine Groups of Babies Defined by the Duration of Complete Breast-feeding

Period of Complete Breast Feeding	Mode of Feeding: Exposure Time in Months from 2nd to 12th Month of Life			
	Breast	Mixed	Other	Total

% of consolidated age period 2-12 months	20.30	19.33	60.37	100

months; while the 166 babies who were weaned in the sixth month were exposed to mixed feeding for 520½ months, to "other" feeding for 558½ months, and to breast milk only for 581 months. These overall "months of exposure" have been used to calculate the attack rates for the three groups of illness shown in Table VII.

Gastro-Enteritis, Bronchitis, and Otitis Media

Between the ages of 2 months and 1 year 118 babies suffered from gastro-enteritis, 108 from bronchitis or bronchopneumonia, and 39 from otitis media or tonsillitis. One of the babies with gastro-enteritis had two distinct recurrences during this period and 20 others had one recurrence. Two babies had separate attacks of bronchitis and bronchopneumonia, and three, after recovery from tonsillitis, subsequently developed otitis media. In Table VII the age and sex incidence of the three disease groups are displayed, together with the attack rates for three categories of "current diet" and five periods of complete breast-feeding. The recurrences are not included in this table, but according to a separate analysis (based on the assumption that a first attack of a specific illness neither protects nor predisposes a baby to a second attack) the recurrence rate for gastro-enteritis doubled expectation while that for bronchitis and bronchopneumonia fell short of expectation. The analysis did not, of course, indicate whether these alterations of risk were determined by biological or social factors.

In Table VII one baby is represented in all three diagnostic groups, 26 in the first two (gastro-enteritis and bronchitis), 8 in the first and the last (gastro-enteritis and otitis

media), and 21 in the second and third (bronchitis and otitis media). The combinations for gastro-enteritis and bronchitis, and for gastro-enteritis and otitis media, are approximately what would be expected for chance associations, but those for bronchitis and otitis media are excessive and accord with the well-known tendency for these two conditions to be associated.

According to Table VII the most conspicuous findings for gastro-enteritis are: (1) that the pre-weaning and weaning attack rates were significantly lower and higher than average; and (2) that the highest recorded rate was for babies weaned in the sixth month and the lowest rate for babies weaned in the second, third, and fourth months. For bronchitis and bronchopneumonia the two lowest rates were for the pre-weaning period and for babies who were completely breast-fed for at least six months, but the differences between these and the rates for other groups are of doubtful significance. There was a slight tendency for the lung infections to affect boys more than girls, babies under 6 months more than those over 6 months, and babies who were breast-fed for less than four months more than those who were weaned later. Otitis media and tonsillitis occurred relatively often in the post-weaning period and after the age of 10 months. The attack rates for different periods of complete breast-feeding showed no signs of being influenced by duration of complete breast-feeding, but during the weaning and pre-weaning periods the incidence was below average.

In general, it is safe to conclude that while the Survey babies were taking nothing but breast milk the risk of intestinal infection was reduced. When finally removed from the breast, however, there was nothing to choose between the sickness experience of the early and late weaners.

Head Colds

During the age period 2 to 12 months only 134 babies remained free from head colds. The remainder shared 916 incidents variously described as a cold, nasal catarrh, sniffles, or influenza. Though there was little or no difference in the cold attack rates for the four feeding groups, when the babies were arranged according to the size of the household to which they belonged, and then according to the number of schoolchildren in the house, a new gradient appeared which indicated a relatively low risk for babies in small households with no schoolchildren (see Table VIII). This finding confirms a suggestion put forward in an earlier paper—namely, that the relationship between "household amenities" and risk of illness in infancy is partly due to the more frequent introduction of infection into the homes with older children (Stewart and Russell, 1952).

Discussion

The unique value of breast milk for small infants with a tenuous hold on life is so well established that failure to find any signs of the breast-fed babies having benefited more than bottle-fed babies may cause some surprise. The findings have, of course, been influenced by the absence of weakly infants in the present group and by the fact that all the babies were under continuous medical supervision. For the former must have reduced feeding problems to a minimum and the latter ensured that, whatever mode of

feeding was adopted, there was every chance of it being carried out efficiently. Nevertheless this is not the only recent survey to suggest that under conditions which prevail to-day the dangers of bottle-feeding are more potential than real.

After analysing the first-year sickness records of 263 babies attending the Harvard Child Health Survey, Stevenson (1947) came to the conclusion that "artificially fed infants do not suffer more from diarrhoea than do nurslings when the feeding is carried out with proper techniques." He did in fact find that in the age group 6-12 months respiratory infections were less common among the babies who had been breast-fed, but the difference was slight, and for all other illness, including gastro-enteritis, the artificially fed babies compared favourably with the breast-fed babies. Norval and Kennedy (1949) also found that "the duration of breast-feeding did not influence the rate of illness." Their work was based on the records of 417 infants who regularly attended welfare clinics in Minnesota, and in this group the incidence of respiratory infections in the second half of the first year was actually higher among the breast-fed than the bottle-fed babies.

Even more convincing than these surveys, which like the present investigation are biased in favour of healthy babies, are the findings of Douglas (1950). He followed up a random sample of the babies born in Great Britain between March 3 and 9, 1946, and discovered that during the first two years of life the incidence was the same in four groups of babies defined by duration of breast-feeding. The only significant difference between the breast- and bottle-fed babies was that the former tended to have their first attack at a later age.

In the light of these earlier findings it should be considered whether the relatively high attack rates for gastro-enteritis among the Oxford babies who were completely breast-fed for five months is evidence of a "nursling risk" which has hitherto escaped attention. It is just possible that these babies had an exceptionally low immunity to infection or that they were more easily upset by the addition of solids to the diet (which frequently coincided with weaning) than the babies who had been bottle-fed. In view, however, of the relatively high prevalence of diarrhoea among all babies during the weaning period, the possibility that the mothers who had never had to prepare a bottle-fed were less skilful in producing "clean meals for spoon feeders" than the other mothers should not be overlooked.

The weight differences revealed in the present investigation also merit close attention. Once again the discovery that bottle-fed babies gain weight more rapidly than breast-fed babies is not unique. Over 20 years ago Glazier (1930) made a similar observation in Boston, Massachusetts, and on the basis of the national survey in this country Douglas (1950) calculated that a baby who is breast-fed to the tenth month may expect to be, at the age of 2 years, 11 oz. (312 g.) lighter than one who has not been breast-fed at all. Hitherto it has not been suggested that these findings amount to evidence of undernourishment among breast-fed babies, but, in view of Vining's (1952) opinion that underfeeding at the breast is "only too common," this possibility can no longer be ignored. Douglas himself suggested that the breast-fed babies may have weighed less because they were unusually vigorous. In support of this view, he estimated that the babies who were breast-fed for ten months walked on average ten days earlier than the babies who were bottle-fed. If, however, the age of walking is an indication of vigour then the breast-fed babies in the present investigation were no more vigorous than the bottle-fed babies.

Forty years ago, when it was fashionable to ascribe all manner of complaints to overfeeding, it might have been suggested that the greater weight of the bottle-fed babies was detrimental to their health. But it is now held that overfeeding in infancy is "a matter of opinion rather than a real disorder" and that it rarely, if ever, causes harm

(Wickes, 1952; Vining, 1952). In any case there was no more illness among the bottle-fed than among the breast-fed babies. We are therefore driven to the conclusion that, in spite of continuous medical supervision, minor degrees of underfeeding among the breast-fed babies had occurred and had been overlooked.

If there is any truth in the opinion that the high prevalence of diarrhoea among babies who were nursed until they were old enough to be spoon-fed is due to faulty technique, and if the weight records constitute evidence of "latent" underfeeding among the breast-fed babies, then the survey findings present a new challenge to the advocates of natural feeding. That breast-feeding has advantages to both mother and child which will never show on a weight chart no paediatrician will seriously deny, but artificial feeding is now so safe and easy that the slightest neglect of the special problems of nurslings could produce a sharp popular reaction against breast-feeding.

Summary

The early progress of 580 babies in the Oxford Child Health Survey has been studied in relation to feeding habits.

At the age of 1 year the babies who were bottle-fed from the beginning were appreciably heavier than the babies who were completely breast-fed for five months or longer. They also showed signs of being slightly more mature. It is suggested that these differences are due to minor degrees of under-feeding among the breast-fed babies.

For three disease groups—gastro-enteritis, bronchitis and bronchopneumonia, and otitis media and tonsillitis—there was no evidence that the duration of complete breast-feeding influenced the overall infection rates. Gastro-enteritis was comparatively rare so long as the babies were receiving nothing but breast milk, but it reached its maximum incidence in the weaning period and was especially common among babies who began to be weaned in the sixth month.

Colds, which were most frequent in large households and households with several children of school age, were almost equally common among breast- and bottle-fed babies.

We are grateful to the Nuffield Provincial Hospitals Trust and the Medical Research Council for covering the expenses of this investigation.

The British Legion Village at Preston Hall, near Maidstone, for tuberculous ex-Service men and women has now been in existence for 28 years, and the record of its accomplishments during that period has recently been published in the form of a souvenir brochure. Its 50 beds in 1925 had grown to 926 by 1948, when they came under the authority of the regional hospital board. The village settlement and industrial training centre includes all the amenities necessary for a self-contained community. Over 11,000 men and women have taken advantage of the services offered. The brochure is a useful guide to the facilities available at Preston Hall for the rehabilitation of tuberculous ex-Service men and women, who during their stay are enabled to live normal family lives.

FUTURE OF SURGERY IN SENILE OBLITERATIVE ARTERIAL DISEASE*

BY

CHARLES ROB, M.C., M.Chir., F.R.C.S.

Professor of Surgery, St. Mary's Hospital, London

Senile obliterative arterial disease, often called arteriosclerosis, is one of the most important problems which the medical profession has to face, and as our population ages this problem is likely to increase in magnitude. All authorities agree that it is a very common disease, that it is much more frequently seen in middle and late life than in the young, that it often exists in a subclinical state before symptoms occur, and that the first clinical effect may be the patient's death from coronary or cerebral vascular occlusion.

When one thinks about the surgical treatment of senile obliterative arterial disease one fact must never be forgotten—that it is a general disease affecting the arteries of the whole body. In some patients the most abnormal vessels are in the lower limbs; they suffer from intermittent claudication or gangrene of the toes. In others the coronary arteries are affected and the patients develop either angina pectoris or coronary occlusion, while some suffer from the well-known symptoms of cerebrovascular disease or an aneurysm of the aorta. In all these patients the whole arterial system is abnormal, but one region is affected more than others, and it is against these local manifestations of a general disease that a surgeon's efforts can be directed.

An anatomical study of the changes in the arteries of these patients shows that the local manifestations are produced in a high proportion of patients by a relatively short thrombosis in a main vessel. Thus a patient with intermittent claudication usually has a thrombosis of a segment of his superficial femoral or popliteal arteries. Fig. 1 is an arteriogram from such a patient; this shows the local thrombosis and the general disease above and below the block, where plaques of atheroma can be seen in the vessel wall. Realization of this fact is changing the whole approach of surgeons to this disease, not only in the case of the superficial femoral and popliteal arteries, but also when the thrombosis is in the abdominal aorta, common or external iliac arteries, the carotid arteries, and even perhaps in the future in the coronary or cerebral vessels.

In the past, surgeons have used an indirect approach when treating the symptoms of senile obliterative arterial disease. They have employed methods designed to increase the collateral circulation such as sympathectomy (Ross, 1935), they have tried to increase the blood flow to the part by creating an arteriovenous fistula (San Martín, 1902), they have ligated the main vein in an attempt to increase the oxygen supply to the tissues by producing venous congestion (Makins, 1919), they have attempted to relieve pain due to ischaemia by interrupting the afferent nerve pathways (Jonnesco, 1920), and they have put the ischaemic muscle at rest by interrupting its motor nerve supply (Learmonth and Slessor, 1952) or by dividing its tendon (Boyd, 1950). In the case of coronary artery disease attempts have been made to increase the blood flow to

*Part of a postgraduate lecture given in New Zealand in September, 1952.

the myocardium by producing adhesions between the heart and the pectoralis major muscle (Beck, 1935), the heart and the great omentum (O'Shaughnessy, 1936), and the heart and the pericardium (Heinbecker and Barton, 1940). Other methods include ligation of the great cardiac vein (Fauteux and Palmer, 1941), the formation of an arteriovenous anastomosis between the coronary sinus and an artery (Beck *et al.*, 1948), implantations of the internal mammary artery into the myocardium (Vineberg, 1952), and various procedures designed either to decrease the activity of the heart such as thyroidectomy (Blumgart *et al.*, 1933) or to relieve cardiac pain (Swetlow, 1926). All these operations, whether on the limbs or on the heart, suffer from one great and obvious defect—the approach is indirect.

The Direct Approach

Probably the first surgeon to realize the importance of a direct attack upon the occluded segment of artery was Leriche; he performed the operation of arteriectomy in which the thrombosed portion was excised (Leriche *et al.*, 1937). Dos Santos (1947) took this step further with his operation of disobliterative endarteriectomy, the first procedure designed to restore the blood flow through the blocked artery. In this operation the vessel is opened, the thrombus removed, and the vessel repaired again. The results if successful are better than with most of the indirect procedures, but the success rate is not very high; Reboul and Laubry (1950) report that of 93 disobliterations 44 (47%) remained patent, 38 clotted again, and 11 patients died. A better method is to replace the thrombosed segment of artery by an autologous vein graft or a homologous artery graft. In our experience between 50 and 60% of all patients with intermittent claudication or gangrene of the toes have a lesion in their arteries which is anatomically suitable for an artery or vein graft. In actual practice only 20% or less of these patients are suitable, the others being rendered unsuitable by such factors as age and the presence of cerebrovascular or coronary artery disease. It is obviously a waste of time to graft a patient who suffers from intermittent claudication at 100 yards for him to be stopped after a successful operation by the worse pain of angina pectoris at 150 yards. In the case of gangrene of the toes the indications for grafting are great; here, particularly if the alternative is a major amputation, a graft is justified whenever it is a practical possibility.

Vein Grafts.—The first successful vein-to-artery autograft in man was performed by Lexer in 1912. He excised a popliteal aneurysm and replaced it by a vein graft. The development of this method of replacing the thrombosed artery in senile obliterative arterial disease has been carried out almost entirely on the continent of Europe. Fontaine and Hubinont (1950) have had considerable experience of this operation, and of their first 18 grafts 8 (44%) were successful and remained patent. The advantages of vein grafts are that they are autologous; this means that they may live and an artery bank is not necessary. If the saphenous or external jugular veins are used no ill effects arise from the sacrifice of these veins. Their disadvantage is that if the host vessel is arteriosclerotic they are technically more difficult to insert than artery grafts. We therefore use vein grafts when the host's vessels are normal or nearly so; as our technique improves we hope to use them more frequently in the treatment of senile obliterative arterial disease, but to date the success rate in these patients has not been as high as with artery grafts.

Artery Grafts.—These are of necessity homologous and do not survive in the host; his tissues gradually grow in and replace the graft by a process of creeping substitution: the media and adventitia by fibrous tissue, the intima to a small extent by growth from the ends of the host vessel but mostly as cells deposited on to the surface of the graft from the blood stream; the elastic lamina, which is an extracellular structure, appears to survive. An artery

homograft therefore acts as a scaffold which maintains the blood flow whilst the tissues of the host are growing in to form a new channel. An essential requirement for efficient artery grafting is an artery bank. The first human artery bank was developed by Gross and his colleagues (1949); they preserved their vessels in nutrient saline, and the results have been excellent. An alternative method which we use is that of Eastcott and Hufnagel (1950): the grafts are frozen and stored at a temperature of -70°C . or less; these grafts are equally satisfactory, and the bank is easier to manage because the grafts can be stored for long periods and perhaps indefinitely. Artery grafts have been used to replace the thrombosed segment of artery in a number of sufferers from senile obliterative arterial disease (Rob, 1953). To date this direct attack upon the thrombosed segment of artery has been confined to the aorta, its main branches, and the major vessels of the neck and limbs. The results have been satisfactory, and Figs. 1 and 2 illustrate a typical femoral arteriogram before and after an artery graft.

FIG. 1

FIG. 2

FIG. 1.—Femoral arteriogram showing a thrombosed segment of superficial femoral artery. This patient suffered from severe intermittent claudication. FIG. 2.—Arteriogram from the patient shown in Fig. 1 after an artery graft. He can now walk for miles without pain.

The direct approach has reached a stage at which it is a practical everyday possibility to replace an occluded segment of a large or medium-sized artery by an autologous vein graft or a homologous artery graft, and operations of this type have been performed in many hospitals all over the world. But what of the future and, in particular, what are the possibilities of grafting such arteries as the coronaries?

Grafting the Coronary Arteries

Murray (1950) has resected a portion of a dog's coronary artery and restored continuity by using a vein graft to bridge the defect. This is a very difficult operation in the dog, but it should be easier in man, in whom the main coronary arteries are about 3 mm. in diameter. The human coronary artery is about the same size as the dog's common carotid, in which a graft succeeds in over 50% of cases (Eastcott and Hufnagel, 1950).

Senile obliterative arterial disease of the coronary arteries is often a diffuse process involving both coronary arteries, but in a minority of patients the disease is relatively localized and suitable, at least anatomically, for replacement by a vein or artery graft. Harrison and Wood (1949) found that of 15 patients who died of ischaemic heart disease eight had diffuse disease with all the major coronary arteries narrowed and irregular, but in seven the disease was limited to one artery, usually the left, or to part of an artery, the remainder of the coronary tree being relatively normal. From a study of the material presented in their paper it appears that two patients (13%) had a lesion in their coronary arteries which was anatomically suitable for a graft.

A personal study of this problem has led me to believe that this figure of about 10% is a fair picture of the proportion of sufferers from angina pectoris or perhaps early coronary occlusion who might receive benefit from such an operation. The difficulty is to select these patients. In this connexion a paper by Blumgart *et al.* (1940) is of interest. They found that the coronary arteries of 12 patients with angina pectoris were diffusely arteriosclerotic, with multiple occlusions in 10 cases, and that the two patients in whom the occlusions were limited to one artery showed diffuse and widespread disease of this vessel. On the other hand, the hearts of 12 patients who died from coronary occlusion without previous angina pectoris showed that in 10 the disease was confined to one artery only. A study of the diagrams in their article leads me to believe that three of this latter group could have been treated with an artery graft.

It is possible that clinical features such as the distribution of the pain or the findings on electrocardiography may give valuable information on this problem. The location of the infarct can be determined by these means, but to date no effort has been made to correlate these features with the suitability of coronary artery disease for an artery graft. Such a study is being carried out, but it will be several years before any worth-while conclusions can be published. An alternative and more direct approach is arteriography of the coronary tree. Radner (1945) carried out coronary arteriography by direct puncture of the ascending aorta in both man and dogs; he obtained a faint outline of the coronary arteries, but the complications were too frequent and the method had to be abandoned. Jonsson (1948) visualized the coronary arteries during catheterization and angiocardiology. The catheter was passed up the brachial artery to the aortic valve, when the contrast medium was injected. No ill effects were noted. On the other hand, Helmsworth *et al.* (1951) catheterized the left carotid artery in 10 human patients; in 5 they obtained a satisfactory coronary arteriogram, but one died—a woman of 88—after her sixth injection of 10 ml. of 70% "diodrast."

Both main trunks of the human coronary arteries are reasonably accessible to the surgeon and both move very little with the heart beat. This latter fact is important, because it is possible in animals, and should be possible in man, to graft the coronary arteries whilst the heart is beating, an extracorporeal circulation being unnecessary. It is probable that patients with complete occlusion of a main coronary artery would be made no worse by temporary interruption of the artery during the operation of grafting. In patients with only partial occlusion ventricular fibrillation might follow interruption of the blood flow; in these it would be necessary to put in the graft over a fine polythene tube and then remove the tube just before the second anastomosis had been completed; by this means the blood flow to the myocardium could be maintained during the greater part of the operation. Murray (1947) has excised the area of infarction from a dog's heart after occlusion of a main coronary artery; the results were good. It may well be that, in man, the treatment of acute occlusion of the main stem of one coronary artery when the other is normal will be an emergency operation to replace the occluded segment of coronary artery by a graft followed by excision of the myocardial infarct with repair of the cardiac defect, while patients with severe angina pectoris will be treated by a graft if the disease is confined to the main stem of one of the coronary arteries; but it is likely that suitable patients for these operations will be rarities.

Other Sites

It can be stated that in selected patients the direct treatment of senile obliterative arterial disease is now an established procedure and that this type of operation may be extended to include some sufferers from coronary occlusion, but what of the other important sites of senile arterial disease?

Intracranial Arteries.—The carotid arteries outside the skull can be replaced by a vein or artery graft, but any direct approach to intracranial obliterative arterial disease has yet to be attempted. An exception to this is provided by the surgical control of bleeding intracranial aneurysms, a proportion of which are due to senile obliterative arterial disease (Falconer, 1952). The replacement of segments of those arteries by grafts has not yet been attempted but should be possible, although the thin nature of their walls will make the operation more difficult than in other situations. The selection of patients should be relatively simple because of the highly developed state of cerebral arteriography.

Aorta.—This vessel between the left subclavian artery and the diaphragm and below the renal arteries has been replaced by a graft on many occasions (Brock, 1953). Progress will be by the extension of such an operation to include either the arch of the aorta or the upper abdominal aorta. In both these situations there are many important branches, and added to the technical difficulty of having to perform several anastomoses would be the necessity of maintaining during the operation an adequate blood flow to such essential structures as the brain, spinal cord, and kidneys. In my opinion these difficulties are not insuperable and it should be possible to replace some simple aneurysms and treat some dissecting aneurysms in these regions by a graft of the appropriate segment of aorta with its branches. The blood flow could be maintained by one or more polythene tubes, placed through the clamps but inside the graft, and removed just before the completion of the final anastomosis.

Conclusion

A direct approach to the local manifestations of a general condition—senile obliterative arterial disease—is now a practical possibility. In the future it may be possible to extend the scope for operations of this type. I feel that grafting the coronary arteries will be performed successfully during the next few years; this is not the difficult hurdle. What is much more important is to study this disease so that we can relate symptoms and signs to those features of the disease which will make a graft successful and will prevent unnecessary operations on patients unsuitable for grafting. This will be far more difficult than the technical perfection of an operation. The problem is being studied.

UNUSUAL SMALL-INTESTINAL CAUSES OF ANAEMIA

BY

J. E. RICHARDSON, M.S., F.R.C.S.

Assistant Director, Surgical Unit, London Hospital

AND

ADRIAN E. FLATT, M.D.

Junior Assistant, Surgical Unit, London Hospital

In 1952 the following three cases of rare small-intestinal lesions producing anaemia were seen on the surgical unit at the London Hospital.

Case 1. Carcinoma of Jejunum

A spinster (record No. 28809/52) was admitted on August 17, 1952, under Mr. Alan Brews with a provisional diagnosis of "malignant ovarian tumours with subacute intestinal obstruction."

Background.—She was born in 1903 and came fourth in a family of seven. Three brothers and two sisters were still living. Apart from her father, who had a haematemesis in 1952 at the age of 81, there was no history of gastrointestinal disease. She was an intelligent woman and had made a career for herself. After her mother's death she looked after her father. She was a life-long non-smoker and did not take alcohol. She took cascara two or three times a week, and remembered being told by her mother that as a child her bowels were stubborn.

Course of illness.—The onset of symptoms was vague. At some time between February and April, 1950, she went to her doctor because of missed periods and was given some tablets. The periods returned and were regular for six months. She next visited her doctor in April, 1951, because she was sleeping badly and had indigestion and was also tired and depressed. In September the war damage to her home was at last repaired. The upset caused by builders in the house "just about finished her off." Possibly she felt too tired to go to her own doctor, and whatever the reason for delay her next visit to him was in April, 1952, when her complaints were more definite. She was passing more wind than usual per rectum, was a little short of breath on going upstairs, and had some diffuse discomfort, which felt like wind. This discomfort got worse and became painful when she was hungry. As soon as she started to eat her appetite went and she felt sick. It is interesting to note that she denied any loss of weight. In fact she complained that she had to buy new clothes because she was developing middle-age spread. While on holiday from June 14 to 19 she began to vomit up "fluid like dirty water." In July she had severe lower abdominal pain for the first time, and this was associated with vomiting up "cascades of dirty water."

In view of the urgent nature of the obstruction it was impossible to investigate her fully. Examination showed bilateral pelvic swellings. The haemoglobin on admission was 46%. Two days later a laparotomy was done, and bilateral ovarian cysts were removed. An annular constricting tumour was found in the jejunum about 9 in. (22.5 cm.) below the duodeno-jejunal flexure. This was removed and an end-to-end anastomosis made.

The patient made a good recovery and left the ward on September 19. Two months later she looked fairly fit. Her bowels were all right for the first time in her life without aperients, but she was getting pain in the back. On examination a hard lump was felt in the right axilla and also in the pouch of Douglas. She died in May, 1953.

Microscopical examination proved the jejunal lesion to be an adenocarcinoma extending into the mesentery. Sections of the ovaries showed bilateral columnar and tubular secondary carcinoma.

TABLE 1.—Carcinoma of Small Intestine (Pylorus to Ileo-caecal Valve). From the London Hospital Records, 1908–52

	Surgical Specimen	Post Mortem	Total
Duodenum	10	28	38
Region of the ampulla of Vater	7	21	
Above the ampulla	2	4	
Below	1	3	
Duodeno-jejunal flexure	3	1	4
Jejunum	6	4*	10
Ileum	15	5	20
Total	34	38	72

* Includes one probable secondary tumour.

Comment.—The habitual use, or rather abuse, of aperients in this case presumably blurred the onset of symptoms due to the stricture. The anaemia was due partly to bleeding and partly to the disturbance of absorption. Carcinoma of the small intestine is rare. From 1908 to 1952 72 cases were seen at the London Hospital (Table 1). If the duodenal cases, which as a class merge into carcinoma of the ampulla of Vater and pancreas, are omitted only 13 cases occurred at or below the duodeno-jejunal flexure.

Eight of the nine jejunal carcinomata were annular constricting growths and one was a polypoid situated 75 cm. beyond the flexure. Fig. 1 emphasizes the interesting point that the site is usually fairly close to the flexure. The 20 ileal carcinomata, on the other hand, tended to occur not far above the ileo-caecal valve.

FIG. 1.—Site of jejunal carcinoma in 13 cases—nine at flexure, two "fairly high," one 65 cm. beyond, and one half-way along.

Case 2. Leiomyosarcoma of Duodenum

A married woman (record No. 24329/52) was admitted under Dr. Donald Hunter as an emergency case from the cardiac department on July 10, 1952, with a provisional diagnosis of "anaemia, cirrhosis of liver."

Background.—She was born in 1906. Neither her parents nor her two sisters and brother had had any gastro-intestinal disease. Since her marriage in 1938 she had looked after her only child, born in 1939, and her home. Her husband, a G.P.O. van driver, served in the Army during the war. She was a non-smoker, took alcohol only at parties, and had never needed opening medicine for her bowels until 1950, when she began to take liquid paraffin.

Course of illness.—The onset of symptoms is difficult to determine. During pregnancy she had attacks of palpitation followed by giddiness and fainting. During the war three further attacks occurred and after the war a few minor ones. In 1952 the attacks became more serious and culminated in her collapsing in a swimming-bath. She was then referred to hospital.

Her doctor's story is slightly different. She attended the surgery from time to time with various minor complaints, but there were no symptoms which could be attributed to anaemia until February, 1952, when she fainted. In July she fainted again, and also vomited blood, and so was sent straight away to the London Hospital.

Examination after admission showed a pale woman with a lump in the right loin. No other abnormality was detected on examination. Her haemoglobin was 48% and the liver-function tests were normal. A barium meal on July 21 and a barium enema on August 8 were reported as being "normal." (Re-examination of the films showed an indentation of the stomach and colon by an extraluminal mass corresponding to the tumour found at operation.) At subsequent physical examinations no lump could be felt.

She was going to be sent home, but on August 24 a further severe haemorrhage occurred and she became disorientated. The lump in the loin was again felt. A laparotomy was carried out after transfusion. A semi-cystic tumour was found arising from the posterior wall of the second part of the duodenum and extending in the mesocolon as far as the hepatic flexure. The tumour was removed together with some duodenum. The hole was repaired, but the consequent constriction of the lumen made it necessary to do an emergency gastro-enterostomy four days later. Her recovery was uneventful, and when last seen in June, 1953, there was no digestive discomfort.

Examination of the tumour showed a very vascular leiomyosarcoma surrounding a diverticulum lined with duodenal mucosa. Presumably the tumour originated as an intramural nodule and as it grew out subperitoneally it carried duodenal mucosa with it. Ulceration of the lining of the diverticulum led to haemorrhage which produced a tense mass. Later, as the blood found its way into the lumen of the gut, the mass became soft and impalpable.

Comment.—The hospital records from 1908 to 1952 show five other cases of leiomyosarcoma of the small intestine (Table II). Four had formed diverticula, the contents of

TABLE II.—*Sarcoma of Small Intestine (Pylorus to Ileo-caecal Valve). From the London Hospital Records, 1908-52*

	Surgical Specimen	Post Mortem	Total
Leiomyosarcoma	2	4	6
Duodenum	1	1	2
Jejunum and ileum	1	3	4
Lymphosarcoma	16	22	38
Duodenum	0	3	3
Jejunum and ileum	16	19	35

three being pus and one of blood. One arose from the duodenum. It perforated and the patient died of peritonitis. At necropsy a coincidental cirrhosis of the liver was found. Another of these patients was known to be well three years after resection in 1927, but it has proved impossible to trace her since that time. The fifth tumour, in the lower ileum, was solid and caused an intussusception.

Case 3. Diffuse Angiomatosis of Intestine

A man (record No. 48660/51) was admitted under Dr. Kenneth Perry from the Brentwood District Hospital on December 28, 1951, because of persistent anaemia.

Background.—He was born in 1917. His parents and his brother were healthy. He was a bachelor living with his parents. He had worked as a carpenter for the local council and had served in the Black Watch during the war. He had always been a light smoker and taken little alcohol. His bowels were regular and he almost never took aperients. He admitted to epigastric discomfort occurring about one to one and a half hours after meals, which first came on in 1944 while he was in the Army; further bouts occurred, especially in the winter, but they were slight and he never went to a doctor about them.

Course of illness.—The first symptoms suggesting anaemia occurred in the summer of 1948, when he began to get very tired. He went to his doctor and his haemoglobin was found to be only 33%. During the next months he was given liver and iron and felt himself again. At Christmas, 1950, there was a relapse and this time recovery was less complete. Throughout 1951 symptoms of anaemia persisted. In December, when he was admitted to the Brentwood District Hospital and investigated, his haemoglobin was 35%. As no cause for the anaemia could be found he was transferred to the London Hospital.

Examination showed a well-built muscular man, 5 ft. 11 in. (1.8 m.) tall and weighing 13 st. 4 lb. (84.4 kg.). There were

no spider naevi, but the tip of his spleen was felt on one occasion. The blood picture was that of severe secondary anaemia. Two barium-meal examinations revealed no abnormality. The findings at laparotomy on February 8, 1952, are shown in Fig. 2. The stomach and large gut appeared normal. The whole of the small gut was affected, the feel being similar to that of a distended pulsating varicocele. Even the peripheral arteries were big and were seen

FIG. 2.—Case 3. Drawing to show the diffuse angiomatosis of small intestine.

to be pulsating vigorously. Apart from this the liver and portal vein were normal. The spleen was about normal size, with a splenunculus of a similar size attached to its lower pole.

Since discharge the patient had a further melaena in August, and had to be readmitted to hospital in 1953 for transfusions following a more severe haemorrhage.

Comment.—There is no record of a similar case at this hospital. Fortunately it was possible for Miss P. Archer to make a drawing from her operation sketch. Peyton (1938) described a similar case in a boy aged 15; and Kalliser (1936) reviewed the literature of intestinal angioma up to 1936.

Summary

Three cases of rare lesions of the small intestine are described. The lesions were carcinoma of the jejunum, leiomyosarcoma of the duodenum, and diffuse angiomatosis of the intestine. All three patients presented with anaemia. The early symptoms were vague and the diagnosis was difficult.

Seventy-two cases of carcinoma and 44 cases of sarcoma of the small intestine have been recorded at the London Hospital since 1908. The sites of the tumours are recorded. The similarity in site and pathology of the jejunal tumours is stressed. The tendency for diverticulum formation in the cases with leiomyosarcoma is also recorded.

We wish to thank Mr. Alan Brews for asking us to undertake the gut resection in Case 1; Miss P. Archer for the drawing of Case 3; and Dr. Denys Jennings for his help in preparing this paper.

THREE CASES OF SMALL-INTESTINAL NEOPLASM WITH UNUSUAL CLINICAL FEATURES

BY

P. A. RECHNITZER, M.D.

AND

J. BLAKE, M.B., M.Sc.

(From the Department of Medicine, University of Edinburgh)

New growths of the small intestine occur infrequently. Ewing (1940) states that the comparative incidence of malignancy in the large and small intestines is 97.5% and 2.5% respectively. Neoplasms of the small intestine may first produce symptoms because of (a) intestinal obstruction, (b) an associated anaemia (see Cases 1 and 2), or (c) rarely because of malabsorption (see Case 3). In the absence of obstructive symptoms the diagnosis may be most difficult to make.

The first two cases are presented because of the long latent period (17 months and four years respectively) between the recognition of an obscure anaemia and the ultimate discovery of its cause in spite of the most thorough investigations. The third case is described because of its initial clinical manifestations as idiopathic steatorrhea.

Case 1

In January, 1948, a 59-year-old woman began to have symptoms of general loss of strength, diarrhoea, and some colicky abdominal pain. She had lost 21 lb. (9.5 kg.) in weight in the preceding year. She was first seen at the blood clinic in April, 1948, when physical examination was negative, except for slight pallor. The haemoglobin was 66% (14.8 g.=100%), red-cell count 3,800,000, and colour index 0.86. The possibility of an alimentary tumour was considered, but an investigation with barium meal and enema was negative. Ferrous sulphate failed to raise the haemoglobin level, and in September she was admitted to hospital. The haemoglobin was 44%, red-cell count 3,420,000, and colour index 0.65. The blood Wassermann reaction was negative and the E.S.R. was 75 mm. in one hour. The stool benzidine test was carried out on six occasions and was strongly positive on three. Fat-balance studies were negative. Gastric analysis revealed a histamine-fast achlorhydria. Sternal puncture showed a normoblastic reaction. A barium meal and follow-through was negative.

On October 25 the first of two injections (200 mg. and 80 mg. respectively) of intravenous iron was given. These were not continued because of unpleasant side-reactions. At the time of discharge (November 24) the haemoglobin had risen to 64%, and 30 gr. (2 g.) of iron and ammonium citrate was given three times a day. This was followed by a rise in haemoglobin to 90% on January 20, 1949, and iron therapy was discontinued. In April the patient was feeling well, but her haemoglobin had fallen to 64%. Iron was started again, but produced no significant rise in the haemoglobin level. On September 8 she complained of loss of appetite and a dull ache on the left side of the abdomen. There was no history of vomiting or melaena. The haemoglobin had fallen to 56%. Manual examination of the abdomen revealed for the first time the presence of a firm, slightly tender mass in the left hypochondrium. It was not fixed to skin and was about the size of an orange. Sigmoidoscopic examination and barium enema were negative.

In November laparotomy was carried out. In the left hypochondrium a tumour of the jejunum was discovered. It was not obstructing the lumen, but was adherent to the descending colon and had spread to the adjacent mesenteric lymph nodes. Microscopical examination revealed a carcinoid tumour with more cellular irregularity than usual and frequent mitotic figures. The tumour was resected, and the patient made an excellent post-operative recovery. She remained well for eleven months, but in September, 1950, the occurrence of upper abdominal pain and tenderness suggested recurrence of the tumour. Her condition gradually deteriorated and she died in April, 1951. The post-mortem examination showed recurrence of the tumour in lymph nodes adjacent to the anastomosis, with further involvement of the bowel wall and metastases in the lungs.

Case 2

A woman aged 58 reported to the blood clinic in January, 1948. She gave a history of general malaise, dyspnoea, palpitations, and precordial pain on exertion of one year's duration. Her appetite was good and her diet satisfactory. There was no history of dyspepsia, change in bowel habit, or melaena, or previous illness. On physical examination no abnormalities were detected apart from a moderate degree of pallor. The blood count showed: haemoglobin, 34%; red cells, 3,440,000; colour index, 0.5. The cause of the anaemia was not apparent and the possibility of a silent alimentary tumour was considered.

The patient was admitted to hospital for further investigation. The stool benzidine test was repeatedly strongly positive. There was free acid in the gastric juice, the E.S.R. was 25 mm. in one hour, and the blood Wassermann reaction was negative. A barium meal and enema were also negative. A total of 1,525 mg. of iron was given intravenously over a period of seven weeks, and on discharge on March 20 her haemoglobin was 70% and red-cell count 3,700,000. In April her haemoglobin was 68% and red-cell count 4,280,000, and she was given molybdenized ferrous sulphate, with no beneficial effects. During the following month she received 600 mg. of iron intravenously. In May her haemoglobin had risen to 82% and the red-cell count was 4,550,000. In July she complained of a gradual recurrence of malaise, breathlessness, and precordial distress on exertion and her haemoglobin had fallen to 56%. From then until June, 1949, her haemoglobin ranged from 60% to 76% in spite of continuous oral iron therapy.

When next seen in February, 1952, her haemoglobin was 37% and red-cell count 2,900,000. She had palpitations, dyspnoea, and precordial distress on exertion. It was estimated that she had lost about 14 lb. (6.4 kg.) in weight during the preceding six months. Abdominal examination revealed a mass the size of a foetal head to the left of the umbilicus. The tumour was smooth and not fixed to skin. At laparotomy on March 10 a large tumour involving the proximal 2 ft. (60 cm.) of jejunum was found. At one point it had invaded the peritoneum, but there was no gross evidence of metastases. The tumour was resected and an end-to-end anastomosis performed. Microscopically the tumour consisted of clumps of polyhedral, epithelial cells with a peripheral zone of columnar cells. No true acinus formation was seen, though foci of degeneration had given rise to pseudo-acini. Mitotic figures were frequent. The appearances were much more suggestive of a carcinoid tumour than of a carcinoma, though they were not altogether characteristic of the former.

On the third post-operative day it was discovered that the patient was leaking bile-stained fluid from her wound. Within a few hours a further operation was performed and a small leak from the anastomotic site was found and repaired. Despite repeated transfusions, she gradually became weaker, and died six days later. At necropsy localized peritonitis following leakage at the anastomotic site was found. Macroscopically there was no evidence of secondary growths, but microscopical examination revealed deposits in the liver.

Case 3

A man aged 43 was well until December, 1949, when he first noticed swelling of both ankles. This subsided spontaneously during the next few weeks. In October, 1950, he first complained of diarrhoea, characterized by four or five frothy, yellowish, watery stools a day. This continued intermittently for eleven months and he was admitted to the Royal Infirmary, Edinburgh, on September 14, 1951, for investigation. During the preceding months he had lost 42 lb. (19 kg.) in weight in spite of a reasonably good appetite. There was no history of abdominal pain. The family, social, occupational, and past histories revealed no information of diagnostic value.

On examination he was seen to be a thin, pale, middle-aged man. The tongue was atrophic. The respiratory, nervous, and cardiovascular systems were normal except for the presence of hypotension; his blood pressure was 90/60. The liver and spleen were not palpable and no abdominal masses were felt. He had gross clubbing of the fingers. There was minimal sacral oedema, but a moderate degree of bilateral ankle swelling. X-ray examination of the chest, urine analysis, and the stool benzidine test were negative. The initial blood count was haemoglobin, 69%; red cells, 4,600,000; colour index, 0.75; mean corpuscular volume, 86.9 μ^3 . The serum calcium was 7.7 mg. per 100 ml., and Trousseau's sign was positive. The serum sodium equalled 136 mEq./l. (312 mg. per 100 ml.); serum potassium, 4.1 mEq./l. (16 mg. per 100 ml.); plasma albumin, 2.37 g.%; and plasma globulin 2.21 g.%. Liver-function tests were negative. The Robinson-Kepler-Power water test gave a positive result. The glucose-tolerance curve was flat. 17-ketosteroid excretion was 8.4 mg. per 24 hours. A three-day fat-balance study showed that there was only 66% fat absorption and a barium meal gave evidence of a "deficiency" pattern.

About a month after admission the patient developed frank tetany with carpal spasm. This was relieved with antitetanic therapy, including calcium gluconate, "parathormone," and vitamin D. The Sulkowitch test consistently revealed the absence of calcium from the urine. A diagnosis of idiopathic steatorrhoea was made and he was given folic acid, 20 mg. daily, ferrous sulphate, 4 gr. (0.26 g.) thrice daily, multivitamin therapy, added salt (10 g. daily), and added protein ("casinal"), 100 g. daily. A total of 100 mg. of intravenous iron was given during his last week in hospital. At the time of his discharge (December 11) he was subjectively much improved. Moreover he had gained 28 lb. (12.7 kg.) in weight, the blood pressure had risen to 100/74 and the serum calcium to 11.3 mg. per 100 ml. The haemoglobin level was 77%. He was having only one or two stools a day and was completely free of oedema.

He returned to work during January and February, 1952, but had to stop because of weakness. In May he developed colicky abdominal pain which gradually increased in severity. Laparotomy was carried out in another centre, and a tumour of the ileum was found completely obstructing the intestinal lumen. Microscopically this was a reticulo-sarcoma which had invaded the adjacent mesenteric glands. The tumour was resected. Although relieved of his obstructive symptoms the patient continued to feel tired and was readmitted to the Royal Infirmary, Edinburgh, in September. The liver was now palpable three fingerbreadths below the right mid-costal margin and a chest x-ray film showed consolidation in the left lower lobe with a large hilar shadow on the left side, suggesting metastatic tumour formation. The patient has continued to become progressively weaker.

Summary and Conclusions

Two cases of tumour of the small intestine are presented in order to emphasize that an obscure anaemia may exist for months or years before obstructive symptoms occur, an abdominal mass is felt, or positive radiological evidence is obtained. The difficulty in arriving at an early correct diagnosis is evident. It is suggested

that the presence of a hypochromic anaemia, with a persistently positive stool benzidine test, the origin of which cannot be explained by clinical, instrumental, or radiological investigations, is an indication for laparotomy. If such an anaemia is refractory to oral iron therapy, this is an additional reason for operation, as it suggests that the loss of blood is of a degree that cannot be counteracted by iron therapy or that malabsorption of iron from the small intestine is occurring.

The third case is described because of the rarity with which the clinical and biochemical features of idiopathic steatorrhoea are associated with a neoplasm of the small intestine (Fairley and Mackie, 1937).

We wish to thank Professor L. S. P. Davidson for his help in the preparation of this paper; Dr. Bruce Cruickshank, who examined and described the pathological specimens; and Mr. F. Gabel, of the Derbyshire Royal Infirmary, who kindly supplied the operative notes of Case 3.

THE SYNDROME OF HIGH-TITRE COLD HAEMAGGLUTINATION

BY

M. G. NELSON, M.D., M.R.C.P., D.T.M.&H.

AND

R. J. MARSHALL, M.D., M.R.C.P.I.

From the Royal Victoria Hospital, Belfast

Occasional normal sera contain an antibody which agglutinates red cells in the cold, but it is usually present only in low titre. The physiological significance of this agglutinin is unknown and its presence is of practical importance only in blood transfusion work. A considerably raised titre of such a cold agglutinin is commonly found in cases of virus pneumonia, and rarely in a variety of unrelated conditions, including haemolytic anaemia, hepatic cirrhosis, and trypanosomiasis. In cases in which the titre is exceptionally high, exposure to cold may result in marked agglutination of red cells in the vessels of the extremities, with symptoms of vascular insufficiency. This is usually a transient phenomenon occurring at the height of the illness or during convalescence.

Cold agglutinins are, however, sometimes found in the blood of persons who have not suffered from any recent illness. They appear suddenly in very high titre and are persistent rather than transient. They give rise to a prolonged illness characterized by Raynaud's phenomenon, peripheral gangrene, intravascular haemolysis, haemoglobinuria, and anaemia.

We have recently had the opportunity of studying two further cases of this syndrome.

Case 1

A 47-year-old cycle-repairer noticed in the winter of 1950 that at times his hands became numb and blue up to the wrists and the fingers dead-white. After each attack he experienced abdominal discomfort and passed black urine. At no time was there numbness or cyanosis of the feet, but the tip of the nose often became blue, and this he recognized as a sign of an impending attack. He was careful to avoid exposure to cold, as he soon realized that

this was the cause of his trouble. However, during the autumn of 1951 further severe attacks occurred when out of doors in cold weather. Mild attacks of digital ischaemia without haemoglobinuria resulted from slight exposure to cold induced in his ordinary occupation by handling cold metal tools or bicycle components. There was no history of pneumonia or of any other serious illness, and until the onset of the present condition he had been able to work for long hours in cold surroundings without ill effects.

On admission to hospital there was no pallor of mucous membranes or any icterus. The skin of the distal segments of the digits was atrophic, but the colour was normal and all peripheral arteries pulsated strongly. The temperature was 98° F. (36.7° C.), pulse 90, blood pressure 138/86. He had bilateral direct inguinal hernias. Otherwise physical examination was negative. The urine contained no protein, red cells, or reducing substances, and there was no excess of urobilinogen. Renal-function tests showed normal excretion and radiological examination of the kidneys showed no opaque calculi.

Clinical Investigations

Exposure to Cold.—The patient was taken for a walk in the hospital grounds on a cold afternoon—temperature 42° F. (5.5° C.)—with the hands exposed. After 25 minutes both hands became numb and blue. Samples of blood were collected at hourly intervals after exposure; there was well-marked haemoglobinuria in the first specimen, but not subsequently. This haemoglobinuria was followed by haemoglobinuria, which was maximal two hours after the exposure to cold.

Rosenbach Test.—The right arm was immersed for 15 minutes in water at 54–57° F. (12–14° C.). Blood samples were taken immediately afterwards from both arms. The chilled hand showed ischaemic changes, but there was no oedema or allergic reaction to cold such as is seen in patients with syphilitic paroxysmal cold haemoglobinuria. Blood serum from the chilled limb was cherry-red, while that from the non-immersed limb was pink. Haemoglobinuria did not occur. The haemoglobin levels in the samples of serum are recorded in the Table, which also shows the results of similar experiments in Case 2 and in a case of syphilitic paroxysmal cold haemoglobinuria. Spectroscopic examination of serum from the chilled limb revealed no pigment other than oxyhaemoglobin, even in a thickness of 4.5 cm.

Results of Rosenbach Test

Case	Free Haemoglobin (mg./100 ml. Serum)		
	A	B	C
1	18	190	110
2	45	220	28
J.	19	250	47

Cases 1 and 2 suffer from high-titre cold haemagglutination, and J. from syphilitic paroxysmal cold haemoglobinuria. Column A=levels of free Hb in blood from right arm before its immersion in water at 54° F. (12° C.) for 15 minutes. Column B=levels of free Hb in blood from right arm following immersion. Column C=levels of free Hb in blood from left (non-immersed) arm.

Observations on the Vessels of the Chilled Conjunctiva.—The anaesthetized conjunctiva was examined in a warm room with a slit-lamp corneal microscope, and its circulation was noted to be normal. Following the direct application of ice to the conjunctiva the blood stream slowed and became fragmented, small clumps of cells alternating with stretches of clear plasma. On subsequent warming the circulation quickly became normal.

Examination of Nail-bed Capillaries after Chilling.—This was unsatisfactory, as the heat of the microscope lamp rapidly warmed the chilled finger-tip.

Laboratory Investigations

On admission the haemoglobin was 88% Haldane (13 g.%); erythrocytes, 4,120,000 per c.mm.; leucocytes, 9,950 per c.mm., with normal distribution; reticulocytes, 0.5–1%; platelets, 224,000 per c.mm.; E.S.R., 33 mm. in 1 hour at

72° F. (22° C.) and 31 mm. in 1 hour at 50° F. (10° C.) (Wintrobe method); osmotic fragility of erythrocytes normal. The blood group was O($\alpha\beta$) rhesus-positive (anti-D) and the Coombs test was strongly positive. Serum bilirubin was 0.8 mg. per 100 ml.; serum proteins, 6.7 g. per 100 ml. (albumin 4.55 g., globulin 2.15 g.). A differential count on marrow aspirated from the iliac crest showed a normal distribution with 24.5% normoblasts of all stages of development.

The Wassermann and Kahn reactions were negative. The serum contained a cold agglutinin active against his own and homologous erythrocytes to a titre which has remained persistently high during the period that he has been under investigation. When this test is carried out with normal saline as diluent the titre at 32° F. (0° C.) has been 1:20,480, but using bovine albumin as diluent the titre is enhanced many-fold, and has been as high as 1:327,680. The activity of this agglutinin falls sharply between 50 and 68° F. (10 and 20° C.) and is completely inhibited at body temperature.

Temperature	Titre	Temperature	Titre
32° F. (0° C.)	1:20,480	68° F. (20° C.)	1:1,280
50° F. (10° C.)	1:20,480	98.6° F. (37° C.)	0

No cold haemolysin could be detected in the serum using the technique described by Dacie and de Gruchy (1951).

The cold agglutinin was found to be absorbed on to the surface of erythrocytes collected from the patient's blood, which was allowed to clot at room or refrigerator temperature but not at 98.6° F. (37° C.). If these erythrocytes were repeatedly washed with warm saline the cold agglutinin was eluted from the cells. A Coombs test then carried out on such washed cells was found to give a positive result, which indicated the presence of an adsorbed cold immune body. The presence of this incomplete immune body can also be demonstrated by adding homologous cells to the serum, chilling the mixture, eluting the cold agglutinin with warm saline, and testing the washed cells with anti-human globulin serum, when a positive result is also obtained. This immune body is regarded by Ferriman *et al.* (1951) as an incomplete cold antibody, and is probably an enhanced titre of the incomplete cold antibody described by Dacie (1950a) in normal sera.

The Donath-Landsteiner test has been repeatedly carried out both without acidification and after adjusting the pH to 6.6. It has always been negative. A control Donath-Landsteiner test carried out on the serum of a patient with syphilitic cold haemoglobinuria has been persistently positive, and this reaction has been enhanced by acidification.

Treatment

The patient was advised to avoid unnecessary exposure to cold by wearing woollen mittens and remaining indoors as much as possible. In order to obtain peripheral vasodilatation tolazoline hydrochloride and nicotinic acid were given by mouth, but there was no evidence that they brought any lasting benefit.

Case 2

A 40-year-old fitter noticed during the winters of 1949 and 1950 that both hands became numb and painful during frosty weather. The hands were deeply cyanosed and the digits showed blue-and-white mottling; there was also cyanosis of the nose and ears, but the feet remained normal. During a cold spell in December, 1951, the tips of both the index and little fingers gradually became dry, black, and extremely painful. The only previous illness was pneumococcal lobar pneumonia in 1947, which had responded satisfactorily to chemotherapy.

On admission to hospital there was a moderate pallor of exposed mucous surfaces but no icterus. The hands showed mottled bluish discoloration, and the fingers were waxy-white, with shiny atrophic skin. Light touch and pin-prick were not appreciated. There was dry gangrene involving the distal segments of the index and little fingers of both hands (see illustration). Arterial pulsation was good in the radial and ulnar arteries, and there were no changes in the

Photograph of the hands of Case 2, showing symmetrical digital gangrene.

vessels or skin of the feet. The temperature was 97° F. (36.1° C.), pulse 84, blood pressure 180/90. No other abnormality was detected on clinical examination. The urine contained no protein, red cells, or excess urobilinogen; there was no haemosiderin in the urinary deposit. X-ray examination showed moderate enlargement of the left ventricle; there were no bony cervical ribs.

After nine days' treatment with local heat to the hands and vasodilator drugs there was no improvement in the gangrene, and the tips of both forefingers were amputated.

Clinical Investigation

Exposure to Cold.—Five days after amputation of the gangrenous finger-tips the patient was up and about in the ward, when he developed a severe attack of digital ischaemia. The amputation stumps were particularly painful, and the tip of the nose and right ear became blue. It was noted that pressure on an area of cyanosis failed to produce blanching (negative Parisius phenomenon). The pain and vascular changes were relieved after a few moments' immersion of the hands in water at 104° F. (40° C.).

Rosenbach Test.—As in Case 1, serum from the chilled limb contained a large amount of free haemoglobin (see Table). Spectroscopic examination showed, in addition to oxyhaemoglobin, a weak band at 630 mμ. It was mostly but not completely removed by bringing up to pH 9, and formed a small amount of haemochromogen (band 560 mμ) in Schumm's test. This could have been methaemoglobin mixed with a little methaalbumin, but the amount present was minute.

Observations on the Chilled Conjunctiva.—The changes following the application of ice to the conjunctiva were similar to those noted in Case 1.

Laboratory Investigations

Initially the haemoglobin was 57% Haldane (8.4 g.); erythrocytes, 2,650,000 per c.mm.; leucocytes, 7,350 per c.mm., with normal differential count; reticulocytes, 2.5%; osmotic fragility of erythrocytes normal. Sedimentation rates per hour determined by the Wintrobe method were: 50° F. (10° C.), 22 mm.; 72° F. (22° C.), 45 mm.; 98.6° F. (37° C.), 21 mm. The blood was group A(β) rhesus-positive (anti-D), and the Coombs test was positive. Serum bilirubin was 1.8 mg. per 100 ml.; serum proteins, 6.6 g. per 100 ml. (albumin 3.8 g., globulin 2.8 g.); thymol turbidity, 2.5 units; alkaline phosphatase, 9 (King-Armstrong) units; bromsulphthalein retention, 5% in 30 minutes. Sternal marrow showed normoblastic hyperplasia with a preponderance of intermediate forms.

The Wassermann and Kahn reactions were negative. An agglutinin active in high titre in the cold against the patient's own and homologous erythrocytes was present in the serum. It has been tested for on six occasions, and with a saline diluent the titre has been relatively fixed at 1:20,480. A higher titre was obtained using bovine albumin as diluent (1:81,920). The agglutinin is most active between 32 and

50° F. (0 and 10° C.), and its activity diminishes rapidly above 68° F. (20° C.)

Temperature	Titre	Temperature	Titre
32° F. (0° C.)	1:20,480	68° F. (20° C.)	1:1,280
50° F. (10° C.)	1:20,480	98.6° F. (37° C.)	0

On frequent testing no cold haemolysin could be demonstrated either with or without acidification of the serum, using the technique described by Dacie and de Gruchy (1951).

An incomplete cold antibody was also present in this serum as demonstrated by a positive Coombs test after elution of the complete cold antibody as in the previous case.

The Donath-Landsteiner reaction gave equivocal results. On two occasions it was negative even with acidification, but on two other occasions haemolysis occurred with acidified serum although all controls were negative.

Treatment

A course of 100 mg. of A.C.T.H. daily for six days produced no clinical or haematological remission. Urethane was then tried, and a total of 63 g. was taken over a period of three weeks. After ten days the titre had fallen to 1:2,048, but despite continuance of treatment the titre rose to its original level and there was no clinical improvement. Peripheral vasodilator drugs were given as in Case 1, and again had no effect. The only effective measure consisted in the avoidance of undue exposure to cold surroundings.

Discussion

The onset of the disease in both cases was characterized by the sudden spontaneous appearance of numbness and cyanosis of the hands during exposure to cold. These changes are produced by massive agglutination of erythrocytes in the blood vessels. This phenomenon can be demonstrated by examining the conjunctival vessels under the slit-lamp microscope after instilling iced water into the conjunctival sac (Iwai and Mei-Sai, 1925, 1926), when slowing and fragmentation of the blood column can be directly observed. That a similar process occurs in the extremities is inferred from the absence of blanching following pressure on the cyanosed fingers (negative Parisius phenomenon). Attempts to examine the nail-bed capillaries of the chilled finger directly with the capillary microscope were not successful, as the heat of the microscope lamp warmed the part and reversed the process of agglutination. Further observations carried out on our two cases have shown that the attacks of numbness and cyanosis of the hands can be adequately explained by intravascular haemagglutination (Marshall Shepherd, and Thompson, 1953).

When exposure to cold is excessively prolonged thrombosis may occur in the vessels distal to the blocked area. This is irreversible and when extensive enough leads to gangrene, which has been described as an unusual complication of high-titre cold agglutination by McCombs and McElroy (1937), Benians and Feasby (1941), Stats and Bullowa (1943), Carey, Wilson, and Tamerin (1948), and Ferriman *et al.* (1951). In our second patient, whose occupation entailed the handling of sheet-metal plates out of doors, prolonged exposure resulted in the development of symmetrical digital gangrene. Microscopical examination of the amputated finger-tips revealed thrombi, and such histological evidence as was available was consistent with these having been initiated by stasis.

It is surprising that the clinical symptoms are not always related to the titre of cold agglutinins. In the case recorded by Erf (1945) there were no symptoms directly referable to haemagglutination, although the titre was reported as 1:4,194,304. It may be that activity of this agglutinin in the body does not parallel that *in vitro*, or that, as Henne mann (1951) has suggested, the thermal amplitude of the antibody is the important factor in determining the occurrence of symptoms.

Exposure to cold causes not only intravascular haemagglutination but also haemolysis. This seems to be purely local phenomenon, and can be demonstrated by

chilling a single limb from which blood samples are collected before and after cooling (Rosenbach test). Stats and Bullowa found only oxyhaemoglobin in serum from the chilled limb, and concluded that simple haemolysis occurs without alteration of the blood pigment. Serum from one of our cases also showed oxyhaemoglobin alone, but in the other there was in addition a small amount of a pigment which may have been a mixture of methaemoglobin and methaalbumin. Although haemoglobinaemia in the single chilled limb is a constant feature in these patients, insufficient pigment enters the general circulation to produce haemoglobinuria during the performance of the Rosenbach test.

There is a wide divergence of views regarding the mechanism of haemolysis. It seems that intravascular stasis in small vessels contributes to haemolysis by allowing more time for the erythrocytes to agglutinate under the influence of cold, and that "cohesion of erythrocytes may lead to their prompt mechanical destruction while in motion in the circulation," as suggested by Shen, Castle, and Fleming (1944). This mechanistic concept is supported by the experiments of Stats (1945), who showed that when mixtures of sera containing cold agglutinins and homologous cells were shaken during refrigeration at 32° F. (0° C.) haemolysis resulted. In contrast with this theory of mechanical fragility, Dacie (1950b) claims to have detected the presence of a haemolysin in the serum. It is demonstrable only by altering the pH of the mixture to the physiological range or a little below it, and the titre is low. We have made repeated attempts, using an identical technique, to detect such a haemolysin in our two cases, but without success.

The anaemia found in patients with this condition is of the haemolytic type. It should be proportional to the extent of intravascular haemolysis as judged by the degree of haemoglobinaemia and haemoglobinuria. However, no distinct relationship between these manifestations and anaemia may be evident. In one of our cases there was well-marked anaemia in the absence of haemoglobinuria.

It is claimed by Benians and Feasby (1941), Helwig and Freis (1943), and Forbes (1947) that the E.S.R. increases when the test is performed at low temperatures owing to the enhanced activity of the agglutinins. However, Stats and Wasserman (1943) maintain that the increased viscosity of blood at low temperatures may retard the E.S.R., and this occurred in the patient reported by Mellinkoff and Pisciotta (1949). In Case 1 a reduction in temperature from 72 to 50° F. (22 to 10° C.) had no significant effect upon the E.S.R., but in Case 2 there was marked retardation.

The treatment of this condition is very unsatisfactory. Some authors have claimed that the use of vasodilator drugs has procured improvement in the Raynaud phenomenon, but in our cases they had no effect. Since there is no evidence that an excessive vasomotor tone contributes to the digital ischaemia, it is not surprising that sympathectomy failed to produce relief in the case recorded by Hanns (1943). The most effective measure consists in avoiding exposure to a cold environment by keeping the extremities well wrapped up and remaining indoors as much as possible during the winter. Attempts have been made to prevent the formation of cold agglutinins or to inactivate them, but without success. Bateman (1949) administered heavy doses of salicylates, which have been shown in animal experiments to be capable of blocking the antigen-antibody reaction, but there was no significant improvement either in the titre of cold agglutinins or in the symptoms. A short course of A.C.T.H. produced no change in one of our patients, and Ferriman *et al.* also noted no benefit from it. More prolonged treatment of the same case with urethane, undertaken in the hope of inhibiting the activity of the reticulo-endothelial system as a producer of immune bodies, was similarly without lasting effect.

Summary

Two cases are reported which readily developed the Raynaud phenomenon and intravascular haemolysis on

exposure to cold. One showed, in addition, bilateral symmetrical gangrene of the finger-tips and severe haemolytic anaemia, while the other was subject to attacks of haemoglobinuria. Examination of the serum of both cases revealed cold agglutinins in high titre. Treatment is unsatisfactory, and the only effective measure is the avoidance of cold surroundings.

We wish to thank Dr. S. B. Boyd Campbell and Dr. J. T. Lewis for permission to publish these cases, Professor D. C. Harrison for performing the spectroscopic analyses, and Mr. D. McA. Mehaffey for the photography.

CONTINUOUS SUCCINYLCHOLINE CHLORIDE WITH PETHIDINE IN ABDOMINAL SURGERY

BY

G. HERINGTON, M.B., B.S., D.A.

Consultant Anaesthetist, Wanstead Hospital

AND

E. JAMES, M.D., D.P.H., D.A.

Medical Superintendent, Rush Green Hospital, Romford

The sequence of thiopentone, nitrous oxide and oxygen, and a relaxant and controlled respiration, aptly described by Gray and Rees (1952) as a pyramid having as its base apnoea with sides consisting of narcosis, relaxation, and analgesia, has for some time held an important place in anaesthesia for abdominal surgery. This technique produces excellent operating conditions, but the use of longer-acting relaxants such as D-tubocurarine chloride and gallamine triethiodide creates special problems, in particular the difficulty in controlling the duration of relaxation without the use of antidotes. The anaesthetist, faced with the problem of obtaining relaxation for peritoneal closure, is loath to give a further injection of a long-acting relaxant, and may use some less satisfactory alternative.

Even when relaxants are withheld during the latter stages of a major abdominal operation the patient is often left in a state of partial curarization, and the anaesthetist must either accept this or administer neostigmine. Here one encounters varying opinions, some advocating neostigmine in every case, some never. However, the decision to give or withhold neostigmine is a delicate one, and each case must be judged on its merits.

The side-effects of neostigmine, such as bradycardia, salivation, and vomiting, and the occasional occurrence

of collapse or bronchial spasm, all of which may occur in a patient well under the influence of atropine, make the routine use of this drug potentially dangerous, so that the antidote may well be more dangerous than the condition for which it is given. Macintosh (1949) and Clutton-Brock (1949) report two fatalities immediately after the injection of neostigmine at the end of operation. On the other hand, the patient who is allowed to return to the ward in a partially curarized state following an abdominal operation may become critically hypoxic and later develop pulmonary complications.

The short-lived but potent action of succinylcholine should make it an ideal agent for prolonged relaxation in abdominal surgery when given by intravenous drip. Thesleff and von Dardel (1951) used the iodide by this method in a series of 132 operations, mainly abdominal, employing a 0.1% solution at a rate of 2 to 8 mg. a minute in patients whose ages varied from 11 to 70 years. They did not aim at complete apnoea, but found muscular relaxation excellent. No toxic effects were noted, even in poor-risk patients. Bourne, Collier, and Somers (1952) used succinylcholine chloride ("scoline") for abdominal relaxation in 68 cases, an unspecified number of which were by continuous drip. They thought the method cumbersome and found that a steady rise in blood pressure often occurred and that respiration was sometimes slow to recover. Foldes (1952), however, criticized what he thought to be the excessive dosage used by these and other British workers, stating that adequate relaxation without apnoea could be obtained with approximately one-fifth of the dosage used in this country. Green (1952, 1953) had good results in 146 abdominal operations, using a 0.1% solution and giving a test dose to the conscious patient. Apart from the initial thiopentone, he used only nitrous oxide for maintenance of anaesthesia, and stressed the need to effect early saturation, a point well demonstrated earlier by Brennan (1952).

In the present series of 289 abdominal operations the sequence of thiopentone, nitrous oxide, continuous succinylcholine chloride, and intermittent intravenous pethidine was used. After some experiment, a 0.15% solution of succinylcholine in normal saline was decided upon as giving simple control without excessive fluid, 750 mg. being added to 500 ml. of saline in the usual transfusion bottle. Most of the patients were adults, but the ages varied from 14 to 82 years.

Description of Technique

Fit adults received "omnupon," 1/3 gr. (22 mg.), and scopolamine, 1/150 gr. (0.43 mg.), one hour before operation. Elderly or seriously ill patients were given atropine,

1/100 gr. (0.65 mg.), with or without a small dose of morphine. Thiopentone, 0.3 to 0.5 g.—a dose which need rarely be exceeded—was followed by 40 to 50 mg. of succinylcholine, and the succinylcholine drip was then started through the same needle, preferably not smaller than size 12, just fast enough to prevent clotting. In one patient to whom a test dose of succinylcholine was given before thiopentone painful muscular contractions resulted, and the method was therefore abandoned.

After inflation of the lungs with oxygen, the cords and trachea were sprayed with 4% lignocaine hydrochloride, and in most cases a cuffed tube was then passed orally. For the next 10 to 15 minutes the patient was hyper-ventilated with 6 litres of nitrous oxide to 2 litres of oxygen, and the succinylcholine drip was speeded up sufficiently to keep the patient just apnoeic. This is an adjustment of some delicacy and one greatly facilitated by the use of a drip control attached directly to the upright of the drip stand and actuated by a large milled head, as shown in the photograph. This arrangement was specially useful to the single-handed anaesthetist engaged in manipulating the bag.

When saturation with nitrous oxide was considered adequate, the closed circuit was used with 1 litre of nitrous oxide to approximately 300 ml. of oxygen and an intentional leak in the circuit. Before the peritoneum was opened 10 to 20 mg. of pethidine was given, and this dose was repeated at the most traumatizing stages of the operation, particularly in gastrectomies and other major abdominal procedures. The succinylcholine drip was stopped as the peritoneum was being closed.

Details of the operations, together with the average doses of thiopentone, succinylcholine, and pethidine, and the average times taken to resume breathing, are shown in the accompanying Table.

Drip control attached to upright of drip stand.

Operation	No.	No. of Emergencies	Average Age	Average Length of Operation	Average Dose of			Average Time to Start Breathing after Stopping Drip	Average Time to Resume Normal Breathing
					Thiopentone	Succinylcholine	Pethidine		
Partial gastrectomy	42	4	50	Minutes	g.	mg.	mg.	Minutes	Minutes
Cholecystectomy	20	—	49	94	0.4	650	65	1.9	5.8

Advantages and Disadvantages

Advantages of Pethidine.—Although a few early cases in the series were maintained on nitrous oxide, oxygen, and succinylcholine alone, the occasional slight movement of a limb or eyelid showed that analgesia was not adequate. The use of small doses of pethidine has, in our experience, prevented such reflex disturbances, has diminished appreciably the amount of succinylcholine required, and has, by providing analgesia with little narcotic effect, contributed materially to the good post-operative condition of the patient. Moreover, its action as a bronchodilator facilitates inflation of the lungs.

Use of the Cuffed Tube.—Succinylcholine provides such perfect intubating conditions that an oral cuffed tube can be passed easily and leisurely. While this was done in all lengthy operations, or in those in which there was any risk of regurgitation of stomach contents, equally good results were obtained by one of us (E. J.) using a simple airway in shorter non-emergency operations such as appendicectomy and herniotomy. However, in view of the possibility of inflating the stomach during hyperventilation, we think that most anaesthetists would prefer to have an endotracheal tube in position.

Indications and Contraindications.—The cases in this series comprise a fairly representative selection of abdominal operations, in all of which extremely good operating conditions were provided. Some of the cases used in this trial were of rather short duration, and, while the method produced ideal conditions for appendicectomies and herniotomies, it should perhaps be reserved for cases in which surgical difficulty is anticipated. Again, a single appendicectomy will probably be over too quickly to justify its use, but where the operation is one of a list, there is no greater difficulty in setting up the succinylcholine drip than in giving repeated injections of *n*-tubocurarine or other relaxant. However, we found that the method was seen to its best advantage in the more lengthy and extensive abdominal operations—for example, gastrectomy, hemicolectomy, and cholecystectomy. In emergencies, too, it was found that the method gave excellent operating conditions, and that the patient's condition at the end of operation was most satisfactory.

Some Special Cases

Eleven cases of caesarean section (lower segment) were anaesthetized by this technique. In one of them the infant was lively and cried immediately, while the mother's condition was excellent. In another case, a toxæmia of pregnancy, anaesthesia was induced with 0.35 g. of thiopentone, and the infant was sleepy and did not cry for five minutes. It was thought that the induction dose of thiopentone was rather high in this case, and that this was responsible for the sleepy condition of the infant.

For gynaecological operations in which the surgeon was satisfied with a moderate Trendelenburg position, the technique was found satisfactory, but where the maximum table tilt was used the technical difficulty of maintaining the succinylcholine drip made the method scarcely worth while. One patient, a very fat woman of 61 undergoing a Wertheim's hysterectomy, required 1.5 g. of succinylcholine in two and a half hours. Although respiratory movements returned within three minutes of stopping the drip, the respirations remained shallow and diaphragmatic in type for a further twenty minutes. Apart from oxygen no special treatment was given, and at the end of this time the respirations had become normal and recovery was uneventful. This is the longest time noted in the series for the return of normal respiration.

A few cases not included in this series have been given continuous succinylcholine for haemorrhoidectomy. Here again operating conditions were excellent, but in one case (a muscular man of 41) the surgeon stated that the anal sphincter was not relaxed, although it was noted at the

time that there was perfect relaxation of the abdominal wall. This is the only case in which failure of relaxation with succinylcholine has been noted. Clearly, however, haemorrhoidectomy is too short an operation to justify the use of a drip, and intermittent injection of succinylcholine would appear to be more suitable.

An Emergency Laparotomy

This case is cited to show that the technique can be used successfully, even in grave emergency, provided that only minimal quantities of anaesthetic and relaxant are used.

The patient, a woman of 59, was admitted in a moribund condition following severe haematemesis, which had been preceded for some weeks by vague dyspeptic symptoms. The blood pressure on admission was not recordable, and her respiration was gasping in character. After a rapid transfusion of 4 pints (2.3 litres) of blood, however, the general condition improved slightly, and the surgeon considered that operation offered the only hope of arresting the bleeding. Just before operation the systolic blood pressure was 50 mm. Hg and the pulse rate 120. Anaesthesia was induced with 0.15 g. of thiopentone followed by 20 mg. of succinylcholine. After a cuffed oral tube had been passed, anaesthesia was continued with a 50% mixture of nitrous oxide and oxygen. The patient was apnoeic for only two minutes at the start—perhaps a tribute to the cholinesterase content of fresh transfused blood—and was kept apnoeic during the 60 minutes of the operation by 100 mg. of succinylcholine. Pethidine was not given. Laparotomy showed a cirrhotic liver, a stomach distended with clotted blood, and large freely bleeding oesophageal varices. Attempts to arrest the bleeding were only temporarily successful, but the pulse rate and blood pressure remained almost unchanged throughout the operation. Respiration started almost as soon as the succinylcholine drip was stopped, and was adequate within three minutes. The patient died one hour after operation from fresh and massive haemorrhage.

Characteristic Effects of Continuous Succinylcholine

In these cases the relaxation of the abdominal wall was always excellent, and the peritoneum during closure was described by one surgeon as "hanging in festoons." A few patients, for purposes of observation, were allowed to breathe spontaneously for a short time, but we found that respirations of any depth were accompanied by the return of tone in the lateral muscles of the abdominal wall. The work of Gray and Rees (1952) and Dundee (1952), who demonstrated the effect of controlled respiration in decreasing the dosage of thiopentone and relaxant, would seem to apply equally well to succinylcholine.

Bleeding in these cases was described by the surgeons as moderate, with little tendency to oozing. Many of the patients awoke on the table, and the others had active reflexes within a very short time. As stated above, post-operative analgesia was provided by the pethidine, and there was little tendency to restlessness. The post-operative condition of the patients was good, and there was very little deterioration during the immediate post-operative period, in contrast to the picture often seen when cyclopropane, or to a lesser extent ether, are withdrawn. The pulse rate tends to remain slow and stable both during and after operation, in contrast to the characteristic changes seen with cyclopropane, gallamine triethiodide, and neostigmine. No case of arrhythmia was observed. The blood pressure sometimes showed an initial fall, ascribed to the thiopentone, followed by a rapid restoration to the normal level. Where pethidine was not used, as in some of the very early cases, the climbing type of blood-pressure chart was sometimes met with, especially in long gastrectomies, and this in spite of adequate lung ventilation. With pethidine, however, this picture was not seen, and the blood-pressure charts pursued a constant course.

The most pleasing observation in these cases has been the spontaneous return of normal respiration within a few minutes of cessation of the drip, although the peritoneum has been perfectly relaxed for closure. The average time taken for the return of respiratory movements in these cases has been one and a half minutes, with a further period of two and a half minutes before full normal intercostal breathing returned. The figures showed considerable individual variation, but the impression was formed that in those cases which took longer than usual to start respiratory movements the return of normal respiration was quicker. No doubt the dosage of thiopentone, pethidine, and succinylcholine, and the degree of ventilation of the lungs, all influenced these figures, but the relative importance of each of these factors in prolonging apnoea is difficult to assess.

Summary

A technique for anaesthesia in abdominal surgery is described, using thiopentone, succinylcholine by continuous drip, intermittent pethidine, and controlled respiration with nitrous oxide and oxygen.

The succinylcholine drip gives a flexibility of control not obtainable with other relaxants, while respiration is quickly restored after the drip has been stopped. No case of prolonged apnoea has been met with. Given a well-trained nurse, the method is no more cumbersome than repeated injections of D-tubocurarine or other relaxant, even for the single-handed anaesthetist.

The technique is suitable for both planned and emergency abdominal surgery, in both fit and seriously ill patients.

The use of pethidine minimizes reflex disturbances and adds greatly to the post-operative well-being of the patient.

Thanks are due to our surgical and theatre nursing staff colleagues at Rush Green and Wanstead Hospitals, and particularly to our resident anaesthetists Dr. M. O'Callaghan, Dr. Pramanik, and Dr. W. R. Lamb.

The Alcoholic Research Foundation, Toronto, was set up to conduct and promote research in alcoholism and the treatment and rehabilitation of alcoholics. Its annual report for 1952 gives an account of treatment methods and problems. In dealing with alcoholism of psychological origin the Foundation advocates informal group sessions under the direction of a psychiatrist and consisting in the exchange of experiences, attitudes, and knowledge by the participants. Many patients make real progress from this method. Others have been helped more by short interviews of 5-10 minutes. "Antabuse" continues to be used, although many who might be helped by it are dissuaded from taking it through previous misinformation. In employing antabuse no use has been made of the trial reaction with alcohol after the patient has been on the drug for a few days; it is considered unnecessary to use this test now that clear information is available to the patient. According to the report, there is room for more careful screening and instruction of patients on the use of antabuse if it is to give the maximum benefit. One problem causing concern is the increasing use of sedatives of the open chain ureide group, to which patients often become habituated.

AN UNUSUAL CASE OF SYPHILITIC PARKINSONISM

BY

K. G. NEILL, M.B., Ch.B.

Medical Registrar, Croydon General Hospital

Although the recent literature on syphilis as a cause of Parkinson's syndrome is scant, it is an accepted fact that *Treponema pallidum* can cause the features of this condition (Guillain, 1935; Kinnier Wilson, 1940). The signs of involvement of the basal ganglia may appear soon after the original infection or may be delayed for some years. Pires (1935) reports the case of a man aged 32 who had a primary chancre five years previously, and three months after finishing a course of arsenic and bismuth injections developed rigidity in the right arm, pill-rolling movements of the fingers, and loss of facial expression.

Cases of Parkinson's syndrome combined with tabes dorsalis or general paralysis have also been recorded (Chavany and Levy, 1926; Dumas *et al.*, 1928; Urechia and Retezeanu, 1936b).

Urechia and Retezeanu (1936a) describe the case of a young woman, aged 24, whose first symptoms were uselessness of the hand for five minutes after she got out of bed in the mornings. She developed a typical Parkinsonian facies later on. This case was of particular interest in that the blood Wassermann reaction was negative but the cerebrospinal fluid Wassermann reaction was positive.

Cases of oculogyric crises, in association with other Parkinsonian features due to *T. pallidum*, are recorded by Pearson (1927) and Cossa *et al.* (1936).

The following case of syphilitic Parkinsonism seen at this hospital is of particular interest in that the patient, aged 43, appears to be a congenital syphilitic. The Parkinsonian features were well marked and were progressing. A survey of the literature failed to reveal a similar case.

Case Record

A professional fur classer aged 43 had not felt really fit since the removal of a papilloma of the bladder two years previously. Soon after discharge from hospital he began to feel tired in the daytime. During the past six months there had also been a great decrease in his usual energy and he had become rather depressed. Shortly before admission he noticed that his hands were shaking (especially the right) and he had difficulty in writing properly. The writing had become small and the letters were poorly formed. About this time his speech had become thick and slurred. There had been a tendency to fall over, particularly when he went out at night or closed his eyes. He had noted that his method of walking had become shuffling and that his arms had ceased to swing. At times he had difficulty in stopping once he had started walking. Dribbling of saliva was often excessive, particularly at night-time.

For the past two years he had had very severe pain in his right lower leg. He described it as "like a hot knife being pushed through the leg." The pain was always transversely through the leg, never vertically. It nearly always came on when he was in bed at night.

Previous Complaints and Illnesses.—As a baby he was said to have had a troublesome nasal discharge. The two upper permanent central incisor teeth were said to have been peculiar, in that they were shorter than the others and decayed early. He had a severe infection of the eyes at the

AUG. 8, 1953

age of 18, and was almost blind for four months. He attended a London eye hospital and received a course of twenty-eight intramuscular injections. There had been no recurrence. The old hospital notes of his own doctor said that he had interstitial keratitis. He denied ever having had sexual intercourse with anyone but his wife, and there was no history of a chancre, skin rash, or other syphilitic manifestation.

Unfortunately, no satisfactory history of his parents was available. His wife and his son, aged 18, are well. Their blood Wassermann and Kahn reactions are negative. On admission he complained of tiredness, especially during the day, but inability to sleep and restlessness at night, dribbling of saliva, trembling of the hands (particularly the right), difficulty in walking properly, and a tendency to fall over.

On examination he was seen to have a typical mask-like, expressionless Parkinsonian facies. Speech was slow and slurred, and saliva dribbled from the corners of his mouth. He had a slight stoop and a shuffling gait, and did not swing his arms.

Nervous System.—Cranial nerves: the following abnormalities were noted. He had slight diplopia at times. The pupils, which did not react to light and reacted minimally to accommodation, were large, irregular, and unequal. The edge of the iris was hazy and irregular. There was slight lateral nystagmus, with a fine tremor of the closed eyelids. A fine tremor of the jaw was present. Ophthalmoscopic examination showed slight pallor of the temporal sides of the disks. The vision and fields were normal.

Limbs.—Power and co-ordination were normal, but there was slight bilateral rigidity, and a fine pill-rolling movement was present in both hands, particularly the right. Although there was no loss of power in the lower limbs, a marked degree of ataxia was present. This was particularly evident when he attempted to slide the right heel down the anterior surface of the left tibia. The reflexes in the arms were all excessively brisk. The knee-jerks were exaggerated, particularly the left. The ankle-jerks were present but not exaggerated. The left plantar response was flexor and the right extensor. The abdominal reflexes were normal. The sensations of touch, temperature, pain, and vibration sense were normal in the arms and legs. Position sense in the arms and left leg was normal, but in the right great toe it was grossly impaired. A marked degree of Rombergism was present. No abnormalities were found in the sphincters. Testicular sensation was normal and there were no areas of cutaneous anaesthesia of the face, forehead, or chest.

The cardiovascular system was normal. The blood pressure was 140/90. The respiratory, genito-urinary, alimentary, and lymphatic systems were normal. The chest x-ray film showed nothing abnormal.

Laboratory Investigations.—Blood: haemoglobin, 102% (15.1 g. per 100 ml.), E.S.R., 2 mm. in one hour (Westergren); white cells, 5,700 (normal distribution); Wassermann reaction and Kahn test, strongly positive. Cerebrospinal fluid: appearance clear (pressure 140 mm.); protein, 110 mg. per 100 ml.; globulin, excess present; chlorides, 700 mg. per 100 ml.; sugar, 65 mg. per 100 ml.; leucocytes, total 16 per c.mm.; lymphocytes, 100%; Gram stain, no organisms; culture, no growth; Lange, 5554320000; Wassermann reaction, strongly positive. X-ray films of the skull, right and left tibiae, knees, hands, wrists, and chest were normal.

Treatment.—The patient was given a course of 10,000,000 units of penicillin, 30,000 units of soluble penicillin three-hourly for 48 hours, followed by 600,000 units of procaine penicillin daily. Within a few days of starting the penicillin an obvious improvement in his general condition was noted. After receiving the full course he was discharged.

When examined one month later he no longer felt sleepy during the day, and at night he had eight hours of undisturbed sleep. He felt more energetic than before treatment,

and no longer dribbled saliva. There was only slight residual trembling in his hands, and he could write reasonably well again. He was able to stand with his eyes shut without feeling unsteady and could go out at night without fear of falling over. He has had no further diplopia. There have been no further lightning pains. His facial expression, however, was still somewhat mask-like, he still walked with a shuffling gait, and his arms moved only a little. There was, however, a considerable improvement compared with his condition before treatment started.

Discussion

This patient had typical Parkinsonian signs, a mask-like face, slow monotonous speech, tremor of the closed eyelids, rigidity and tremor of the arms, and a characteristic gait, but there were several unusual features. Irregular pupils with no reaction to light and a poor contraction on accommodation may occur in Parkinsonism, particularly the post-encephalitic type, but exaggerated tendon-jerks and extensor plantar response, impairment of position sense in the right big toe, a positive Romberg sign, and lightning pains in the legs are not part of the clinical picture of the disease. The past history of interstitial keratitis suggested the possibility of congenital syphilis, and the presence of syphilitic involvement of the nervous system was confirmed by the excess of lymphocytes and the raised protein content in the cerebrospinal fluid, the first-zone Lange curve, and the positive Wassermann reaction in the blood and cerebrospinal fluid.

Neurosyphilis and Parkinson's disease are both fairly common disorders, and the association of the two conditions in the same patient may at times be coincidental (Schaeffer and Bize, 1935; Kinnier Wilson, 1940). In this patient, however, the improvement in the Parkinsonian features following treatment with penicillin suggests strongly that the syphilitic infection of the nervous system was the cause of the Parkinsonian syndrome as well as of the other neurological signs. The syphilitic infection was in all probability congenital, and the development of neurological involvement occurred at an unusually late age. It is possible that the course of treatment which was given at the age of 18, when he had interstitial keratitis, though inadequate to control the infection completely, was enough to delay the appearance of neurological involvement.

There is little doubt that acquired syphilis can occasionally cause a Parkinsonian syndrome. Stevenson and Allen (1937) record a case resembling the present one, but with the addition of considerable mental deterioration, in which post-mortem examination showed typical changes of dementia paralytica in the cortex, together with widespread lesions in the corpus striatum and its connexions. Mella and Katz (1924) also record typical mesodermal syphilitic involvement of the basal ganglia. Their case was that of a man aged 46 who was admitted to hospital with a diagnosis of "paralysis agitans." He gave a history of a chancre ten years previously. His blood Wassermann reaction was positive. The cerebrospinal fluid Wassermann reaction was negative. No other tests were done. He died in hospital with bronchopneumonia. At the post-mortem examination two types of microscopical lesions were found: a perivascular infiltration of round cells and rod cells in the globus pallidus, and nerve-cell degeneration. The first is indicative of neurosyphilis, and this was further borne out by the gross findings of chronic leptomenigitis, atrophy of frontal convolutions, and granulations in the fourth ventricle which are pathognomonic of neurosyphilis. Although Mella and Katz suggest that the neurone changes may be secondary to vascular changes, they point out that the neurone change may be a primary one like that found in pre-senile paralysis agitans, and that two pathological processes are going on at the same time without any definite association.

Cases of a Parkinsonian syndrome occurring in the thirties and forties without a previous history of lethargic encephalitis are not uncommon, and the possibility of syphilis as the cause should be considered, especially if there

are unusual neurological signs such as were found in the present case; in this event, adequate antisyphilitic treatment may help in averting further progress of the disease and bring clinical improvement.

Summary

A case of the Parkinsonian syndrome apparently due to congenital syphilis is described. The response to treatment has been satisfactory.

Although syphilis is a rare cause of the condition it should be considered when the Parkinsonian syndrome develops in the 30-50 age group, particularly if there are any anomalous clinical features.

I thank Dr. G. McComas for permission to publish the case and for advice and criticism in the preparation of this paper and Dr. J. W. Aldren Turner for advice on this case and for valuable help in its presentation.

Medical Memoranda

Fatal Suppurative Cholangitis without Obstruction

Acute suppurative cholangitis is almost unknown, save in the presence of chronic biliary obstruction or of intrinsic disease of the bile ducts. Rogers (1903) found gall-stone obstruction in 18 out of 20 cases. The following case is recorded because of the occurrence of fatal suppurative cholangitis in the absence of recognized obstruction or of antecedent jaundice.

CASE REPORT

A housewife, aged 65, previously in good health, noticed slight, painless distension of the upper abdomen in July, 1952. This was accompanied by some flatulence but no other dyspeptic symptoms. Three weeks later she had sudden violent abdominal pain while out walking. The pain was in the epigastrium and right hypochondrium, and was of such severity that she went straight home to bed. Antacids, hot water, and local heat all failed to relieve it, and it was aggravated by lying on her left side. The next day she felt feverish, anorexic, and nauseated, and sweated profusely. No rigors were described. Her urine became darker than normal, but the colour of the stool was unchanged. Her doctor then found she was pyrexial, and very tender to palpation, with "guarding" over the whole upper abdomen. The pain persisted, constant in intensity, without remission. Four days after the onset two attacks of vomiting occurred, and on examination a tender hepatomegaly and persistent pyrexia were found. She was not jaundiced. The next day she was admitted to hospital.

On examination she was drowsy but conscious, in obvious pain, and moderately dehydrated. Feter hepatitus was present. She lay on her right side with her knees flexed. She was not jaundiced. A few cutaneous petechiae were present, together with several De Morgan spots. The cardiovascular system was normal. The blood pressure was 130/80, but ocular fundi showed grade 2 hypertensive retinopathy. The liver was enlarged to 7 cm. below the

right costal margin; it was exquisitely tender, and had increased in firmness; its margin was difficult to define. Gall-bladder enlargement was not present. Splenomegaly and ascites were not present, and rectal examination was negative. The urine gave a position reaction for bile constituents.

Investigations.—Blood: Hb, 102% Haldane (15.1 g.%); white cells, 12,700 per c.mm., with 92% polymorphonuclear leucocytes, showing a "shift to the left"; serum van den Bergh, direct reaction positive; serum bilirubin 1.3 mg. per 100 ml.; alkaline phosphatase, 20.5 units per 100 ml.; thymol turbidity, 2 units; serum proteins, total 4.75 g.% (albumin 2.8 g., globulin 1.95 g.); blood urea, 440 mg. per 100 ml. Urine: bile salts and urobilinogen present; albumin, 70 mg. per 100 ml.; large numbers of erythrocytes and pus cells present; culture yielded a heavy growth of *Bact. coli*. Stool: benzidine test strongly positive. A hepatic puncture biopsy, subsequently taken with a Terry biopsy needle, showed the characteristic changes of acute suppurative cholangitis.

No pyrexia occurred while under observation. A diagnosis of acute hepatitis with cholaemia and uraemia was made. Treatment consisted of intravenous administration of dextrose, saline, and water, later followed by Latner's intravenous regime for acute hepatic failure.

Five days after admission the patient's general condition showed further deterioration, with the development of drowsiness, disorientation, and minimal icterus. The skin of the abdominal wall and upper arms showed dusky purpuric blotches. Menaphthone (vitamin K₁), 10 mg., was given intramuscularly preparatory to hepatic puncture biopsy. A few hours later she collapsed and died.

At necropsy, 18 hours later, the lungs showed early pulmonary oedema. No bronchopneumonia or abscess formation was present. Many subpleural ecchymoses were present over both lungs. The cardiovascular system showed no abnormality beyond mild atheroma. The brain and meninges were normal. The oesophagus, stomach, and rest of the intestines were normal, except for a few diverticula of the sigmoid colon; these were not inflamed. There was no inflammation of the appendix or inflammatory lesion of the rectum. A fairly large blood-stained ascitic effusion was present. A large blood clot (approximately 300 ml.) was present in the peritoneal cavity in the region of the hepatic flexure and right lobe of the liver. The liver was large (2,720 g.). Three small puncture marks were present in the right lobe, but no tearing. A cut surface of the liver showed numerous small abscesses, containing yellow or occasionally greenish-coloured pus. Abscess walls showed recent inflammatory tissue. The gall-bladder was distended and thin-walled, and contained bile and several small and medium-sized black gall-stones. The bile was slightly turbid but not frankly purulent. The common bile duct was patent and appeared normal. Culture of the gall-bladder bile yielded a profuse growth of pure *Bact. coli*. The appendix and rectum were normal. The pancreas, kidneys, and urinary tract showed no abnormality.

The haemorrhagic ascites was attributed to bleeding from the site of the hepatic puncture biopsy—a matter of some interest in view of the frequency with which this investigation is nowadays carried out.

COMMENT

I have been unable to trace a necropsy-proved case of non-obstructive acute suppurative cholangitis, save in the presence of artificial regurgitation of chyme, as a post-operative phenomenon—for example, in cholecystgastrostomy (Zaslow and Counsellor, 1946; Cole, 1947). A single case was described by Bassler (1937) in which no obstruction was discovered during laparotomy with exploration of the bile duct: this patient recovered.

On the other hand, chronic infective cholangitis without clinically recognizable jaundice and biliary obstruction is well known. It takes a remittent course without suppuration, and may be but one manifestation of an underlying "cholangitis

lenta" (Schottmüller, 1921) as a separate entity. This "low-grade" cholangitis is recorded in the enteric fevers and bacillary and amoebic dysenteries (Umber, 1929; Lyon, 1932), but many observers doubt its existence as an entity. Grant (1945) drew attention to the difficulty of excluding calculi in the relatively inaccessible retroduodenal portion of the common bile duct.

The frequent absence of jaundice in this group was attributed by Weiss (1944) to the essentially chronic nature of the infection: "owing to inflammatory changes the hepatic system of lymphatics—which would otherwise carry the bile into the general circulation—becomes impermeable and consequently jaundice fails to appear." Virulent infection is generally believed to depend on the factors of biliary stasis and diminished resistance of the duct epithelium.

It would seem possible that in this instance a fulminating ascending infection occurred during the passage of a "silent" gall-stone. Closer examination of the bowel contents might have revealed such a stone in the process of evacuation.

I have to thank Dr. J. S. Richardson for permission to publish this case under his care, and Dr. C. Pike for the account of the morbid anatomy.

Carcinoma of the Submandibular Gland

A man aged 60 was admitted to hospital complaining of a painless swelling of the lower jaw of twelve months' duration which had enlarged rapidly during the four months preceding admission.

On examination a solid mass 6 by 5 cm. was present at the lower border of the body of the mandible on the right side. The mass, tender to pressure, was firmly fixed to the mandible and the overlying skin. The floor of the mouth was infiltrated, there was no discharge from the right submandibular duct, and the related cervical lymph nodes were not enlarged.

Investigations.—A white-cell count was within normal limits; the Wassermann and Kahn reactions were negative. Radiographic examination of the mandible showed a translucent area with well-defined margins in the left premolar region suggestive of a cyst. There was slight bone absorption of the right half of the mandible in the region of the tumour, the impression being that of a tumour outside the jaw invading it or causing bony resorption. Immediately anterior to this area was an outgrowth of dense bone on the external aspect of the mandible. A chest radiograph did not reveal the presence of secondary deposits. The tumour was thought to be a primary malignant neoplasm of the submandibular gland, and radical excision was advised.

Operation.—Under thiopentone, oxygen, and cyclopropane anaesthesia with an endotracheal tube, a preliminary ligation of the external carotid artery was performed and the tumour excised, together with that portion of the mandible extending from the symphysis menti to just below the coronoid and condyloid processes.

Pathological Report.—The specimen consisted of the right half of the mandible, excluding the upper part of the ramus. Apparently arising from the body of the mandible was a large tumour mass causing swelling on both the external and internal aspects. Over the external aspect was an elliptical portion of skin measuring 5 by 4.5 cm. The cut

surface of the tumour appeared white and fleshy. **Microscopical Examination.**—The tumour is a cystic type of squamous-cell carcinoma of the submandibular salivary gland, with adamantinoma-like structure in places. It is arising from the larger ducts and is invading the adjacent muscle. There is no evidence that the tumour arose from the skin or skin glands. Sections of the decalcified mandible showed osteoclastic absorption of the cortex (due to compression) with no evidence of origin of the tumour from the enamel organ or enamel organ rests.

When seen six months after operation a local recurrence was present in the neck and had produced ulceration of the overlying skin; dysphagia and pain in the neck had been present for five months. Nine months after operation the patient died as a result of haemorrhage from the internal carotid artery.

COMMENT

In a review of 150 cases of salivary gland tumours treated at the Lahey Clinic, Marshall and Miles (1947) found only 12 cases in which the submandibular gland was affected; 11 of these were cases of mixed tumour, and in the other the glandular enlargement was due to lymphadenoma.

Dockerty and Mayo (1942) reviewed 500 cases of submandibular tumours at the Mayo Clinic and found only 81 primary malignant neoplasms. These were classified into four groups: (1) Adenocarcinoma of mixed tumour type (51); the capsule was often thin and frequently invaded; 14 cases showed squamous-cell metaplasia. (2) Cylindroma type (15); most were associated with marked capsular invasion, tissue infiltration, and invasion of perineural lymph spaces; 30% of these cases showed lymph-node metastasis; 80% were associated with local recurrence after removal; 50% of the patients died within five years. (3) Intermediate type (7): these showed a histological picture with features both of adenocarcinoma and of cylindroma, but clinically were highly malignant, showing extensive metastasis. (4) Miscellaneous tumours (8): these included such neoplasms as papillary adenocarcinoma, primary epidermoid carcinoma, and other atypical tumours demonstrating none of the features of mixed tumours or cylindromata.

Stanford Cade (1949) stated that the value of pre-operative radiation, while accepted at Radiumhemmet and the Memorial Hospital, New York, has been doubted in this country. In his own experience the treatment of choice is pre-operative radiation followed by wide excision, only those patients with visceral metastases or in very poor general condition being rejected. Radiosensitive tumours (those of the type of basal cell carcinoma) may be submitted to either x or γ radiation, but radio-resistant types (squamous-cell carcinoma or adenocarcinoma) are better treated with radium.

I am indebted to Mr. W. Skyrme Rees for permission to publish this case, and to Dr. W. Whitelaw for the pathological report.

Reviews

THE R.A.M.C. AT WAR

The Army Medical Services: Administration. Volume I. Medical History of the Second World War. By F. A. E. Crew, F.R.S. (Pp. 530. £2 10s.) London: H.M. Stationery Office. 1953.

To give the background to Army medical administration Professor Crew has very rightly delved into history, and in this eminently readable story he presents one of the best pictures of the development of the R.A.M.C. that is to be found.

A complete review of this large volume of 530 pages is impossible in the space available, but among the many highlights one or two stand out, and lessons are there to be learnt if the will to learn from and profit by experience exists in this materialistic world to-day. Students of the fortunes of the senior partner of the three corps which form the medical services will find much of interest. It may surprise them to learn that the arguments for and against the D.G.A.M.S. being a full member of the Army Council are no new thing. In 1904, when a complete reorganization of the structure of the War Office took place, the Army Medical Department ceased to hold its honourable niche in the Army hierarchy and became subordinate to the Adjutant-General's department. Since that time repeated efforts, so far unsuccessful, have been made to restore the *status quo ante*. Many consider that a reorganization, now proved by two world wars, is a real necessity if the universal impact of medicine on the life of the soldier is to be placed in its proper perspective. The story demonstrates that adequate provision of medical manpower has a most marked effect on the potential fighting strength of an army. No doctors, no army, is almost axiomatic. Those now deliberating on the means to preserve the very existence of the R.A.M.C. would do well to ponder before they permit the Corps to sink below the state of even financial restoratives.

War greatly increases the size and complexity of problems which receive but scant attention in peace. Not the least of them is an adequate yet accurate assessment of the physical standards of the civil population called up for service with the armed Forces. The problems of medical classification of both officer and man are presented here in a most interesting manner, culminating in the birth of the Pulheems system but stopping short of the stage where this method of classification was universally adopted for the Army. May we hope that in these times of comparative peace the many advantages of this system can be perfected so that every peg, whether round or square, finds its appropriate lodging-place.

The anonymity of the principal actors in this drama of war is maintained to a greater or lesser degree throughout the book, but surely it is only fair that the D.G.A.M.S., who bore the greater part of the responsibility, should receive open praise and recognition, if for no other reason than the inimitable way in which he kept the peace among and controlled the persistent and insistent demands of the consultants in some twenty specialties. That he did so so successfully—and those consultants are the first to admit that he did—stamps him as a man of outstanding capabilities. His continuous "war" with the powers that be is also well told. The Medical Services were fortunate, indeed, in having a man of his attainments at their head during these anxious years.

In the 1914-18 war the Medical Services strove to ensure that they were given ambulance cars for their exclusive use to transport their wounded, and they won the battle on its merits. We read in this history a vivid story of a similar contest in an air-minded decade for the recognition of the essential facts that casualties must have the advantage of air transport and that air ambulances must be provided for the

exclusive use of the Medical Services. This battle still goes on. May the Air Council read, mark, learn, and inwardly digest this chapter and so realize that the needs of the sick and wounded are of almost equal importance to operational demands in a well-balanced fighting force.

The history is concerned almost entirely with the R.A.M.C. One short chapter on dental manpower is included, but the nursing service, though forming a most important partner in the tripartite service, receives scanty attention. The choice of author was an inspiration. The standard of the presentation of his facts is high, and, as might be expected from one of his reputation, the phrasing is well-nigh perfect.

YOUNG CHILDREN

The Normal Child: Some Problems of the First Three Years and Their Treatment. By Professor Ronald S. Illingworth, M.D., F.R.C.P., D.P.H., D.C.H. (Pp. 342; 64 illustrations. £1 10s.) London: J. and A. Churchill. 1953.

Some years ago the view was expressed in the Goodenough Report that the teaching of paediatrics should "run like a golden thread" throughout the medical curriculum. It can hardly be said that this Utopian ideal has yet been realized, and Professor Illingworth starts with the assumption that the English medical student knows far too little about normal infancy and childhood when he comes to study or treat disease in these age periods. There are clearly various ways in which this deficiency may be made good. Before reaching the clinical years the student may be taught to integrate the physiology of the human infant with that of the mature adult. The special problems of the childhood community may receive particular attention in the teaching of social medicine. Finally a clinical study may be made of the infant and child in health, observing the widening scatter of developmental phases and behaviour which occur with advancing age.

While an understanding of individual variation in infancy and childhood is most necessary to the practitioner advising parents, it is one which is seldom provided for the medical student within the confines of an overcrowded curriculum, no doubt partly owing to the difficulty of making it even tolerably interesting to those who are in the first flush of studying disease. Professor Illingworth is writing primarily for the doctor who finds himself ill-equipped to decide what is normal and what is abnormal, when to offer reassurance, and when to feel concern. The sub-title of this book gives a better idea of its scope than does the title, since he is concerned with the infant up to 3 years of age rather than with the older child, and to a large extent with those "problems" of feeding, behaviour, and development which he himself regards as within the range of normality. Since, however, there is often no clear landmark in that twilight region where a normal universe overlaps with an abnormal, his definitions will be respected as the considered opinion of an experienced clinician rather than as absolute standards.

The book contains much valuable advice, which, although the author has provided abundant references, is clearly based to a large extent on personal experience. Against this experience the observations of other writers have been checked. As is perhaps inevitable in a volume of this compass and purpose, there is a tendency to over-simplification and dogmatism which will not altogether satisfy the more inquiring reader but will prove a comfort to those requiring immediate practical guidance. The influence of Dr. Gesell, with whom the author studied, is clearly seen and fully acknowledged. Although this book should not be regarded as a comprehensive study of the normal infant (since detailed studies of physiology, biochemistry, nutrition, and embryology have been deliberately omitted), it is a valuable addition to the English paediatric literature and should appeal to those concerned with the upbringing and health of infants and young children.

A NEUROSURGEON'S LIFE

Brain Surgeon: The Autobiography of William Sharpe. With foreword by Sir Cecil Wakeley, Bt., President of the Royal College of Surgeons of England. (Pp. 244. 16s.) London: Victor Gollancz. 1953.

Every autobiography necessarily gives a one-sided view of its subject. It would be interesting and instructive if to every such account there were appended a short impartial character sketch of the subject by someone who knew him well.

This reflection comes to mind on perusing this readable book by Dr. William Sharpe, an American neurosurgeon. The story of his life is interesting, and there are few inhibitions in the telling of it, but there are so many other details we should have liked to know. Dr. Sharpe's father was a rigidly orthodox pastor of the Scottish Presbyterian Church who worked all his active life on a very small salary amid the slums of Philadelphia, and was loyally supported by his wife. The three sons had to go to church five times each Sunday, and perhaps it is no wonder that this overdose in youth caused a reaction after they left home. All of them became doctors.

William Sharpe went to Harvard and never had any financial difficulty, for he was a born teacher and earned a very good living by coaching his fellow students. After qualification he studied in Germany, visited Russia and Italy, and returned to America to work for a time under Harvey Cushing, who inspired him to devote his attention to neurosurgery. For a year he worked at the Harvard medical centre at Shanghai, and had the distinction of operating successfully on a son of the President of China. Back in America he had a successful career as a neurosurgeon, taking a special interest in the prevention and early treatment of cerebral spastic paralysis. His enthusiasm for this subject was one of the main reasons for writing this book.

Not everyone will appreciate the sardonic sense of humour betrayed in the incident connected with the necropsy on the author's brother, and it is likely that Presbyterians may heave a sigh when they read of the manner in which the widow of such an orthodox pastor spent her last years. Nevertheless the book holds the interest of the reader to the end.

ZACHARY COPE.

THE RIDDLE OF EXISTENCE

Sinn und Gehalt der Sexuellen Perversionen. By Dr. M. Boss. Second edition. (Pp. 136. 17.50 Swiss francs.) Bern and Stuttgart: Hans Huber. 1953.

It is perhaps regrettable that the younger generation, completely under the spell of analytic-dynamic psychology, has lost sight of the many other approaches to psychopathology. In this book the well-known Swiss author examines the "sense and content of the sexual perversions." He calls his book an "existential-analytical contribution to the phenomenon of love." The existential-analytical school of thought, prevalent chiefly in the German-speaking countries of the Continent, regards the problem of human existence as fundamental. Based on Jaspers', Heidegger's, and L. Binswanger's works and linked with the philosophical movement towards existentialism, it brought a revival of some neglected features of the humanist tradition to psychopathology. It does not debunk or flatter human nature, but recognizes human existence as ever resisting being shackled by any system. The English reader will find a good introduction to this school in R. D. Loewenberg's paper "Jaspers on Psychotherapy" (*Amer. J. Psychother.*, 1951, 5, 502).

In the first part of his book the author examines the two theories which have been put forward to explain fully the immense variety of sexual perversions—namely, Freud's psycho-analysis and the anthropological school of Gelbsattel, Strauss, Kunz, and others. While he appreciates and uses psycho-analytic techniques, he criticizes certain Freudian theories as being "hasty identification based on super-

ficial similarities." He attacks Freud's biological-physical approach and states that the libido theory, and especially the Oedipus and castration complexes, do not go to the heart of the real problem of human love, and that therefore the riddle of human existence escapes Freud. The author rejects as well the anthropological theories pertaining to love and sex. Here he finds unproved and unacceptable the assumption that destructive and aggressive impulses account for perversions.

The second part contains eight case histories of a fetishist, a coprophiliac, a kleptomaniac, an exhibitionist, a sadomasochist, and three homosexuals. These case histories are excellently written, and show the author's great power of insight. In all of them he shows how the capacity of "being in the world lovingly" (*liebend in der Welt sein*)—a basic feature of human existence—becomes partly disturbed or totally lost. All perversions mean but frantic attempts to express love in spite of all limitations of this capacity. Here he meets Freud, who said once: "The omnipotence of love is perhaps never more strongly proved than in its aberrations."

In spite of some objections which the reader may raise against a rather nebulous terminology, the book is well worth studying as a challenge to our own basic assumptions and a stimulus to reviewing our own work.

T. A. WERNER.

ASSORTED MONOGRAPHS

Monographs in Medicine, Series 1. Editor: Professor W. B. Bean, M.D., Associate editors: M. Hamburger, M.D., J. A. Leutscher, jun., M.D., and Professor S. Wolf, M.D. (Pp. 655; 21 plates, 21 line drawings. 91s. 6d.) Baillière, Tindall and Cox. 1953.

This books adds another to the annual collections of lectures or monographs on medicine. This field, in which that admirable quarterly *Medicine* reigned in unique splendour for a generation, has now been invaded by a number of competitors. Presumably the public for such books has been increased by the upgrading of hospitals throughout the western world and the increasing numbers of people who are interested in medicine as a specialty. Professor Bean, the editor of the present volume, thinks that "medical progress is not delayed by taking time out to survey the scene from the medium hills, neither staying on the flats of day-by-day affairs, nor climbing the high mountain for the grand and inclusive spectacle." He and his team have provided fifteen monographs averaging about 40 pages each. They vary from such subjects as "Talking with the Patient," which has eight references, to "The Seasonal, Arthropod-borne, Virus Encephalitides," which has 146; "Sickle-Cell Anaemia" has 481 references.

Most of these monographs are admirably written, but they are hard reading, just because of the anxiety to mention all recent work. It is high time an enterprising psychologist discovered how much of importance is remembered per hour spent in reading medical literature of different kinds. If the weekly and monthly journals correspond with the newspaper, then these annual volumes correspond with the magazine, which is possibly not the best instrument of education. A friend said of a bachelor colleague, "He goes home and reads all night, but he remembers little of what he has read because he has not got a special interest to which to attach it." One cannot help feeling that an annual volume of this kind encourages disconnected reading, which is not well remembered.

L. J. WITTS.

The last complete revision of Lewis's Library Catalogue, which covered books up to the end of 1949, was noted in the *Journal* (June 16, 1951, p. 1370). A supplement listing books added to the library during the years 1950-2 has now been published, bringing this useful reference book closer to the present. Over 6,000 new books or new editions are given under both author and subject entries. The supplement may be obtained from H. K. Lewis and Co. Ltd., 136, Gower Street, London, W.C.1, price 6s. (3s. to subscribers to the library).

SATURDAY AUGUST 8 1953

GENETICS AND CLINICAL RESEARCH

Human genetics was once said to be a harmless occupation pursued by doctors who knew no genetics or by geneticists who knew no medicine. While the taunt was never altogether justified, some writings by medical men and geneticists have lent it a certain sting. For the different parties are usually interested in different things. The pure geneticist is concerned with such matters as the mapping of human chromosomes, and he studies serological characters or diseases with good Mendelian ratios; and these diseases rarely come the way of the general physician. But formal genetics is only part of a much wider field, and, since the techniques of the laboratory worker cannot be transferred directly to clinical research, other methods have had to be devised. Among these is the study of twins. It has certain limitations, perhaps the chief being the rarity of twins. In studying such a common disease as acute rheumatism, for example, a very large population has to be surveyed, for under 1% of the patients are likely to be one of a pair of twins, and of these about a quarter will be monozygotic and the remainder dizygotic. Though it is desirable to carry out more systematic studies of twins, there is plenty of scope for other and less complex investigations. It is important to know, for instance, whether a disease appears more frequently in certain families than in others. Some recent work illustrates the kind of methods that may be used in clinical medicine to study such a problem.

The pathogenesis of atherosclerosis is debatable, but few would deny that sometimes a disturbed lipid metabolism is of importance.¹ It has long been known that families in which xanthomatosis occurs also show a high incidence of coronary disease, and this has led Adlersberg and his colleagues to a genetic study of coronary disease in general. Adlersberg, Parets, and Boas² made a study of families with

xanthomatosis and of a certain number of patients who did not come from such families but who had contracted coronary disease before the age of 50. In a later study Adlersberg and Boas³ studied the families of patients who had suffered from coronary disease after the age of 60. In all these the serum cholesterol of patients was compared with that of such close relatives as were available.

The genetical deductions made from the first of these studies are faulty in various ways. The writers maintain that "hypercholesterolaemia" is determined by a partially dominant gene which gives rise to xanthomatosis when homozygous. There is no evidence to support this. If it were so, one would expect a high incidence of cousin marriages among the parents of such families, which the authors state is not the case. Discussing the families of the patients with coronary disease before the age of 50, these writers also claim that hypercholesterolaemia shows Mendelian segregation to give a close approximation to a 1:1 ratio. This again is unjustified. They classify a person as hypercholesterolaemic if the serum cholesterol is over 300 mg. per 100 ml. as estimated by Bloor's method. But this is arbitrary. While it is convenient for general clinical use to have some upper limit of normal, it should not be used as a method of classification in genetical work unless it can be shown that people fall sharply into two groups, say one in which the value is never over 200 mg. per 100 ml. and another in which it is never less than 300 mg. In the later study of Boas and Adlersberg the data are of more use; a graph shows the distribution of the serum cholesterol in patients and their sibs, the values ranging from about 150 mg. to over 400 mg. per 100 ml. Both groups show much the same type of distribution, with the mode (that is, the most frequent class) being between 250 and 280 mg. per 100 ml. Analysis of such data is admittedly difficult, partly because age must be allowed for. The population studied consisted largely of Jewish people. It is possible (as the authors seem to believe) that a gene favouring a high serum cholesterol is common in this community, but it has not been demonstrated. It is necessary to know the frequency distribution of the serum cholesterol for this particular population before one can be sure that high values do show an undue concentration in certain families. Even if it is finally demonstrated that there is a significantly high correlation between sibs, there remains the question of interpretation. The investigator must bear in mind that families and larger communities often share dietary habits as well as genes.

Cancer has been extensively studied genetically both in the laboratory and clinically, and some of

AUG. 8, 1953

the clinical studies are indeed open to the criticism that they show little knowledge of genetics. If there is one generalization about malignancy that is acceptable it is that "cancer" is not a single disease. This is shown nowhere better than in cancer of the uterus. Cancer of the cervix is associated with a high fertility and a low standard of living, while precisely the reverse is true for growths of the fundus. Murphy⁴ has conducted an investigation in America of the families of patients with carcinoma of the cervix, while Brøbeck⁵ in Denmark has done similar studies on cancer of both cervix and fundus. Murphy compared the families of patients with a control group; Brøbeck used both a control group and the statistics of the Danish Cancer Registry. The proper selection of a control group is a thorny problem, and it is desirable wherever possible to have other confirmatory evidence as well. For this reason Brøbeck's results are the more convincing. Both were handicapped by the fact that death certificates often failed to state which part of the uterus was primarily affected. The results of the two workers differ somewhat, but not to a degree that amounts to contradiction. It would appear that there is a slight but definite tendency for cancer of the uterus to be more frequent in the female relatives of patients with carcinoma of the cervix; Murphy found this to be most striking in the case of mothers and aunts, while Brøbeck found it in the case of sisters. Another interesting finding by the latter author was that an unusually high proportion of the fathers of his patients had carcinoma of the oesophagus. Growths at both these sites show the same social distribution, and it is quite likely that the results are due to some environmental factor common to the families affected.

As to carcinoma of the corpus uteri, Brøbeck found a significant increase in cancer of various sites in the families of these patients. He is inclined to invoke the existence of a general cancer gene to explain this. A similar conclusion was reached in Denmark by Jacobsen⁶ when studying cancer of the breast. There are reasons for treating this with some reserve. Penrose, Mackenzie, and Karn,⁷ working in Britain, confirmed Jacobsen's finding—and that of most workers in this field—that cancer of the breast does show a significant concentration in certain families, but they did not find any significant increase in other forms of malignant disease. We are faced with a direct contradiction in which it is not possible to point to any obvious fault on either side, and here twin studies may prove to be of great value. Once again Danish workers are to the fore. Busk, Clemmesen, and Nielson⁸ have surveyed over 30,000 cancer patients and obtained 184 useful twin pairs. We shall have

to wait many years before a final judgment can be made, since many of the pairs have been observed for only a short time, but as things stand now their evidence is against some general cancer gene being common in Denmark.

The work of such investigations as these may give the impression that only a large organization can obtain valuable results in human genetics. Often this is true, but by no means always. Nor is it true that an intimate knowledge of statistics is required. McFeeters,⁹ one of those doctors who has found in general practice the opportunity to do some research, published a most interesting survey of the distribution of certain pathological conditions in an isolated rural community. This sort of work is of great potential value. In obtaining the results sound clinical sense and skill in handling people are the prime assets; some knowledge of genetics is needed, but advice can always be obtained. The results have to be assessed statistically, but the final biological assessment is another matter. The worker should beware of fitting results to some Mendelian scheme without due thought. The discovery of some non-genetic factor common to certain family groups may be of much greater value than the announcement of a new gene.

SHORTAGE OF HOSPITAL RESIDENTS

Many hospitals, particularly in areas remote from the teaching centres, are complaining of the difficulty of obtaining applicants for the posts of house-officer, senior house-officer, and registrar. In Parliament the other day the Minister of Health said that he was considering how this problem could be solved. It will not be an easy task. The number of recognized pre-registration house appointments is larger than the six-monthly output of qualified men from all the medical schools, yet many hospital management committees have protested that their allowance of pre-registration posts is far below their requirements. In the United States also there are more internships than young doctors to fill the posts, and a number of official bodies, including the Council on Medical Education and Hospitals of the American Medical Association, have set up a National Intern Matching Program, Inc. This bureau receives information from students about the several internships they have applied for and from the hospitals about students whose applications they would like to accept, transfers the details to punched cards, and uses machines to do the actual matching between students and hospitals. The arrangements made by the machines are said to work satisfactorily.

⁷ *Brit. J. Cancer*, 1948, 2, 168.

⁸ *Ibid.*, 1948, 2, 156.

⁹ *British Medical Journal*, 1939, 1, 218.

In attempting to give the best possible service hospital authorities should bear in mind the benefits likely to accrue to the patient if history-taking and the preliminary examinations are carried out by a senior member of the staff. Therefore the shortage of house-officers would not be an unmixed evil if compensated by more generous staffing at the consultant, senior hospital medical officer, and senior registrar levels. Despite the great expansion of hospital specialist staff since 1948 there is still need for increase in the number of consultants and, in the appropriate specialties, senior hospital medical officers.

Some hospitals have tried to get over their difficulties by arranging for general practitioners, on a rota system of duty, to take on the work which normally falls to house-officers and registrars. Such schemes are of only limited value. General practitioners can be given a much wider field of hospital work as clinical assistants, with duties more akin to those of senior registrars, in association with the consultant staff. It need not be more than a step from this to the employment in hospitals on a sessional basis of suitably qualified general practitioners in the specialty of their choice. There would be more encouragement for ex-senior registrars to go into general practice if the prospects of obtaining sessional work in hospitals were brighter than they are now.

In the past two years the hospital service has been discredited as a bountiful source of consultant posts for existing senior registrars and for new entrants to the registrar group. If doctors of senior house-officer and registrar status are to be recruited and retained in greater numbers they must have reason to feel that they are improving their personal fitness for general practice and their prospects of obtaining an opening in general practice. They must also feel that while working in hospital they are not being exploited as cheap labour. An additional year or two in well-chosen resident hospital appointments, with perhaps an M.D. degree acquired in that time, ought to be a strong recommendation on behalf of an applicant for an assistantship with view to partnership in general practice. It is doubtful whether it works that way at present. In the interests of general practice, at least as much as in the interests of the hospital service, this doubt should be removed from the minds of young doctors.

The hospital service must face the fact that the present rates of pay for senior house-officers and registrars are not high enough to attract and retain

for three years or so doctors whose ultimate aim is general practice. The young doctors who should be applying for these hospital posts will have spent a year in pre-registration house jobs and then two years in the Services in addition to their six-year medical course. Besides, the duties of experienced hospital residents are arduous and carry what seems to be an increasing risk of legal actions—a point emphasized by Mr. W. Gissane¹ in a recent letter. A possible improvement which the hospitals should consider is the provision of flats or small houses for young married doctors. Those management committees whose advertisements carry the promise of such accommodation are seldom short of suitable applicants. The suggestion has been made that a new grade of senior house-officer might be established for those waiting to enter general practice. The salary would be the same as that of an assistant, and of course suitable living accommodation for married men would have to be provided. With such an arrangement as this some young doctors might be prepared to extend their period of hospital work by two or three years. Incidentally, the holders of these posts would avoid the stigma of "failed specialist" which tends to be attached to registrars and senior registrars when they attempt to transfer to general practice. A more drastic change has recently been proposed by Mr. N. J. Logie,² who suggests that a joint hospital and general-practice appointment might replace both the trainee assistant scheme and first-year registrar posts. But probably the quickest way to obtain an increase in senior house-officers would be for the armed Services to permit deferment of call-up for a year after the pre-registration year. This might cause embarrassment to the Forces for a time, but once that period was over they would obtain just as many, and more experienced, doctors, some holding higher qualifications.

NEONATAL ASPHYXIA

There are many reasons why a baby may be reluctant to breathe adequately at birth. They include central depression caused by intrauterine anoxia, narcotic drugs, raised intracranial pressure, or prematurity, and it is more appropriate to consider the morbid condition present than to hope for any universal remedy. A wider appreciation of this has led to the abandonment of older methods of stimulation which were little better than punitive, and traditional types of artificial respiration are now regarded as ineffectual and often mischievous.

The baby cannot oxygenate its vital centres and therefore remain alive unless its airway is clear and its blood circulation and respiratory movements are adequate. The first essential is therefore to remove foreign material

by suction from mouth, nostrils, and pharynx at the earliest possible moment, and preferably before the first inspiratory gasp has sucked it out of reach. Bronchoscopy in these circumstances may be too late to be effective, since the source of the child's continuing atelectasis may already lie too deep for removal by mechanical means. The aspiration of regurgitated stomach contents is particularly apt to occur in premature babies and after caesarean section.¹ In these cases there should be no hesitation in passing a fine rubber catheter down the oesophagus and emptying the stomach by suction. The vigorous baby with an active cough reflex is well able to protect itself from this risk, but prematurity, narcosis, foetal shock, or serious asphyxia may diminish coughing and add peril to respiratory efforts already handicapped.

The shocked baby is toneless and breathes with intermittent gasps. Tracheal intubation is particularly beneficial here, and it is facilitated by the flaccid state of the baby. It ensures an effective airway, and the trachea can be aspirated and oxygen supplied at intermittent positive pressure of 25 cm. of water.² The purpose of this is not so much to blast open the collapsed alveoli as to flood the bronchial tree with oxygen, which is then available during the smallest inspiratory effort. Foetal shock (or white asphyxia, to give it the older and less adequate name) demands gentle handling, so that the baby is disturbed as little as possible and heat loss is kept to a minimum. Such cases are often injudiciously overtreated. Oxygen is the first need in asphyxia; of carbon dioxide there is already more than enough. But no atmosphere will count for much if the baby is incapable of breathing it. In the absence of vigorous respiration the oxygen deficit can be partially made good by absorption from the gastro-intestinal tract,³ and the supply of a very gentle trickle of oxygen through a fine polythene tube passed into the stomach often helps to tide a baby over the immediate crisis of asphyxia. The use of Eve's rocking method⁴ of artificial respiration or a mechanical rocker of the Roberts-Talley type⁵ disturbs the child very little and encourages circulation by increasing venous return to the heart.

Where narcosis is to blame—for example, from morphine recently given to the mother in labour—the effects can to some extent be countered by the intravenous use of N-allyl normorphine. Nikethamide, too, will often rouse a narcotized infant to respiratory activity, but it may do more harm than good when shock is present.

Bloxson's positive pressure oxygen-air lock⁶ is now popular in the United States. In it the whole baby is subjected to alternating positive pressure ranging every forty seconds or so between 1 and 3 lb. per square inch (0.07–0.21 kg. per sq. cm.) in the belief that these conditions reproduce the pressures of the second stage of labour, that a continuation of these circumstances is desirable, that bronchial drainage is improved, and that

oxygen absorption is increased, to mention a few claims. But these arguments have not been wholly supported by analysis,⁷ though the child in such an apparatus is at least safe from meddlesome interference and is left at peace to enjoy warmth and an atmosphere rich in oxygen. The phrenic-nerve stimulator, introduced by Cross⁸ is a more active line of treatment, and operates by supplying an electrical stimulus over the point of stimulation of the phrenic nerve in the neck. Further reports of its usefulness are awaited.

When atelectasis persists, especially in premature infants, the condition of the child, though initially fairly good, is liable to deteriorate in the course of several hours, and hyaline membrane, intraventricular haemorrhage, or a combination of both take their toll. Hyaline membrane is now becoming increasingly recognized in association with neonatal atelectasis. It consists of acidophile material which, on microscopy, is found plastered round the walls of the alveolar ducts, causing secondary resorption with non-aeration. Its origin is still disputed, and death from asphyxia and atelectasis usually occurs within the first three days of life. Various types of respirator to work in cycles determined by the baby's own irregular respiration are being developed by Donald⁹ in order to help in expanding atelectatic lung by augmenting spontaneous respiratory effort, but further development and simplification in practical handling are required.

There is no surer guarantee of healthy respiration in the newborn than full-time normal delivery, and the science of obstetrics has still far to go in meeting the hazards that delivery and premature labour hold for the foetus. Here lies a rich field in prophylaxis. The emergency of neonatal asphyxia is all too common, but research into its prevention and treatment is gathering momentum. In the meantime treatment must still rely mainly on rest, warmth, oxygen, and a clear airway in the comforting knowledge that a baby that has a chance to breathe will usually take it.

SURGERY FOR CORONARY DISEASE

Surgery to-day plays a limited part in the treatment of coronary artery disease. Two principles are invoked. First, as a palliative procedure the afferent visceral nerves carrying impulses from the heart may be destroyed to relieve the pain of angina. This is most surely done by bilateral excision of the upper four thoracic sympathetic ganglia. Although pain is then absent, some sensation as of tightness or choking is still felt on exertion, so that the warning signal is not entirely lost. Secondly, an attempt may be made to increase the blood supply of the myocardium to prevent ischaemia. Coronary arteriosclerosis is often far advanced when arteries elsewhere are scarcely affected. Such patients should be ideal subjects for surgical revascularization. Unfortunately a reliable method has not yet been established, so few patients have been treated by operation. Much experimental work has been carried out, mostly by operations on dogs, who can be protected from the effects of ligature of a

coronary artery by various preliminary manoeuvres. Since the initial work of O'Shaughnessy¹ in Britain, who showed that suture of the omentum to the surface of the heart was an effective method, most reports have come from the U.S.A. The simplest of the techniques attempted is the injection of an irritant substance into the pericardial sac to promote vascular adhesions between the parietal layer and the surface of the heart. Beck,² whose experience is the widest, recommended finely powdered asbestos. This method can be combined with other manoeuvres. Various organs and tissues have been applied to the epicardium, such as lung or muscle; vascular communications can be demonstrated, but their value is equivocal. Attempts have been made at the direct anastomosis of an artery, such as the internal mammary, to one of the coronary arteries; technical difficulties are great. Success has been reported after implantation of this vessel into the myocardium. Ligature of the great cardiac vein was advised by Fauteux.³ And Professor Charles Rob, in an article at p. 308 of this *Journal*, discusses the possibility of restoring the blood flow by means of grafting in new blood vessels.

A new approach has recently been reported by Bailey and others,⁴ who were continuing work initiated by Beck. Arterial blood is supplied through the coronary sinus. The capillaries of the myocardium of the left ventricle are conceived as in communication with the branches of three sets of vessels—the coronary arteries, the coronary sinus system, and the deep myocardial veins, the latter normally draining 40% of the deoxygenated blood. The coronary sinus tributaries are considerably more numerous than those of the coronary artery. The coronary sinus system communicates with veins of the other chambers of the heart, and with veins opening into the right atrium—these collaterals forming a safety-valve mechanism after arterialization, while the blood which has passed through the capillaries can drain by the deep myocardial veins system. Arterial blood is supplied to the coronary sinus by a free vein graft the other end of which is anastomosed to the aorta. After an interval, the atrial end of the sinus is narrowed by partial ligation. When this procedure has been successfully carried out in dogs, the blood flow from the distal end of a divided coronary artery, measured directly, is greatly increased compared with a normal dog; this increase is reduced by clamping the graft. Bailey and his colleagues report the results of this operation in eighteen human patients; two died, and in seven the graft remained patent. These were all improved.

It is difficult to assess results of treatment of coronary disease, first because its natural course is extremely variable, and secondly because, except for subsequent myocardial infarcts, assessment must be founded on subjective evidence. These provisos must be remembered in evaluating any procedure. A sound basis can be established only by the observation of large numbers of patients for long periods, and so far there have been no opportunities.

SUN ON THE SKIN

Sensitivity of the skin to light is so common that sunburn is accepted as almost normal by people taking holidays in the middle of the summer, even in the United Kingdom. For most people the full summer sun is necessary to cause sunburn, but people with an abnormal hypersensitivity to light may suffer symptoms from about May onwards in this country. The skin of normal people is damaged only by the invisible rays of wavelength below about 3170 Å, and in natural sunlight the ultra-violet band around 2900 to 3170 Å is the part of the spectrum responsible. Shorter wavelengths produced by the mercury vapour lamp also damage the skin, but are not to be found in natural sunlight. Light in the visible range and in the infra-red may give rise to skin reactions, but not in normal people.

The type of response in the skin varies a good deal. The familiar common sunburn starts as a simple erythema with oedema of the surface, and may proceed to vesiculation. When abnormal sensitivity is present the reaction may be one of simple urticaria or of vesiculation and blister formation. Less often appears the papular excoriated polymorphic light eruption which may be associated with abnormalities of porphyrin metabolism.

The position of xeroderma pigmentosum in the general classification of light sensitivity remains uncertain. Although the eruption is strictly limited to areas exposed to light, sensitivity to ultra-violet cannot be demonstrated by simple testing, and the changes produced are those of chronic light dermatitis without the acute or subacute phase. The peculiar sensitivity of the skin in lupus erythematosus has also never been explained. It is an important feature, accounting for the seasonal variations in that disease and sometimes apparently being responsible for converting the chronic form into the acute disseminated and malignant variety.

It has long been known that porphyria, whether natural or produced experimentally, is likely to be accompanied by sensitivity to light. Porphyrinuria¹ is not constantly present, and an examination of the stools is sometimes necessary in order to demonstrate abnormalities in porphyrin metabolism. Certain drugs may increase sensitivity to light, the most common being the sulphonamides. A few years ago, when sulphonamide contact dermatitis was more common, light sensitivity was often found too. The skin usually returns to normal as the dermatitis clears up, but occasionally light sensitivity has persisted for many years after all signs of sulphonamide dermatitis have disappeared. The reason for this is obscure.

Far more common in ordinary practice is the development of light sensitivity from local applications to the skin. The term "phyto-photo-dermatitis" introduced by Klaber² covers all those states in which sensitivity

THE SWEET TOOTH

The belief is widespread that an excessive consumption of readily fermentable carbohydrates, particularly in the form of sweets, is an important cause of dental caries. Yet in several of the investigations made in the past no increase in caries rates has been recorded when additional sweets have been given to children living in institutions. In an attempt to evaluate the part played by fermentable carbohydrates in dental caries, the Swedish Government and the Swedish Dental Institute organized a long-term investigation at Vipeholm Hospital, Lund, in 1945. This hospital houses about 1,000 patients suffering from mental deficiency or other ailments. Reports on some of these studies, with thorough statistical analyses, have now been published.^{1,2} Sugar was added to the basic diet of different groups of patients in the following ways: (1) dissolved in beverages and semi-fluid foods, (2) baked in bread, (3) plain chocolate, (4) 8-9 toffees daily, (5) 24 toffees daily, (6) 22 pieces of caramel daily. In groups 3, 4, 5, and 6 the supplements were given between meals. In a control group fats were substituted for the fermentable carbohydrates to compensate for loss in calories. The highest caries experience occurred in the group taking 24 toffees daily; these patients showed an average of 4.02 new carious tooth surfaces per person per year. The controls showed the lowest increase, with 0.30 carious surfaces. The caries experience of the beverage group did not differ much from the control, and the groups receiving daily 8-9 toffees and 22 pieces of caramel respectively did not differ notably from the group on 24 toffees. Caries in the chocolate and the bread groups was intermediate, but was considerably less than in the toffee groups.

As another part of this investigation samples of saliva were taken from these patients at 15-minute intervals during the day, and analysed quantitatively for sugar. From a correlation of these findings and the caries experience the following were among the conclusions drawn: first, sugar in the form of sticky sweets consumed between meals causes a marked increase in the number of new carious cavities; secondly, sugar taken with meals is not so deleterious; and, thirdly, chocolate appears to be less apt to produce caries than toffees.

All the same, individuals varied greatly in these tests. Some could consume sweets between meals over long periods without an increase in caries, while others deprived of sweets and consuming little sugar in their food developed many new cavities. It is clear that there must be other factors in the causation of dental caries, but there seems to be good evidence that the frequent eating of sticky sweets between meals is of primary importance as a cause of caries in many people. These studies also showed that thoroughly rinsing the mouth with water, which was then swallowed, immediately after eating sweets or after meals would greatly reduce the concentration of sugar in the mouth. This would seem a practical method of caries control for parents to teach their children when they are not prepared to ban the eating of sweets between meals.

of the skin results from contact with plants or from their juices. More than a hundred plants have been named as possessing this quality; some of them, such as the milky juice of the fig, will sensitize regularly most normal subjects on the area of skin to which they are applied. With others there seems to be an element of personal idiosyncrasy or sensitivity. This appears to be the case with Berloque dermatitis. It must surely be fairly common for people who have applied eau de Cologne to the skin to expose that area to sunlight a few hours afterwards; and yet Berloque dermatitis, which results from this sequence of events, is quite uncommon. The same may be said of that form of cheilitis which results from light sensitization of the mucous membrane of the lip by eosin. Under experimental conditions some proprietary face creams can be shown to heighten the sensitivity of the skin to light in most normal subjects. The degree of sensitization thus induced is slight and does not appear to cause trouble. But perhaps the melanosis of the face and neck seen in some women is traceable to such a cause. It has long been suspected that this melanosis was in some way connected with the application of face creams.

It is not easy to increase tolerance to light by systemic treatment. Taking mepacrine by the mouth allows an increase in the dose of ultra-violet light needed to cause erythema, and possibly the beneficial effect of mepacrine in lupus erythematosus is brought about, at least in part, by this mechanism. According to Eder³ the administration of large doses of iron to infants increases their tolerance of natural sunlight and enables the skin to pigment evenly without burning. He attributes this to an increase in the concentration of iron in the tissues. And it is well known that the presence of haemosiderin in the skin will favour melanin pigmentation. This is seen in varicose dermatitis and in haemochromatosis, and arises presumably because the metal attracts sulphhydryl groups and liberates tyrosinase.

It is far easier to protect the skin with local applications. The normal skin may be protected from ultra-violet light with a variety of invisible substances, and 5% of tannic acid in vanishing cream is probably as good as anything.⁴ Para-aminobenzoic acid is also remarkably effective, but may perhaps be more apt to produce epidermal sensitization. In an interesting survey of the whole subject of light sensitivity, Kesten and Slatkin⁵ give the results of examining some light-screening lotions and creams which are on the market. It is encouraging to learn that most of them have a good light-screening effect, at least up to five times the ordinary erythema dose. In abnormal light sensitivity when visible wavelengths must be screened the problem is more difficult, and the best results are probably obtained by opaque applications, which must then be carefully tinted so as not to be conspicuous in use. The cream devised by Smithers and Wood⁶ for use in xeroderma pigmentosum is of this kind, and serves the double function of protecting the skin from light and at the same time concealing much of the disfigurement of the disease.

REFRESHER COURSE FOR GENERAL PRACTITIONERS

CORTISONE AND A.C.T.H.—II

BY

C. L. COPE, D.M., F.R.C.P.

Physician, Postgraduate Medical School of London

Both cortisone and A.C.T.H. are scarce, and demand is likely greatly to exceed supply for a number of years. It will not be possible, nor indeed is it desirable, to use the drugs indiscriminately, and one of the main problems confronting the physician therefore will be how to use a limited allocation to the best effect. The diseases for which the drugs have been used with success are many, but some stand out as having a much stronger claim than others; the conditions considered below all deserve high priority. The strongest indication for cortisone or A.C.T.H. therapy is for replacement in conditions where the endogenous adrenal or pituitary hormone is inadequate.

If the adrenals are absent or diseased then A.C.T.H. will have no target organ on which to act and so will prove useless. The most compelling reason for cortisone therapy therefore is after bilateral total adrenalectomy, an operation sometimes employed experimentally for the treatment of certain inoperable neoplasms and for severe hypertension. These cases should be handled only by experts, and the operation should never be carried out unless cortisone is available for maintenance.

Addison's Disease and Hypopituitarism

Both Addison's disease and hypopituitarism are conditions in which the indications for cortisone therapy are strong. Patients with Addison's disease are not always well controlled by salt and D.C.A. Some of them remain in a mildly subnormal state and others suffer from symptoms due to an abnormal tendency to develop hypoglycaemia. Both these states can be much improved by small daily doses of cortisone, 25 mg. orally each day usually being adequate for maintenance. Patients with hypopituitarism, especially those chronic cases due to post-partum necrosis of the anterior pituitary lobe, are greatly benefited by testosterone therapy, but even with such treatment they often continue to suffer from hypoglycaemic symptoms and even coma; in these patients there may also be transient attacks of coma not clearly related to a low blood sugar. Both these symptoms are considerably alleviated by a small daily dose of cortisone; usually 12.5 mg. twice a day is sufficient. In both diseases ability to withstand the stress of operation or infection is much impaired: during fevers, such as influenza or pneumonia, it is desirable to increase the dosage to 100 mg. daily, and before and after major operations a daily dose of 200 mg. is of the greatest value.

In the acute emergency of an Addisonian crisis parenteral and oral cortisone are also of very great value, and ideally all patients with Addison's disease should carry with them an emergency pack of cortisone tablets for use when subjected to unforeseen stress.

In the substitution therapy of hypopituitarism oral cortisone is greatly to be preferred to A.C.T.H., as the frequent injections of the latter are a heavy burden to the patient. In Addison's disease A.C.T.H. is not indicated, since the adrenal glands are only sluggishly responsive, or even completely resistant, to the stimulus of the A.C.T.H.

The extra benefit bestowed by regular cortisone in either of these diseases may be undramatic if hypoglycaemic symptoms are not present. But cortisone is likely to increase efficiency and to enable the patient to carry out his job

more satisfactorily—a very important matter. All established cases should have access to the drug, and theirs should be a priority claim when supplies are restricted.

Rheumatoid Arthritis

So much publicity has been given to the effects of cortisone and A.C.T.H. in rheumatoid arthritis, and so impressive is the prompt response, that popular clamour for the use of the drugs is strong. Most cases of rheumatoid arthritis will respond, though in very varying degree. The main exceptions are advanced cases with severe contractures and with burnt-out inflammation. Pain, joint tenderness, and stiffness diminish early; periarticular swelling and inflammation diminish in more variable degree and more slowly. There is renewed optimism and improved sense of well being and appetite. If any fever has been present, it will be reduced or abolished. The erythrocyte sedimentation rate starts to fall and may return completely to normal. The persistent and resistant anaemia, so frequent in rheumatoid arthritis, is improved. The general mobility and agility of the patient is much increased, the extent of this benefit being largely determined by the state of the disease process in the various joints.

With such great benefit to be expected in a majority of cases it is clear that the case for cortisone is strong. Yet great caution must be observed in exhibiting the drug. The curiosity of physician and patient to see the effect is not alone sufficient reason. Most patients in the chronic stages of rheumatoid arthritis have become fairly well adjusted to their own degree of disability. If now a drug is given which produces a dramatic alleviation of their symptoms, and if later this drug has to be stopped because of shortage of supply, then the patient will be precipitated into a state of acute disappointment and dissatisfaction. To start a patient with established rheumatoid arthritis on a course of A.C.T.H. or cortisone thus imposes a very heavy responsibility on the physician so doing. He must either see his way clear to obtaining steady supplies of the drug for an indefinite period for his patient, or must most carefully warn him that, owing to shortage of supply, whatever effect the drug may have can only be temporary. If such warning is not given, more harm than good is often done by a short course of the drug.

Although supplies are steadily increasing, they are likely to remain far below demand for some years to come. It is desirable, therefore, for physicians to develop a plan of action in relation to the drug. As a general guiding principle it is suggested that highest priority should be given to those sufferers from rheumatoid arthritis who are bread-winners and who can be improved sufficiently to continue remunerative work by cortisone maintenance therapy, but who are unable to work without it. Similarly of high priority are those housewives who can be raised from invalidism to usefulness and who have several children to look after. In both these groups a trial course is justified, but the nature of the trial should be carefully explained to the patient. Each case must be considered on its merits. While supplies remain scarce, the continued use of cortisone cannot readily be justified in those who, even with it, remain bedridden or severely disabled.

In some other circumstances there will be a strong case for the drug. Thus a rapidly progressive and disabling attack of rheumatoid arthritis, if resistant to other measures, is a strong indication for cortisone. Investigation is also

being made into the use of cortisone therapy as a temporary cover during remedial orthopaedic procedures, but no final conclusions on its value have yet been reached.

With A.C.T.H. initial daily dosage should be 80 to 100 mg. divided in four six-hourly doses, or one single injection of 40 mg. of gel. Larger doses may occasionally be needed. When remission is obtained, dosage is gradually lowered to the lowest figure that will maintain useful control of the disease, often 10 to 30 mg. daily.

With cortisone, the daily initial dose should be 200 mg. This may usually be lowered after a few days to 100 mg. Either injections or oral tablets may be used. Here also dosage is reduced to the minimum that will exert effective control. A daily maintenance dose of 75 mg. is an average need.

Acute Rheumatic Fever

The suppressive effect of cortisone or A.C.T.H. on acute rheumatic fever is equally dramatic. Within a day or two temperature will often have fallen to normal and malaise have been abolished. Tender and swollen joints will become practically normal and the general condition of the patient will be greatly improved. The classical manifestations of activity of the rheumatic process are suppressed, often almost completely.

The two major dangers in rheumatic fever are immediate heart failure and permanent valvular and myocardial damage. Heart failure often responds well, the good effect on the myocardium outweighing the less important tendency to increased sodium retention; but traditional methods of treatment such as salt restriction and mercurials should not be omitted. Heart size may diminish and the P-R interval on the electrocardiogram shorten. The action is, however, apparently purely suppressive, and relapse will often occur on stopping therapy, unless in the meantime the disease has burned itself out spontaneously. Greatest interest naturally centres round the possible value of early cortisone or A.C.T.H. therapy in preventing valvular damage. Unfortunately it is not yet possible to state with certainty that such protection is achieved. Nevertheless, acute rheumatic fever patients should get the benefit of the doubt whenever supplies permit. For full effect, treatment should be prompt and in full dosage. The starting dose should be 200 mg. daily of cortisone or 100 mg. of A.C.T.H. (preferably as the gel). After a week or two this dosage may be gradually reduced to a maintenance figure of 100 mg. daily of cortisone or 25 to 40 mg. of A.C.T.H. This will usually need to be continued for four to six weeks or until on further reduction there is no sign of recurrence of activity. Proportionately smaller doses may be given to children. In the more chronic cases of rheumatic fever the results of therapy are much less impressive, as so much damage has already been done.

Disseminated Lupus Erythematosus and Some Other Collagen Diseases

Disseminated lupus erythematosus is one of the so-called collagen diseases and responds well to A.C.T.H. or cortisone therapy. Suppression of activity can usually be achieved, with relief of most of the symptoms. Like acute rheumatic fever, the best results are obtained with early treatment. The main difficulty is that of sufficiently early diagnosis; it is desirable that the characteristic L.E. cells should have been found in blood or bone marrow. Therapy may be expected to abolish the fever, joint symptoms, and skin manifestations more slowly, and to hasten resolution of pleural or pericardial effusions. Renal abnormalities, however, are not affected, and it is generally held that, when renal damage is severe, treatment is less satisfactory. The sedimentation rate falls, but anaemia may persist. Remission of symptoms of sufficient degree to maintain patients ambulant and even at work for very many months may be expected in a high proportion of early cases, but relapse often follows promptly on cessation of therapy. The diagnostic L.E. cells do not disappear on A.C.T.H. or cortisone therapy, and treatment must be continued for

long periods. In late cases the rapid downhill course is not significantly prevented by A.C.T.H. Associated bacterial infection should be treated with antibiotics.

In *periarteritis nodosa* the activity of the lesions can be reduced, but the general course of the disease is not much benefited. Some degree of remission will often occur in early cases, but in more advanced cases with severe cardiac or renal damage no benefit can be expected, and the metabolic changes produced by treatment with A.C.T.H. or cortisone may actually be harmful.

In *scleroderma* the benefit is usually slight. By the time the disease is diagnosed much collagen will usually have been laid down, and this will not be affected by the hormone therapy. In very early cases some remission may occur.

In *temporal arteritis* the pain and tenderness in affected arteries can be reduced, but, if vision has been lost, this is not likely to be restored.

In *dermato-myositis*, also, the main effect is to reduce pain and oedema, a purely symptomatic improvement.

Asthma and Allergic States

Status asthmaticus is an acute emergency. It may completely fail to respond to adrenaline and other adrenergic drugs, and may terminate fatally in two or three days. Viscid plugs of mucus too thick to be coughed out play a big part in the lung failure. In such patients prompt use of A.C.T.H. may have a dramatic, even life-saving, effect. If adrenaline is not producing relief it should not be continued in large doses, but intravenous A.C.T.H. or, as second best, A.C.T.H. injections should be promptly substituted. For the intravenous drip 25 to 40 mg. dissolved in 500 ml. of saline and delivered slowly over several hours will often produce an effective response; with intramuscular injections 25 mg. six-hourly is usually sufficient. Not all will respond, but the treatment should be tried in all serious cases.

In *severe chronic bronchial asthma*, which in this country usually has a big infective factor in its aetiology, effects are more variable and less dramatic. A two-week course of 40 to 60 mg. daily of A.C.T.H. gel may be tried, the dose being reduced gradually for the last few days. If improvement does occur it may persist for several weeks after cessation of therapy.

Allergic Asthma and Allergic States.—In acute attacks of allergic asthma good results may be expected from A.C.T.H. or oral cortisone therapy in a good proportion of cases. It is indeed possible that the benefit in the infective group is largely due to the effect on the allergic factor in these cases. In drug sensitivities and other allergic skin manifestations good results may also result from prompt and full dosage.

Pemphigus

Pemphigus stands out among skin diseases as one with cogent indications for A.C.T.H. or cortisone. Occurring in several forms, it has a high mortality. With intensive therapy with A.C.T.H. or cortisone the distressing skin lesions may be brought under control and indeed healed in the great majority of patients. But it is now realized that large doses are needed to ensure full control. Forty milligrams of A.C.T.H. daily by intravenous drip or 40 to 60 mg. six-hourly intramuscularly are often needed in the early treatment. Of cortisone, 300 to 400 mg. orally may be required daily. When the disease is under control dosage is gradually reduced to low maintenance levels, which must be continued for many months. It is too early to say in what proportion of cases a complete cure can eventually be achieved. Failure to get great improvement is usually a sign of inadequate dosage. With adequate therapy, new lesions should cease to form within four to seven days, though healing of existing lesions may take several weeks. If toxic side-effects develop, a compromise dose may have to be found. Since in most cases of pemphigus therapy may be life-saving, sufferers from it should have high priority for these drugs.

Other Skin Diseases.—Good therapeutic responses have been obtained in dermatitis medicamentosa, particularly that due to penicillin. Generalized exfoliative dermatitis often responds well to A.C.T.H. and cortisone. The drugs should be used when they are likely to be life-saving or to relieve severe but temporary distress. In general they should not be used in chronic or recurrent skin diseases.

Eye Diseases

In such a wide field, only certain general points can be mentioned here. Cortisone or A.C.T.H. therapy produces a prompt subsidence of inflammatory reaction and diminution of fibroblastic activity. Their value, therefore, is to minimize the danger of residual damage from an excessive acute inflammation. The local application of cortisone to the eye is so effective that the use of A.C.T.H. or parenteral cortisone is seldom necessary and indeed may be less effective. Cortisone may be applied directly as drops, the standard preparation being diluted 1:4 for the purpose. It may be instilled every hour until inflammation subsides. Alternatively an ointment of 15 mg. per gramme in lanolin or a similar base may be applied every three hours. Cortisone may also be given by subconjunctival injection, but this is not usually necessary.

Results are often dramatic. In acute iridocyclitis the symptoms and signs may resolve completely in two to three days. In subacute and chronic cases results are much less impressive. In conjunctivitis the acute inflammatory process is readily reduced, but the infecting organism is not affected and the signs of infection will return when therapy is stopped. Other methods of treatment, such as with antibiotics, should therefore not be neglected.

In acute corneal ulceration the prompt exhibition of cortisone may prevent or greatly delay vascularization and infiltration, thus minimizing later scarring. Cortisone tends to delay wound healing, but in most corneal ulcers the benefits tend to outweigh the disadvantage of slower healing.

Cortisone is likely to prove of great value in cases of sympathetic ophthalmia and lead sometimes to the saving of sight. There is considerable uncertainty about the effects of cortisone on tuberculous processes. Cortisone should not generally be used for ocular conditions suspected of being tuberculous unless skilled anti-tuberculous chemotherapy is also available, as the cortisone may light up a relatively quiescent focus.

Since so many ocular conditions can be greatly influenced by local applications, very small amounts of cortisone are required and such cases can usually be given a high priority for the drug.

Ulcerative Colitis

The place of cortisone or A.C.T.H. therapy in this disease is still a matter of exploration and discussion. It is rather less well defined than in many other diseases. There is no doubt that beneficial effects can often be produced in the inflamed colonic mucosa. In a number of cases the mucosa will be seen, on sigmoidoscopy, to have improved greatly, to be less inflamed, and less liable to bleed; it may even return to normal. General remission of other symptoms, with improvement in the condition of the patient, may be expected in a good proportion of cases. Though relapse may not follow immediately after cessation of therapy, it is likely to occur sooner or later, and the relapse may not prove so responsive as the earlier attack; results are rather unpredictable. We have seen one man have a two-year remission after a 10-day course of A.C.T.H., and, in contrast, another who deteriorated so rapidly whilst on A.C.T.H. that he had to have an emergency colectomy, treatment which led to his eventual recovery. A.C.T.H. does not provide a cure; it may prove of value in bringing a relapse under speedier control or in improving the general condition sufficiently to make surgical intervention safer. In troublesome cases it is unlikely to replace surgical treatment.

It is unlikely also that prolonged maintenance therapy will have any important place in the treatment of the

disease. The most hopeful use for the drug is promptly at the commencement of a relapse.

Blood Disorders

The value of A.C.T.H. and cortisone therapy in blood disorders does not seem to be high. In only two conditions are there reasonable chances of improvement. In *acquired haemolytic anaemias*, whether idiopathic or symptomatic, a favourable response may be expected in most cases. Improvement may persist for several months after cessation of therapy, occasionally for more than six months.

In *thrombocytopenic purpura* also, whether toxic or essential, remission may be induced in a high proportion of cases by cortisone or A.C.T.H. therapy, but relapse is more likely to occur promptly when treatment ceases. Occasionally, however, cure seems to be complete. These two disorders present the most favourable conditions for the use of A.C.T.H. and cortisone, but in neither is the prospect of a cure high.

In *acute leukaemia in children* a beneficial response may often be obtained and sometimes almost complete remission. The benefit is purely temporary, and in the long run little is gained in such cases. Parents should therefore be warned not to draw too strong a hope from any initial improvement. No appreciable response is obtained in adult forms of leukaemia, in aplastic or refractory anaemias, in congenital acholuric jaundice, or in paroxysmal nocturnal haemoglobinuria.

Renal Disease

Chronic renal damage with poor renal function is usually regarded as a contraindication to cortisone or A.C.T.H. therapy: in cases of chronic or subacute nephritis the results of therapy have not been impressive. There is, however, one condition in which benefit from A.C.T.H. or cortisone therapy may be expected in about half the cases.

In nephrotic children without significant nitrogen retention A.C.T.H. causes the usual tendency to sodium retention, but when therapy is stopped then a diuresis often occurs which leads to removal not only of this retained sodium but also of the greater part of the nephrotic oedema fluid. Younger children respond better than older ones. The child should be put on a low-salt diet with a high-potassium content. Full dosage should be given, a child of 60 lb. (27 kg.) requiring 20 mg. six-hourly for about 12 days, or 60 mg. of gel once daily. During the course particular attention must be paid to the cardiovascular system: signs of increasing jugular venous pressure or of cardiac dilatation will necessitate a reduction of dosage. After six to eight days dosage may be gradually tailed off and then an effective diuresis may be expected in about half the cases so treated.

Conclusion

The catalogue of diseases which benefit from cortisone or A.C.T.H. therapy can be continued very much longer. Inevitably, for some time to come, supply will fall far behind demand, and principles of priority allocation will need to be applied. As a guiding principle, the most economical use of these drugs will usually be in the alleviation of acute situations occurring in inherently recoverable diseases. Chronic diseases for prolonged maintenance therapy should be selected with caution and care. Those chosen should preferably be those where useful life may be restored or where a major economic crisis in a family can be averted by treatment.

Next Refresher Course Article.—"Spectacles," by Mr. J. H. Daggart.

THE PRACTICE OF MEDICINE FOR ANIMALS*

BY

TOM HARE, M.D., B.V.Sc., M.R.C.V.S.

You have invited me to talk about the practice of medicine for animals and to compare it with your own. Please allow me to avoid the abstract and to talk of such living things as doctors and veterinary surgeons; how they learn the one body of knowledge, exploit the same discoveries, meet with the same problems, and use the same methods in trying to solve them.

The veterinary schools are in the Universities of London, Edinburgh, Dublin, Glasgow, Liverpool, Cambridge, and Bristol. Among the medical and veterinary students I find little if any difference in social origin, upbringing, dress, deportment, and contributions to university life. In their hobbies possibly more of the city clings to the medical and more of the country to the veterinary.

Syllabus

In 1912, when I entered the veterinary school of the University of Liverpool, medical and veterinary students together attended the courses in the basic sciences, physiology, materia medica, and general pathology. They separated for anatomy and the clinical studies; but, through the friendships forged in junior days, ways and means of the sharing experience in the schools were devised. A veterinary student disguised in the short white coat would be smuggled into an operation or ward round; medicals in the long white veterinary coat did the meat-inspection tour of the abattoir, studied castrations with relish, or wallowed in the post-mortem examination of a horse. Of course, our teachers knew, and pretended they didn't.

An objective survey of the training of the senior students of the two schools would bog me in a morass of detail. The superiority of the medical training was in its clinical teaching, the art of recording the case history, diagnosis, and prognosis. The highlight of the veterinary training was animal management, a huge subject which includes the characteristics and behaviour of the domestic animals, their husbandry, breeding, housing, feeding, hygiene, transport, and marketing. It equips the veterinary student with standards against which he can compare his patients and assess the efficacy of his treatments and their economic value. I missed such training in my medical course; the teaching about man and his environment was incidental and insipid. The superb qualities of the medical training in hospital tended to condition the student to the outlook of the specialist. Despite the comparative poverty of his intramural clinical training the veterinary student knew it as equipment for general practice and supplementary to pupillage.

Veterinary students are advised to spend the vacations of their first year on farms as a preparation for pupillage. For my pupillage I entered into a written agreement with, and paid a premium to, a partnership of father and son in a mixed town and country practice. The son's house, where I boarded, included the consulting-room and dispensary. It formed one side of a paved yard, which was bounded by operating theatre, garage, smithy, kennels, coach-house, harness rooms, stables, and loose boxes. Facing the office at the entrance were three houses tenanted by the head groom, head shoeing-smith, and chauffeur. There were ten whole-time employees.

The "chief" was strict, just, generous, upright, handsome, and always immaculate. Woe to the yardman if the "chief" picked up a straw or the stub of a woodbine; little escaped

*Presented to the Mid-Herts Division of the B.M.A. on October 10, 1952.

his eye. He had lovely hands, which charmed a knife or a horse. He and his horse were one, a picture of power and grace, which, as he rode to the meet, warmed the hearts of Lincoln folk. He was an external examiner in surgery, a master craftsman, and a leader.

I accompanied the "chief" on his rounds and devilled for him; sometimes, and on most night calls, I went with the junior partner or his assistant. I was expected to memorize particulars of each client, his whims and oddities, his stock and husbandry, and to avoid party politics. Morning surgery began at 8.30, by which time I had dusted the dispensary, helped with the cleaning, feeding, and dressing of the in-patients, packed the gear-bags, and eaten my breakfast. Usually we were off on the rounds by 10.30; the transport consisted of two cars, a motor-bike, and a stable of horses for riding and driving. The night staff came on duty at 8 p.m., by which time I was usually washed and changed for dinner. After dinner on one evening a week stock medicines were put up and stored; farmers ordered them in lots of a dozen for home-doctoring. The system is natural, and fortunately prevails in many practices; the veterinary surgeon knows what his client has already administered and the client takes the credit for all recoveries; *noblesse oblige* goes a long way in the country. On another evening each week the accountant attended to enter up the ledger, while the professional staff deciphered entries in the day-book, costed their journeys, and checked up records of work done for Government, local authorities, and insurance companies.

There was no "clocking on and off"; I do not think it had been invented. There were occasions for leisure and recreation; I had my fill of riding and cricket, and my Sundays, after 10, were my own except for emergencies. The "chief" arranged for me to visit neighbouring veterinary surgeons when they had a particular technique or case to demonstrate; also, as a guest, I attended meetings of the local division. In all I spent 24 crowded, healthy, and happy weeks as a pupil in the practice, and I returned to it as assistant for some of the vacations of my medical course.

From my enthusiasm for pupillage I would not have you infer that it is invariably a success for student or principal. A few students do not seem to have the temperament to enjoy or profit by it. I think the need for improving the medical training for general practice would be met by re-introducing pupillage during the vacations. It would avoid any major upset in the existing system of hospital training, which in some respects is of superb quality.

Surgery

The differentiation of the medical general practitioner from the specialist does not obtain in the veterinary profession. Some veterinary surgeons restrict their practice to a particular animal; others develop a special aptitude, for which they are consulted by their colleagues. The majority of veterinary surgeons undertake major surgery at the patient's home or in their own theatres. Except for emergencies many veterinary surgeons reserve one or more periods of the week for their operations. Usually they have a nurse-secretary to maintain anaesthesia, attend to instruments and apparatus, and dress and nurse patients. All parts of the small animals, except the central nervous system, are explored by the knife.

Major surgery on the large animals is usually done in the open, sometimes at a distance from tap-water and other hygienic conveniences. The physical means for preparing and controlling large animals, during and after operations, have to be carefully planned. Nowadays veterinary surgeons have the additional difficulty of finding competent assistance on farms. For major operations on the viscera there is a preference for the large animal to stand at its manger under local analgesia. Casting the patient on a bed of straw for general anaesthesia, even when skilfully done, severely upsets the animal and influences its after-treatment and behaviour. The less the interference with the

patient's posture and surroundings the better the prognosis. Another limiting factor of major surgery of the large animals is the size of their organs and the difficulty of bringing some of them into the incision through the body wall. Nevertheless, capacious viscera have their advantages: with his arm in the rectum a veterinary surgeon can explore the organs as far forwards as the kidneys.

The structure, functions, and diseases of the foot occupy an important place in the veterinary curriculum. It is the seat of many troubles, to which, in the horse, must be added the many injuries from faulty shoeing and work. Veterinary students receive practical instruction in the smithy. In my medical course instruction about footwear and the everyday troubles of the foot was insignificant.

For measuring a patient's fitness both professions employ similar manual, instrumental, and athletic procedures. When all these have been done for a horse the veterinary surgeon mounts and puts it through its movements and speeds. Riding with skill and judgment, he comes to his diagnosis and something more. In the exhilaration of their rhythmical movements there is evoked a mutual sympathy, which calms the apprehensive animal. I believe this sympathy uniting two creatures to be the essence of "clinical touch." Without it the doctor or veterinary surgeon, for all his knowledge, is a mere technician.

Obstetrics

The pathology of reproduction is a major subject of veterinary practice which adheres to orthodox principles and is admirably set out in the textbooks. It is governed by economics. Livestock owners at subsistence level rarely can afford veterinary obstetrical practice; they make do with primitive methods and ideas. Knowing his hill and his sheep, the shepherd can forecast where and when each ewe will drop her lambs. If a ewe is unable to lamb he does his best to deliver her. If he fails he opens his knife, cuts her throat, opens her abdomen, removes the lambs, clears their nostrils, and fosters them on to ewes with single lambs. Most of the ills of fertility, pregnancy, parturition, and infancy of animals are primarily due to infectious disease. But the voice of Pasteur rarely penetrates to those who look on lambing as the harvesting of a crop and their bread for a twelvemonth.

For three lambing seasons I was working in the Pennine Hills. One bitter night a hill farmer fetched me to his mare. I followed him over the bosom of the hill to a stable, a lamp, the mare, and three chaps fatigued by midwifery. I stripped to the waist, lathered my right arm with soap, corrected the presentation, and the mare delivered her first foal. When I turned to wash in the bucket the farmer said, "Don't waish th'onds lad, cum to th'ole wumon; she's took bad." But I washed and put on my shirt. Next door I had a look at the farmer's wife, sat on her bed, and spoke reassuringly while she gave birth to her third girl. The farmer's diagnosis was shrewd; his wife was a multipara and could wait on nature; the mare's foal was her first and nature was stuck. As for his ideas of hygiene: if hands are mucked in lambing they are wiped on the fleece and you get on with the next job.

Infectious Disease

This is the major problem of veterinary practice. It accounts for more illness than that due to autonomous, physical, and chemical causes. Domestic animals live at risk of infection from diseased contacts, insanitary surroundings, infected food, and diseased wild creatures. They live with their dung, droplets, and discharges, which, as the means of spreading infection, become more potent with crowding.

The notifiable infections, which include rabies, glanders, and anthrax, are specified in the Diseases of Animals Acts and Orders. On detection and report to the authorities they are dealt with by the veterinary officers of the Ministry of Agriculture. Of more concern to general practice are the

endemic infections, such as helminthiasis, coccidiosis, tuberculosis, Johne's disease, brucellosis, and streptococcal infection.

The parasite of the ubiquitous intestinal infection coccidiosis is expelled in the patient's dung. It can survive outside the animal for 18 months. In young animals the infection tends to an acute course with a high mortality; in adults it is a common cause of invalidity. Coccidiosis is curable, but, relative to the market value of the animal, the treatment is costly in drugs, labour, and time.

Infection by the haemolytic streptococcus is also very prevalent in domestic animals. Its foetal and infant mortality and adult morbidity rates are high. When penicillin and sulphonamides can reach it, as in septicaemia, they slay it. But the spread of the haemolytic streptococcus is by droplets, and its natural habitat is mucous membrane, particularly that of the pharynx. Under the protective coating of mucus it is relatively quiescent for a period, and then it has a burst of activity, during which it produces a toxæmia. Also from mucous membrane it may emigrate to sites of stress, such as the pregnant uterus, the mammary gland of the milking cow, or the strained capsule of a horse's joint.

From what I have said of endemic infection I would not have you infer that usually the animal patient is suffering from only the one species of parasite. In the large majority of my cases more than one specific infection was found: three specific infections were found in about 10% and four or more in about 3%. The symptomatology of polyinfection may be far removed from the sum of the signs expressed by each specific infection. Animals infected by the haemolytic streptococcus and suffering from coccidiosis show spasmodic, which varies from the intermittent spasms of a single muscle in the mild case to the tetany, hysteria, or epilepsy of the more severe case.

Prophylaxis

In my experience the incidence of endemic infection has been increasing during the past 25 years. I see no signs of the reverse trend. This is a disappointing contrast to the impressive advances in diagnosis and specific biological and chemical treatments. Moreover, the meaning and value of these advances have been made known to stock-owners by their veterinary surgeons through the advisory schemes of the British Veterinary Association and Ministry of Agriculture. The technical means for subduing endemic infection are available, but it is not being subdued. Why?

The responsibility for seeking and accepting veterinary advice rests on the stock-owner, who tends to refrain from anticipating disease, and, after it has come, to set a greater value on curative treatment and prognosis than on specific diagnosis and prophylaxis. This attitude is encouraged by the fact that animals suffering from endemic infection are convertible into the nation's meat ration. The practices of the stock-owner are a contributory but not the essential cause of the rising incidence of endemic infection. To illustrate this I will cite one of my experiences. The story began with two sows on a farm and a public demand for pork. The two were multiplied to two dozen sows, which bred litters averaging nine. The farmer increased his pig population beyond his resources for clean husbandry. Parasites multiplied and increased the mortality and morbidity rates. The demand for pork declined and increased the farmer's losses. The story ended in the fifth year with two sows on the farm.

Wherever animals are assembled together in farm, field, market, showground, ship, and hospital, their parasites appear. They appear with the undetected infected animal. They spread in its dung, discharges, and droplets. This is no new knowledge. It and the essential preventive methods were systematized during the second half of the nineteenth century and incorporated in the veterinary curriculum as the hygiene of animal management. Fifty years ago the veterinary profession was advocating routine cleanliness as an effective control of such endemics as tuberculosis and Johne's disease; it does so to-day. Forty years ago I began

my pupillage in a practice of which the animals, equipment, and buildings were kept as clean as a new pin. To keep them clean was a veterinary surgeon's duty, pleasure, and pride. It was so even 20 years ago with many city veterinary surgeons, who maintained large establishments for the treatment of small animals. To-day the maintenance of an animal hospital is beyond the means of private practice. The routine cleanliness of animals and their surroundings can be effective demands intelligence, ceaseless vigilance, and rained labour.

Faced with the difficulty of obtaining the trained labour, and its high cost, the veterinary surgeon has dispensed with his animal hospital. The farmer, faced with the same economic problem, has to keep his animals, saturate them in antibiotics, and trust to luck. To-day all of us are haunted and frustrated by the same ghost. Few of us can afford to keep our homes as clean as we did. I do not see medical hospitals so well scrubbed as in my student days. Cleanliness is too expensive, and its practice fades as the welfare State slides into slumdom.

My selection of vignettes of veterinary medicine must end here. It has been a great privilege to show them on behalf of my friends in general practice. Instead of presenting their thoughts and experiences I seem to have given you far too many of my own. My only defence is to acknowledge them as my own, the best I have to give you.

ELECTRONICS AND MEDICINE

[BY A SPECIAL CORRESPONDENT]

The eighth annual exhibition of the Institution of Electronics, organized by the North-west Branch, was held at the College of Technology, Manchester, from July 15 to 21. It was opened by Sir Geoffrey Jefferson, F.R.S., emeritus professor of neurosurgery at Manchester University. The exhibition was organized in two sections: a Scientific and Industrial Research Section, in which the applications of electronics to medicine featured prominently; and a Commercial Section displaying the astonishing versatility of this infant science in solving the problems of modern industry.

The Christie Hospital and Holt Radium Institute, Manchester, demonstrated the precautions necessary in handling radioactive isotopes, and also the uses of I^{131} in estimating thyroid function, P^{32} in treating chronic leukaemia and polycythaemia and in locating brain tumours, and of radio-cobalt in irradiating neoplasms. The Department of Medical Physics, Leeds University, showed an arrangement for taking dynamic measurements of blood pressure, using a blood-pressure manometer and commercial capacitance meter which is easily constructed and apparently trouble-free. Other exhibits by this department included an electromyograph and an experimental scintillation counter in which the difficulty of distinguishing signal and noise impulses has been overcome. The Lewisham Hospital exhibit showed how x-ray films can be automatically named and numbered, and also an apparatus for recording foetal heart sounds audibly by loudspeaker and visually on both cathode screen and tube. This instrument has already been in use for about 18 months for research purposes.

The Postgraduate Medical School, London, exhibited a number of interesting devices including a trigger mechanism for taking x-ray exposures of the heart when studying the relationship of cardiac volume to the E.C.G. cycle; an exposure meter for low light levels, as, for example, in photomicrography; and an amplifier for recording uterine contractions and cervical dilatation. The mechanical heart-lung machine recently described by Melrose and Aird in the *British Medical Journal* (July 11, p. 57) was also on view: it is an impressive example of what can be achieved by combining the skills of medicine, engineering, and electronics. The Department of Physics, Royal Cancer Hospital, London, had a very fine piece of machinery for recording

visually on a large television screen the distribution of ionizing radiation. But the exhibit of the Radiochemical Centre, Amersham, was disappointingly limited to a high β source emitter. No attempt had been made to show the work of the Centre in supplying radioactive isotopes for medical use; even a request for a catalogue of the preparations available met with the reply that the catalogues had all been taken up at a recent Continental exhibition.

The Commercial Section of the exhibition introduced one to a Jules Verne world of streamlined grey boxes and flickering eyes which appeared to be capable of telling one everything about everything, from counting the various emissions of radioactive isotopes to telling how thick one's cigarette paper is, from determining the quality of a turbine blade in a jet engine to measuring the amount of haemoglobin in the blood. A handy table-model electron microscope will photograph bacteria at $\times 60,000$ magnification, or one can sit back in a chair at the console model of the flying-spot microscope while pathology slides are projected on to a television screen for leisurely consideration.

Preparations and Appliances

COMFORT IN CALLIPERS

Dr. H. L. ROGERSON, of Bergh Apton, Norfolk, writes: A few years ago I complained in the correspondence columns of the *Journal* (1948, 2, 724) of the antiquated design of the walking-calliper. Recently, seeing that no advance had apparently been made, I thought that, as a patient and doctor with some enthusiasm for mechanical devices, I was myself in a fair position to design and have made a walking-calliper for my own use. This I did, and for 18 months have worn the resulting product in complete comfort.

My poliomyelitis is of eight years' duration, my right leg being completely paralysed up to and including the muscles around the hip-joint. The left leg is paretic to the extent of about 50%, but no calliper has been needed for this leg.

I had two main objectives, lightness in weight and as near perfect fitting as possible. A paralysed leg, even without any attachment, feels heavy and cumbersome. Lightness has been achieved partly by simplicity in design as well as by the use of duralumin, and the total weight of the instrument is 3 lb. (1.36 kg.). A high standard of fitting has been obtained by wearing the instrument in its skeleton form at first, and returning it to the makers for adjustments until considered perfect. In my case it was returned three times in the rough state before the final finishing process.

The basis of the design is the use of one "iron" only. This, in my case, for a weight of less than 140 lb. (63.5 kg.), is of duralumin strip $\frac{3}{4}$ in. (1.9 cm.) wide by $\frac{1}{4}$ in. (0.6 cm.) thick. The following are the details of construction, starting at the proximal end of the instrument.

The pelvic band is of the usual type, but without the usual metal stiffening. This stiffening is most uncomfortable for the thin patient and quite unnecessary, except as a mounting for the band in the form of a strip about 6 in. (15 cm.) long, shaped to fit comfortably below the iliac crest on the affected side. The band mounting is attached and hinged in the usual manner, so that the hinge is just clear of the skin over the greater trochanter of the femur. It is important that the portion above the hinge be moulded inwards so as to fit accurately, with its upper edge passing just inferior to the anterior superior spine of the ilium.

The leather thigh casing of usual design is laced in my original instrument, but the straps shown in my duplicate instrument are equally satisfactory.

The knee hinge is self-locking in extension and can be unlocked either directly at the knee or indirectly by means of the extension, which can be reached by a hand in the trousers pocket. The locking assembly is spring-loaded.

The eccentric arrangement of the hinge whereby the ratchet protrusion disappears on flexion between the two outer circular layers is worth adopting on account of the lessened damage to clothing. The below-knee cage is of usual design and strapped. It is fitted so that the upper level just covers the tuberosity of the tibia.

From the knee to the heel down the outer side of the leg passes the single duralumin strip, which is shaped so that it is approximately parallel to the outer side as it passes down the leg. The heel of the shoe is provided with a round socket in the usual manner, and the iron bar which enters it is 2 in. (5 cm.) long. This side strip just described, since it is not strapped to the leg or shoe in any way, is sprung in slightly towards the heel to prevent its coming away from the heel of the shoe of its own accord. In my case this arrangement has been entirely satisfactory, and only rarely has the rod shown a tendency to come out to the extent of about $\frac{1}{4}$ in. (0.6 cm.). Sitting with the legs crossed has been the only cause of this, and the bar has clicked back again when the knee has been re-extended. A toe-raising spring has not been necessary, the foot, when lifted off the ground during walking, remaining at right angles to the leg. The distribution of weight-bearing

between the tuber ischii and the heel is important, and approximately 50% to each site has been the aim. It is also important that in full extension during standing there is no feeling of strain at the back of the knee as though hyperextension were being produced.

A good and simple way of testing the instrument for perfect fit is to ask the patient to stand with the weight of the body equally divided between both feet. If the knee cage is undone there should be no flexion at the knee, and therefore the patient should have no feeling of insecurity. Now, if the knee cage is refastened and the thigh casing unlaced, there should still be no flexion at the knee and no feeling of insecurity.

There is no doubt that an instrument with a single bar is much more comfortable than one with a double bar, and not the least luxury is the ability to sit down with one's knees touching each other.

I have to thank Messrs. F. G. Ernst, of 110, Great Portland Street, London, W.1, for their co-operation in making this instrument to my specification.

Trusts and Foundations, a valuable select guide to the charitable trusts and other grant-making bodies in Britain and the Commonwealth, has recently been published by Bowes & Bowes Ltd., Cambridge, price two guineas. The book has been compiled by Mr. Guy W. Keeling, a former secretary of Aslib and of the Library Association. It represents the first serious attempt to bring together in a single volume all the available information on nearly 1,000 charitable trusts and foundations. Entries are arranged alphabetically and give full details of the trustees and the history, purposes, provisions, and conditions of the trusts. There is also an alphabetical subject index and a subject index classified by the Dewey decimal system. This most useful book will go a long way to filling the need for such a guide expressed in the report of the Nathan Committee on the Law and Practice Relating to Charitable Trusts.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

The Banning of Heroin

SIR,—Your annotation (*Journal*, July 25, p. 196) on this subject concludes that omission from the B.P., 1953, of heroin would be a most respectable precedent for Government authorities to make the use of the drug illegal. Now a precedent tends to be used as justification for further bans on liberty of action, and should be regarded most critically before being accepted. The main argument for the disappearance of heroin is that it is a drug of addiction, a fact which is exemplified by 500,000 Egyptians in its toils. It may be significant that this huge number has developed since the institution of repressive measures against the less harmful cannabis, which used to render the appalling conditions of the fellaheen endurable. By and large it may be accepted that widespread drug addiction is the outcome of poverty, ill-health, and misery, and it is to the remedy of these conditions rather than interference with therapeutics that governments should direct their energy and money. If the argument that heroin can be satisfactorily replaced by other drugs is sound, no exception should be taken to its banishment. But is this, in fact, the case? Clinical impressions may be notoriously fallacious, but they are not always so, as was exemplified in the history of ergot by the triumph of the general practitioners when ergometrine was discovered.

The incidence of vomiting, often severe, from morphine is high; that following heroin is rare. Amidone and pethidine are by no means as reliable as the first-mentioned drugs, and pethidine vomiting can be troublesome. Are we to suffer our patients to vomit for the sake of potential addicts? As to the suppression of cough, it is true that in adequate doses codeine will be effective, only too often, however, with the addition of severe constipation, lethargy, and depression.

The laws governing the use of dangerous drugs in this country are very strict, and rightly so. Let us then not give countenance to remote control by an organization detached from the day-to-day problems presented by the sick and suffering.—I am, etc.,

London, W.1.

A. H. DOUTHWAITE.

Sex Ratio at Birth

SIR,—I was much interested in your annotation on this subject (*Journal*, July 18, p. 142) and would like to draw attention to two further aspects.

The inconstancy of the sex ratio at birth is well established. Judging from the decennial census figures (my source was *Papers of the Royal Commission on Population* Vol. II), this ratio was quite close to 100 boys per 100 girls born during the period 1841–1901. Thereafter, it rose steadily so as now to stand at approximately 106. The tables in the above-mentioned source do not show the sudden rises in sex ratio at the time of the two wars referred to in the annotation, but merely a steady climb.

The explanation of changes in the sex ratio at birth is as you rather indicate, not altogether satisfactory, and I would venture to suggest what must be an important factor in determining these changes—namely, variations in the abortion rate. This depends upon the fact that the primary sex ratio—that is, the number of males to females at the time of conception—is a good deal higher than the ratio at birth; the evidence for this conclusion is the excess of male over female abortuses. Just as, in post-natal life, the human male at all ages has a higher death rate than the female, so, it seems, does the male foetus in intrauterine life. The primary sex ratio is, of course, indeterminate, but

the available evidence places it at about 120 males to 100 females conceived. It is easy to show that an increase in the abortion rate will lower the sex ratio at birth while a decrease in the abortion rate will raise it. One possible explanation, therefore, for the steady rise in the sex ratio during the last half-century is a progressive fall in the abortion rate, perhaps the result of steadily improving ante-natal care.

By making use of the considerations in the above paragraph, I was led to the conclusion that the spontaneous abortion rate is probably nearer 20% than the 10% figure usually quoted. In a series of pregnancies occurring among women attending a fertility clinic (where the likelihood of overlooking spontaneous abortion was small) the abortion rate was 19.1%; the sex ratio of the babies born was 107 males per 100 females. Being so close to the general sex ratio at birth, it was reasonable to suppose that the abortion rate was not dissimilar from the general one. Had the latter in fact been only 10%, the sex ratio of the babies in this series should have been about 92 for a 19% abortion rate.—I am, etc.,

London, W.C.1.

G. I. M. SWYER.

SIR,—For the research worker much of the interest of variation in the sex ratio of live births has derived from the possibility that it reflects variation in the ratio at conception. Since the sex ratio of live births is influenced by the incidence and sex ratio of foetuses lost as abortions and stillbirths, reasons have recently been suggested for doubting whether this interpretation is correct.¹ The composition of abortions and stillbirths by cause of death changes from month to month of gestation, and the various causes have different sex ratios. Indeed, it is not even certain that the sex ratio of the same cause of abortion and stillbirth remains constant throughout pregnancy—for example, the sex ratio of anencephalus (expressed as the percentage of males) increases from about 20 at 7 months to 40 at 9 months. It is therefore certain that variation in the sex ratio of live births in association with war, birth order, maternal age, and social class is influenced by changes in the incidence and composition of abortions and stillbirths, and it is possible that there are no corresponding changes in the ratio at conception.

In view of these results the statement in your annotation (*Journal*, July 18, p. 142) that "variations in the sex ratio at birth are due to variations in the composition of the birth orders forming the population" is clearly inadequate. And since birth order is only one of the variables with which variation in incidence and composition of abortions and stillbirths is associated, the statement is also inaccurate.—We are, etc.,

Birmingham.

A.C.T.H. in Delirium Tremens

SIR,—Within the last few months I have had the opportunity of treating two cases of delirium tremens with A.C.T.H. I am not aware of any similar published cases, though there may be many, but the results of treatment were so rapid and favourable in both cases that it might be worth while recording these.

Case 1.—A man aged 30 years was admitted to hospital acutely delirious and with the usual hallucinations. The attack may have been precipitated by a wound, accidentally sustained, on the back of the right hand which severed one of the extensor tendons. In a few days, after treatment with sedatives, vitamin-B complex orally, and large doses of vitamin B₁ parenterally, the mental condition had considerably improved and it was decided to suture the cut tendon. He was anaesthetized with thiopentone intravenously and the operation was completed in 18 minutes. From this day the patient sank into a state of low muttering delirium; his temperature rose and ranged between 100° and 103° F. (37.8° and 39.4° C.), and he became completely disorientated as to time and place. Blood films were negative for malarial parasites. He lay on his back and frequently reached forward with his hands, going through the "rope-climbing"

movements which are said to be typical of serous "meningitis" (wet brain). Lumbar puncture produced normal cerebrospinal fluid at a pressure of 110 mm. Penicillin, streptomycin, and sulphadiazine had no effect on the fever.

Fourteen days after the operation and 20 days after admission to hospital, it was decided to try 20 units of A.C.T.H. every six hours. After two doses the mental condition had improved almost to normal, and in 24 hours he was perfectly sane. The temperature dropped to normal in 24 hours and convalescence was rapid after that. The A.C.T.H. was gradually reduced to 5 units once daily, and this was continued for three days and then stopped.

Case 2.—A woman aged 57 years was admitted to hospital in subacute delirium, completely disorientated as to time and place, restless and running a temperature of between 98° and 100° F. (36.7° and 37.8° C.). After 24 hours she was given 40 units of A.C.T.H. every eight hours, and after one dose the mental condition was almost normal. Recovery was rapid and the patient was discharged in six days. The A.C.T.H. was stopped after four days, by which time it had been reduced to 20 units once daily.

The striking feature of these cases was the extremely rapid response to A.C.T.H. Case 1 was in a critical condition, so much so that a relative had been notified and was about to fly out from England, but he responded to treatment almost as quickly as the other case. Twelve hours after the start of treatment he was able to speak intelligently on the telephone.—I am, etc.,

Georgetown, British Guiana.

S. C. BETTENCOURT-GOMES.

Malaria in Ex-Servicemen

SIR,—Last year a number of attempts were made to draw the attention of practitioners to the possibility of malaria occurring in men recently returned from military service in the Far East.¹ A steady stream of such cases with *P. vivax* (B.T.) malaria is still being admitted to the Hospital for Tropical Diseases (U.C.H.), London. Unfortunately, owing to misdiagnosis, a proportion are unnecessarily ill on admission here. Some give a history of fever for two months or more, having a haemoglobin between 50 and 60%, and spleens palpable well below the left costal margin. They have been treated for pyelitis, bronchitis, or gastro-enteritis. The majority have served in Korea.

It should be realized that proguanil, which is issued daily to soldiers in malarial areas, is an excellent suppressive drug but not a causal prophylactic for B.T. infections. Therefore, if these men were taking it as ordered, they will give no history of a previous attack of malaria. The latent period is often long in the Korean cases. Six months or more may elapse between the stopping of proguanil and the onset of fever.

If the possibility of malaria as the cause of fever in men who have served in the Far East is remembered, a positive blood slide will establish the diagnosis, provided that no antimalarial drug has been given. It is with the hope of bringing this condition once again to the attention of general practitioners throughout the country that this letter is written.—We are, etc.,

London, N.W.1.

Rubella

SIR,—During the last two years I have seen three cases of German measles associated with "rheumatic" pains. All three were women, between the ages of 25 and 35 years. All three complained of pains in the eyes, which they felt on moving the eyes, thus suggesting that the origin of the pain was in the external ocular muscles.

All three, however, did not recover immediately. One, a lady of about 27, was left with a pain in her left wrist joint, and she was referred to an orthopaedic consultant. His opinion was that this was a simple arthritis of infective origin. It did not respond to salicylates, but subsided eventually. The second lady, aged 34, who was treated with salicylates as soon as German measles was diagnosed, was left with generalized rheumatic pains in her back, arms, and

legs. This went on, although gradually subsiding, for about seven months. The third lady, aged 32, who was also treated with salicylates, recovered completely in ten days.

In J. J. Conybeare's *Textbook of Medicine*¹ there is the sentence: "Neuralgic and 'rheumatic' pains and mild encephalitis have occurred as complications [of German measles]." I have never seen the encephalitis, but neck stiffness, due to occipital lymph node enlargement, together with pain on moving the eyes (not photophobia), did once suggest it.

In allergic conditions, particularly in serum sickness, similar pains in the joints are encountered, which may persist long after the acute condition has passed off in one or in many joints. These pains are sometimes referred to as polyarthralgia, which, of course, describes the symptom but not the disease.

For my part, I regard these phenomena as similar to those which we find in the beginning of the majority of infections. The pains are usually in the muscles, and it would appear that in the more severe conditions, lesions, presumably exudative, occur in the joints. In my experience, in German measles there is a tendency for the pains to persist for some months afterwards. Conybeare has it that a "multiple arthritis may occur in the course of many diseases, such as pneumonia, dysentery, scarlet fever, pyaemia, syphilis, gout, and typhoid." Beaumont, in his book *Medicine*,² mentions that some authorities believe that focal sepsis produces "a chronic allergic state, which on stimulation results in acute rheumatism."

In my view, the similarity between the joint pains in serum sickness and those in German measles—and indeed many other infective conditions—should lead us to regard these phenomena as allergic.—I am, etc.,

Barnard Castle.

Transverse Arrest of the Head

SIR,—Although not wishing to prolong this correspondence, I think a few simple facts concerning Kielland's forceps may call for emphasis. Dr. E. Parry Jones's letter (*Journal*, June 6, p. 1278), which I read with great interest, is a notable account of the history of these forceps, but it taught me scarcely anything about their use that I did not learn nearly 20 years ago. I certainly doubt whether as a result of its publication present-day British obstetrics is going to see a great surge back to Kielland's, nor, indeed, will Dr. Parry Jones expect it; they have a place, but essentially a limited one. So far as their use by general practitioners is concerned, surely comparatively few possess a pair, since their purchase would hardly be justified in domiciliary practice. I use my own pair quite rarely in spite of being very fond of them, and so far as I know I use them as aptly as most obstetricians. The method of application surely is very much a matter of personal preference. I do not care for the "wandering method," but every craftsman differs slightly in his methods, and it seems rather pedantic for Mr. Bryan Williams (*Journal*, April 18, p. 865) to declare that "the classical method . . . is nowadays unnecessary," though he may be assured I have always admired him as a sound obstetrician.

As a practising obstetrician I hope I shall be required to deal with transverse arrest of the head many more times, and I shall deal with each case slightly differently, as befits any artist loving his craft. I regard Kielland's forceps as another trick in the bag of the experienced obstetrician, but I cannot quarrel with one of Professor Gilbert Strachan's eminence when he wrote some years ago, "The main indication for their use is transverse arrest of the head . . . but this type of case is rare and can usually be treated by other methods, while the forceps are difficult to apply. Therefore, although they attracted some favourable attention when they were first introduced, their use has largely been abandoned."—I am, etc.,

Liverpool.

Generalized Actinomycosis with Possible Cardiac Involvement

SIR,—I read with interest the case reported by Drs. R. S. Savidge and D. M. Davies (*Journal*, July 18, p. 136). I note that a blood culture yielded a spore-bearing organism which was rejected as a contaminant. In the final sentence of their discussion they stress that in cases of doubtful pyaemia an unusual spore-bearer isolated from a blood culture should not be lightly disregarded.

Had the spore-bearing organism from this patient's blood stream been further investigated it would have been of but little assistance in arriving at the correct diagnosis, since *Actinomyces bovis* does not, of course, form spores.—I am, etc.,

London, S.E.1

KEVIN ANDERSON.

Controlled Respiration and Apnoea in Anaesthesia

SIR,—Drs. G. J. Rees and T. C. Gray (*Journal*, July 11, p. 97) refer to an article by Cournaud and his colleagues written in 1948.¹ I think it only right to point out that this article refers to some experiments carried out on the cardiac output of 29 human subjects when exposed to various types of intermittent positive pressure breathing in the conscious state, using respirators that "followed the slightest breathing efforts of conscious patients."

Undoubtedly there was little disturbance of cardiac output when the correct type of intermittent pressure was used, but can it be assumed that these results apply equally well to the apnoeic, curarized patient? They may give a sense of security to the anaesthetist who is using "assisted" respiration, but I should like to see some convincing results from experiments which measured the cardiac output during "controlled respiration" in the completely atonic, apnoeic patient. Further, the investigation should cover both cases with and without their chest cavities open, because I feel that the problem is different in the two types of case. We are all genuinely gratified (and perhaps sometimes surprised) to see how well thoracotomy cases do under modern anaesthesia, but for other non-thoracic cases I must agree with Professor E. A. Pask (*Journal*, May 9, p. 1048) "that there are critically ill patients who do better if they are allowed to breathe for themselves." It might be as well to recall the generalization made by Dr. F. Prescott in 1947,² that there was one maxim to be followed whenever a curarizing drug was used: Keep the patient breathing. Perhaps it is old-fashioned to try to keep to this maxim, but I would still strongly recommend its acceptance where possible, particularly by junior anaesthetists.—I am, etc.,

London, N.18.

Tic Douloureux

SIR,—Dr. R. Wyburn-Mason's article entitled "The Nature of Tic Douloureux" (*Journal*, July 18, p. 119) prompts me to correct a common terminological error which has arisen owing to the incorporation of the unfortunate diagnostic label "tic douloureux" into the English language. The seemingly appropriate translation "painful tic" is, in fact, incorrect and misleading. "Facial neuralgia" is preferable, since the condition is predominantly a sensory disorder, and it avoids the use of the term "tic," which has a specific definition completely unrelated to facial neuralgia.

The word "tic" has appeared in the French literature for the past 300 years to describe such characteristic motor phenomena as eye-blinking, nose-twitching, and head-flinging. It was first defined precisely by Meige and Feindel¹ as:

"a co-ordinated purposive act, provoked in the first instance by some external cause or by an idea; repetition leads to its becoming habitual, and finally to its involuntary reproduction

without cause and for no purpose, at the same time as its form, intensity, and frequency are exaggerated; it thus assumes the characters of a convulsive movement, inopportune, and excessive; its execution is often preceded by an irresistible impulse, its suppression associated with malaise. The effect of distraction or of volitional effort is to diminish its activity; in sleep it disappears. It occurs in predisposed individuals who usually show other indications of mental instability."

It must be emphasized that no definition of tic includes any reference to a sensory component. A survey of the literature on tics and a detailed personal investigation of more than 70 tiqueurs has not revealed a single case of pain accompanying true facial tics. Hence the expression "painful facial tic" which Dr. Wyburn-Mason frequently employs is incorrect.

Dr. Wyburn-Mason states that spasms of painful facial tic are often accompanied by flickering or twitching of the facial muscles or may be associated with facial palsy or spasm (p. 120). The facial movements to which he refers are not true tics. As Wilson² has pointed out, tics and muscle spasms are not synonymous, and even the use of the term habit spasm as an alternative for tic is not strictly accurate, for the same reason. These points will be discussed more fully in a future publication.

In the interests of precise scientific definition a plea is made to reject the incongruous historical term "tic douloureux" and to substitute the more accurate English equivalent "facial neuralgia."—I am, etc.,

Liverpool.

Fluoridation of Water

SIR,—In your otherwise excellent leading article on the above subject (*Journal*, July 11, p. 88) you appear to suggest that diet is more important than "fluoridation" in connexion with the control of dental caries. But is it possible, short of another major war, to change the confirmed dietetic habits of the population? Our American friends certainly do not think so. The British public are certainly more long-suffering, but experience hardly suggests that even they are likely to change in favour of a reduced sugar intake and a higher extraction rate of flour for their daily bread.

Is it not rather that diet and fluoridation are two complementary factors both highly desirable in themselves? Fluoridation helps to build a more resistant tooth enamel and a self-cleansing diet reduces the power of the attack. In this connexion I would like to draw attention to an article by Dr. R. Weaver, of the Special Services Branch of the Ministry of Education.¹

In this he compared the results of two surveys which he had carried out on 500 5-year-old children and 500 12-year-old children in both North Shields and South Shields in 1943 and 1949. In North Shields the fluoride content of the water supply is negligible, whereas at South Shields at that time it contained 1.4 parts per million of fluoride. The figures expressed in terms of decayed, missing, and filled teeth speak for themselves. In North Shields the average D.M.F. figure for the 5-year-olds had fallen from 6.6 in 1943 to 4.4 in 1949, and for the 12-year-olds from 4.3 to 2.4. In comparison in South Shields, the natural fluoride area, the figures for 5-year-olds were 3.9 in 1943 and 3.4 in 1949, and for the 12-year-olds 2.4 and 1.3 respectively. These figures show that the dental caries inhibiting factor of fluoride was reinforced by the more rigorous diet of wartime conditions but still showed nearly 50% better figures as far as the permanent teeth were concerned. What is even more striking is that in South Shields there was between five and six times less decay in the upper incisor teeth than in North Shields.

In your editorial reference is also made to the Report of a Select Committee of the House of Representatives to Investigate the Use of Chemicals in Drugs and Foods, 1952. It might also have been pointed out, as indeed the mission's report does, that, in spite of the Select Committee's somewhat cautious conclusions, fluoridation of the water supply of Washington, D.C., itself was started shortly after the publication of its report.

As regards possible long-term toxic effects of the daily ingestion of small quantities of fluorine, Colorado Springs is looked upon as a well-known health resort. The fluorine content of its water supply is 2 parts per million.—I am, etc.,

JEFFREY FLETCHER.

The Judet Operation

SIR,—I have read with interest the comments of Mr. A. Webb-Jones (*Journal*, April 25, p. 935) and of Mr. T. M. Hennebry (*Journal*, May 23, p. 1166) regarding pain following the Judet operation. Some pain may follow any type of arthroplasty of the hip-joint whether carried out by the Judet or by the Smith-Petersen method. Though the former operation appears largely to have superseded the latter, at least for the present, it seems dubious if there is much to choose between the final results. Subsequent pain may be due to a variety of causes, of which I would suggest the following as being the more important.

Muscular Insufficiency.—If the operation is carried out on a person whose muscles are weak on account of poor physique, advanced age, atrophy from long-standing stiffness or disuse, or on one who is ill-adapted to co-operate in after-treatment, subsequent ambulation imposes an undue strain on these muscles, with resulting pain. This usually passes off in time as tone is regained, but some selection of patients is necessary. Those with poor muscles that are unlikely to improve may be better served by arthrodesis.

Post-operative Periarthritis.—Post-operative wound infection or "sub-infection" may cause fibrosis and painful stiffness. This may yield to manipulation, but a new operation may be needed. Fibrosis and painful stiffness may similarly be caused by unsatisfactory haemostasis at operation. If haemostasis cannot be made complete by ligature, diathermy, or coagulating substances, the wound should be drained. Bone chips and bone dust are potent causes of aseptic inflammation and fibrosis, and these must be completely removed. Digital exploration is the most effective means: if cotton gloves are placed over the rubber gloves at this stage of the operation, the rubber gloves are protected from puncture, and the use of a layer of cotton may mitigate the opposition of those who regard any departure from a rigid "no-touch technique" as anathema. I have reoperated upon patients in whom the capsule has been so impregnated with bone dust from reamers that it resisted a scalpel and had to be cut with an osteotome.

Subluxation.—Subluxation is due to failure adequately to deepen the acetabulum, a point of detail so often emphasized by Dr. Smith-Petersen. It stretches the rotators and produces pain in the groin. It can readily be recognized by taking an x-ray picture while the affected hip is bearing weight.

No Capsulectomy.—Complete capsulectomy is not usually considered to be essential routine in the Judet operation, but if not carried out where indicated the result is likely to be disappointing. Some arthritic hip-joints have very thick rigid capsules which contribute largely to the stiffness, and removal of such obstacles to movement is imperative.

Venous thrombosis and thrombophlebitis.

Finally, I would agree with Mr. Hennebry's remarks regarding the obsolescence of displacement osteotomy. This operation has no advantages over simple abduction osteotomy with nail and plate, which is occasionally indicated in cases with reasonable movement where there is marked distortion with coxa vara and also adduction deformity. Simple abduction osteotomy is less mutilating and can more readily be followed by arthroplasty at a later date if needed.—I am, etc.,

Melbourne, Australia.

F. V. STONHAM.

Post-mortem Examinations

SIR,—I do not know whether Dr. C. F. J. Baron, H.M. Coroner for Surrey (*Journal*, July 18, p. 152), is being facetious in accusing me of inaccuracy in my letter (*Journal*, July 4, p. 44). I hope he is not providing an excuse for by-passing the direction in Rule 4, paragraphs 1 and 2(b), of the Coroners Rules, 1953. Rule 4 is long, and for brevity's sake I did not quote it all. No one expects the impracticable to be done. The Coroner (through his officer) and the

doctor decide when the necropsy will be done having regard to all the circumstances, and the general practitioner is then informed. If the general practitioner asks for a different time that is arranged if practicable.—I am, etc.,

Worthing.

W. O. PITT.

*Paragraph 4 (1) of the Coroners Rules, 1953, reads as follows: "Where a coroner directs or requests a legally qualified medical practitioner to make a post-mortem examination, the coroner shall inform the persons and bodies set out in paragraph (2) of this Rule of the date, hour and place at which the examination will be made, unless it is impracticable to inform any such persons or bodies or to do so would cause the examination to be unduly delayed." Paragraph 4 (2) of the Rules reads: "The persons and bodies to be informed by the coroner are as follows: . . . (b) the deceased's regular medical attendant; . . ."—ED., *B.M.J.*

Cancer and the Public

SIR,—Lord Horder in his letter (*Journal*, July 18, p. 148) concerning cancer education states that "there are opposing views among medical men and laymen." This is undoubtedly true, but after many years' experience of such education I am convinced that if a questionnaire were sent to laymen and laywomen it would be shown that an overwhelming majority are in favour of cancer education. This conviction is further strengthened by the work I am doing in Yorkshire.

Recently the Yorkshire Council of the British Empire Cancer Campaign decided to try to assess the value of cancer education in York, Hull, and the East Riding (Scarborough about to be included). To carry this out, information concerning the symptoms "suggestive of the accessible cancers" is being distributed by means of lectures, pamphlets, etc., and the results will be judged by any change in the delay that occurs between such symptoms being noticed and the doctor visited, also by the number of early-stage cases of cancer arriving at the hospitals. Statistics of these symptoms and the number of early-stage cases of cancer are being collected in ten hospitals in the area.

When the work first started, I wrote—after obtaining the co-operation of the local authorities—to every general practitioner and consultant in the area. I asked if they would co-operate in the investigations (a) by filling in a special printed letter giving the "delay figure" whenever they send a patient to hospital complaining of any symptoms which the public are being taught should be reported without delay, and (b) by volunteering to give lectures. Of the 247 general practitioners written to, 129 (52.2%) replied. Of the 129, 128 agreed to fill in the letter, one refused, and 33 have volunteered to give lectures, the latter number including some consultants. Many of the consultants answered through their hospital committees, which have agreed to co-operate.

It will take two or three years before sufficient statistics are available to show whether education has diminished the delay in reporting symptoms suggestive of the accessible cancers—symptoms of other cancers are not taught—and the area may have to be enlarged before enough cases of accessible cancers can be collected to judge whether the number of early-stage cases has increased. "Knowledge is the antidote to Fear" (Emerson).—I am, etc.,

York.

MALCOLM DONALDSON.

SIR,—May I suggest that the good which is likely to come of educating the public in cancer may be estimated by comparing the cancer mortality in doctors, nurses, and the lay public? It may be that doctors and nurses have advantages besides education over the lay public, and the lower mortality in the educated groups would not necessarily be an argument for education of the public. If, on the other hand, the mortality is not significantly lower in the educated groups there can be very little argument in favour of a campaign to educate the public.—I am, etc.,

London, W.1.

JOHN GARDHAM.

Obituary

MERVYN H. GORDON, C.M.G., C.B.E., D.M., F.R.S.

Dr. Mervyn Henry Gordon, whose death on July 26 at the age of 81 was briefly recorded in last week's *Journal*, was one of the outstanding bacteriologists of his day. His whole working life was passed at St. Bartholomew's Hospital, where he worked in the bacteriological laboratories for nearly fifty years, living for a long period in High Holborn to be near his work. After his official retirement in 1937 he remained consulting bacteriologist to the hospital.

Mervyn Henry Gordon was born on June 22, 1872. His father was Canon H. D. Gordon, rector of Harting, in Sussex, and his mother was a daughter of the celebrated Dean Buckland. From Marlborough College he went on to Keble College, Oxford, and then to St. Bartholomew's to study medicine. He graduated B.M., B.Ch. in 1898, and proceeded M.D. in 1903, having taken the degree of B.Sc. two years earlier.

Gordon was appointed to the staff of the pathology department at Bart's soon after qualification, and it was not long before his name came to be known for original work of the most enterprising kind. His first major achievement was a study of the aerial transmission of bacteria suggested by the work of Flügge; this led him to practical experiments not only within the walls of his own institution but in no less august an environment than the Debating Chamber of the House of Commons, where his advice was sought about improved ventilation. He established the recovery of salivary streptococci from air as an indicator of aerial pollution from the mouth and throat, and it is a pity that the findings of this extensive and ingenious study are buried in Blue books which must long have been unobtainable.

Streptococci were among his favourite bacteria, and at an early stage he sought to distinguish the streptococcus of scarlet fever from others; his later work on the serological classification of *Str. pyogenes* antedated that of Griffith and Lancefield by ten years, and laid the foundations for it. With Andrewes and Horder he made a systematic study of the characters of streptococci generally, on which their present broad classification into the principal species is still based. The 1914-18 war provided the opportunity for the work by which he will be remembered longest, a widely comprehensive study with Glover and Hine of the epidemiology, diagnosis, and serotherapy of cerebrospinal fever, in the course of which distinct serological types of the meningococcus were defined for the first time. The material for this study was largely provided by epidemics in Army barracks. He had been appointed an original member of the Army Pathological Advisory Committee in 1909, and he continued to serve on the committee for many years. From 1915 to 1919 he was consulting

(Walter Stoneman, London.)

bacteriologist to the Army, being given the honorary rank of lieutenant-colonel. For his services he was appointed C.M.G. in 1917 and C.B.E. in 1919.

In 1923, the year before he was elected F.R.S., he resigned his appointment to the hospital and teaching staff at Bart's and became a whole-time research worker, at the same time abandoning the study of bacteria for that of viruses. His first effort in the new field was an extremely thorough restudy of the properties of the virus of vaccinia, the results of which are embodied in a Medical Research Council report which is now a classic. He also succeeded for the first time in transmitting mumps to the monkey, and took part in the work on psittacosis which followed the discovery that this was a virus disease. In 1929 an opportunity presented itself to organize a team of workers to investigate the aetiology of Hodgkin's disease; this research was supported by the Rose bequest, of which funds had accumulated which were only to remain available for this purpose for a limited period. Gordon's enthusiasm for this project communicated itself to the clinical staff at Bart's, under whose care many patients with Hodgkin's disease and other reticulososes were admitted to the hospital, furnishing the material for valuable histological studies as well as for those aimed more directly at discovering the cause of the disease.

The report on this work, a book entitled *The Rose Research on Lymphadenoma*, may have puzzled some of its readers, since some chapters deal with hypotheses now known to have been false. Gordon's belief about this problem passed through several phases, but crystallized eventually into a firm conclusion that the causative agent was a virus. He observed incidentally that a peculiar form of ataxia, not further transmissible, is produced in rabbits by intracerebral inoculation with affected tissue, and this is widely known as the "Gordon Test." Later observations showed that any material containing eosinophils will produce the same effect. The viral hypothesis rested mainly on the demonstration of elementary bodies, "E.B.s" as he almost affectionately called them, in tissue from patients. Where this eventually led him may be gathered from the paper by him which appeared in this *Journal* no longer ago than April 18 (p. 860). Later he believed that he had incriminated a virus as the cause of fibrositis and acute rheumatism, and he also interested himself in the possible part played by viruses in the aetiology of cancer.

Gordon was twice vice-president of the Section of Pathology and Bacteriology at Annual Meetings of the B.M.A., and in 1938 he was president of the Section. He also served on a number of B.M.A. committees, including the Committee on Research, Causes, and Treatment of Arthritis and the Vaccination and Immunization Subcommittee. In 1936 the honorary degree of LL.D. was conferred on him by the University of Edinburgh.

Gordon was a giant in his earlier days, and did magnificent work despite multifarious duties as a teacher and hospital bacteriologist. At that time he not only examined many specimens, but took the liveliest interest in the patients from whom they came. Some time after he became a pure research worker the methods to which he was accustomed may be said to have failed him for the more difficult and ambitious projects with which he was then faced, and the more refined techniques by which viruses are now studied were developed at a time in his career when few men can adjust themselves to a fresh approach.

As a man he was the most selfless and devoted worker his friends have ever known. He had no interest in money and very little in honours; apart from a fondness for old books and a leaning towards archaeology, he seemed to have no interests outside his work. The simplicity of his life is illustrated by the fact that he used to buy sixpenny ties from barrows in the Farringdon Road—these were also a hunting-ground for old books—and give them an hour in a paraffin oven to rid them of any possible vermin. His work was everything to him, and the enthusiasm with which it was pursued was an inspiration. He handled cultures in a delicate and almost loving way, and delighted in good microscopic preparations. His enthusiasm was not only for his own work, but for that of others, however elementary or unimportant. His junior colleagues, from whom he suffered endless interruptions in quest of his advice, owe him an inestimable debt for the care and kindness with which he went into their problems. Visitors to his laboratory were all the more numerous because he was a most entertaining talker, with an inexhaustible stock of anecdotes, told with immense gusto. No one who heard him will forget the officer with a chance to whom he showed his spirochaetes wriggling under dark ground illumination—"... the fellow was absolutely delighted"—or the officer with beautiful new riding boots which disintegrated as he walked away from Millbank after a new antiseptic had been tried on him in the steam inhalation chamber for treating meningococcus carriers. The high lights of his description of experiments in the House of Commons were the frequent recovery of a characteristic streptococcus from the mouth of a certain Cabinet Minister in plates exposed in the Ladies' Gallery, and the smoke test during which a policeman in the lobby was only just prevented from summoning to Westminster every fire-brigade in London. His stories—and stories about him—still abound. No one at Bart's for many years has inspired or deserved greater affection.

In 1916 Gordon married Mildred Olive, daughter of Sir William Power. She predeceased him by four months, and they had no children.—L. P. G.

R. O. MOON, D.M., F.R.C.P.

Dr. R. O. Moon, a distinguished and scholarly member of the older generation of London consultants, died after a short illness at Wallingford, Berkshire, on July 28 at the age of 88.

Robert Oswald Moon was born in London on March 17, 1865. From Winchester he went on to New College, Oxford, where he read "Greats." When he began his medical training at Guy's Hospital he was rather older than most of his fellow students, and he qualified in 1896 at the age of 31. He took the degrees of B.M., B.Ch., and the diploma of M.R.C.P. in 1899, proceeding to the D.M. a year later. In 1909 he was elected F.R.C.P., and he was assistant registrar at the College from 1926 to 1933. Throughout his long life Moon displayed a remarkable energy and enthusiasm for the object immediately in hand. Shortly after he qualified the urge to serve a worth-while cause took him out to the Balkans, where he worked as a surgeon to the Phil-Hellenic Legion in the Graeco-Turkish War of 1897; and he had hardly obtained his degrees in medicine before he was abroad again, this time to take part in the war in South Africa in 1900 as a trooper in the Hampshire Yeomanry. In 1901 he was appointed a civil surgeon to a field force, with which he went into action, being mentioned in dispatches.

After returning to London he became clinical assistant at the National Hospital for Nervous Diseases, and at the Hospital for Sick Children, Great Ormond Street. Later he decided to specialize in diseases of the heart, and was appointed to the honorary staffs of the National Hospital for Diseases of the Heart, the Royal Waterloo

(Elliott and Fry, London)

Hospital, and the Western General Dispensary. In 1914 war again interrupted his work, and early in 1915 he was back in the Balkans acting as medical officer to Lady Paget's Hospital at Skoplje. Falling a victim to typhus fever, he returned to England, and in 1916 he described his experiences as a patient in his Chadwick Lectures in that year. In the following year he entered the R.A.M.C. as a major.

In the ensuing years he continued to serve on the staffs of the National Hospital for Diseases of the Heart and the Royal Waterloo Hospital, and built up a consulting practice in Wimpole Street. He often took part in discussions at the Royal Society of Medicine, where he was president of the Section of the History of Medicine and St. Cyres lecturer in 1937, and he contributed many articles on this specialty to this and other journals, besides being the author of two books on cardiology, *The Prognosis and Treatment of Diseases of the Heart* (1912) and *The Growth of Our Knowledge of Heart Disease* (1927). His interest in the classics led him to a study of Hippocrates, Galen, and other early medical writers, and in the FitzPatrick Lectures which he gave before the Royal College of Physicians in 1921 and 1922 he discussed Hippocrates and his successors in relation to the philosophy of their time. He was also an authority on Goethe, and published a translation of *Dichtung und Wahrheit* in 1932 and also of *Wilhelm Meister*. In 1938 he translated the autobiography of Goethe's friend, Jung Stilling. Other books of which he was the author were *The Relation of Medicine to Philosophy* (1909)—a subject which always interested him—and *Medicine and Mysticism* (1934).

A well-known member of the Reform Club, Moon made several unsuccessful efforts to obtain a seat in Parliament as a Liberal. In his attitude to life he had a certain toughness that served him well in his early adventures. He was never seen to wear an overcoat, and he enjoyed good health until his fatal illness. He married Ethel, daughter of General Waddington, and had one son and four daughters. His wife died in 1933.

We are indebted to Sir ARTHUR MACNALT for the following appreciation: For Robert Oswald Moon I have always had great affection since the far-off days when he used to take me on cycling expeditions in the country round Winchester. When I came to London as a medical student I often visited him at his house in Green Street—he was then in consulting practice—and we had talks together on the classics, Goethe, medicine, and many other subjects. Moon first contemplated entering the diplomatic service after taking "Greats" at Oxford. To that end he was proficient in French and German, and well read in both languages, becoming an authority on Goethe and Heine. He took up medicine later in life and specialized in diseases

of the heart. Two other fields of action attracted him—politics and military service. In politics he was unfortunate, for as a Liberal he was given entrenched Conservative seats to fight. In war he won distinction. As a student he interrupted his studies at Guy's Hospital for the Graeco-Turkish war. I saw him ride forth from Winchester as a trooper in the Imperial Yeomanry to the South African War. When it was discovered he was a doctor, authority transferred him to the R.A.M.C. In the first world war he nearly died of typhus in Yugoslavia. He spoke to me of his disappointment in not going on active service in the second world war. He was accepted as a medical volunteer for the expedition to Finland, which was abandoned subsequently. His trim figure with pointed beard reminded one of the Elizabethan heroes, and in his distinguished career, like some of them, he was a mixture of the scholar-philosopher and the man of action. In life he fought a good fight in more senses than one, and was a skilled and sympathetic physician, a learned medical historian, and a good friend to many.

JAMES M. WYATT, M.B., F.R.C.S., F.R.C.O.G.

Obstetrics and gynaecology in this country has lost a noteworthy figure in the death of James Wyatt, which took place on July 31 in St. Thomas's Hospital after a short terminal illness, though he had been in indifferent health for a long time. It was only his strength of character and pertinacity in the face of great physical handicaps which had kept him going for the last few years. He died in the hospital in which his entire career had been spent, from his entrance there as a student 53 years ago to his final eight years as consulting obstetrician. There he had taught generations of medical students and pupil midwives, and had established his reputation as one of the foremost obstetricians and gynaecologists of his time.

James Montagu Wyatt was born in 1883, one of a large family, all of whom achieved distinction in their various ways. His father, Thomas Henry Wyatt, was a senior Civil Servant at the War Office. James Wyatt went to the Merchant Taylors School, and from there in 1900 to St. Thomas's, where he was a distinguished student both in the field of sport and academically winning prizes in obstetrics and gynaecology. After qualifying in 1905 he passed through the various residencies, registrar, and tutor appointments in the specialty which he had decided to take up both at St. Thomas's and at Queen Charlotte's Hospitals. In 1910 he took the F.R.C.S., and in the following year graduated M.B., B.S. (London). It was then that his very successful career began with his appointment to St. Thomas's Hospital as obstetric physician to out-patients, and later as gynaecologist to the Grosvenor Hospital for Women. His colleagues were John Fairburn and J. P. Hedley and for many years they formed an excellent team. During the first world war Wyatt's career as gynaecologist was interrupted when he served in the R.A.M.C., T., as a surgeon to the 5th London General Hospital. He was also medical officer in charge of hospital for officers run by Lady Ridley at her home in Carlton House Terrace. After this military diversion he returned to St. Thomas's as obstetric physician and lecturer in midwifery and diseases of women, and eventually in 1936 on the retirement of J. P. Hedley he became senior obstetric physician. As a teacher he was in his element, for he was able to hold the attention of his audience by his effective presentation of his subject combined with a pleasant touch of dry humour. Besides his hospital work Wyatt also had an extensive private con-

sulting practice in Queen Anne Street and later in Harley Street.

The second world war again greatly interfered with his professional life, but he devoted himself wholeheartedly to the welfare of his hospital and medical school. He was responsible for much of the organization behind the move of St. Thomas's down to Surrey, and he was himself warden of the Manor House, Godalming, where a large number of students were in residence. With the return of the medical school to London in 1946 he retired from the active staff of the hospital three years after the usual retiring age, but he became an active member of the governing bodies of St. Thomas's, Queen Charlotte's, and the Chelsea Hospital for Women.

Wyatt was a leading spirit in the foundation of what afterwards became the Royal College of Obstetricians and Gynaecologists in 1929, and was one of its original Fellows. He was vice-president of the College in 1946-9, and also served as a member of the Fellowship Selection Committee and of the Examination Committee, of which he was chairman in 1947-9. The Section of Obstetrics and Gynaecology of the Royal Society of Medicine knew him as a very prominent member, and at one period no important discussion in that Section was complete without some contribution from Wyatt. He entertained his fellow members on one occasion by describing how he had acted as accoucheur to a chimpanzee at the Zoo. For many years he was chairman of the Children's Sanatorium at Holt, Norfolk. He served the Universities of Oxford, Cambridge, London, and Manchester, and the Conjoint Board as examiner in midwifery and diseases of women.

Retirement from active hospital work in 1946 meant for him an extension of activity in wider fields. From 1947 to 1952 he served as representative of the Royal College of Surgeons on the Central Midwives Board. When the South-west Metropolitan Regional Hospital Board was constituted he was from the first a very active member, putting in arduous duty in his zeal to bring the hospital service under the National Health Service Act safely through the perils of parturition. He was an indefatigable committee man, and once, counting up the committees of which he was or had been a member, he found that they came to nearly 40.

Wyatt was a bachelor and was able to devote much of his time to the welfare of his students, being particularly interested in the amalgamated clubs at St. Thomas's. He was president of the Rugby Club for many years, and in this capacity he will be remembered with gratitude by a great number of St. Thomas's men. The Rugby tours based at the Watch House at Mevagissey are the treasured memory of hundreds. He was a generous host and a kindly friend, and his help and advice were always sound and invaluable. His jovial laugh and ability to join in with everyone were characteristic of his geniality. It was typical of his generosity that he lent his lovely house at Mevagissey to many for honeymoons, holidays, or convalescence. Among his other great interests was amateur boxing, and he was president of the Amateur Boxing Association for ten years, being responsible for much of the organizational work which preceded the Olympic Games at Wembley in 1948.

James Wyatt was a happy man, devoted to his work, his patients, his family, and his students. He will be remembered with respect and love by them all.

MARGARET C. TOD, M.B., F.R.C.S.Ed., F.F.R.

Miss Margaret Tod, deputy director of the Christie Hospital and Holt Radium Institute, Manchester, died at her sister's home in Edinburgh on July 26, aged 60, after a long illness borne with the utmost courage in the full knowledge of the inevitable outcome.

Margaret Christine Tod began the study of medicine comparatively late, for during the first world war, after training as a V.A.D. and in physiotherapy, she opened a naval auxiliary hospital with the consent of her father, Mr. T. W. Tod, at her home in Corstorphine, and for four years worked practically single-handed, dealing with patients referred to her by Mr. C. P. G. Wakeley (now Sir Cecil Wakeley), then a young naval surgeon at South Queensferry. The patients were mainly suffering from injuries to bones and joints, and she soon learnt to handle them in a manner now recognized as rehabilitation. She continued this work for four years, at the end of which time she was appointed an Associate of the Royal Red Cross, an honour which she greatly prized.

She began her medical studies at Edinburgh University in 1919, graduating M.B., Ch.B. in 1924 with first-class honours, and being awarded, among many other prizes, the Ettles scholarship and Leslie gold medal for the most distinguished student of the year, this being the first occasion on which this prize was gained by a woman. After holding resident posts at Bruntisfield Hospital for Women and the Royal Hospital for Sick Children, and visiting clinics in the United States, she became F.R.C.S.Ed. in 1926. Further postgraduate work followed, and in 1927 she was appointed honorary assistant surgeon at Bruntisfield Hospital, and later she acted for a short time as temporary assistant surgeon at the Royal Hospital for Sick Children.

After a short period of practising surgery, Miss Tod's interest gradually turned to the treatment of malignant disease, and she accordingly took the diploma of radiology in Edinburgh in 1936, at the same time working in the radiology department of the Royal Infirmary, where she developed the newly established follow-up clinic of malignant cases. After gaining her diploma she worked with the late Mr. J. J. M. Shaw at the Beechmount Annexe to the Royal Infirmary, where radiotherapy was then carried out, being appointed honorary associate assistant surgeon. In 1937 she obtained the post of deputy director, under Dr. Ralston Paterson, to the Christie Hospital and Holt Radium Institute in Manchester, and for the past fifteen years had worked there with great distinction, gaining an international reputation in radiotherapy. She was the author of a large number of papers in this specialty, and latterly undertook several visits, sponsored by the British Council, to South America, to Italy, and to Austria, for the purpose of furthering the knowledge of modern methods of radiotherapy in these countries.

In 1945 she was appointed a member of the Radium Commission, and for the last eighteen months of its existence she acted as secretary to this body. She was a Fellow of the Faculty of Radiologists, and at the time of her death was editor of the *Journal of the Faculty of Radiologists* and secretary of the Radiology Section of the Royal Society of Medicine. In 1951, in recognition of her distinguished work, she was awarded the Röntgen medal by the British Institute of Radiology.

Dr. GERTRUDE HERZFELD writes: Peggy Tod was a woman of outstanding character and ability, and her loss

will be deeply felt by a wide circle of friends in Edinburgh, in Manchester, in Europe, and in South America. Behind a modest and unassuming manner she hid a firm determination to give of her best in her medical career. She was a staunch and loyal friend, honest and sincere, and showed her generosity on many occasions when she helped some of her colleagues who were less well off than she, though her gifts were invariably anonymous. She was a delightful companion, very hospitable, and enjoyed taking her friends through her lovely gardens and woods in Corstorphine, surrounded by Shetland sheepdogs, which she bred for many years. She was widely read, very musical, and interested above all in human beings. Her loss will be widely felt, and we extend our sympathy to her sister, who nursed her so devotedly, and to her nephew.

T. B. SELLORS, M.D.

Dr. Thomas Blanchard Sellors died suddenly at his home in Chesham on July 22 at the age of 80. He led a full and valuable life, being regarded by his many friends as a fine example of the family doctor. Born in Warwickshire on August 21, 1872, he was educated at King Henry VIII School, Coventry, and studied medicine at the Middlesex Hospital. After qualifying in 1898 he entered general practice in South London. Some years later he moved to Westcliff-on-Sea, then a small seaside resort, and worked there for thirty years before retiring to Berkhamsted just before the second world war. During the war he returned to practice, and up to the time of his death never relinquished his interest in medicine and in his old patients. Though primarily a family general practitioner, he made a specialty of dermatology, which led to his being appointed as physician to the Victoria Hospital, Southend, and for many years he acted as clinical assistant to Dr. Harry MacCormac at the Middlesex Hospital, where he maintained a friendship with those members of the consulting staff whom he first knew in his student days. The recent death of Victor Bonney caused him considerable sorrow.

Throughout his career his ability as a teacher was well recognized, and he spent many hours lecturing and examining for the St. John Ambulance Brigade and the British Red Cross Society. He was also a divisional medical officer of the National Fire Brigades Union. During the early days of the first world war he was instrumental in training a Voluntary Aid Detachment which proved of yeoman service in staffing a hospital, and from 1916 to 1918 he served in France as a captain in the R.A.M.C. Shortly after demobilization he took the degree of M.D. at Durham University. In 1944 he was appointed an Officer of the Order of St. John of Jerusalem.

An active member of the British Medical Association, he was president of the Essex Branch in 1931-2. His enthusiasm for Freemasonry lasted until the time of his death, and he contributed several works on the historical aspects of the subject. In his younger days he was a keen cricketer and played until well into middle age, while in later years he enjoyed fishing and playing bowls. The classics and a study of church architecture occupied much of his holidays, and were absorbing relaxations to him after retirement, but these were only part of his diverse interests, which covered motoring, gardening, and carpentry. Indeed, there was little that he could not claim as a hobby.

By his first wife, Anne McSparron, who died in 1943, he had a son, Mr. T. Holmes Sellors, the well-known thoracic surgeon, and a daughter. His second wife,

Mary Edwards, was principal matron of Princess Mary's Royal Air Force Nursing Services, and to her our deepest sympathy is extended.

We are indebted to Sir GORDON GORDON-TAYLOR for the following appreciation: The death of Dr. Tom Sellors in his 81st year brings to mind a group of general practitioners of the very highest type whose sphere of activity lay in the Southend-Westcliff area, and of whom he must have been one of the last survivors. Of West of Scotland stock, he received his medical education at the Middlesex Hospital, and throughout his professional life was an almost constant attendant in the dermatological clinics of the late Dr. J. J. Pringle and Dr. Harry MacCormac. He was himself the dermatologist at the old Royal Victoria Hospital, Southend, for many years. The 1914-18 war took him to France, where he served as a regimental medical officer, and subsequently in the thoracic wards at No. 10 General Hospital, Rouen. He interested himself in good literature, in work for the St. John Brigade, in Freemasonry, and in cricket, being an enthusiastic member of a Southend medical cricket eleven which flourished before the outbreak of the second world war. Loyal to his own Scottish roots, he sent his son to Loretto and survived to see him obtain the high position that he holds in the world of thoracic surgery to-day. Tom Sellors belonged to the very highest type of general practitioner, a group of which this country has reason to be mighty proud.

Medical Notes in Parliament

PRIVATE SOLDIER'S DEATH

Replying on July 28 to seven Questions on the death of Private D. Harrison in a military hospital and the court-martial at which Lieutenant-Colonel A. Gleave was acquitted of the charges against him,¹ Mr. ANTONY HEAD, Secretary of State for War, said:

"Hon. Members will recall that as soon as the allegations of ill-treatment of Private Harrison were brought to my notice I ordered an immediate court of inquiry. On receiving the report of the court of inquiry, I had to decide what I should say to the House on the facts as presented to me, and what action I myself and the responsible authorities ought to take. On June 16 I gave a full and frank reply to the House about this case, and I said that the medical specialist and the day sister concerned would be reported to the appropriate professional bodies. About Colonel Gleave I said, 'As far as I can ascertain, no thorough inquiry was instituted by the commanding officer although on May 18 he stated that a full inquiry had already been made by himself.'

"The commanding officer was subsequently tried by court-martial on charges that he failed to investigate or report the allegations, and that he agreed a statement to the Press that the allegations had been fully inquired into when he knew that they had not. I still believe that the decision that Colonel Gleave should be tried by court-martial was correct, and I would point out to the House that, if he had not been tried, he would have had no subsequent opportunity of vindicating his reputation, which had been impugned. It will be realized that the charges against Colonel Gleave were concerned solely with the action which he took after the alleged ill-treatment of Private Harrison; and I would stress that it was never at any time suggested that the commanding officer was himself personally responsible for that treatment. This fact I felt must be made quite clear in my statement to the House because, had I not been specific about the reasons why Colonel Gleave was to be tried and had I baldly stated that he was to be court-martialled, it might well have appeared by inference that he was alleged to be personally concerned in the treatment of Private Harrison.

"Now that Colonel Gleave has been acquitted on the first charge and honourably acquitted on the second the House will wish to know whether this affects either the evidence or the action taken regarding the treatment of Private Harrison while in hospital. I have now had time to examine the full court-martial

¹British Medical Journal, July 25, p. 230.

proceedings of which I have placed a copy in the Library, and, in the light of them, to review the court of inquiry's evidence where it concerns Private Harrison's treatment. After having done so, I am still of the opinion that the evidence relating to the medical specialist and the day sister should be placed before the appropriate professional bodies.

"I have also reconsidered whether I should institute a further inquiry into all the circumstances of this case. I see no reason to change the view which I previously expressed to the House that this regrettable occurrence did not arise from any fault in the medical system but was due to a failure within that system."

Serious Aspersions

After this statement Mr. Head answered supplementary questions. Replying to Mr. F. J. BELLENGER, who asked whether the Minister had additional evidence which warranted his casting very serious aspersions on the honour and conduct of the commanding officer, Mr. HEAD said his remarks had been based on the court of inquiry and the G.O.C. in C.'s comments on the court of inquiry. Had he made no specific references to why Colonel Gleave was being tried, the public and the House could not have come to any conclusion other than that it was due to his own personal conduct in the treatment of Private Harrison. The holding of a court-martial was not necessarily a sign of misconduct by an officer. It provided an opportunity for an officer to clear his own conduct.

Replying to Mr. M. STEWART, he said his opinion on the evidence presented to him was that there was a fault arising out of the fact that the second thorough and statutory examination after admission was not made. That evidence had been reported to the appropriate professional bodies. As to the cross-questioning of witnesses for the prosecution, the House would appreciate that in a court-martial it would be improper for the prosecution in any way to institute a state of affairs giving special protection of witnesses for the prosecution. The main case for the defence was concerned with the discrediting of the witnesses against Colonel Gleave. Replying to Mr. J. STRACHEY, Mr. HEAD said that, once a diagnosis had been made and those who were acting on it were doing their duty, there was often a tendency to stick to the treatment which had been prescribed despite the fact that circumstances might suggest that it was false. It was due to the fact that this was not spotted earlier that the regrettable occurrence took place.

Pillorying a Specialist

Mr. C. S. TAYLOR asked whether it was not wrong to try to pillory a medical specialist for making what he had admitted to be an imperfect diagnosis. Had not nearly every doctor at some time made a wrong diagnosis? Mr. HEAD said he would be the first to agree about that. What he said about the medical specialist in this case was that it was statutory that another thorough examination should be made after admission. Because that thorough examination was never made he had reported the officer.

Mr. HERBERT MORRISON asked whether it would not be a good rule that when a court-martial was to be held the Secretary of State should not express judgment on a person or on facts likely to be the subject of inquiry at the court-martial. Mr. HEAD replied that he had specified these charges because if he had not specified them it would have been assumed that Colonel Gleave was being tried for his own personal conduct.

Mr. HEAD said he had reminded all hospitals that the existing procedure should be strictly adhered to in all cases of admissions.

Mr. HAROLD DAVIES asserted that the number of patients in the hospital had increased from 150 to 450, but the staffing, apparently, was still the same as when there had been only 150 patients.

Mr. HEAD replied that this was incorrect. The medical officers and the subordinate nursing staff were at full strength. There was a deficiency of 18 nursing officers of the Queen Alexandra's Royal Army Nursing Corps, which

reflected a world-wide shortage. He was trying to increase recruits for that service.

The Speaker then closed the discussion.

Grievous Injustice

In the course of the debate on the Consolidated Fund Bill on July 29 Mr. F. J. BELLENGER said he wanted to ask the Secretary of State for War about the diagnosis made in the case of the late Private Harrison. He could not imagine that in an illness so serious as a malignant disease, which was found out quite quickly when physical examination was carried out, it was not possible to make an earlier diagnosis. He asked why not only the Army doctors failed but also the Ministry of Labour doctors failed to diagnose the disease when they examined the man. Why were no x-ray photographs taken of him? He also questioned whether such men as Private Harrison were really of any use to the Army. Was it any use filling up Army ranks with third-rate individuals who could only be a liability to the Service? He then referred to the personal position of the Secretary of State for War (Mr. Antony Head). He believed that statements made by the Secretary of State in the House before the court-martial had been held had done a grievous injustice to one of his officers. The Secretary of State had said about one of his commanding officers:

"I have been into the whole of this serious occurrence most carefully."

He then went on to say that he was convinced that it was not a fault in the method of procedure, but the failure of certain individuals to carry out their duties. He also said:

"Members of the Army Medical Service carry heavy responsibilities, and those who fail to discharge them must be called to account."

He concluded by saying:

"The commanding officer will be called to account for his conduct in this matter, and is to be tried by court-martial."

Mr. Head had given the impression yesterday that he was giving Colonel Gleave an opportunity to clear himself of certain accusations by way of a court-martial.

Mr. HEAD: Will the right hon. gentleman allow me to explain that these words "called to account" literally mean "given an opportunity to state why"?

Mr. BELLENGER: By his own statement the right hon. gentleman had assumed, as a result of the court of inquiry, that there was a prima-facie case of guilt against this commanding officer.

If the Secretary of State, he continued, thought that Colonel Gleave should be court-martialled he should have said so, but he should not have coupled with that a statement which pointed to Colonel Gleave as guilty of a very serious offence.

Mr. ANTONY HEAD, Secretary of State for War, replied that if he had said that Colonel Gleave would be court-martialled there could have been nothing in the public mind but the inference that Colonel Gleave was accused of being responsible for the ill-treatment of Harrison.

Mr. BELLENGER continued that the Secretary of State had impugned Colonel Gleave's honour. Officers in the Army were not allowed to answer the Secretary of State back. It was therefore incumbent on him to be very careful about what he said, otherwise the morale of the Service might suffer. At the trial defending counsel had referred obliquely to Mr. Head's statement and used it to show that Colonel Gleave had been prejudiced, at any rate so far as his military career was concerned, by something that Mr. Head had said. Mr. Belenger concluded by saying that Colonel Gleave had been acquitted by court-martial of the two limited charges laid against him, but he suspected that the administration of the hospital under Colonel Gleave was not all that it might be.

Dr. H. MORGAN said surely that was a disgraceful charge and insinuation to make against an officer who was now subject to a review of his general conduct in connexion with this incident. It was quite unfair. Mr. BELLENGER said he did not think this was subject to review.

Mr. Head's Reply

Mr. HEAD said in reply that Mr. Bellenger implied there was a scandal in the hospital and that he (Mr. Head) decided to avoid difficulty in the House by being extremely rough with his own officers, but he thought there were few things more contemptible than such conduct. First, Mr. Bellenger had said it was wrong that there were no subsequent examinations of this man after admission to hospital and that was a thing which should be investigated, but he (Mr. Head) had reported the officer concerned to the professional body. Secondly, Mr. Bellenger had said that they should not allow grade-3 men to go into the Army, but it was Mr. Bellenger's Government which had introduced the admission of grade-3 men. As to the charge of a grievous injustice to Colonel Gleave, Mr. Head said that he had the report of the court of inquiry and the G.O.C.'s comments on it, and after consultation with the Director-General of the Army Medical Services and other advisers he decided that the only fair thing was to ensure that Colonel Gleave's Army career would not be prejudiced.

If he had said nothing, the general public would have inferred that it was Colonel Gleave's fault that this boy had had wrong treatment. What Colonel Gleave had been court-martialled for was nothing to do with Harrison's alleged ill-treatment. It was purely concerned with what had happened after it was all over. He believed that that was better for Colonel Gleave. If he was wrong he accepted it, but at the time he was not being vindictive against Colonel Gleave, nor was he attempting to get out of the situation. He thought that was the best thing to do.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in the week ending July 25 (29th week of the year) were as follows: paralytic, 151 (147); non-paralytic, 115 (76); total, 266 (223). This is an increase of 43 compared with the previous week, the figures for which are in parentheses. Districts which have notified 15 or more cases in the year to July 25, with incidences per 100,000 in parentheses, are as follows: Southend-on-Sea C.B., 32 (21.12); Liverpool C.B., 18 (2.28); Hendon M.B., 15 (9.63); Birmingham C.B., 38 (3.40); Coventry C.B., 53 (20.31); Pewsey R.D.C., 16 (87.77); Manchester C.B., 15 (2.13); Leicester C.B., 15 (5.25); Lewisham M.B., 16 (7.05).

Total notifications remain at a slightly higher level than in the corresponding week in any previous year. But the increase during the week ending July 25 was largely due to non-paralytic cases. So far in no part of the country is there a focus of undue size, and it would be premature to forecast this year's incidence. A further seasonal rise is to be expected throughout August.

Infectious Diseases

During the week ending July 18 there were fewer notifications of most infectious diseases in England and Wales. Scarlet fever notifications fell by 54 from 1,072 to 1,018; whooping-cough by 189 from 4,407 to 4,218; measles by 709 from 5,504 to 4,795; and dysentery 145 from 525 to 380.

The largest returns of dysentery were Bedfordshire 31 (Luton M.B. 19); Lancashire 57 (Liverpool C.B. 19, Preston C.B. 11, and Warrington R.D. 15); Middlesex 34 (Tottenham M.B. 12); Surrey 31 (Barnes M.B. 13); and Yorkshire West Riding 34.

There were 284 cases of food-poisoning notified from Flintshire (Prestatyn U.D.).

Week Ending July 25

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,037, whooping-cough 4,357, diphtheria 17, measles 4,394, dysentery 309, paratyphoid fever 11, typhoid fever 2, and food-poisoning 516.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending July 18 (No. 28) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1953					1952

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Lunacy in Britain.—At the end of last year there were nearly 150,000 patients in mental institutions in England and Wales, according to notifications received by the Board of Control. The great majority were Health Service patients, but the total includes 5,000 private and 1,000 Broadmoor patients. For the last four years the number of patients in mental hospitals has been increasing at an average rate of over 1,000 a year. In their annual report to the Lord Chancellor the Board of Control stresses the serious overcrowding in the mental hospitals: according to the prescribed standards there were 17,500 more patients in these hospitals than they were designed to take. Equally serious is the shortage of nurses, as this has meant that many wards have had to remain closed. Nor is there much sign of improvement in the recruiting of mental nurses. The tuberculosis rate, at 6.1 cases per 1,000 resident patients, was the lowest for 13 years, and dysentery is said to have become a much less formidable illness.

Medical Research in New Zealand.—The Medical Research Council of New Zealand differs from its British counterpart in that most of its members are nominated by learned bodies, the remainder being *ex officio*. In Britain the Council (with two exceptions) elects its members itself, on the basis of their personal scientific attainments. Two years ago the New Zealand M.R.C. was reconstituted by Act of Parliament, one of the main objects being to remove its yearly financial anxiety and thus permit long-term planning, and it has now issued its first annual report (for 1952) since the change. It received a Government grant of £40,000 for the financial year 1951-2, and with this much has been achieved. In the clinical field most of the work has been concerned with the action of the hypotensive drugs; dental research has taken the form of epidemiological surveys and a physico-chemical study of caries; studies on the thyroid gland, started over 30 years ago by Sir Charles Hercus, are continuing, though now interest is centring on the role of the pituitary gland and the hypothalamus. Other fields of research activity include microbiology, neurophysiology and neuropathology, and nutrition. There is a small committee to direct research in each field.

Nuffield Medical Fellowships.—Each year the Nuffield Foundation offers a number of fellowships to medical graduates. Their aim is to fit the recipients for senior appointments in medical teaching and research in Britain. The usual annual value of each fellowship is between £900 and £1,300 (subject to income tax), and if the recipient goes abroad for study his travelling expenses are paid. Application forms and further details are obtainable from the secretary, Nuffield Foundation, Nuffield Lodge, Regent's Park, London, N.W.1. Selection for fellowships is made once a year; and applications must be received by May 1.

Occupational Therapy at Park Prewett Hospital.—On July 29 a new occupational therapy centre at Park Prewett Hospital, Basingstoke, was opened by the Duke of Wellington. This pleasant ceremony was preceded by a lunch at which there were a number of distinguished guests, the chairman for the occasion being Mr. R. P. Chester, chairman of the Park Prewett Group Hospital Management Committee. Park Prewett is a large mental hospital with nearly 1,500 beds, and in addition it provides accommodation for the well-known plastic surgery unit at Rooksdown House. The hospital has had a flourishing occupational therapy department for some time past, and the new centre, which has been cheaply provided by the adaptation of huts formerly used for war purposes, will enable many more patients to take part in some form of creative activity. A display of work done by the patients was on view at the opening of the centre, and in particular some of the sculpture in Bath stone and many of the drawings were more

than competently executed and quite out of the usual run of amateur work. One piece of sculpture by a patient has recently been bought by Lincoln Cathedral. The management committee and the medical superintendent, Dr. I. Atkin, are to be congratulated for not allowing lack of capital to deter them from adding to the assets of the hospital.

Travelling Awards.—The Medical Research Council announces the following travelling awards for the academic year 1953-4:

Rockefeller Travelling Fellowships in Medicine (tenable at centres in the U.S.A.).—Dr. J. R. Anderson, Lecturer in Pathology, University of Glasgow; Dr. D. H. L. Evans, Lecturer in Anatomy, University College, London; Dr. O. F. Hutter, Assistant Lecturer in Physiology, University College, London; Dr. R. I. McCallum, First Assistant, Nuffield Department of Industrial Health, King's College, Newcastle-upon-Tyne; Dr. J. Paul, Assistant Lecturer in Biochemistry, University of Glasgow; and Dr. G. Watkinson, Lecturer in Medicine, University of Leeds.

Eli Lilly Travelling Fellowships in Medicine (tenable at centres in the U.S.A.).—Dr. J. G. Millichap, Chief Assistant, Children's Department, St. Bartholomew's Hospital, London; and Dr. G. H. Sloane Stanley, Assistant Lecturer in Biochemistry, Institute of Psychiatry, Maudsley Hospital, London.

Alexander Pigott Wernher Memorial Travelling Fellowships in Otolaryngology.—Dr. D. R. Haynes, Department of Otolaryngology, Johannesburg General Hospital (second year award tenable at King's College Hospital, London).

French Exchange Scholarships in Medical Science (in association with the Centre National de la Recherche Scientifique).—Dr. D. Rowley, Bacterial Chemistry Department, Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London.

Applied Psychology Unit.—Dr. N. H. Mackworth has been appointed director of the Medical Research Council's Applied Psychology Research Unit at Cambridge as from October 1, 1952. He was formerly assistant director. Most of the unit's work will in future be done outside the University Department of Experimental Psychology (which is under Professor O. L. Zangwill) in accommodation acquired by the M.R.C. at 15, Chaucer Road, Cambridge.

British Standards Institution moves next week to its new quarters at 2, Park Lane, London, W.1 (Telephone No. MAYfair 9000). The move is expected to be complete by August 17.

Dr. Janet Vaughan, principal of Somerville College, Oxford, is at present the only medical member of the committee which the Chancellor of the Exchequer, Mr. R. A. Butler, has appointed to review the economic and financial problems involved in providing for old age.

COMING EVENTS

The Seventh Congress of the International Scientific Film Association will be held in London from September 18 to 27. During this time there will be meetings of the General Assembly of the Association and of the permanent committees dealing with medical, research, technical, and industrial films, and a festival of scientific films. These will take place in the Royal Festival Hall and National Film Theatre, London, S.E.1. Further particulars may be obtained from Dr. R. C. Mac Keith, Guy's Hospital, London, S.E.1.

Conference on Medical Photography.—The fourth annual conference of the Medical Group of the Institute of British Photographers will be held at Devonshire Hall, University of Leeds, from September 25 to 27. Full details and tickets can be had from Miss C. E. Campbell, Department of Medical Photography, St. James's Hospital, Leeds, 9.

The 22nd General Hospital Reunion Dinner will be held at the Stork Hotel, Liverpool, on September 26. Further particulars may be obtained from C. Cooke, 17, Greenhill Avenue, Liverpool, 18.

NEW ISSUES

Medical and Biological Illustration.—The next issue (Vol. 3, No. 2) will be available in a week's time. The contents include:

A PUBLISHER SPEAKS. Charles Macmillan.
MOUNTING: PART II. THE MOUNTANT. Sylvia Treadgold.
THE PHOTOGRAPHY OF SURGICAL INSTRUMENTS. Eric Freeborn.
THE PHOTO KERATOSCOPE. E. F. Fincham.
A HOME-MADE SOUND PROJECTOR. H. Dekking.
A METHOD OF INVESTIGATING SMALL THREE-DIMENSIONAL OBJECTS. S. Engel.
EQUIPMENT AND METHODS:
LOCAL CONTROL IN PRINT CONTRAST.
CABINET FOR LANTERN SLIDES.
A TECHNIQUE FOR RECORDING RADIATION CHANGES IN FINGER-RIDGE PATTERNS.
INTERCHANGEABLE FILTER HOLDER.
THE HASSELBLAD CAMERA.

Issued quarterly; annual subscription £2 2s., single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

Abstracts of World Medicine.—The August issue (Vol. 14, No. 2), which is now available, contains abstracts of important papers on both medical and surgical subjects drawn from the medical literature of some 20 different countries and of all five continents. In addition to clinical medicine and surgery, the subjects covered include pathology, bacteriology, pharmacology, and chemotherapy, and there are also sections dealing with public health and industrial medicine, toxicology, anaesthetics, radiology, and the history of medicine.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; a specimen will be sent free on request.

APPOINTMENTS

HOPKINS, E. H. BEYNON, M.R.C.S., L.R.C.P., D.P.H., Medical Officer of Health for the Llanelli Division of Carmarthenshire.
SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—J. C. Barker, M.B., B.Chir., Registrar in Diseases of the Chest in the Bristol Clinical Area; J. Roger Boule, M.B., Ch.B., Surgical Registrar, Taunton and Somerset Hospital; P. A. Ritchie, M.B., B.S., M.R.C.P., Registrar in Psychiatry, Moorhaven Hospital, Ivybridge; Elsie M. Sibthorpe, M.D., M.R.C.O.G., D.Obst., R.C.O.G., Senior Registrar in Obstetrics and Gynaecology in the Bristol Clinical Area.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Purdie.—On July 25, 1953, at North Middlesex Hospital, Silver Street, Edmonton, London, N., to Erica (formerly Roberts), M.B., B.Ch., wife of Anthony W. Purdie, F.R.F.P.S., F.R.C.O.G., a daughter.
Raphael.—On July 29, 1953, at the Royal Infirmary, Sunderland, to Gwen, wife of Dr. Montague Raphael, a daughter.

DEATHS

Alderson.—On July 15, 1953, at Tunbridge Wells, Kent, Frederick Herbert Alderson, M.B., aged 85.
Briggs.—On July 12, 1953, at Premier House, Gregory Boulevard, Nottingham, John Arthur Oswald Briggs, M.D., F.R.C.S., aged 80.
Burnier.—On July 17, 1953, at Lausanne, Switzerland, Edmond Etienne Louis Burnier, M.D.
Calverley.—On July 11, 1953, at Folkestone, Kent, Joseph Ernest Goodfellow Calverley, C.M.G., M.D., aged 81.
Ellis.—On July 20, 1953, at Kimbolton, Hunts, John Weaver Ellis, M.C., M.R.C.S., L.R.C.P., aged 64.
Forrest.—On July 10, 1953, at Beira, East Africa, Hugh Forrest, M.B., Ch.B., L.D.S.R.F.P.S., of Glasgow.
Forster.—On July 19, 1953, Albert Forster, M.B., B.S., of 28, Lemington Gardens, Fenham, Newcastle-upon-Tyne.
Forsyth.—On July 21, 1953, at 7a, College Lane, Bury St. Edmunds, Suffolk, Charles Forsyth, M.B., B.S., aged 85.
Goodwin.—On July 15, 1953, at the R.N. Hospital, Haslar, Hants, Ernest St. George Sagar Goodwin, M.D., D.P.H., Surgeon Captain, R.N., retired.
Mavor.—On July 25, 1953, at Ballater, George Alexander Mavor, M.B., Ch.B., D.P.H., late of 14, Grange Road, Edinburgh.
Maxwell.—On July 22, 1953, in hospital, Leslie Blyth Maxwell, O.B.E., M.B., B.Ch., of Warren Grange, Sandy Lane, Cheam, Surrey.
Meakin.—On July 10, 1953, Leslie Meakin, B.Chir., M.R.C.S., L.R.C.P., late of Ashton Keynes, Wilts, formerly of South Croydon, Surrey.
Rutter.—On June 16, 1953, Hubert Llewellyn Rutter, M.B.E., M.D., F.R.C.S., D.P.H., of 54, Middle Park Road, Selly Oak, Birmingham, aged 85.
Scouloudi.—On July 23, 1953, Mary Scouloudi, M.B., B.S., of 29, Pembroke Gardens, London, W.
Shaw.—On July 15, 1953, at the Nottingham General Hospital, James Denis Freshwater Shaw, M.R.C.S., L.R.C.P.
Stokoe.—On July 11, 1953, at his home, 10, Belmont Road, Scarborough, Yorks, John Stokoe, M.D., B.Hy., D.P.H., aged 51.
Tetley.—On July 17, 1953, at Hobground, Great Barugh, Malton, Yorkshire, Thomas Walsh Tetley, M.R.C.S., L.R.C.P., aged 79.
Vassallo.—On July 23, 1953, at 150, Great Tattenhams, Epsom, Surrey, Saviour Michael Vassallo, M.D., F.R.C.S.Ed., D.T.M.&H., late Senior Surgical Specialist, E. Africa, Lieutenant-Colonel R.A.M.C., Chairman Medical Board M.N.I., aged 62.
Vilvandre.—On July 26, 1953, at The Thatched Cottage, Redbourn, Herts, George Ernest Vilvandre, M.R.C.S., L.R.C.P., F.F.R.
White.—On July 7, 1953, at St. Thomas's Hospital, London, S.E., Henry Dennis White, M.R.C.S., L.R.C.P., of Wargrave, Berks, and Lynton, Devon, aged 32.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Sweet Taste in Diabetic's Mouth

Q.—A diabetic patient complains of a very sweet taste in his mouth which puts him off his food. What treatment is advised?

A.—This symptom is not uncommon in diabetics, but in my experience it is very difficult to treat, as it seems to bear little or no relationship to the degree of control of the diabetes. Nevertheless, I think this is important, and the first step should be to obtain good control of the sugar level and the complete absence of ketosis. These patients are often introspective, but reassurance seems to be of little value. My own practice is to advise the use of chewing-gum, the flavour of which seems to mask the sweet taste; if the gum is used for a reasonable length of time the taste often fails to return when the gum is discontinued. It is, of course, advisable to exclude dental sepsis, but I presume that this has already been done.

Besnier's Prurigo

Q.—What treatment is advised for an 18-month-old infant with severe and intractable Besnier's prurigo, present since the age of 3 months?

A.—It is assumed that the problem is that of the severe asthma-eczema-prurigo syndrome and not a mere flexural persistence of infantile eczema. The problem in general has been dealt with in a reply to an earlier question (September 6, 1952, p. 573). In this particular instance it is desirable to know more about the child, the parents and family, and the immediate environment, including psychological factors, which are the most important.

It may be assumed that there is an inborn functional, if not structural, variation from the normal, and that teething is likely to be an immediate provocative cause. Such infants readily harbour infection and even in early life acquire specific allergic sensitivities which must be investigated and dealt with. The latter are treated by removing allergens rather than desensitization, though resort to non-specific desensitization may be necessary.

The parent-child relationships, which are usually of prime importance in these cases, demand careful study, and the parents will need guidance. Ideally, treatment would include complete removal from the emotionally strained environment of the home to an indifferent atmosphere, but this is rarely practicable or desired. Nevertheless the parents must have some insight into this aspect of the problem for the benefit of the infant.

Otherwise treatment is symptomatic and empirical, including small doses of sedatives to quieten the child, relieve irritation, and favour rest. The writer does not approve of the antihistamines for this purpose. Locally, crude-tar pastes, gentian violet applications, and unsaturated fatty-acid creams help. Soap and water aggravate the eczema. Antihistamine and local anaesthetic creams should be avoided. Many subjects are xerodermatous, and vitamin A in large dosage helps—100,000 i.u. daily. Vitamin B and especially liver extract may be used with benefit. It would seem unwise to employ A.C.T.H. or cortisone at this age, since it is of only temporary value. Similarly x-ray therapy should not be given. In milder cases the condition may clear, though much depends on management and the environmental circumstances. In a few patients the affection persists.

Premenstrual Mastalgia

Q.—An unmarried girl of 19 has painful enlarged breasts for about a week before her period is due. When examined at this time her breasts are very much enlarged, with engorged lobules and a slight discharge from the nipples. She complains of pain in the sub-clavicular region due to the weight of the breasts, which necessitates a larger brassière. On taking stilboestrol, 0.5 mg. three times a day for five days mid-menstrually, she gained some relief from pain and a diminution in size of the breasts was noticed, but her menstrual cycle was prolonged to 35 days. What treatment is advised?

A.—Premenstrual mastalgia in a minor degree is so common that it can be regarded as normal. In its more severe form, as in the case in question, it is often part of a premenstrual tension state in which a background of over-anxiety may be important. The first line of treatment should be to restrict the intake of fluids to not more than 30 ounces (850 ml.) in 24 hours for two weeks premenstrually, and at the same time the patient should avoid salt as far as possible. Sodium retention is also discouraged by giving ammonium chloride, gr. 10 (0.65 g.), in capsules three times daily. This, together with reassurance and a well-fitting brassière, may be enough. Hormone therapy is not very satisfactory. Oestrogens may reduce the discomfort, but, as the inquirer has found, at the cost of disturbing the menstrual cycle. Androgens are preferable, but involve some risk of producing masculinizing effects even though the dosage is small. If any form of hormone treatment becomes necessary, ethisterone, 5 mg. sublingually three times daily for 7 to 10 days before each period, should be tried first. It is unlikely to have any undesirable side-effects and sometimes appears to be helpful.

Streptothrix Organisms in the Vagina

Q.—What is the significance of the recovery of organisms of the streptothrix group from the vagina in a case of leucorrhoea? The patient is due to be married shortly. Is any treatment recommended?

A.—This finding is of little significance in itself—especially if the particular organism has not been cultured and identified. Many organisms of the streptothrix group are non-pathogenic. In any case, the presence of organisms of any kind in the vagina means little unless the discharge contains an appreciable number of pus cells. Only if the discharge is purulent can it be assumed that an infection requiring treatment is present.

Effect of Poor Soil and High Altitude on Vitamin Content of Cereals and Vegetables

Q.—To what extent do a poor soil and high altitude (over 12,000 ft.—3,600 m.) affect the vitamin content of vegetable and cereal crops?

A.—Most experiments on the effect of the state of the soil on the nutritive value of plants have indicated that poor soil depresses the quantity of crops rather than their vitamin content. It has been found, however, that the carotene content of grasses is greatest in young, rapidly growing plants. The vitamin C content of potatoes, moreover, increases as the plants reach maturity, and therefore depends upon factors, such as the state of the soil and the geographical latitude, which affect the rate of maturing. Any conditions which make grass parched and brown, or which retard the maturing of potatoes, might therefore be expected to lower their vitamin content.

As yet there is no evidence to show that an altitude of 12,000 ft. (3,600 m.) affects crops directly, although associated drought, poor soil, or rapid changes in temperature certainly hinder growth.

Tinned Orange Juice

Q.—How does the vitamin content of orange juice from tins compare with that of fresh oranges? Is it reduced by the canning processes?

A.—Orange juice is mainly valuable as a rich source of vitamin C. Although this vitamin tends to be unstable to heating and storage, any competent manufacturer can adopt precautions during the canning of the juice which will ensure the preservation of almost all of its original contents of vitamin C. A statement of the vitamin C contents on the label of the can makes the manufacturer legally responsible for his product containing the amount indicated. Glass containers would appear to offer no advantages over cans, except possibly when the juice has to be stored for unusually long periods.

Desquamation of the Soles

Q.—What is the cause of recurrent irritation followed by superficial desquamation of the soles of the feet, especially over the metatarsal heads? The condition first developed in a healthy boy of 8 years towards the end of the summer, after wearing sandals without socks for a few months, but has recurred after wearing socks and boots for several months. The skin appears normal until desquamation occurs, but the preceding irritation—which lasts several weeks—is most tiresome. The skin between the toes appears normal.

A.—The possible internal causes of the attacks of irritation and desquamation described are an allergy to drugs, a focus of sepsis, or emotional and nervous causes. In the latter case an accompanying hyperhidrosis would be probable. The pompholyx of nervous origin is closely allied. Local causes would include possible sensitization to rubber soles or some other element of the footwear, and—less likely from the history—fungal infection.

Whisky Rash

Q.—I gave a patient some injections of penicillin and then the patient took some whisky (after the fourth daily injection). Within a few hours the patient developed an urticarial rash, which in the course of a day or so spread all over his body. He felt very ill and ran a temperature of 101 to 102° F. (38.3 to 38.9° C.) for a few days. Treatment cleared up the trouble after four or five anxious days. Now this patient finds that every time he has a drink of whisky he breaks out in an urticarial rash. He is very anxious to know if he will always have this trouble, as he is very fond of his drink.

A.—There is unfortunately no indication of the time that has elapsed since the development of the first rash and the subsequent attempts at drinking whisky. It is, however, highly unlikely that the patient has developed a sensitivity to whisky. The probable explanation is that the whisky acts as a peripheral vasodilator and causes a reappearance of the rash, which has not completely subsided. Should the unfortunate patient still be experiencing this difficulty he should try taking 50 mg. diphenhydramine hydrochloride ("benadryl") about half an hour before taking a drink, and if this is not sufficient the dose could be increased till the symptoms are suppressed.

Calcified Veins and X Rays

Q.—Is there any known relationship between exposure to x rays and calcification of veins? A man aged 66, employed as a radiographer, has been complaining of pain, heaviness, and weakness in his legs. A radiograph has disclosed calcification in the veins of the thigh. What is likely to be the cause?

A.—There is no known relationship between x rays and venous calcification. It is, in fact, a rare condition, unlike arterial calcification, which must not be confused with it. Old thrombosis, particularly that caused by sclerosing injections for varicose veins, is the commonest cause. If this

is excluded general metabolic diseases such as hyperparathyroidism, in which renal lithiasis, osteoporosis, and hypercalcaemia occur, must be sought. Unless a specific cause is found the treatment is symptomatic—by the use of oral analgesics and a supporting bandage.

Chloroform and Trichlorethylene

Q.—Is there any truth in the belief that the use of chloroform after trichlorethylene analgesia during labour is specially dangerous?

A.—There is little published work to indicate whether the previous administration of trichlorethylene increases the dangers of chloroform anaesthesia. The extra danger involved is probably small compared with the already considerable one of the chloroform itself.

NOTES AND COMMENTS

Holiday T.A.B.—Mr. ANDREW HICKS (Nairobi) writes: I was in a somewhat similar position to your questioner ("Any Questions?" June 6, p. 1289) last year before coming out here with two children aged 11 months and 4 years. Inquiries among my colleagues, clinicians and pathologists, revealed a general consensus of opinion similar to your expert's. However, within a few months of arrival I came across a case of paratyphoid B in an infant of 11 months, and practitioners out here say that such a happening is by no means a rarity. I would suggest that the later months of the first year of life are a dangerous time from this point of view, as the child is crawling and walking, is widening the scope of his diet, and popping all sorts of interesting things into his mouth. Might not an upper limit of six months be safer than twelve? The position is simplified here, there being available a specially diluted alcoholic vaccine for young children, which has produced very little local or general reaction in my experience.

OUR EXPERT writes: Acute gastro-intestinal infection (food-poisoning) with the Salmonella group of organisms can certainly occur, and is sometimes severe in infants. I suspect that the paratyphoid infections that occur at this age mostly fall into this category, and it is doubtful if prophylactic vaccination will give much protection against this kind of infection. But I agree that there is no harm in giving an infant of 6 months injections of a suitably diluted vaccine.

Midge Repellents.—Dr. J. T. INGRAM (Leeds) writes: With reference to the question on this subject ("Any Questions?" July 18, p. 162), some patients are protected against midges by taking ephedrine, $\frac{1}{4}$ gr. (16 mg.), once or twice a day. An old-fashioned repellent, used as local application, is cod-liver oil. It can be effectively dispensed in a non-greasy base with phenol and oil of citronella to mask the smell.

Corrections

In our report of the meeting of the Section of Anaesthetics (July 25, p. 216) the name of the speaker who gave an account of 500 cases of hypotension should have been given as Dr. W. N. ROLLASON, of Hull.

The diplomas of Surgeon Rear-Admiral T. N. D'Arcy, C.B., C.B.E., should have read L.R.C.P.&S.I., and not L.R.C.P.&S.Ed., as stated in the list of promotions in, and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem (*Journal*, July 18, p. 146).

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

INSULIN AS A GROWTH HORMONE

BY

JAMES SALTER, M.A.

Research Assistant, Department of Physiology, University of Toronto, Toronto, Canada

AND

CHARLES H. BEST, M.D., F.R.S.

Director, Department of Physiology and Banting and Best Department of Medical Research, University of Toronto, Toronto, Canada

[WITH SPECIAL PLATE]

The effect of insulin on the growth of animals deprived of the pituitary gland has not previously been reported.* The well-known obstacle has been the great sensitivity of the hypophysectomized animal to the antidiabetic hormone. Using slow-acting insulin in gradually increasing amounts and a high carbohydrate diet attractive to the animal and constantly available, we have been able to stimulate rapid growth in completely hypophysectomized rats. These animals exhibit an increase in all the main body constituents and a very definite augmentation of skeletal growth. The methods used, the details of the results, and their potential significance in physiology and medicine will be presented and briefly discussed.

Methods

The hypophysectomized rats were secured from the Hormone Assay Company. Completeness of the operation was confirmed at necropsy and no anterior pituitary tissue has thus far been found. One daily injection of protamine zinc insulin (Toronto), 40 units per ml., has been administered subcutaneously. The first lot may have contained a little hyperglycaemic factor, but this material could not be detected in subsequent ones. The composition of the diet was as follows: commercial dog food containing horse meat 892 g., white bread crumbs 345 g., whole wheat flour 396 g., glucose 80 g., and 1 quart of whole milk.

Animals in all groups ate the same diet *ad libitum*. The food intake and the weight of each rat were measured

*Preliminary notes on this work have appeared (Salter and Best, 1952, 1953).

daily. Organs were removed at necropsy, weighed, and returned to the carcass, which, minus the contents of the gastro-intestinal tract, was finely minced and then homogenized in a blender. Representative aliquots were thus available for the determinations of protein, fat, and water, which were carried out by standard and regularly checked methods. The tibia test of Greenspan *et al.* (1949) was performed to evaluate skeletal growth. In our second experiment two tibiae were removed from each carcass. One was placed in neutral formalin for the above-mentioned test, and the second was fixed in formol calcium. Paraffin sections were prepared and stained with H. and E. and Mallory's connective-tissue stains.

Experimental Procedures and Results

Anticipating hypoglycaemia at many points in the 24 hours, a "pilot" experiment using two rats was performed. It was found that small amounts of protamine zinc insulin were well tolerated by the hypophysectomized animals, and that when a suitable diet was made available at all times constant attention became unnecessary. Before this goal was reached in this experiment one animal succumbed to hypoglycaemia, but the other grew rapidly, nearly doubling its weight in 20 days, and it served as a model for the many larger series of animals which have subsequently been studied. In this rat it was found that the tail had lengthened by 1 cm. during the 20 days of insulin therapy. At necropsy the thymus, kidney, and heart weights were within the normal range. The liver was heavier than normal. The testes, adrenals, and thyroid were atrophic.

Experiment A.—In this experiment 40 male rats, 14 days after hypophysectomy, were divided into three groups of

10, 18, and 12. The 10 animals were sacrificed on the initial day to secure basal values. Each member of the second group received daily for 15 days a dose of protamine zinc insulin, which was increased whenever the previous dose failed to produce a definite increase in weight. The 12 animals in group 3 received no insulin and were sacrificed at the same time as those in group 2. The analytical results secured on the surviving animals are given in Tables I and II, and the growth curves are plotted in Fig. 1.

FIG. 1.—Weight changes and food intake of hypophysectomized rats. —, controls. ----, receiving protamine zinc insulin.

In Table I the figures demonstrate that insulin has produced an absolute increase in the weights of thymus, kidney, heart, and liver. In Table II the figures show that the gain in weight of the insulin-treated animals was due to an absolute increase in the main body constituents. The results of the tibia test showed that very definite skeletal growth had occurred. Total body fat increased to a greater extent than protein and water. There was, however, a definite increase in protein. There appears to be a slight reduction in total protein in the control animals, but this may not be significant. The curves in Fig. 1 are self-explanatory.

Experiment B.—In this experiment 40 male rats, 14 days after hypophysectomy, were divided into groups of 20, 10, and 10. Each rat in group 1 received, as in Experiment A, one daily dose of protamine zinc insulin. Each rat in group 2 received a daily subcutaneous dose of growth hormone, which was regulated to produce approximately the same rate of growth as exhibited by the insulin-treated animals. Group 3 served as a control and received the same diet *ad libitum* as the other two groups. All the animals were sacrificed on the 15th day of the experiment. The analytical findings in the surviving animals are presented in Tables III and IV and the growth curves in Fig. 2.

*Maximal amounts of growth hormone were not administered. Somewhat larger doses of insulin might also have been given. In this experiment the weight gains of the two groups were matched by design.

The findings confirm those of Experiment A and indicate that under the conditions of this study the insulin-treated hypophysectomized rats stored more fat and less water than similar ones treated with G.H. The animals receiving P.Z.I. consumed more food (including protein), but their total body protein was slightly less than that of the animals treated with G.H. The insulin-treated rats retained a smaller proportion of the ingested nitrogen. The average weight gain and final weight were the same in both experimental groups.* Insulin appeared to produce a greater gain in weight of kidneys, heart, liver, and thymus. Neither hormone exerted any definite effect on the adrenal, thyroid, or testes.

Experiment C.—In this experiment 53 hypophysectomized rats were divided into groups 1, 2, and 3, consisting respectively of 14 controls, 14 treated with growth hormone, and 25 treated with protamine zinc insulin. The procedure followed was identical with that described in Experiment B. During the experimental period 8 of the insulin-treated animals died. All rats in groups 1 and 2 survived. The increase in weight of both insulin- and growth-hormone-treated animals was 42 g. in the 15 days. The dosage of both materials was approximately the same as in Experiment B (see Fig. 2). The gain in protein was 2.6 g. per animal in the insulin-treated and 4.0 in the G.H.-treated group. The increase in width of the epiphyseal disk was 75 μ in the insulin-treated group and 154 μ in the G.H.-treated. In a normal rat weighing the same as the insulin-treated animal the epiphyseal disk was approximately the same width. The growth hormone increased the width of the disk to almost twice that of a normal intact control rat of the same weight. Fig. 3 (Special Plate) shows sections of the epiphyseal disks of treated and untreated hypophysectomized rats.

JAMES SALTER AND CHARLES H. BEST: LEGENDS TO PLATE

FIG. 3A represents a section of the epiphyseal disk of a hypophysectomized control rat. All zones of the epiphyseal disk are very narrow. The trabecular bone is very coarse and the bone marrow is very fatty in both epiphysis and metaphysis. This section illustrates the characteristic effects of hypophysectomy on the tibia of a young rat.

FIG. 3B shows the stimulating effect of insulin administration on the skeletal growth of hypophysectomized rats. Professor W. S. Hartroft chose as a representative disk one which was roughly twice as wide as the disks of untreated hypophysectomized rats. The histological picture approximates that of a normal intact rat of the same weight (see Fig. C). The organization of both the epiphyseal and metaphyseal bones is coarse and irregular, with pronounced growth lines indicated by irregular waves and bands. The marrow of the epiphysis and metaphysis is less fatty than that of the control animals.

FIG. 3C is a representative photomicrograph made through the epiphyseal disk of a normal intact male rat weighing the same as the average weight of the insulin-treated hypophysectomized animals (143 g.). The organization and arrangement within the disk are very orderly and no irregularities are apparent.

Discussion

It is well established that insulin plays an important part in anabolic processes, and that it reverses the series of catabolic reactions which are collectively known as diabetes mellitus. Insulin causes resumption of growth in the depancreatized animal. It increases the rate of formation of glycogen and fat and of the incorporation of amino-acids into proteins. The only catabolic effect of physiological amounts is to increase the combustion of sugar. Under physiological conditions insulin works synergistically with the somatotrophic factor of the anterior pituitary and with other hormones which in the complete absence of insulin exert predominantly catabolic effects.

When the pituitary gland is removed growth may be prevented (Allen, 1916; Evans and Long, 1921). The animals remain at approximately the same weight level. The growth rate is zero. But in many species when the source of insulin is completely removed there is a rapid loss in weight. The growth rate is negative. Removal of the pituitary from these depancreatized animals may restore the growth rate to zero.

The hypophysectomized animal may develop fatal hypoglycaemia during even a short period of fasting, without receiving any exogenous insulin, and this is probably the

principal reason why experiments such as we are reporting have not previously been carried out. We have used only one daily dose of P.Z.I. It is quite probable that a more continuous insulin therapy might reveal even more dramatic effects of insulin upon the growth of hypophysectomized animals.

The well-established anabolic effects of somatotropin in the normal or hypophysectomized animal do not require comment here. The protein retention and skeletal growth are both much greater than that which we have produced with insulin alone. In the somatotropin-treated series both insulin and the pituitary growth hormone were available. Somatotropin without insulin produces no nitrogen retention or skeletal growth (Milman *et al.*, 1951). Our experiments provide no further evidence on this latter point or on the debatable question of the liberation of insulin from the islets by the indirect or direct action of somatotropin.

It is remotely possible that somatotropin, which produces a large increase in the volume of the pancreatic islets, causes a more effective liberation of insulin than we have accomplished with one daily dose of P.Z.I., but there is no direct evidence as yet that somatotropin causes any liberation of insulin.

It has been reported that somatotropin may cause liberation of glucagon, the pancreatic hyperglycaemic factor (Bornstein *et al.*, 1951), and, recently, that glucagon may stimulate growth, as evidenced by widening of the epiphysal disks of hypophysectomized rats (Elrick, 1953). In these latter experiments the most potent preparation of glucagon did not produce a convincing widening of the epiphysal disks. Convulsions, relieved by sugar, were frequently a late result of the injection of other preparations. These could have been produced by some residual insulin or perhaps, as suggested by the author, by the reaction of the beta cells to the hyperglycaemia. In an extension of findings by earlier investigators, Dr. O. Sirek, in our laboratory, has demonstrated that a purified growth preparation may produce no hyperglycaemia in a normal dog but a large further increase in blood sugar in the same dog after pancreatectomy. The blood-sugar changes that occur under these conditions suggest that during a period of growth-hormone administration the hypoglycaemic factor may be

liberated from the pancreas in more effective amounts than is the hyperglycaemic principle.

The clinical significance of this experimental demonstration—that is, the production of rapid growth in the "pituitary" dwarf animal by giving insulin—merits consideration. Is a failure of insulin liberation one of the many factors which may limit growth in the human pituitary dwarf? Removal of the pituitary in animals does not cause atrophy of the islands of Langerhans, but it prevents their growth and presumably the augmented liberation of insulin which this normal growth would require and elicit. It may be argued that any factor or factors which produce general body growth will cause growth of islet tissue. This is probably true under most circumstances (Haist, 1953). It would not be expected in this present study, since the excess of insulin would lessen the need for islet activity, reduce the granule count of the beta cells, and lower the insulin content of the pancreas.

Some human "pituitary" dwarfs are very sensitive to insulin; others are not. The evidence implicating the pituitary at all is frequently most unconvincing. Our findings show that in one species the presence of low blood-sugar values and great sensitivity to insulin do not eliminate administration of insulin as one means of producing a dramatic growth effect. To what extent the hypoglycaemic effect of insulin may be modified by other hormones without interfering with its growth effect is being investigated both experimentally and clinically.* A more fundamental clinical question is whether or not a failure of growth ever occurs, apart from the frank diabetic state, in which the limiting factor is the ability of the beta cells to produce and liberate insulin. Our findings *do not* show that exogenous insulin is necessary for growth of hypophysectomized rats. Somatotropin, when endogenous insulin is available, is more effective. But a clinical condition might exist in which the pancreatic beta cells, while still capable of preventing the diabetic state at the existing reduced rate of growth and demand for insulin, are one of the factors limiting normal development. Somatotropin and insulin together might produce results where one alone would be inadequate. The clinician watches for evidence of decreased function of thyroid, adrenal, and gonads in cases of suspected pituitary dwarfism. He may attempt to stimulate these glands or to provide their products. We are suggesting that, in addition, a condition may exist in which the stimulus exerted by somatotropin or by an increased food intake may prove inadequate to provide an optimum liberation of insulin from the pancreas. Would this situation always be revealed by the appearance of diabetes? Are there other procedures which may stimulate the beta cells? Will insulin administration further decrease the response of the beta cells?

Some growth studies have been made in animals with small amounts of insulin and large amounts of somatotropin available, but many other variations of dosage of these two hormones and of insulin with other hormones will certainly yield new and interesting findings. Some investigators have confused the issue by assuming, without justification, that the alloxan-diabetic animal has *no* insulin available.

With our high-carbohydrate diets the effect of insulin on fat synthesis has been conspicuous. With very high protein diets a different picture might be obtained, but the tolerance for insulin would probably be reduced. The findings in Querido's laboratory in Leyden (personal communication) indicate that the duration of feeding periods and their spacing throughout the day may affect the composition of body tissues. The time of administration and the duration of action of the various hormones might affect appetite, the pattern of food intake, and perhaps the composition of body tissues.

*Mr. Robin Lawrence and one of us (J.S.) have found that cortisone may prevent the effect of insulin on the widening of the epiphyseal disk, but the hypophysectomized animals receiving both hormones gained appreciably in weight.

As illustrated in Figs. 1 and 2, the insulin-treated hypophysectomized rats consumed more food than the controls. There is evidence that insulin-treated normal rats (Maassen, 1951) grow faster than paired-fed controls, and this is certainly clearly seen when somatotropin is the growth stimulant (Li and Evans, 1948; Young, 1952). The effect of forced feeding on the growth of hypophysectomized rats is controversial. Samuels, Reinecke, and Bauman (1943) state that force-fed hypophysectomized rats exhibit an increase in femur and body weight. Levin (1944), in repeating these experiments, reported that the increase in body weight could be totally attributed to fat deposition. It will be difficult to give much insulin to hypophysectomized rats which are not permitted to eat more than the controls. A careful comparison of force-fed and insulin-treated hypophysectomized animals with identical food intakes might provide valuable data. Great care in the interpretation of results would be necessary, since the effect of insulin, liberated physiologically by the demands of a forced food intake, might not affect growth in exactly the same way as would an identical food intake stimulated by an excess of exogenous insulin given in one or more daily doses.

Summary and Conclusions

The sensitivity to insulin of hypophysectomized animals has prevented investigation of the effects of the antidiabetic hormone on their growth. By using a slow-acting insulin in gradually increasing doses an average increase in weight of 38 g. in 15 days has been secured in completely hypophysectomized rats. The width of the epiphyseal disk of the tibia in these three experiments showed, on the average, an increase of 65%. The average increase in body protein was 2.6 g. per rat. The control hypophysectomized animals which ate smaller amounts of the same diet remained essentially stationary in weight, protein content, and skeletal size. These findings therefore demonstrate that insulin may stimulate growth under these conditions and strengthen the possibility that decreased liberation of insulin may be one of the factors limiting growth in the hypophysectomized animal. The physiological and clinical significance of these findings has been briefly discussed.

We are indebted to Professor W. Stanley Hartroft for his interest and help. This work has been supported by a grant from the Canadian Life Insurance Officers' Association.

The Council of the Yugoslav Academies has commenced publication of a quarterly *Scientific Bulletin* in English, French, and German, the chief purpose of which is to give information on scientific activities in that country. Most scientific work in Yugoslavia appears only in periodicals published in the Croatian or Serbian languages, which makes it difficult for those abroad to become acquainted with current research work. For this reason alone the *Bulletin* should prove of considerable interest. It is edited by Dr. A. Peterlin, Institut de Physique J. Stephan, Ljubljana, Yugoslavia.

THE INSULIN-LIKE ACTION OF GROWTH HORMONE*

BY

J. H. OTTAWAY, Ph.D.

(From the Department of Biochemistry, University College, London)

It has been reported that pituitary growth hormone affects the rate of glucose uptake by isolated rat diaphragm (Ottaway, 1951). Two types of effect were observed. When the diaphragm was given a preliminary soaking for 20 minutes in a growth-hormone solution without glucose, and then incubated in a second solution containing glucose but no growth hormone, the glucose uptake was found to be increased. When the diaphragm was incubated straightforwardly in one solution growth hormone depressed the glucose uptake. The concentration of growth hormone in both types of experiment was 100 μ g. per ml.

The effect of growth hormone *in vitro* in a straightforward incubation of rat diaphragm has now been investigated further. The inhibitory effect of growth hormone at a concentration of 100 μ g. per ml. was confirmed, but at lower concentrations, especially at 1–5 μ g. per ml., the results were conflicting. Some series of experiments showed an inhibition, and others an activation. The mean of all the observed glucose uptakes with growth hormone present at concentrations of 5 μ g. per ml. or below did not differ from the mean control uptake, but the variance was significantly greater than that of the controls. It was felt that the growth hormone could indeed produce two quite different effects, but their induction depended on unidentified changes in experimental conditions.

The elucidation of these changes proved difficult because of the wide scatter of the control rates of uptake, and it was first necessary to find some means of making the muscle metabolize more consistently. Perlmutter *et al.* (1952) and Park *et al.* (1952) have both recently drawn attention to this problem of variance in work with rat diaphragm, and Krahle (1951) has evolved a technique which greatly reduces the variance of the control glucose uptake. The diaphragm is allowed to remain, after excision from the rat, for 5 to 15 minutes in ice-cold bicarbonate buffer. The glucose uptake subsequently is found to be at a higher rate than usual, but there is much less variation between pieces of muscle from one diaphragm. This method, which has apparently been in use for some years in Krahle's laboratory, has been tried by us and its effectiveness confirmed. Unfortunately, as Krahle himself found, after this treatment the diaphragm of the normal unoperated rat is quite insensitive to growth hormone added *in vitro*.

Experimental Technique

Another technique, described below, has been developed in this laboratory. Hitherto experiments on rat diaphragm have been carried out by a single operator, using four pieces of muscle from one diaphragm; in these circumstances it is inevitable that one hemi-diaphragm will be dealt with at a later time than the other. Study of results suggested that the later, or second, hemi-diaphragm often had a higher glucose uptake than the former. At first it was thought that the difference might in some way be connected with a

*The tables included in this paper have already been reported in *Biochimica et biophysica acta*, 1953, **11**, 443.

leakage of potassium from what is to some extent a damaged tissue. However, this explanation was found not to be the correct one, which agrees with the findings of Perlmutter *et al.* Another possible cause was thought to be the fact that one half of the diaphragm remained in more or less anaerobic conditions for a longer time than the other, and a technique was developed in which both hemi-diaphragms are treated in an identical way (see also Stadie *et al.*, 1949).

For the experiments reported in this paper the medium devised by Stadie and Zapp (1947) was used. It was modified by raising the proportion of dibasic sodium phosphate to bring the pH up to 7.2. This was done to ensure that the growth hormone (I.E.P. 6.75) remained in solution. The diaphragm was excised whole from a fasted male albino rat, and washed for a moment in medium to remove adhering blood. It was then placed in a Gooch crucible containing 10–15 ml. of medium with glucose; nitrogen was passed at a steady rate through the sintered glass bottom of the crucible. This precaution was taken to ensure that the muscle had the same pO_2 in all the experiments. It remained in this solution for two minutes, during which time it was divided into two along the central tendon, without removing it from the liquid. The addition of ascorbic acid (0.005M) to the medium used in this preliminary gassing was found to reduce the variation in control uptakes; its use did not affect the type of result obtained. Each hemi-diaphragm was taken simultaneously by one operator, blotted, and divided into two, and the four pieces were placed into four Warburg flasks. The flasks were being gassed in the bath (with oxygen) three and a half to four minutes after excision.

Results

The rigid use of this routine led to the finding that growth hormone stimulated the glucose uptake of normal rat diaphragm at the concentration used, which was 25 μ g. per ml. in all the experiments reported here. A stimulation was also observed at 10 μ g. per ml., but at 40 μ g. per ml. the hormone was apparently without effect. The hormone was dissolved in a small quantity of medium with the aid of a drop of N/10 NaOH, and this solution was diluted as required. The insulin-like activity disappears quite rapidly from the solution, and it is necessary to use it not more than 20 minutes after making. The results were very consistent: a stimulation was found in 26 out of 29 pairs of observations. The results are summarized in Table I.

TABLE I.—Effect of Growth Hormone on Glucose Uptake in mg./g. of Tissue/Hour of Normal Rat Diaphragm After Two Minutes in Anaerobic Conditions. Growth Hormone Added *in vitro*, Concentration 25 μ g./ml. Glucose Concentration, 2 mg./ml. Incubated for 1–2 Hours

Difference, +0.62 $\pm$ 0.13; $t = 2.70$, $P = 0.01$.

It seemed desirable to show whether insulin was in some way responsible for this increase in glucose uptake before postulating a new stimulating principle. It seems unlikely that, prepared by the usual methods, growth hormone itself contains insulin (see, in particular, the work of Krahle and his colleagues). There remained the possibility that insulin was in some way liberated by growth hormone after the preliminary anaerobic treatment of the diaphragm, either in the muscle cells themselves or in the blood remaining in the blood vessels of the diaphragm after excision.

The experiments were therefore repeated, using alloxan-diabetic rats. The rats were not used until at least ten days after subcutaneous injection of 25 mg. of alloxan per 100 g. of rat, after the method of Kass and Waisbren (1945). Table II shows that growth hormone had no effect on the glucose uptake from diabetic rat diaphragm—that is, from animals with a fasting blood sugar greater than 150 mg. per 100 ml.

TABLE II.—Effect of Growth Hormone on Glucose Uptake in mg./g./hr. of Diabetic Rat Diaphragm, After Two Minutes in Anaerobic Conditions. Growth Hormone Added *in vitro*, Concentration 25 µg./ml. Glucose Concentration, 2 mg./ml. Incubated for 1–2 Hours

		Difference, -0.11±0.16	

(Significantly different from the normal difference) $t=2.65$, $P=0.01$.

This work was done before the results of Groen *et al.* (1952) became available. These workers found that it may be as long as three weeks before the last trace of insulin disappears from the blood of a diabetic animal. The present work would thus have been more conclusive if the animals had been kept for a longer time before use. However, the Chart shows that the stimulation induced by growth hormone added *in vitro* varies inversely with the fasting blood sugar: with the most severely diabetic animals there was indeed a slight inhibition of glucose uptake. This relationship between stimulation and severity of diabetes may be regarded as further evidence that it is insulin which is directly responsible for the stimulation.

As a corollary to these experiments it is desirable to show that the stimulation is increased when the concentration of insulin in the tissue is raised above normal—for example,

Chart showing effect of growth hormone on glucose uptake.

by injection of insulin into the intact animal. Injection of insulin into normal animals, with the consequent fall in blood-sugar concentration, might, however, have led to secretion of the anti-insulin factor, which has been shown by Somogyi (1948) to play a large part in the regulation of the blood-sugar level in human beings. A preliminary experiment showed that injection of 1–2 units of insulin subcutaneously

TABLE III.—Effect of Growth Hormone on Glucose Uptake in mg./g./hr. of Diaphragms from Fasting Diabetic Rats. The Rats had been Injected 30 Minutes Previously with 1–2 Units of Insulin. Other conditions as in Tables I and II

Mean Fasting Blood	Mean Blood Sugar at Death	No. of Observations	Glucose Uptake	
			Control S.E.	Growth Hormone S.E.
160 mg./100 ml.	60 mg./100 ml.	20	4.59	5.04

into fasting mildly diabetic rats 30–45 minutes before death caused the insulin-like effect to rise to a significant level. This is shown in Table III; all results from animals in which the blood sugar at death was greatly below normal have been excluded.

per 100 ml. Some animals were given a supplementary dose of about 0.1 unit about 30 minutes before death. Table IV shows that this treatment effectively restored the "insulin-like" response to growth hormone. As a control, tissue was taken from uninjected diabetic animals from the same batch and from fed normal animals, and incubated at the same time.

TABLE IV.—Effect of Growth Hormone on the Glucose Uptake in mg./g./hr. of Fed Diabetic Rats Injected Two Hours Previously with 0.2 Unit of Insulin. Results from Uninjected Diabetic Rats and From Normal Animals are Included for Comparison. Conditions as in Table I

	Mean Blood Sugar Before Injection	Mean Blood Sugar at Death	No. of Observations	Glucose Uptake

Normal rats	130	6	6	3.11	3.58
				Difference, +0.47±0.17 (significantly greater than zero); $t=2.75$, $P=0.05$.	

Conclusions

These experiments show that growth hormone can have, in certain conditions, an insulin-like effect on muscle from normal rats, but that it does not have this effect on muscle from diabetic rats. Two explanations suggest themselves: that insulin in some way "potentiates" the tissue so that it is able to respond to the growth hormone, or that growth hormone is able to liberate insulin from a complex in which it is inactive; the existence of a compound in human serum which reduces the activity of insulin has been inferred by Marsh and Haugaard (1952). I prefer the second hypothesis as being more fruitful, especially if it is considered that endogenous growth hormone may also liberate insulin in anaerobic conditions. This concept applied to *in vitro* experiments suggests that the great variation in rate of glucose uptake observed in diaphragm experiments is due to the fact that insulin is set free to an extent depending on the oxygen tension of the muscle during the preparation of any experiment. Again, the fact that Krahl was unable to show an insulin-like effect upon muscle from normal animals may have been because in his conditions the "liberation" may have been complete before incubation of the tissue was begun; only with muscle from hypophysectomized animals, lacking any endogenous growth hormone, would it then be possible to demonstrate an *in vitro* effect.

The evidence that this reaction occurs *in vivo* is not at present conclusive. It has been shown that an injection of growth hormone into rats raises the glucose uptake of diaphragm excised at a later time (Park, 1953), and also that more massive doses cause a fall of blood sugar in all but diabetic rats (Milman and Russell, 1950). Both these are insulin-like effects. If the reaction can be shown to occur in physiological conditions it might be regarded as a device to ensure a greater supply of glucose for muscle rendered temporarily anaerobic by a sudden muscular effort.

Two problems arise from this work. One is the nature of the compound which insulin forms in the blood, and the mechanism by which it is liberated; some progress has been made in this direction. The other problem is the characterization of the entity which is responsible for the liberation, and which has been referred to in this paper as "growth hormone." No serious attempt has yet been made in this laboratory to relate the effect to growth potency, or to attempt the preparation of an active submolecule from crystalline growth hormone.

Summary

Conditions are described in which pituitary growth hormone consistently produces an "insulin-like" effect on the glucose uptake of diaphragm from normal rats.

The effect is shown to be absent when the rats have been made diabetic, and to return when diabetic rats are injected with insulin. It is postulated that the effect is due to the liberation by growth hormone of insulin held in an inactive state in the blood or tissue.

STRUCTURAL CHANGES IN PROSTATIC CANCER AFTER BILATERAL ADRENALECTOMY

REPORT OF A CASE

BY

L. M. FRANKS, M.B., B.S.

(From the Laboratories of the Imperial Cancer Research Fund, at the Royal College of Surgeons of England)

[WITH SPECIAL PLATE]

Bilateral adrenalectomy and orchidectomy is claimed by Huggins (Huggins and Scott, 1945; Huggins and Bergenstal, 1952; West *et al.*, 1952) to have induced substantial clinical improvement in some cases of advanced prostatic carcinoma. It is also claimed that post-operative substitution therapy enables the patient to enjoy a fair measure of health and activity. The operation is still in the stage of therapeutic trial, but is being carried out on an increasing number of patients in this country. Most of the published evidence in its support is clinical in character, and remarkably little has been written on the effects of deprivation of adrenal cortical hormones on the structure of the growth and its metastases.

This report concerns a man of 63 with an oestrogen-resistant prostatic carcinoma, who was subjected to orchidectomy with no clinical improvement and finally to bilateral adrenalectomy. He died from an acute pulmonary infection 40 days after this operation. Massive necrosis was found in the primary growth and in its metastases in the regional lymph nodes, liver, and lung. The changes in all these situations had occurred simultaneously a few weeks before death, and, although incapable of rigid scientific proof, it is reasonable to suppose that this widely scattered necrosis was the direct consequence of total deprivation of adrenal hormones.

Case Report

A man aged 63 was admitted to hospital on August 14, 1952, complaining of rectal pain and urinary frequency for six weeks. The prostate was hard, craggy, and fixed. Serum acid phosphatase was 3.3 units (King-Armstrong).

An x-ray film of the spine and pelvis showed osteoarthritis; no metastases. An endoscopic resection on August 19 relieved the urinary symptoms, but the rectal pain persisted, and on September 16 a bilateral subcapsular orchidectomy was done. Severe rectal pain and dysuria increased in spite of this, and was not relieved by large doses of stilboestrol (30–60 mg. daily). He was then transferred to St. Philip's Hospital, where an enlarged liver and palpable enlarged lymph nodes in the groin were found. Bilateral adrenalectomy was advised, and he was transferred to the Central Middlesex Hospital for operation. A pre-operative blood-sugar curve revealed moderately severe diabetes mellitus, but the patient's general condition remained fair.

Substitution therapy with cortisone acetate (200 mg. decreasing to 66.5 mg. daily), deoxycortone (5 mg. daily, decreasing to 5 mg. on alternate days), and sodium chloride (5 g. decreasing to 3 g. daily), as described by Huggins and Bergenstal (1951), was begun on December 4 and continued post-operatively. Both adrenals were removed on December 5 by Mr. J. D. Fergusson. The left kidney was absent. There was no immediate clinical improvement, and stilboestrol, 100 mg. daily, was given from December 22 onwards. The diabetes mellitus remained unchanged and was controlled by diet and insulin, but in spite of this there were a number of hypoglycaemic episodes. On January 14, 1953, he collapsed, complaining of dyspnoea, and died the next day, apparently from a pulmonary embolus.

Post-mortem Examination

Neeropsy was performed eight and half hours after death. The lungs showed basal congestion, scattered bronchopneumonic areas, many small tumour nodules, and a large wedge-shaped area at the periphery of the right upper lobe showing central degeneration and haemorrhage—apparently an infarct, but the pulmonary arteries, which showed nodular atheroma in the large branches, contained no embolus. There were many large and small tumour deposits in the liver, some with a zone of congestion around them. The right kidney was large (weight 13½ oz.; 383 g.). The left kidney and ureter were absent, and the renal vessels on this side were of normal size but ended blindly in a dense mass of fibrous tissue. The adrenals were absent. The bladder was dilated and there were several small diverticula. The left ureteric orifice could not be found. The prostate was largely replaced by a firm nodular tumour mass spreading into the seminal vesicles, periprostatic tissues, and the base of the bladder. The rectum was compressed but not obviously infiltrated. There were large tumour deposits in left and right internal, external, and common iliac, left inguinal, para-aortic, and mediastinal lymph nodes, some of which showed central degeneration. The breasts were normal. Bones (8–12 thoracic, 1–5 lumbar vertebrae, and sacrum) were normal. The pituitary was small. All other organs were normal. The immediate cause of death was thought to be the lesions in the lung.

Histology

Tissues were examined by a "big section" technique which has been in routine use in these laboratories for the past two years. By this method histological sections (5–8 µ) of whole organs are cut and examined microscopically. The pathological changes in this case might have been overlooked had smaller sections been cut, because the extent and distribution of the degenerative changes was much greater than was apparent to the naked eye. In all sections from the primary tumour and metastatic deposits in lymph nodes, liver, and lung there was a massive central necrosis involving both neoplastic tissue and stroma. The necrotic central mass was surrounded by a narrow zone of granulation tissue and, beyond this, a rim of surviving tumour cells (Plate, Figs. 1, 2, and 3). The change involved both large and small deposits, and the zone of granulation tissue was apparently about the same age (2–3 weeks) in all. The ratio between the amount of necrotic and surviving tumour tissue was approximately the same in the primary growth as in its

metastases. No comparable lesions were found in any tissue other than the tumour and its secondaries. In the larger necrotic areas there was some haemorrhage, and occasional blood vessels around the margin were filled with hyaline thrombus and their walls were necrotic. However, in the smaller lesions clumps or even single tumour cells had undergone a hyaline eosinophil necrosis without obvious change in the blood vessels.

In some of these smaller lesions and at the margins of the larger ones a series of degenerative changes were noticed. The outer zone of surviving tumour with cells arranged in solid cords surrounded an inner zone where the cells were separated, the nuclei smaller and more deeply staining, and the cytoplasm more eosinophilic. Towards the centre of the nodule the nuclei had become pyknotic and finally disappeared, leaving clumps of degenerate eosinophil cytoplasm which fused to form a central necrotic mass in which the "ghost" outline of the cells could be seen. This succession of changes suggested that cell degeneration might still have been going on at the periphery, although much more slowly than at first. It would seem that the first change had been necrosis of central tumour cells with secondary necrotic change in the stroma, where large numbers of cells had been destroyed. This stromal change is perhaps due to the release of enzymes from the damaged tumour cells. The surviving tumour is pleomorphic, with solid trabecular, small acinar, and anaplastic areas.

The lung showed bronchopneumonia and some haemorrhage into the wedge-shaped area in the right lower lobe. There were tumour emboli in the subpleural lymphatics. All secondary nodules showed central necrosis.

Discussion

There seems to be no doubt that degenerative changes in the tumour occurred shortly after bilateral adrenalectomy. Necrotic areas in rapidly growing tumours are of course commonly seen, but not as a rule involving both primary and secondary tumours simultaneously. No similar change has been seen in 29 other cases of prostatic carcinoma examined by the "big section" method using post-mortem material. Other possible causes are oestrogens, cortisone, insulin, or some other unknown agent. The first can probably be excluded because the cytotoxic changes it produces in prostatic cancer (Schenken *et al.*, 1942; Fergusson and Franks, 1953) differ from those seen in this case. There is little convincing evidence that cortisone affects the growth of human prostatic tumours (Huggins and Bergenstal, 1952), but a report on one case which showed clinical improvement after such treatment has recently appeared (Hayward, 1953).

It is also unlikely that insulin or the diabetic state could produce such massive necrotic lesions. On the whole the evidence suggested that the changes which occurred in this case were caused by the removal of both adrenals, but the possibility remains that the necrotic changes may be due to the interference with vascular supply so commonly seen in malignant tumours. The histological appearances, however, seem to show that the first degenerative changes took place in the tumour cells, and that these caused secondary changes in the stroma. If blood vessels are involved in this process an added ischaemic necrosis may occur in the area supplied by the vessel.

One further point of interest in this case is the absence of clinical evidence of regression in spite of the massive and widespread destruction of tumour cells.

Summary and Conclusions

Massive central necrosis apparently involving primary and secondary tumours simultaneously was seen in a patient dying six weeks after bilateral adrenalectomy for advanced prostatic cancer. A narrow zone of actively growing tumour cells surrounded these necrotic centres. It is highly probable (but not proved) that

these regressive changes were directly related to the removal of both adrenals. It is important that any similar material should be examined by methods which allow the extent and distribution of any degenerative changes to be appreciated.

The patient was operated on by Mr. J. D. Fergusson, and I am indebted to him and to the research department of the Institute of Urology for the clinical notes and post-mortem material: the case forms part of his series of advanced cancer cases treated by bilateral adrenalectomy, which will be described more fully later. My thanks are also due to Professor G. Hadfield for many helpful suggestions and to Dr. J. Craigie for the photographs.

HAEMOLYTIC ANAEMIA IN TYPHOID FEVER

A REPORT OF SIX CASES, TOGETHER WITH THE EFFECT OF CHLORAMPHENICOL AND A.C.T.H.

BY

A. J. S. McFADZEAN, M.B., M.R.C.P.

Professor

AND

G. H. CHOA, M.B., M.R.C.P.

Lecturer

The Department of Medicine, University of Hong Kong

Acute haemolytic anaemia with haemoglobinuria has been reported as a rare complication of typhoid fever. Osler (1895) encountered one case in his series of 1,500. Curschmann (1898) and Castellanos and Montero (1940) each described one case with recovery. Wright (1945) reported two fatal cases in East Africans. Batty Shaw (1951) described two cases with recovery, but one of these was subsequently thought to be a case of familial haemolytic anaemia. Gordon Smith (1951) reported one case to which chloramphenicol had been given before the onset of the haemoglobinuria.

Before 1945 the occurrence of haemolytic anaemia without haemoglobinuria was reported very infrequently. Under the guise of "acute pernicious anaemia" Mouisset, Mouriquand, and Thévenot (1906), Sicard and Gutmann (1911), Marcora (1919), and Stanzani (1924) reported, in all, five cases. There is no doubt that these were cases of severe haemolytic anaemia. According to Batty Shaw (1951), Kadrnka in 1928 described two cases of acute haemolytic anaemia complicating typhoid fever. Davidson and Fullerton (1938) reported haemolytic crises in a woman with *Salmonella dublin* infection, but she was thought to have a latent haemolytic anaemia.

Berman, Braun, and Rachmilewitz (1945) investigated 152 cases of typhoid fever and found nine cases of haemolytic anaemia of varying degrees of severity. The criteria employed were anaemia, increased reticulocyte count, retentive jaundice, and increased urobilinogen in the urine. In one case there was unequivocal evidence of haemolysis in that urobilinogen excretion in the urine and faeces was estimated quantitatively and found to be significantly raised.

One of us (A. McF.) became interested in the anaemia of typhoid during military service in the Middle East. In the course of haematological investigation of cases of typhoid fever in British and Italian soldiers it became obvious that in a small yet significant number the anaemia was haemolytic in type. Regrettably, most of the records were lost. The investigation was restarted in Hong Kong.

The purpose of this communication is to report six cases of haemolytic anaemia, one of which was associated with haemoglobinuria, occurring during the course of typhoid fever, and to report the effect of chloramphenicol and A.C.T.H. on the course of the anaemia.

Incidence.—From January, 1949, to May, 1952, 129 consecutive cases of *Salm. typhi* infection have been investigated and six cases of haemolytic anaemia encountered, an incidence of 4.6%. In the series reported by Berman *et al.* (1945) the incidence was 5.9%. No cases have occurred in a series of 47 cases of enteric fever due to *Salm. paratyphi* A, B, or C occurring in the same period.

Clinical Findings

All six patients (four male and two female) were Chinese. The age incidence ranged from 19 to 38 years: the ages of the cases are set out in Table I. There was

TABLE I.—Relevant Clinical Findings and Bacteriological Findings in Six Cases of Haemolytic Anaemia Complicating Typhoid Fever

Case No.	Age	Sex	Day of Disease Admitted	Toxaemia	Jaundice	Spleen	Liver	S. typhi Isolated		
								Sternal Marrow Culture	Blood Culture	Stool Culture
1	27	M	10	Moderate	++	7 cm.	5 cm.	+	+	+
2	32	F	14	Severe	++	6 "	4 "	+	+	+
3	19	M	11	"	+	Just palpable	4 "	+	+	+
4	28	F	12	Moderate	++	6 cm.	3 "	+	+	+
5	36	M	9	Severe	++	2 "	4 "	+	+	+
6	38	M	12	"	++	Not felt	6 "	+	+	+

neither personal nor family history of jaundice or anaemia. None had been exposed to toxic substances, nor had any taken drugs recognized as producing haemolysis. There was no history of blood loss.

All patients were admitted in the second week of the disease. With the exception of Case 6, the patient with haemoglobinuria, the history obtained was in no way different from that of uncomplicated typhoid. Again with the exception of Case 6, none of the cases were aware of being jaundiced. Case 6 had a 12-day history of increasing fever, severe frontal headache, progressive general malaise, and abdominal discomfort and distension. He was noticed to be jaundiced for 48 hours before admission. Twelve hours before admission he complained of shivering, backache, and generalized

bone-aching, and a specimen of urine passed six hours later was dark red in colour.

The salient clinical features are set out in Table I. Toxaemia was severe in four cases and moderate in two. Two cases (Nos. 1 and 3) had an unusually profuse eruption of rose spots. All six cases were mildly or moderately jaundiced on admission. The spleen was palpable in five cases, and in three of these it was larger than would be expected in cases of typhoid in the second week. The spleen was not felt in the patient with haemoglobinuria (Case 6). The liver was palpably enlarged in all cases. It was not tender.

Laboratory Findings

The bacteriological findings are set out in Table I and the remaining laboratory findings in Table II. The diagnosis of typhoid fever was established by the isolation of *Salm. typhi* from both sternal marrow and blood cultures in two cases, in two cases from sternal marrow culture alone, and in one case each from blood culture and stool culture.

Cases 1 to 5 inclusive showed a marked increase in the urobilinogen excretion in the urine. This was estimated quantitatively in Cases 3, 4, and 5, and was found to be 31, 21, and 28 mg. a day respectively. In these five cases the direct van den Bergh test was negative, but the indirect van den Bergh was positive, the serum bilirubin ranging from 2.2 to 3.6 mg. per 100 ml. In Case 6 the urine contained haemoglobin and methaemoglobin and there was haemoglobinaemia.

Satisfactory collection of stools from our patients was impossible, consequently the quantitative estimation of urobilinogen in the faeces by the method described by Watson (1937a) could not be carried out. The difficulty of collecting stools from acutely ill patients was appreciated by Watson (1937b), who, to circumvent it, described an application of the qualitative test as a rough quantitative test, according to whether the intensity of the reaction is weak, moderate, or strong. These reactions are recorded as +, ++, and +++ respectively. In Cases 2, 3, 4, and 5, in which this test was carried out, the reaction was strongly positive.

The haematological findings on admission are set out in Table II. It will be seen that all cases were anaemic on admission; the red-cell counts ranged from 1.8 to 2.8 millions per c.mm. and the haemoglobin from 5.8 to 9 g. per 100 ml. The M.C.V. ranged from 100 to 120 μ^3 . The reticulocyte count was raised in all cases to between 8 and 14%. The fragility of the red cells to hypotonic saline was determined in all cases, employing in Case 6 washed red cells. The red-cell fragility range was within normal limits in Cases 1, 5, and 6, whereas it was increased in the remaining three cases. The direct Coombs test was carried out in Cases 1, 2, 3, and 4. It was strongly positive in Cases 3 and 4 and weakly positive in Cases 1 and 2.

TABLE II.—Laboratory Findings in Six Cases of Haemolytic Anaemia Complicating Typhoid Fever

Case No.	Urine		Faecal Urobilinogen	Serum Bilirubin (mg./100 ml.)	Total R.B.C. (mills. per c.mm.)	M.C.V. (μ^3)	Reticulocytes (%)	Osmotic Fragility Range of R.B.C.	Direct Coombs Test	Haemoglobin (g./100 ml.)	White Cell Count				Sternal Marrow	
	Urobilinogen	Haemoglobin									Total W.B.C. (per c.mm.)	Differential				
												N %	E %	L %		M %
1	++	—	Not done	3.6	2.8	111	8	Normal	+	9.0	6,100	82	2	14	2	Normoblastic erythropoiesis with hyperplasia of the erythroid series

6	"	+++	Not done	3.6	1.8	120	8	"	" "	5.8	12,800	78	3	17	2	

The leucocyte count in Cases 2, 4, and 6 showed an increase to between 9,000 and 12,800 per c.mm. In these three cases and in Case 1 the differential count was unusual in that there was a predominance of polymorphonuclear leucocytes, which constituted from 74 to 82% of the total white cells. In Cases 1 and 6 another

unusual finding was the presence of eosinophils in the peripheral blood. Smears of sternal marrow in all cases showed normoblastic erythropoiesis with hyperplasia of the erythroid series.

Since Cases 1 and 2 occurred before the introduction of chloramphenicol and Cases 3 and 4 before A.C.T.H. was available, the six cases may be divided into the following groups:—Group 1: Cases 1 and 2, in which the disease pursued an uninterrupted course. Group 2: Cases 3 and 4, which were treated with chloramphenicol. Group 3: Cases 5 and 6, which were treated with A.C.T.H. and chloramphenicol.

Group 1

The details of the progress of Cases 1 and 2 are set out in Figs. 1 and 2, respectively.

In Case 1 the haematological findings persisted substantially unchanged until the onset of lysis on the 28th day of illness. During the course of lysis the evidence of haemolysis disappeared. There was a fall of serum bilirubin, and urobilinogen was no longer present in excess in the urine after the 34th day. The reticulocyte count declined and the red-cell count and haemoglobin rose progressively. On discharge 52 days after onset the red-cell count was 4.7 millions per c.mm., the haemoglobin 13.8 g. per 100 ml., and the reticulocytes less than 1%.

In Case 2 the severity of the anaemia increased. The red-cell count fell to 1.7 millions two days after admission, when a blood transfusion of 2 pints (1.1 litres) was given. The effect of the transfusion was transient, for after four days the red-cell count had fallen almost to the pre-transfusion level. The patient remained gravely ill for a further period of six days, when, on the 27th day of illness, resolution of the temperature by lysis began. Thereafter there was evidence of improvement. As in Case 1, the indications of haemolysis ceased during lysis. The serum bilirubin fell, and on the 39th day of illness urobilinogen was no longer detected in excess in the urine. On discharge 57 days after onset of the fever the red-cell count was 4.3 millions per c.mm., the haemoglobin 13.4 g. per 100 ml., and the reticulocyte count less than 1%, and the fragility to hypotonic saline within normal limits.

In both cases the direct Coombs test, previously and repeatedly positive, became negative during the phase of resolution of the fever.

Group 2

The details of the progress of Cases 3 and 4 are set out in Figs. 3 and 4, respectively. Treatment with chloramphenicol was started in

Case 3 within 24 hours of admission and in Case 4 four days after admission. In each case a loading dose of 60 mg./kg. of body weight was given and thereafter 60 mg./kg. every 24 hours in divided doses four-hourly for 14 days.

Case 3 was apyrexial five days after starting treatment. Despite control of the infection and improvement in the patient's clinical condition there was deterioration in the blood picture. The red-cell count fell from 2.2 to 1.5 millions per c.mm. and the reticulocytes increased from 9 to 15%. Despite this increased haemolysis the serum bilirubin had fallen from 2.2 to 1.2 mg. per 100 ml. A blood transfusion of 2 pints (1.1 litres) was given on the fifth day of treatment. The effect was transient, for after four days the red-cell count had fallen to 2.0 millions per c.mm. On the 12th day of treatment, the 23rd day of illness, there was a significant drop in reticulocyte count. Thereafter the red-cell count and haemoglobin progressively rose, the reticulocyte count fell to within normal limits, and urobilinogen was no longer detected in excess in the urine on the 27th day of illness. On discharge from hospital on the 34th day the red-cell count was 4.2 millions per c.mm., the haemoglobin 12.2 g. per 100 ml., and the reticulocytes less than 1%.

Case 4 was apyrexial three days after starting treatment with chloramphenicol, but the haematological findings persisted substantially unchanged for a further period of nine days. In this period the serum bilirubin fell from 2.8 to 1.1 mg. per 100 ml. On the 28th day of illness, 12 days after starting treatment, there was a fall in the reticulocyte count. This was followed by a progressive climb in the red-cell count and haemoglobin. Urobilinogen was no longer detected in excess in the urine on the 30th day. On discharge from hospital on the 41st day of illness the red-cell count was 4.8 millions per c.mm., the haemoglobin 14 g. per 100 ml., and the reticulocytes less than 1%.

The Coombs test in each case was positive seven days after resolution of the fever, but it was negative when repeated seven days later. The red cells in both cases on

FIG. 1.—Progress of Case 1.

FIG. 2.—Progress of Case 2.

FIG. 3.—Progress of Case 3.

FIG. 4.—Progress of Case 4.

admission had shown an increased fragility to hypotonic saline. Prior to discharge the fragility was within normal limits.

Group 3

The details of the progress of Cases 5 and 6 are set out in Figs. 5 and 6, respectively.

Case 5

Treatment with chloramphenicol was started within the first 24 hours after admission in the same dosage employed in Group 2. At the same time, because of the haemolytic anaemia A.C.T.H. was given. It was administered in 5% glucose by slow intravenous drip, so adjusted that 20 mg. was given over 24 hours. Gordon, Kelsey, and Meyer (1951) have shown that A.C.T.H. by slow continuous intravenous drip induces a quantitatively greater response than does periodic administration. The response to intravenous A.C.T.H. by the method described has in our experience proved satisfactory when treatment is required only for a short period.

Clinical Response.—Improvement was noted within a few hours of starting the drip. Within 24 hours the temperature had fallen to normal and the toxæmia was so reduced that a stuporous confused patient became alert and able to carry on a normal conversation. On the third day the temperature rose to 101° F. (38.3° C.), but fell again to normal on the fourth day and remained so thereafter. On the fourth day the dosage of A.C.T.H. was reduced to 10 mg. over 24 hours, and was discontinued on the 10th day. Chloramphenicol was continued for a further period of four days to a total of 14 days.

Haematological Response.—Two days after starting treatment the serum bilirubin had fallen from 3.4 to 1.8 mg. per 100 ml. In this period the reticulocyte count had risen by 5 to 15%, the haemoglobin by 1.2 to 8.3 g. per 100 ml., and the red-cell count by 0.5 million to a total of 2.6 millions per c.mm. From the second day of treatment there was a rapid decline in the reticulocyte count and a progressive rise in haemoglobin and in the red-cell count. Neither the reduction in dosage nor withdrawal of A.C.T.H. affected the climb. Urobilinogen was no longer detected in excess in the urine on the eighth day of treatment. Thirteen days

after starting treatment the red-cell count was 4.4 millions per c.mm., the haemoglobin 12.6 g. per 100 ml., and the reticulocytes less than 1%.

Case 6

The patient when first seen was confused and an adequate history could not be obtained. A tentative diagnosis of acute haemolytic anaemia of undetermined aetiology was made. Though the haemolysis had produced no circulatory disturbance, in view of the acute onset of the anaemia he was given a transfusion of 1 pint (570 ml.) of blood. A.C.T.H. was administered in the same dosage and by the same technique as in Case 5.

Clinical Response.—The response to treatment was as in Case 5. Improvement was noted within a matter of hours. Eighteen hours after starting treatment toxæmia was much reduced, the temperature had fallen from 104.6 to 100° F. (40.3 to 37.8° C.) and the patient was alert and able to carry on a normal conversation. His appetite returned. The temperature remained around 100° F. (37.8° C.) for a further three days, then rose to 103° F. (39.4° C.) without deterioration in the clinical condition. On the fifth day the bacteriologist reported the isolation of *Salm. typhi*, and chloramphenicol was started in the dosage as in Group 2. On the same day the dose of A.C.T.H. was reduced to 10 mg. over 24 hours. He became apyrexial on the seventh day of treatment and remained so thereafter. A.C.T.H. was withdrawn after 10 days and chloramphenicol after 14 days.

Haematological Response.—The blood transfusion raised the red-cell count from 1.8 to 2.4 millions per c.mm. A specimen of urine passed 22 hours after starting treatment

was free from haemoglobin, as was also a specimen of serum obtained at the same time. The bilirubin content of this specimen of serum was 3.6 mg. per 100 ml., and 24 hours later the serum bilirubin had fallen to 2.0 mg. per 100 ml. Three days after starting treatment the reticulocytes had fallen from 15 to 9%, and the red-cell count had risen to 2.8 millions per c.mm. Thereafter there was a rapid fall in the reticulocyte count and a progressive rise in the red-cell count and haemoglobin, which was unaffected either by reduction of the dose of A.C.T.H. or by its withdrawal. Urobilinogen was no longer present in excess in the urine six days after starting treatment. Fourteen days after starting treatment the red-cell count was 4.8 millions per c.mm., the haemoglobin 12.2 g. per 100 ml., and the reticulocytes less than 1%.

Discussion

The anaemia in all six cases can be accepted as haemolytic in origin. It was associated with an increased reticulocyte count, and sternal marrow biopsy showed a normoblastic hyperplasia. In the absence of blood loss this picture suggests haemolysis.

In Case 6 there was unequivocal evidence of haemolysis. In the remaining cases there was a retentive jaundice. Urobilinogen, measured by the intensity of the qualitative reaction, was present in excess in the urine, and in the three cases in which it was quantitatively estimated the excretion in 24 hours was greatly increased. Faecal urobilinogen, estimated by the intensity of the qualitative reaction as described by Watson (1937b), was increased in the four cases in which it was done. This test has been performed on a series of 20 uncomplicated cases of typhoid, and a strongly positive reaction has never been encountered.

The evidence supports a diagnosis of acquired haemolytic anaemia. There was an absence of family history of

anaemia or jaundice. The Coombs test was positive in the four cases in which it was done, and in Cases 2 and 3 blood transfusion had only a transient effect. Furthermore, the haematological response to A.C.T.H. would appear to confirm this diagnosis. Dameshek (1950), Gardner (1950), Dameshek, Rosenthal, and Schwartz (1951), Davidson, Duthie, Girdwood, and Sinclair (1951), and Clearkin (1952) have reported the satisfactory response of symptomatic or "idiopathic" acquired haemolytic anaemia to A.C.T.H. The haematological response of Cases 5 and 6 to A.C.T.H. was satisfactory. The manifestations of haemolysis ceased, and within 48 hours there was evidence of increase in the red-cell counts and haemoglobin levels, an increase which was progressive. The response of Case 5, to which chloramphenicol was coincidentally administered, can be attributed only to the A.C.T.H., since no response to chloramphenicol alone was encountered in Cases 3 and 4 and since A.C.T.H. alone in Case 6 produced a similar response.

The haemolysis would seem to be intimately associated with the typhoid infection. There was no evidence of exposure to toxic substances or of the taking of drugs recognized as producing haemolysis. There was no previous personal history of jaundice or of anaemia. Although there is no direct evidence of the precise time of onset of the anaemia, in view of the absence of previous history and the cessation of the haemolytic process with resolution of the disease it would seem reasonable to assume that the haemolysis began during the course of the disease. With this assumption, in the present series the onset of haemolysis was in the first two weeks of the disease. Although haemoglobinuria occurred in Case 6 on the 11th day, because of the appearance of jaundice 48 hours before it would seem that haemolysis had already occurred and the haemoglobinuria was due to an exacerbation of the haemolytic process. The time of onset—that is, in the first two weeks—is in agreement with that reported by Berman *et al.* (1945). They record the day of disease in which five of their nine cases were admitted. All five showed evidence of haemolysis on admission; four were admitted towards the end of the second week and one at the end of the first week. Of the 10 cases of haemoglobinuria complicating typhoid fever found in the literature the haemoglobinuria occurred in the first week in five, in the second week in three, and in the third week in two. As in Case 6, the onset of haemoglobinuria does not necessarily indicate the time of onset of haemolysis; for example, the case reported by Gordon Smith (1951) was jaundiced for three days before the onset of haemoglobinuria.

The pathogenesis of the haemolysis is obscure. Members of the *Salmonella* group are normally anhaemolytic, but, as originally shown by Friedberger and Vallen (1923), the addition of bacteriophage to a freshly inoculated sheep-blood-agar plate may turn an anhaemolytic culture of *Salm. typhi* into a haemolytic one. Schiff and Bornstein (1940) confirmed these findings, and concluded that haemolysis occurs if a potentially haemolytic culture is combined with a specific phage of adequate strength. With a surplus of phage no haemolysis occurs, because the phenomenon is bound to the presence of live bacteria. On the other hand, no haemolysis is obtained with too small amounts of phage. It is most unlikely that this mechanism plays a part *in vivo*, for the following reasons. The bacillus/phage haemolysis has been found for sheep's red cells but not for human red cells. As the process requires a nice adjustment of phage and organism it cannot explain the persistence of haemolysis despite control of the infection by chloramphenicol in Cases 3 and 4. Finally, Clearkin (1952) has shown that in guinea-pigs A.C.T.H. does not prevent the action of haemolytic sera *in vivo*; consequently it is unlikely that the effects of a bacillus/phage haemolytic agent would be inhibited.

In Cases 1 and 2, in which the disease pursued an uninterrupted course, the haemolytic process ceased during lysis. This also was the finding of Berman *et al.* (1945). Coincidental with the cessation of haemolysis the direct

Coombs test became negative in both cases. Spontaneous resolution consequently results in the removal of the agent responsible for the haemolysis.

Cases 3 and 4 responded satisfactorily to chloramphenicol and were apyrexial in five and three days respectively. There was, however, no immediate change in the intensity of the haemolytic process; indeed, in Case 3 it was intensified. In this case blood transfusion had a transient effect even though administered while the patient was apyrexial. There was no indication of improvement in the blood picture for seven and nine days respectively following resolution of the fever. The reduction of serum bilirubin which occurred in this period must be attributed to improvement of liver function consequent upon the control of the infection. Furthermore, the direct Coombs test was positive in both cases seven days after the fever had resolved. It was negative when repeated on the 14th day after resolution of the fever. I am aware of only one case of typhoid fever complicated by haemolysis treated with chloramphenicol, and that is the case reported by Gordon Smith (1951). Although haematological details are lacking in his report, it would appear that for 11 days after the patient became apyrexial no improvement in the haematological findings occurred. The significant time lag following control of the infection before cessation of haemolysis and disappearance of the auto-antibody suggests that the typhoid bacilli are not directly responsible for the haemolytic process.

Dameshek and Rosenthal (1951) analysed 36 cases of acquired haemolytic anaemia and found 8 to be idiopathic and 28 symptomatic. Of these 28, 8 were due to chronic lymphatic leukaemia, 4 to Hodgkin's disease, 2 to reticulum-cell sarcoma, 2 to lymphosarcoma, and 1 to infectious mononucleosis. It seems reasonable to suggest that, if these pathological conditions of lymphoid and reticulo-endothelial tissue can result in the appearance of auto-antibody and the occurrence of acquired haemolytic anaemia, the haemolytic process occurring in *Salm. typhi* infection may result from the hyperplasia of lymphoid and reticulo-endothelial tissue which occurs as an essential part of the pathology of the disease. The response of Cases 3 and 4 supports this conception, for resolution of the pathological changes produced by the infection is delayed for a significant period of time following control of the infection by chloramphenicol.

Berman *et al.* (1945) considered that in their series dietary deficiency may have played a part in the production of the haemolysis. In our series the nutrition of all six patients was satisfactory and there was no evidence of any deficiency state.

The effect of A.C.T.H. upon the typhoid state was impressive. The reduction in toxæmia was rapid, improvement being obvious within a few hours. Within 24 hours a stuporous patient in low muttering delirium became alert and rational. This reaction to A.C.T.H. has been reported by Roche (1951). Further experience in the treatment of the severe typhoid state with a combination of A.C.T.H. and chloramphenicol has shown that the response is not invariably so dramatic as in the two cases reported here, but A.C.T.H. is a useful adjunct in the management of typhoid with severe toxæmia in the first few days of chloramphenicol treatment.

Summary

Six cases of haemolytic anaemia, one of which had haemoglobinuria, were encountered in an investigation of 129 cases of *Salm. typhi* infection.

The relevant clinical and laboratory findings are described and discussed.

Evidence is presented that the anaemia is a symptomatic acquired haemolytic anaemia intimately related to the typhoid infection.

The response to chloramphenicol of two patients indicates that the salmonellae are not directly responsible

FIG. 5.—Progress of Case 5.

FIG. 6.—Progress of Case 6.

for the haemolysis. It is suggested that the haemolysis may be related to the reticulo-endothelial hyperplasia which occurs in typhoid.

The administration of A.C.T.H. in two cases controlled the haemolytic phenomena and produced prompt improvement in the typhoid state.

MYXOEDEMA COMA

BY

V. K. SUMMERS, M.D., M.R.C.P.

Consultant Physician, Walton Hospital, Liverpool

In the report of a committee of the Clinical Society of London (1888) on myxoedema it was stated that "intense anaemia, and a variety of nervous symptoms, such as maniacal excitement, coma, etc., precede the fatal event." Scant reference to coma as a terminal event in the natural history of myxoedema is made in modern textbooks or in recent accounts of the disease. The modern tendency is to look upon myxoedema as a readily curable disease and, indeed, hardly to consider it as a cause of death. Le Marquand *et al.* (1953) call attention to the scarcity of recent references to myxoedema as a cause of death and report two fatal cases. The purpose of this paper is to call attention to a terminal coma which is often the manner of death in myxoedema.

The following account is based on five examples of coma seen in four cases of myxoedema during the past few years; in all the cases the diagnosis was subsequently confirmed at necropsy. In one case two episodes of coma occurred.

Case 1

A man aged 59 was admitted to hospital in January, 1950, with a history of watery eyes for 10 weeks and of puffiness of the face for three weeks. There was little of significance in his past history, and apart from malaria during the 1914-18 war he had enjoyed good health. For many years he had complained of "rheumatism" in his right knee. A few days before admission he burned his right leg whilst sitting close to the fire. His face was puffy, especially round the eyes, the lips were thick, and the skin was pale. Axillary hair was absent and the pubic hair scanty. Cerebration was slow, but it was possible to obtain a reasonable history from him. His condition on admission did not give rise to any anxiety, and a series of investigations were planned to assess his endocrine state.

Within 72 hours of admission his condition greatly deteriorated; he became very confused mentally and had delusions of a persecutory nature. Next day he became very drowsy and it was extremely difficult to rouse him; 12 hours later he was stuporous and the plantar responses became extensor. His rectal temperature was 83° F. (28.3° C.). Thyroid extract, 1 gr. (65 mg.) thrice daily, was given as soon as the change in his state was observed, and when he became too drowsy to take oral therapy thyroxine sodium, 1 mg., was given subcutaneously every six hours. This treatment had no effect whatsoever and he died about 96 hours after the first change in his condition was noticed.

Post-mortem examination confirmed the clinical diagnosis of myxoedema. Sections from both lobes of the thyroid showed marked fibrosis. The adrenal glands were of normal size and showed no histological change. The pituitary was normal.

Case 2

A woman aged 65 was admitted to hospital in March, 1951; she had been in hospital on four occasions, and in 1946 a diagnosis of myxoedema was considered. At the time of her admission in 1951 she presented a typical myxoedematous appearance, with a puffy sallow face, sparse head hair, and thin eyebrows. Her voice was croaking. The mental state was one of stupor which gradually, within 48 hours, progressed into deep coma. The vaginal temperature on admission was 75° F. (23.9° C.) and the systolic blood pressure was 70 mm. Hg. The pulse was thin and the rate 60 a minute. The skin was pale and cold; the limbs were flaccid; the deep reflexes could not be elicited, and the plantar responses were extensor.

Thyroxine sodium, 2 mg., was given subcutaneously every six hours from the time of admission. In view of the pronounced hypothermia, and of previous successful experience in hypopituitary coma of raising the temperature by means of immersion in a hot bath, it was decided to attempt this method of treatment. The temperature was raised from 75 to 98.6° F. (23.9 to 37° C.) by immersion in a bath of water, the temperature of which was gradually raised (to avoid burning) to 98.6° F. (37° C.). This procedure had no effect on the coma, and, although the vaginal temperature remained at 98.6° F. (37° C.), the patient died on the following day.

Post-mortem examination showed an extremely small thyroid; in the right lobe was a nodule the size of a cherry stone and in the left a nodule the size of a small bean. Histologically the gland tissue was completely replaced by fibrous tissue in which there were a few groups of shrunken acini. The pituitary and adrenal glands were normal.

Case 3

A man aged 63 was admitted to hospital in February, 1952. Myxoedema had begun about four years previously, and he had taken thyroid intermittently until about a year before his final admission. Clinically he presented gross myxoedematous features, with a flabby yellow face, oedematous infra-orbital tissues, dry swollen hands, thin eyebrows, and sparse head hair. Axillary hair was completely absent and the pubic hair scanty. The voice was croaking and deafness was severe. The blood pressure was 155/100 and the pulse 66. He was mentally clear but sluggish. The rectal temperature was 91.4° F. (33° C.). An electrocardiogram showed slow voltage complexes with flat T waves in all leads. The haemoglobin was 11 g. per 100 ml. and the red-cell count 3,700,000 per c.mm.

Within 48 hours of admission the patient became drowsy, and, with the experience of the previous two cases as a guide, treatment was begun immediately. Thyroid siccum, 1 gr. (65 mg.) thrice daily, was given by mouth, and cortisone, 100 mg., and deoxycortone acetate, 10 mg., were given via an intravenous saline drip. There was no change in his condition during the next 24 hours, but on the following day he was stuporous. The rectal temperature was now only 87.5° F. (30.8° C.), and it was decided to substitute thyroxine

sodium, 2 mg. every six hours, for the thyroid extract, to continue with cortisone, and to attempt to raise the falling body temperature by immersion in a hot bath. This method was followed, and the final rectal temperature was 98.6° F. (37° C.). His condition steadily worsened, and a further 200 mg. of cortisone acetate was given. No improvement was effected and death occurred on the next day.

Post-mortem examination showed an extremely small thyroid in which histologically there was almost complete replacement of glandular elements by fibrous tissue. The pituitary and adrenal glands were normal.

Case 4

A man aged 59 was admitted to hospital in July, 1951. About a year before admission he had noticed that his skin was becoming dry and scaly and that he felt the cold. His hearing was impaired and his memory was failing. At the time of admission his eyes were puffy, the skin was dry, and the voice was croaking, but there was fairly abundant head hair, although the eyebrows were sparse. No thyroid tissue was palpable. The blood pressure was 130/75 and the pulse rate 64. The temperature ranged from 96 to 98° F. (35.6 to 36.7° C.). An electrocardiogram showed low-voltage complexes and negative T waves in all leads. An electroencephalogram showed, with maximum amplification, irregular 8-9 per second rhythm, with the greatest amplitude in the parietal region and also a certain amount of more rapid low amplitude activity in the parietal region. The B.M.R. was -30%, and the 17-ketosteroid excretion ranged between 0.6 and 0.75 mg. a day.

Cerebration at the time of admission was extremely slow and became progressively more sluggish, until on the fourth day after admission the patient was semi-stuporous. Thyroxine sodium, 1 mg., was administered six-hourly. Improvement was observed within 24 hours, and there was a gradual return to a normal conscious level during the next few days. Treatment was continued with thyroid extract.

This patient was readmitted to hospital in November, 1951, and at this time he was very drowsy when first seen. The rectal temperature was 83.5° F. (28.6° C.), the pulse rate 75. Treatment was begun with thyroxine sodium, 1 mg. every six hours, and cortisone acetate, 100 mg. every six hours. Despite treatment he lapsed into unconsciousness and died 48 hours after admission.

Post-mortem examination showed gross thyroid atrophy with replacement of glandular tissue by fibrous tissue. The adrenal glands were normal histologically, but the pituitary showed an excess of basophil cells.

Comment

In these cases it was not possible to carry out all the blood and urine analyses which are normally performed in endocrine investigations. Biochemical investigations were carried out as fully as possible during the terminal stage of the illness, and the results are shown in the Table.

Results of Biochemical Investigations (All Amounts are Given in mg. per 100 ml.)

Case	Sodium	Potassium	Phosphorus	Chlorides	Urea	Glucose	Cholesterol
1	323	22	4.2	—	40	110	180
2	280	22.5	3.9	500	31	140	160
3	276	24	4.0	515	53	94	280
4	304	22	4.1	568	48	—	310

The onset of coma in each case was gradual and progressed from drowsiness to deep, fatal coma within a few days. Le Marquand *et al.* (1953) report a case, however, in which the onset of coma seems to have been more rapid. Case 4 above appears to have had a pre-coma state, and this was prevented from progressing to full coma by prompt treatment.

All the patients were severely myxoedematous at the time of their admission to hospital. The coma in each case was

deep: the limbs were extended and flaccid, and the extremities were cold. The skin was pale, dry, scaly, and cold. The pulse was thready but the rate ranged from 60 to 75 a minute. The systolic blood pressure ranged from 70 to 130 mm. Hg. The tendon reflexes could not usually be elicited, and the plantar responses were sometimes extensor. In view of the occurrence of very low body temperature in hypopituitary coma (Sheehan and Summers, 1952), special note was made of this in these cases. Vaginal or rectal temperatures during coma ranged from 75 to 91.4° F. (23.9 to 33° C.), and was lower than the temperature recorded in some of the patients when not in coma. An incubator thermometer was used to record temperatures below the usual range of a clinical thermometer. Once coma develops it seems to be irreversible, and none of the methods of treatment used were successful.

Diagnosis should not present any difficulty; very gross myxoedematous changes were present in all the cases, and the history, when obtainable, was typical. Hypopituitary coma, particularly when myxoedema features are prominent, may present difficulty. In the common post-partum type of hypopituitarism the history will often make the diagnosis clear.

Discussion

The occurrence of coma as a terminal event in myxoedema is of interest, first, as a problem in the disordered physiology which results from loss of the thyroid secretion, and, secondly, because a very similar type of coma occurs in hypopituitarism (Sheehan and Summers, 1952).

All the cases in the present series had hypothermia, and a similar condition was observed in hypopituitary coma. Le Marquand *et al.* (1953, Case 1) also report hypothermia, and note that their patient was admitted to hospital during the middle of the winter, when they suggest that the risk of hypothermia is greatest. My experience of the present cases supports this observation, all the patients being admitted during the winter months. Although the body temperature was successfully raised to normal in two cases, no improvement was produced and the coma persisted. The temperature regulatory mechanism in severe myxoedema would seem to be influenced by low external temperatures in much the same manner as the temperature of cold-blooded animals. The changes produced by extremely low body temperature in these severely myxoedematous patients are apparently irreversible and elevation of the temperature to normal does not lead to recovery. It becomes a matter of great importance therefore to protect patients with gross myxoedema from severe external cold.

It is tempting to suggest that hypothermia is the cause of coma in these cases, and that these low temperatures are due to the depression of metabolism which results from loss of thyroid secretion. In only one case, in which the development of coma was presumed likely, was it possible to restore the patient with thyroid extract or thyroxine sodium. Once coma had developed administration of thyroxine was without effect, even when used in conjunction with hydrotherapy. Either lack of thyroid is not entirely responsible for the development of hypothermia or the body reaches a state in which it can no longer respond to the stimulus of thyroxine.

Consideration of the first of these possibilities—namely, that lack of thyroid is only part of the story—leads to a study of the recent work on the failure of adrenal cortical function which occurs in myxoedema (Statland and Lerman, 1950) in order to find an explanation of the occurrence of coma. In one of the present cases the 17-ketosteroid excretion was in the range of 0.6 to 0.75 mg. daily, an excretion rate similar to that found in hypopituitarism, and in two cases low levels of serum sodium and chloride were found. The administration of cortisone acetate in one case, and of deoxycortone acetate, saline, and cortisone in another, failed to revive the patients.

Further study of the coma in myxoedema is required to elucidate the pathology of this condition, and it is hoped that further cases of this interesting but rare complication of myxoedema will be reported.

Summary

Four cases of terminal coma occurring in myxoedema are reported. Extremely low body temperatures were recorded in all cases. No treatment so far tried has reversed the coma once it has developed.

TURNER'S SYNDROME IN THE FEMALE CONGENITAL AGONADISM COMBINED WITH DEVELOPMENTAL ABNORMALITIES

BY

W. P. U. JACKSON, M.D., M.R.C.P., D.C.H.

AND

R. SOUGIN-MIBASHAN, M.B., Ch.B., B.Sc.

(From the Department of Medicine, University of
Cape Town)

Hypogonadism, manifesting itself as primary amenorrhoea and lack of development of uterus, vagina, and breasts, without any evident disease of or operative interference with ovaries, thyroid, or intracranial structures, is usually attributed to pituitary insufficiency. The tiny, frail, delicate, fair-skinned dwarf demonstrating the Lorain-Lévi syndrome is the prototype of primary hypopituitarism. One should not, however, label as examples of pituitary deficiency all other hypogonadic individuals with no resemblance whatever to the Lorain type. One such group has now been conclusively proved to be due to primary lack of development of ovaries.

Historical Background

This is recent. In 1938 Turner described seven cases with webbing of the skin of the neck, cubitus valgus, and infantilism. He noted that the short webbed necks of his cases were not due to any vertebral abnormalities, and bore no relation, therefore, to the Klippel-Feil group of conditions. He thought the syndrome might be of pituitary origin.

In 1942 Varney, Kenyon, and Koch reported the cases of four short, sexually retarded females who showed an increase of pituitary gonadotropins in their urine. Laparotomy demonstrated ovarian aplasia, which could not have been pituitary in origin in view of the urinary findings. The same year Albright, Smith, and Fraser (1942) independently demonstrated the primary origin of the syndrome and discussed in detail its differentiation from hypopituitarism on the basis of 11 cases of their own.

In 1944 Wilkins and Fleischmann published an interesting and thoughtful analysis of this syndrome of ovarian agenesis. They again showed a primary lack of development of the ovaries, which were "developed but little, if at all, beyond the stage of the primitive genital ridge." They point out that affected persons, though sexually underdeveloped, are obviously female in appearance, habitus, organs, and inclinations, so that female differentiation itself must be entirely independent of the embryonic gonad. They divide the syndrome into three constituents—first, the gonadal agenesis and its conse-

quences; secondly, the skeletal abnormalities, which cannot be directly occasioned by the ovarian agenesis but must be associated congenital developmental anomalies; and thirdly, other congenital dysgeneses, particularly involving the eye, ear, and aorta. They could find no evidence that the condition is hereditary.

Lisser and his co-workers (1947) were able to report on 25 cases which they had personally observed. They remark upon their extraordinary uniformity in appearance and build, and use the term "shield-like chest" to describe their patients' frontal aspect.

Salient Features of the Syndrome

1. *Gonadal*.—Primary:—Lack of development of ovaries—surgical exploration of some cases (Wilkins and Fleischmann) has revealed "ovaries" consisting of a primitive genital ridge composed only of stroma-like cells. Epithelial or primordial germ-cell proliferation is absent. Secondary:—Primary amenorrhoea—this is invariable, and the usual presenting complaint. The vagina and uterus are infantile in size and in mucosal differentiation. The breasts are non-existent, the nipples pin-point. The pubic hair is usually present but scanty; sometimes absent. Bone age is normal, or only slightly backward. Generalized osteoporosis of varying degree is present. Urinary gonadotropins are increased, the number of mouse units (depending on the method used) usually considerably exceeding 50 in 24 hours (Wilkins and Fleischmann, 1944; Sohval, 1951). Urinary 17-ketosteroids are diminished but not absent, typical values being around 2–5 mg. in 24 hours. Insulin tolerance is normal, with normal hypoglycaemic responsiveness. The appearance is female. Libido is usually present, often strong, and normally heterosexual. Oestrogen therapy leads to development of secondary sexual characters.

2. *Skeletal*.—Stature is short—around 53 in. (135 cm.)—not really dwarfed; rarely tall (Sohval). The build is stocky, thick-set, with wide "shield-like" chest. The span is often wide, some inches greater than the height; otherwise the proportions are normal. Minor vertebral chondrodystrophy is common; the cervical spine, although occasionally bifid, or fused as in Klippel-Feil's disease, is usually normal. Webbed neck is usually but not invariably present. It is remarkable that this odd deformity is so commonly associated with ovarian agenesis and occurs only very rarely in other circumstances. Cubitus valgus—a decreased "carrying angle" was part of the original syndrome described by Turner, but is not invariable. This obtuse angle between the humerus and radius is normally slightly smaller in females than in males, averaging 167 degrees (Gray's Anatomy, 1944). Pes cavus, talipes, syndactyly, and various minor vertebral anomalies also occur.

3. *Associated Anomalies*.—Ocular defects are curiously frequent, squint, ptosis, and cataract being the most common. Coarctation of the aorta has been found several times, and hypertension of independent occurrence is mentioned by Wilkins and Fleischmann. Mental defect and deaf-mutism are reported by those authors.

Diagnosis

Originally the diagnosis of primary ovarian agenesis was established by two special procedures—the direct examination of what genital tissue there was, usually by laparotomy, and the demonstration of increased urinary pituitary gonadotropins, which exculpated the pituitary gland. It was gradually realized, however, that the clinical syndrome as outlined above was so characteristic that it could be diagnosed without such elaborate enterprises; in fact, it has become one of the select group of disorders that can be diagnosed on sight (Case 2). The complaint of primary amenorrhoea, the stocky, thick-set, broad-chested, short individual, with webbed or at least short-looking neck, the lack of breast tissue, pin-point nipples, and minute pale-pink areolae make an unmistakable picture. Cases have

even been diagnosed before the time of puberty (Lisser *et al.*, 1947), the skeletal changes being so characteristic (cf. Case 3).

The elimination of hypopituitarism is easy: sufferers from this are truly dwarfed rather than small, frail and delicate rather than stocky; their necks are normal, their pubic hair is completely absent, their bone age is very backward, their gonadotropin output is very low, and their 17-ketosteroids are minimal. They are extremely sensitive to insulin, so that only one-fifth to one-tenth of the normal amount should be used for tolerance test if hypopituitarism is suspected; and they show hypoglycaemic unresponsiveness (Albright, Smith, and Fraser). Finally, oestrogens do not produce any response in respect of secondary sexual characters.

The following cases all presented themselves at Groote Schuur Hospital within the course of a few weeks.

Case 1

A girl aged 18 complained of never having menstruated. She had always been somewhat smaller than her friends of the same age. Pubic and axillary hair had developed at 15. She was mentally bright and had done well at school. Her sex feelings were apparently normally strong. She had a

FIG. 1.—Case 1. Webbed neck, thick-set build, pin-point nipples, fair pubic hair.

were infantile, and uterine scraping produced no endometrial tissue. Other systems were normal. The blood pressure was 140/90 mm. Hg.

Radiographs showed slight general osteoporosis. The bone age was within normal limits, a little behind that of the control of same age and sex. The right twelfth rib was missing, and there were minor irregularities of vertebral bodies. The skull was normal except for slight porosis of the middle table. The B.M.R. was -13% and -19% (two estimations on Sanborn metabor); E.C.G. normal; and the Wassermann reaction negative.

The first insulin-tolerance test showed resistance:

Fasting	105 mg. per 100 ml.
10 minutes after 4.5 units insulin I.V.	99 mg. per 100 ml.
20 "	94 "
30 "	98 "
40 "	108 "
60 "	98 "

Repetition of the test gave more normal figures; certainly no undue sensitivity was shown. The 17-ketosteroids were (1)

2.4 mg. per 24 hours (normal 6–15 mg.); (2) 2.6 mg.; serum cholesterol, 360 mg. per 100 ml.; urine gonadotropins (F.S.H.), positive at 96 mouse uterine units per 24 hours (method of Klinefelter, Albright, and Griswold, 1943).

Stilboestrol, 1 mg. a day, was given for three weeks of every four, with ethisterone, 10 mg. a day, for the last 14 days of each four-weeks cycle. An apparently normal period of five days' duration occurred after the first month. Development of breasts and growth and pigmentation of nipples and areolae were evident after two months.

Comment.—This was a very typical case of ovarian agenesis, with the low B.M.R. and high cholesterol (not repeated) as the only unexpected features. She bore no mental, clinical, or skeletal resemblance to a cretin.

Case 2

Within a week of the admission of Case 1, a coloured girl aged 17 presented herself, quite fortuitously, to one of us at the out-patient department. Her very appearance—short, dumpy, and short-necked, with ocular asymmetry—was enough to suggest the syndrome. After a complaint of primary amenorrhoea, we were able to predict the other typical features. She denied all sex feelings. All her family were normal, including two sisters.

Examination revealed a short, thick-set girl with much redundant fat around the trunk. Her neck was short and broad, but without a definite "web." Her eyes were asymmetrical in setting, the palpebral fissure being lower on the right. They also showed divergent strabismus, with nystagmus on looking to the right. Pubic and axillary hair was absent. Breast tissue was also absent; the nipples were tiny and inverted. Her chest was thick-set and fitted the description "shield-like." Her weight was 91 lb. (41.3 kg.); height, 51 in. (130 cm.); span, 51 in. (130 cm.); pubic height (lower segment), 24 in. (61 cm.); upper segment, 27 in. (69 cm.); head circumference, 21 in. (53 cm.). Internal examination of the genitalia was not permitted. Other systems were normal. The blood pressure was 145/85 mm. Hg.

FIG. 2.—Case 2. Asymmetry of twelfth ribs and only four lumbar vertebrae.

Radiographs showed slight generalized osteoporosis with coarsened trabeculation, particularly well seen in the sacrum (Fig. 2). Bony cortices were poorly defined. The hand bones were thin, but the bone age was normal. The twelfth ribs were small and asymmetrical, and one lumbar vertebra was missing (Fig. 2). The cervical vertebral line was straight but there were no individual abnormalities. The Wassermann reaction was negative. The insulin tolerance was normal:

Fasting	84 mg. per 100 ml.
10 minutes after 4.5 units insulin I.V.	82 "
20 "	62 "
30 "	55 "
40 "	75 "

The 17-ketosteroids were (1) 4.2 mg. per 24 hours, (2) 5.2 mg.; serum cholesterol, 210 mg. per 100 ml.; urine gonadotropins, strongly positive at 192 mouse units (normal, under 50).

Comment.—This was another typical case, though without true webbing of the neck. Complete absence of

secondary hair is not usual, but may occur in this syndrome. Her measurements are actually the opposite of eunuchoid (with larger lower segment), and lend weight to the belief that the statural peculiarities are not themselves due to gonadal deprivation. She did not bother to follow her treatment schedule.

Case 3

A red-haired girl aged 9½ complained of a discharging ear. Her performance at school was quite good. There was no relevant family history. She is an only child.

FIG. 3.—Case 3. Marked webbing of neck. Tiny nipples, good muscular development.

Examination revealed a short stocky girl, with strong muscles and a stumpy figure (Fig. 3). Her neck was very plainly webbed. Her head and eyes were not abnormal, except that her palate was high-arched. Although she was under 10 years old her nipples were certainly smaller than normal (Fig. 3)—almost invisible. The "shield-shape" of her chest was undeniable. Her blood pressure was 160/100 mm. Hg. Her height was 44½ in. (113 cm.)—normal 52 in. (132 cm.); span, 46 in. (117 cm.); lower segment, 20½ in. (52 cm.), upper segment, 24 in. (61 cm.).

Radiographs again showed mild generalized porosis with coarsening of bone structure, well marked around the acetabula. The bone age was normal.

Comment.—Despite the young age and the absence of special examinations, we have no hesitation in forecasting a lack of development of breast tissue and of menstruation. The hypertension was noteworthy.

Factors Involved in the Syndrome

The curious clinical attributes of these patients have made them subject to much pathogenetic speculation. Most writers, accepting a genetic ovarian defect, agree that this alone cannot explain all the abnormalities. The occurrence of multiple congenital anomalies in the syndrome makes it likely that shortness of stature is but one manifestation of a germinally defective soma, not directly related to the degree of ovarian agenesis (Sohval, 1951; Wilkins and Fleischmann, 1944). Indeed, a feature such as cubitus valgus is an anthropomorphic feminism, while skeletal lengthening, rather than shortening, typically follows oestrogen lack at an early age ("eunuchoidism").

The frequent osteoporosis may be ascribed to the loss of osteoblastic effect of oestrogens, and is comparable to the similar condition of menopausal women (Albright and Reifenstein). In this syndrome of ovarian agenesis, however, the osteoporosis, although slight, is more universal than is the typical vertebral rarefaction of menopausal females.

By the same token it has been suggested by Wilkins and Fleischmann that hypertension (present in some degree in our three cases, without evidence of coarctation) is comparable to that found in Cushing's syndrome and the postmenopausal state in which there is also an oestrogen deficit associated with persistence of adrenocortical androgens.

The extremely rare findings of good breast development (Lisser *et al.*, 1947; Hertz *et al.*, 1950) and of diminished urinary gonadotropins (Hertz *et al.*) with proved absence of ovarian tissue are not readily understood.

Role of Adrenal Cortex

The presence of a little pubic and axillary hair and urinary 17-ketosteroids in Turner's syndrome is ascribable with fair certainty to adrenal activity. Albright *et al.* (1942) contended that this adrenal cortical function is nevertheless below normal, conceivably as a result of altered pituitary stimulation in the anovarian state. He therefore blames the adrenal cortex for a decreased growth rate and consequent shortness of the patients.

With this problem in mind, we applied some of the recently adopted tests for adrenal cortical function (Thorn and Forsham, 1950) to our Cases 1 and 2. Circulating eosinophils and the urinary uric-acid/creatinine ratio were determined before and after an intramuscular injection of 25 mg. of A.C.T.H. (see Table).

Thorn Test

Case No.	Eosinophils per c.mm.			Uric-acid/Creatinine Ratio		
	Before A.C.T.H.	After A.C.T.H.	Fall	Before A.C.T.H.	After A.C.T.H.	Rise
1	120	50	58.3%	0.36	0.67	83.7%
2	80	30	62.5%	0.66	0.96	46.4%

A fall of 50% or more in circulating eosinophils and a rise of more than 50% in the uric-acid/creatinine ratio are said to denote adequate adrenal cortical function. By these criteria, in neither Case 1 nor Case 2 were the adrenals responsible for any of the shortcomings; but it is by no means acceptable that such procedures test all functional modalities with equal fairness. Bartter, Forbes, and Albright (1950) measured the effects of A.C.T.H. administration on steroid, electrolyte, and nitrogen metabolism in a case of ovarian agenesis. They interpreted the results as confirming slight hypofunction of the adrenal cortex, but concurrent findings in a normal control are not given. Further study in this field may be of value in augmenting the scope of hormonal treatment in these little women.

Summary

All congenital hypogonadism is not of pituitary origin. The syndrome of primary ovarian aplasia is described, starting with a brief account of the history of the recognition of the condition. Turner in 1938 first remarked the peculiar combination of webbed neck, short stature, and female infantilism. The important features of the condition are considered, and these are so characteristic as to present an unmistakable and readily diagnosable picture, plainly distinct from primary hypopituitarism, cretinism, eunuchoidism, or any other clinical state. Final proof of diagnosis is to be sought in the urinary gonadotropin level and the laparotomy finding of lack of ovarian tissue, but these are really unnecessary embellishments of a cast-iron clinical diagnosis.

Two illustrative cases are described, both with high urinary F.S.H. A third case is presented, and although the patient is only 10 years old we believe the diagnosis to be ineluctable.

The curious conglomeration of congenital anomalies in the clinical picture is discussed. The modern tests of suprarenal function were applied to the first two cases, and normal responses were obtained.

We are pleased to thank Professor F. Forman for his interest and advice in this article, and Dr. W. H. Opie for permission to report the third case. Dr. H. Zwarenstein kindly performed the tests for gonadotropins. We are indebted to the radiological department of Groote Schuur Hospital for the x-ray film and to Mr. B. Todt for the photographs.

TURNER'S SYNDROME IN THE MALE

BY

R. SOUGIN-MIBASHAN, M.B., Ch.B., B.Sc.

AND

W. P. U. JACKSON, M.D., M.R.C.P., D.C.H.

(From the Department of Medicine, University of Cape Town)

Turner's syndrome in the female (Turner, 1938; Wilkins and Fleischmann, 1944; Lisser *et al.*, 1947; Jackson and Sougin-Mibashan, 1953) is characterized by lack of development of the ovaries, short stature, webbing of the neck and other skeletal abnormalities. Ovarian agenesis means lack of Graafian follicles and hence an absence of both ova and female sex hormones (germinal and endocrinal deficiency). The affected person therefore is not fertile, does not menstruate, and lacks breast development, while her pituitary gland produces large amounts of gonadotropic hormone in an attempt to stimulate a non-existent end-organ.

The Male Homologue

It is not so easy to define the homologous condition in the male, because in the testis the germinal tissue and the endocrine tissue (believed to be situated in the Leydig cells) are separate, so that a lack of development of either one or both might be claimed to represent the sexual side of "male Turner's syndrome." Engle (1950) suggested that an absence of tubular germinal epithelium should be the basic

TABLE I.—Theoretical Features of Pure Germinal Agenesis, Pure Testicular Endocrinal Agenesis, and a Mixture of Both

	Germinal	Endocrinal	Mixed
Testes	Small	Normal	Small
Sperm	Azoospermia	Present (biopsy)	Absent
Penis	Normal	Small	Small
Potency	Potent	Impotent	Impotent
Body hair	Normal	Diminished	Diminished
Voice	Normal	High	High
Gynaecomastia	No*	May occur	May occur
Span	Normal	Large	Large
Osteoporosis	No	Yes	Yes
F.S.H.	Normal*	High	High
17-Ketosteroids	Normal	Reduced	Reduced

* These are doubtful because of the possibility that the germinal epithelium may also form a specific hormone (Sohval, 1951).

analogous condition. Sohval (1951), apparently agreeing with this, points out that there may be variable impairment of testicular secretory function in addition. There may thus be a variability in the presence and degree of hormonal disturbance in the "male Turner." The theoretical effects of pure germinal and pure endocrinal agenesis are shown in Table I.

This consideration explains why the five cases of male Turner's syndrome so far reported (Flavell, 1943; McCullagh, 1948; Greenblatt and Nieburgs, 1948; Reforzo-Membrives *et al.*, 1949; Sohval, 1951)* are less homogenous than the female group, since they show varying degrees of endocrinal deficiency and will not, for instance, be expected necessarily to have high urinary gonadotropins. The K.R.A. syndrome (Klinefelter, Reifenstein, and Albright, 1942) is somewhat comparable, comprising azoospermia, small testicles, high urinary F.S.H., and gynaecomastia. The basic lesion is different—a hyalinization and sclerosis of tubules rather than a lack of development. This syndrome has been expanded by Heller and Nelson (1945) and Howard *et al.* (1950) to contain cases without gynaecomastia and with a variable degree of androgen insufficiency, while retaining the basic pathological change. As with the "male Turner," therefore, the K.R.A. syndrome becomes a resultant of mixed germinal and endocrinal deficiencies. The special features of Turner's syndrome in the male, as in the female, include shortness and stockiness in stature and the various skeletal anomalies of which webbing of the neck is most outstanding, while the gonadal lesion is one of lack of development.

Table II shows the nature of the "mixture" of germinal and endocrinal defects in reported cases of male Turner's syndrome and compares this with the K.R.A. condition. This table includes the following case, which we believe to be an example of male Turner's syndrome.

* Rossi and Caffisch (1951) mention other cases from the Continental literature, but we lack detailed information concerning these.

TABLE II.—Features of the "Male Turner" and the Klinefelter-Reifenstein-Albright (K.R.A.) Syndrome

	Classical K.R.A.	Modified K.R.A.	Flavell's Case	McCullagh's Case	Greenblatt's Case	Reforzo-Membrives's Case*	Sohval's Case	Present Case
Testes	Small	Small	Small	Small	Small	Small	Small	Small
Sperm	Azoospermia	Azoospermia	—	—	Azoospermia	—	No semen	No semen
Penis	Normal	Variable	Normal	—	Large	Normal	Small	Normal
Potency	—	—	—	—	—	—	No ejaculation	Totally impotent
Body hair	Masculine	—	—	—	—	—	—	Very hairy

Span	Normal	Normal	—	Short	—	—	—	Wide
Congenital anomalies	Nil	Nil	Webbed neck, cubitus valgus, cervical spina bifida	Webbed neck, cubitus valgus, microphthalmos	Webbed neck, cubitus valgus	Webbed neck, cubitus valgus, epicanthic folds	Cubitus valgus, cervical vertebral anomalies	Webbed neck, no valgus
Osteoporosis	No	No	—	—	—	—	No	Yes
17-Ketosteroids	Normal	Low	—	Low	Low normal	Low	Low normal	Low
F.S.H.	High	High	—	Normal	Normal	—	High	High
Testicular biopsy	—	Tubular sclerosis and hyalinization; clumps of Leydig cells	—	Hypoplasia, no Leydig cells	Tubular hypoplasia, Leydig cells present	As in pituitary dwarfism	Tubular aplasia, Leydig cells present	—

The sign — denotes lack of information. * Two similar cases in early childhood (aged 7 and 3 respectively) have been reported by Cunningham and Harley (1951) and Dorff *et al.* (1948) without testicular biopsies.

Case Report

A coloured houseboy aged 30, of simple, facile, cheerful, and deceitful character, came to hospital complaining of a vague respiratory illness. He had always been of small stature: height, 58½ in. (149 cm.); span, 60½ in. (154 cm.); lower segment, 29 in. (74 cm.); upper segment, 29½ in. (75 cm.). His neck was markedly webbed (Fig. 2). There was no cubitus valgus. His muscles were very well developed—a midget "Mr. Universe." Sexually he also appeared fully equipped (Fig. 1), yet he denied having ever experienced sexual feelings of any kind and stated he had never had an erection or an emission. (Curiously, one of the few reported male cases had an enlarged phallus (Greenblatt and Nieburgs, 1948) as a possible additional congenital abnormality.) We were unable to obtain a specimen of semen. There was some disagreement regarding the size and consistency of the testes—possibly smaller and firmer than usual. The prostate was small. The blood pressure was 145/75 mm. Hg.

FIG. 1.—Short and muscular, with masculine stature and well-developed phallus.

Radiographs showed mild generalized osteoporosis. The 17-ketosteroids were 5.9 mg. per 24 hours (single estimation—method of Holtorff and Koch, 1940). The Wassermann reaction was negative. Urinary gonadotropins: 96 units per 24 hours (method of Klinefelter, Albright, and Griswold, 1943).

Unfortunately the crucial test—a testicular biopsy—was refused, and the patient left not only hospital but also the district with his employer's belongings before we could get urine to repeat our estimations. However, the high gonadotropins certainly confirm the presence of primary gonadal deficiency.

Summary

We have observed a case representing Turner's syndrome in the male—the homologue of ovarian agenesis

FIG. 2.—Note webbing of neck.

with short stature and congenital anomalies. We have made this an excuse for a consideration of what the male homologue should be and for a comparison of this with the Klinefelter-Reifenstein-Albright syndrome.

We conclude that the absence of homogeneity in the various reports of these conditions is due to the separation of endocrinal and germinal tissue in the male gonad,

whereas in the female gonad one single tissue—the Graafian follicle—serves both endocrinal and germinal functions.

We wish to thank Professor F. Forman for his interest, Professor G. C. Linder and Dr. H. Zwarenstein and their departments for the special assay, and Mr. B. Todt for the photographs.

ELECTROLYTE IMBALANCE AFTER
OPERATION FOR PITUITARY
TUMOUR

BY

E. A. W. HOUGHTON, M.B., Ch.B.

Senior House Officer, Department of Neurological Surgery,
Frenchay Hospital, Bristol

A proportion of patients who have a pituitary adenoma or cyst present clinical evidence of hypopituitarism. Further light has been shed on this syndrome by Sheehan (1939) and Sheehan and Summers (1949), and by the development of biochemical tests of endocrine function.

In patients undergoing surgical treatment a hypopituitary crisis may be precipitated by the stress of the operation and by disturbance of function of the remaining pituitary tissue. This may prove fatal. Grant (1948), in his series of 71 cases, reported three in which a relatively simple operation was followed by stupor, coma, and death on the fifth, ninth, and twelfth days. At necropsy on two of these atrophy of the gonads and adrenal and thyroid glands was demonstrated.

The crisis may present with a variety of endocrine and biochemical disturbances, but is commonly characterized by the gradual onset of drowsiness progressing to stupor and coma, usually over a number of days. It is sometimes preceded by convulsions (Sheehan and Summers, 1952).

The management of hypopituitarism has advanced considerably in recent years. A combination of testosterone, thyroid, and deoxycortone acetate (D.C.A.) as substitution therapy is usually employed (Robertson and Kirkpatrick, 1951a), but cortisone and adrenocorticotrophic hormone (A.C.T.H.) have been used with more striking effect (Robertson and Kirkpatrick, 1951b; Summers and Sheehan, 1951; Rolland and Matthews, 1952).

Treatment of the emergency of hypopituitary coma has been discussed by Sheehan and Summers (1952):

intravenous glucose, testosterone, thyroid, and the control of hypothermia, if present, are all of value. Allott and Simmons (1951) describe a case which rapidly improved with cortisone. Caughey, James, and Macleod (1952) describe four patients who passed into a state of stupor following removal of pituitary adenomas, associated with a low blood sodium and chloride. In two cases cortisone was given with good effect, and subsequent substitution therapy with testosterone, thyroid, and D.C.A. was used.

The following case is one of a series in which A.C.T.H. is being employed pre- and post-operatively in patients with pituitary tumours who show clinical or laboratory evidence of pituitary hypofunction.

Case History

A man aged 41 was first seen in March, 1950, complaining of headaches and impaired vision for the previous three months. He had also noticed impotence and loss of libido for about a year, and had come to dislike cold weather intensely.

On examination he was found to be of normal physique. His skin was soft and pale, with absence of pigmentation. The facies was flabby, with pallor of the cheeks; his speech was quiet and slow. Scalp hair was fine and silky and pubic hair was present, but the axillary hair and beard were scanty; he shaved twice a week. The thyroid was not palpable, and there was marked atrophy of the testes. The blood pressure was 100/70 mm. Hg. There was early optic atrophy. Perimetry showed an early incomplete bitemporal hemianopia. The lumbar cerebrospinal fluid (C.S.F.) pressure was normal, and the protein 65 mg. per 100 ml. A radiograph of the skull showed an enlarged pituitary fossa with preservation of the posterior clinoid processes.

During the next month the headaches became less severe and his vision returned to normal. Surgical intervention was deferred. After a few months of relief, however, his headaches returned, and during the latter part of 1951 his vision became steadily worse. He also suffered from intense lassitude and the facial hair became sparser.

When readmitted to the neurosurgical unit in February, 1952, his visual acuity was 6/9 partly for both eyes, there was marked bilateral optic atrophy, and the bitemporal hemianopia had increased. The blood pressure was 114/90 mm. Hg; plasma cholesterol, 290 mg. per 100 ml.; and the C.S.F. protein had increased to 120 mg. per 100 ml. Laboratory tests of metabolic and endocrine function confirmed the clinical evidence of a severe degree of pituitary hypofunction. The glucose-tolerance curve was "flat" (rising to 100 mg. per 100 ml. one and half hours after 50 g. of glucose by mouth), and a fractional test meal showed a low gastric acidity. The Kepler test for adrenocortical insufficiency gave a coefficient A of 10.8 (normal over 30). The plasma chloride level was 605 mg. per 100 ml., and the urinary chloride concentration during the Kepler test was 11 g. per litre.

Pre-operative A.C.T.H. substitution therapy (40 mg. daily intramuscularly) was begun 12 days before operation. This produced improvement in his physical energy, and he felt less lethargic than for many years. The laboratory tests were repeated after a week of treatment and significant changes in the results were noted. The glucose-tolerance curve assumed normal proportions (rising to 182 mg. per 100 ml. one and half hours after 50 g. of glucose) and there was an increase in the gastric acidity. The Kepler coefficient A was now 25.5 and the plasma chloride 630 mg. per 100 ml. During the test the urinary chloride concentration was 2.3 g. per litre.

A right frontal craniotomy was performed on April 15 by Mr. D. G. Phillips. Elevation of the frontal lobe revealed a rounded swelling arising from the pituitary fossa and displacing the optic chiasma forwards. Aspiration produced 4 ml. of dark-brown fluid containing cholesterol

crystals. This was enough to decompress the chiasma, and after removal of a fragment of cyst wall the wound was closed without drainage.

The immediate post-operative period was without incident. The blood pressure was maintained, and there was a rapid return of consciousness. A.C.T.H. (40 mg. daily) was continued for the next six days, being reduced to 20 mg. over the final 48 hours. The urinary output remained within normal limits (1–1.5 litres a day) and there was no polydipsia. Two days after A.C.T.H. had been discontinued the patient vomited twice and the urinary chloride concentration was found to be 11.8 g. per litre. He became rather lethargic and disinterested and continued so for the next few days.

Twelve days after the operation he vomited again and complained of numbness in the left hand. He was found to have a hemiparesis affecting this side. Next day (April 28) the lethargy and drowsiness were more evident, and there was a marked generalized muscular weakness. The blood pressure was 100/80 mm. Hg, pulse rate 92, and temperature 98.6° F. (37° C.). Testosterone, 100 mg., D.C.A., 5 mg., and thyroid, ½ gr. (16 mg.), were given daily.

During the next 48 hours the blood pressure fell to 90/65 mm. Hg, the stupor and hemiparesis became worse, and he had a number of epileptic attacks affecting the left side. Because of this, on April 30 the craniotomy wound was reopened under local analgesia. Apart from a small subdural blood clot and a localized collection of C.S.F. in the region of the optic chiasma, nothing abnormal was found. There was no significant brain oedema and it was doubtful if the findings adequately accounted for the late deterioration. The wound was resutured with drainage, the bone flap being removed as a precautionary measure lest brain oedema occur. Penicillin, 100,000 units, was given four-hourly.

On return to the ward the blood pressure fell to 80/65 mm. Hg, and the pulse rose to 140. Blood transfusion and intravenous "methedrine" (30 mg.) had no effect on the hypotension. Estimation of the blood electrolytes revealed that there was a severe sodium and chloride deficiency. The plasma sodium was 287 mg. per 100 ml., plasma chloride 539 mg. per 100 ml., and serum potassium 18 mg. per 100 ml. (normal ranges being 310 to 345 mg., 590 to 625 mg. as NaCl, and 17 to 20 mg. respectively).

A.C.T.H., 60 mg., was given intramuscularly, together with 30 g. of sodium chloride—20 g. as a hypertonic solution intravenously, and the remainder, with 5 g. of potassium chloride, by oesophageal tube. Within an hour of the saline administration the blood pressure rose to 100/75 mm. Hg, and remained at this level; the patient also became more alert and easily roused to take fluids by mouth.

Throughout the next day his improvement continued and the hemiparesis was now only just perceptible. Estimation of the blood chemistry showed that the plasma sodium was 306 mg. per 100 ml., and the chloride and potassium 585 mg. and 18.4 mg. per 100 ml. respectively. The blood sugar was 164 mg. per 100 ml. Substitution therapy with 80 mg. of A.C.T.H. per day was continued, plus supplementary sodium chloride by mouth to balance the urinary loss.

His relative well-being was short-lived; four days later he again became drowsy and unresponsive to questions. This was accompanied by pyrexia and signs of pneumonia. The penicillin was stopped and chloramphenicol, 1 g. six-hourly, substituted. He remained very ill during the next two days, and developed slight oedema of the hands and sacral region; because of this the supplementary oral salt was reduced. An electrocardiogram at this stage showed low-voltage waves, but no evidence of hypoalkalaemia or hyperalkalaemia or of hypocalcaemia or hypercalcaemia. The jugular venous pressure was not visibly raised.

The urinary output, which had been balancing his fluid intake, fell on May 5 to 0.5 litre. Accompanying this, the

plasma sodium increased to 414 mg. per 100 ml. and the chloride to 719 mg. per 100 ml. There was a fall in the serum potassium to 14 mg. per 100 ml. These figures show sodium and chloride retention. Oliguria persisted for a further three days, his oedema became worse, and his general condition deteriorated still further. Intake of fluids meanwhile was 2-3 litres a day. Urea, 60 g. a day, was then given as a diuretic for three consecutive days, and produced a good response. The urine output increased to 3 litres a day and the oedema lessened. The blood electrolytes fell to normal limits.

With the return of his blood chemistry to normal, his condition began to improve steadily; his temperature settled and the antibiotic dosage was reduced. Nine days after the second operation testosterone and thyroid were started, while the A.C.T.H. was gradually reduced in dosage each day, being finally discontinued two weeks later. During the following month his fluid and electrolyte balance remained satisfactory with a normal diet, and blood electrolyte estimations from time to time showed normal figures. Testosterone and D.C.A. were continued, but he remained lethargic and rather uncooperative in spite of his hormone treatment. Cortisone was not available.

Discussion

In this case A.C.T.H. substitution therapy appeared to be successful in tiding the patient over the stress of the operation on the pituitary cyst. After cessation of the treatment he slowly lapsed into the form of stupor characteristic of "endocrine failure." This was accompanied by a fall of blood pressure and loss of body sodium and chloride; in fact, a high concentration of chloride in the urine together with a normal fluid excretion had been observed during the period before the collapse, but the significance of this was not then recognized. Daily estimations of the amount of salt excreted therefore appear to be important in such a case.

Concurrently with his deterioration the patient developed a hemiparesis of the side opposite to that of the surgical approach. Focal epileptic attacks followed. These phenomena may have been due to local thrombosis, but it is strange that they improved so suddenly once the electrolyte balance was restored and A.C.T.H. recommenced.

Re-exploration of the operation field did not reveal adequate cause for the late deterioration, and failed to produce an immediate improvement. The level of consciousness and the blood pressure improved after the replacement of body salt and the administration of A.C.T.H.

The second relapse was associated with elevation of plasma sodium and chloride, oedema, and respiratory infection. This responded to restriction of salt and the use of a diuretic and antibiotics.

An abnormal water and electrolyte metabolism is often found in hypopituitarism, and is essentially similar to that occurring in Addison's disease and in adrenalectomized animals; there is failure of normal water diuresis, deficiency of sodium and chloride, and accumulation of potassium in the body. These features were present in the case described. Although the secretion of the electrolyte-regulating hormones of the adrenal cortex is not under the influence of the anterior pituitary to the extent, for example, of the hormones controlling carbohydrate and protein metabolism, in the absence of the adenohypophysis the adrenal cortex is unable to regulate the reabsorption of electrolytes by the renal tubules so as to preserve the constancy of the internal environment when confronted by physiological changes, variations in diet, and stress (Sayers, 1951). An interesting feature is that throughout the period of observation of this patient in hospital before and after operation, and also while he was being given A.C.T.H., most of his urine was passed at night, a reversal of the normal diurnal rhythm. This is in keeping with previous observations in hypopituitarism (Robertson, 1951).

Summary

A case of hypopituitarism due to a pituitary cyst is described in which A.C.T.H. was given before and after operation.

Several days after cessation of treatment with A.C.T.H. the development of hemiparesis, epileptic attacks, and stupor was associated with sodium and chloride depletion.

Rapid improvement followed correction of the electrolyte depletion and resumption of A.C.T.H. therapy.

Onset of respiratory infection and oedema, with sodium and chloride retention, was associated with a relapse. This was relieved with antibiotics and induction of a diuresis.

The pituitary-adrenal relationship is discussed.

It is concluded that constant attention to electrolyte balance is important in the management of such a case.

I am grateful to Mr. D. G. Phillips for permission to publish this paper and for help and encouragement in its preparation. My thanks are due to Mr. W. B. Yeoman for many of the laboratory investigations.

MYOCARDIAL CALCIFICATION ASSOCIATED WITH PITUITARY ADENOMA AND OBESITY

BY

P. G. CRONK, M.B., B.Chir.

Lieutenant, R.A.M.C., Late House-physician, King George Hospital, Ilford

Myocardial calcification without evidence of extensive tuberculous, rheumatic, or ischaemic heart disease is not common, and few cases have been reported. In the following case the gross obesity and large pituitary tumour add to the interest.

Clinical History

A woman aged 64 was admitted to hospital on a Saturday afternoon and died 36 hours later, before radiological or pathological investigations could be undertaken. Owing to her poor mental state an accurate history was out of the question, but her relatives said that her legs had been swollen for some 30 years and that more recently she had been short of breath. Nevertheless, in spite of her increasing disability—she had virtually been confined to bed for two years—she had refused to allow her doctor to see her. She had not had diphtheria or tuberculosis, nor had she been abroad. There was a family history of obesity, both parents and three siblings being overweight, and two of these had died of heart failure.

Examination was made difficult on account of her vast size and rather bovine mentality. Her weight was estimated

at 23-25 st. (146-159 kg.) and her obesity was generalized. However, her legs appeared to be the most affected. The skin on her legs was hard and irregular, with gross hyperkeratosis and some hard pitting oedema, somewhat resembling elephantiasis at first sight (Fig. 1).

On examination the pulse rate was 100, regular, and of fair volume, and the blood pressure was 160/120 mm. Hg.

Fig. 1.—Pseudo-elephantiasis and proci-dentia.

The heart sounds were of fair volume and seemed normal, although there was a harsh apical systolic bruit. Both lung bases were very congested. Complete proci-dentia was present, and there were many intertriginous areas in the groins and buttocks; the axillary and pubic hair was scanty. Unfortunately the optic fundi and visual fields were not examined on admission, as the pituitary adenoma was unsuspected. Digitalis folium, 1 gr. (65 mg.) twice daily, mersalyl, and a reducing diet were prescribed. While in hospital the patient appeared to suffer from polyuria. She was not able to do very much for herself, partly on account of her size; she was therefore nursed on a mattress on the floor, as her weight was such that the combined efforts of four nurses were necessary to move her. She died rather suddenly for no apparent reason during her second night in hospital.

Post-mortem Examination

Her height was 5 ft. 3½ in. (161 cm.) and her weight 26 st. 4 lb. (167 kg.). A smooth firm solid adenoma of the pituitary was found in a deep and wide pituitary fossa measuring ½ by 1 in. (1.9 by 2.5 cm.); the tumour weighed 4.1 g. (normal weight about 0.5 g.), and was closely attached

Fig. 2.—Myocardial calcification and caseation.

to the left optic nerve and internal carotid artery and had indented the hypothalamus. The cerebral arteries showed advanced atheroma without evidence of thrombosis. Several nodules about the size of a pea were found in the space behind the posterior lobes of the thyroid and in the superior mediastinum, but none of them contained parathyroid tissue and they showed only lymphatic tissue on sectioning. The thyroid, ovaries, adrenals, kidneys, and gastro-intestinal tract were macroscopically and microscopically normal. The lungs showed no evidence of new or old tuberculous infiltration, there was no apical fibrosis or calcification, and pleural adhesions were absent. The spleen was congested but normal histologically and weighed 450 g.; the liver weighed 2,150 g.

and was of normal texture, with no fatty degeneration histologically. The gall-bladder contained a large cholesterol stone.

The heart weighed 950 g. when stripped of the very abundant surrounding fat. The pericardium was normal in colour and thickness, and there was very little pericardial fluid. The coronary arteries were patent throughout with only minimal atheroma, and their openings into the aorta were not stenosed. There was moderate aortic atheroma. The heart valves were all normal, with no fibrotic thickening or calcification, and the chordae tendineae were not shortened or thickened. On sectioning the ventricles three or four large calcific masses (½ by ¼ in.—1.3 by 1.9 cm.—in diameter) with central areas of white caseous material (Fig. 2) were cut across with difficulty. Stained films of this caseous matter revealed no acid-fast bacilli. The calcareous masses extended from behind one of the mitral valve cusps (but not continuous with it) about 2 in. (5 cm.) downwards in the interventricular and left ventricular walls; the masses were quite separate from each other and from the pericardium and epicardium. The myocardium between these masses looked healthy and was not fatty. Prolonged search was made for areas of calcification in other organs, especially the kidneys, lungs, and stomach, but no other calcified foci were found. The long bones were not examined, although the skull seemed normal.

The histology of the pituitary adenoma was reported on as "lightly staining cells forming a poorly organized tumour of the chromophobe type." The heart contained "caseous lesions in the myocardium into which extensive calcareous deposits have been laid down; there is a foreign body reaction around these calcified lesions with occasional foreign body giant cells, but no sign of a reaction suggestive of a specific granuloma."

After the necropsy the husband was interviewed, and in response to specific questions said his wife had had polyuria and polydipsia for three to four years. Her eyesight had been failing for the past two years; and for the past three months she had had severe frontal headaches and had been drowsy in the daytime but wakeful at night. She had always been rather obese but had put on much weight since the age of 35. About a week previously he thought she had coughed up a little blood. Her periods had ceased at the age of 59. She had had no previous illnesses except "bronchitis."

I wish to thank the Director-General, R.A.M.C., and Dr. R. B. Niven, under whose care the patient was admitted, for permission to publish this case record. I am grateful to Dr. T. B. Dunn, senior medical registrar, for his invaluable advice and criticism in the preparation of this report; to Dr. J. Spencer, pathologist, for the histological report; and to Lieutenant-Colonel J. B. Neal, for office facilities.

All surgical operations likely to cause pain to animals must be carried out under an anaesthetic according to the Protection of Animals (Amendment) Bill published on July 30. The effect of the Bill, which was formally introduced as a private member's Bill by Lord Stamp, is to repeal the Animals (Anaesthetics) Act, 1919, an extends the scope of the Protection of Animals Acts, 1911 to 1933. The Bill does not apply to operations performed on birds, fowls, fish, or reptiles. It covers "any operation with or without the use of instruments which involves any surgical interference with the sensitive tissues or the bone structure of an animal." Operations excluded from this ruling include any experiment to which the Cruelty to Animals Act, 1876, applies; first aid in emergencies; docking dogs' tails before their eyes are open; castrating domestic animals before they reach the prescribed age; and any minor operation which, because it is quick or painless, is not normally performed by a veterinary surgeon. The Bill is being put forward because of the great advances in the development of anaesthetics since the 1919 Act was passed.

HOP DERMATITIS IN HEREFORDSHIRE

BY

J. S. COOKSON, M.D.

County Medical Officer of Herefordshire

AND

ANN LAWTON, M.D.

Dermatologist, Hereford and Shrewsbury Hospitals

The object of this investigation was to try to discover the incidence of hop dermatitis among workers in the hop-yards in Herefordshire and also try to establish the cause and nature of the dermatitis.

The use of hops for flavouring and preserving beer was known long before 1549, when it is thought hops were first cultivated for this purpose on any large scale in England. For a time in the sixteenth century hops were regarded as noxious and their use was forbidden. Hereford City Regulations, 1557 (Morgan, 1945), has the following entry: "And that no bruer shall sett Anye hoppes or asshes in theire Ale upon peyne of XXs for evy defalte." Hereford people, however, thought the risk of this "peyne" worth taking, as in 1513 the following culprits were brought before the jury at Views of Frankpledge: "Wyllm Collyer for bere Hoppis in ye ale, Alson Coke for bere hoppis in hyr ale," with a number of other citizens. It can be assumed therefore that Hereford people have been picking hops at least since the early sixteenth century.

In the county "hop rash" is well known by all hop-workers. It is thought to vary in incidence from year to year in relation to the weather and to be fairly common among pickers but rare among other hop-workers. Hop rash is usually assumed by pickers to be caused by the hop-washes.

History of Hop Dermatitis

In 1924 O'Donovan described two cases of acute contact dermatitis on exposed surfaces developing in two girls after visits to the hop-gardens of Kent. He says that, in spite of the annual exodus of Londoners to the hop-gardens, the dermatitis had not been seen previously at the London Hospital, and suggests that this is because the condition is rare, that hop-picking is a holiday, and that people who develop dermatitis do not again go hop-picking. O'Donovan quotes Samuel Dale, who in 1693 wrote on hops: "De Lupulo Salictario—Extrinsicus sedebat dolores," and Badham, who in 1834 described the case of a girl of 14 who developed dermatitis of the hands and face after placing her hands in a bin of hops to warm them.

Lewith (1928) did patch tests with hop-cones on three cases in female hop-pickers, with positive results. His attempt to reactivate the dermatitis by giving lupulin, a hop extract, by mouth failed. He thought there was no doubt that the dermatitis was due to contact with the hop-cones. Smithies (1929) saw 52 cases of hop dermatitis among 1,172 patients attending a clinic for hop-pickers. She quotes the observation of Galbraith (1924) that a number of cases of hop dermatitis appeared in a year when no washes were used, and also points out that the regular garden workers who use the washes most do not suffer from the condition. She suggests that a protein sensitization from inoculation of hop juices or pollen through scratches from the spines on the hop-bines may be the cause. Schwartz *et al.* (1947) state that hop dermatitis is often accompanied by conjunctivitis, but have nothing further to say about the cause of the dermatitis.

Incidence in Herefordshire in 1952

In the previous four years only one case of hop dermatitis had been referred to the dermatological out-patient department in Hereford. The district nurses and medical practitioners working in the hop-picking areas were therefore asked to report cases of hop dermatitis to the dermatologist. As it was thought that this method would miss most of the mild cases, at one hop-yard employing 450 pickers the bushelling clerk, a V.A.D. nurse, who saw all the pickers at work every day, sought out and reported every case.

As dermatitis is almost unknown except at hop-picking time, the investigation started with the picking season on September 4, 1952, and continued until the end of picking on October 7. The first case was reported on September 13, the last on October 4. The estimated number of adults regularly employed in hop-picking in Herefordshire in 1952 was 30,000 (G. P. Chater, 1952, personal communication). This does not include an unknown number of people who visit their friends and relations in the hop-yards for short periods of perhaps half a day. These people make an accurate estimate of the incidence of dermatitis impossible.

Twenty-two cases were reported to the dermatologist and were classified as follows:

Severe: forced to give up picking 11
Moderate: carried on picking, rash persisted but cleared when picking stopped 5
Mild: carried on, rash cleared before the end of picking 6

Apart from the difficulty of casual pickers, this total does not give a true picture of the real incidence of hop dermatitis for the following reasons: (1) Hop-picking is a pleasant and lucrative occupation; pickers will not give up before the end of the short season unless forced to do so by the severity of their dermatitis. (2) Many cases are mild and even transitory, the cause is known, and recovery is certain when picking stops, therefore pickers do not seek medical help even in 1952. However, the 11 severe cases may be a fairly accurate figure for the incidence of this type of case among the 30,000 (plus) pickers in 1952, as such cases would have been forced to seek medical help. The most that can be said, therefore, is that in Herefordshire in 1952 severe dermatitis was uncommon, about one case in 3,000 pickers.

Some idea of the incidence of all types of hop dermatitis can be obtained from the figures supplied by the V.A.D. nurse working in a hop-yard employing 450 pickers. She reported 12 cases: six were of a mild transient type and were not seen by the dermatologist; six were seen—one severe, two moderate, and three mild. From this report, so far as it goes, it seems possible that a mild dermatitis was fairly common in Herefordshire in 1952, about one picker in 30 being affected.

Clinical Findings

Unlike most cases of contact dermatitis seen in out-patients, the history in these cases could be obtained fairly accurately, and the dermatitis appeared in healthy cheerful people bent on a lucrative holiday and not bedevilled by thought of compensation. The dermatitis was therefore seen in an unusually clear field.

Of the 22 cases reported, 17 were seen personally—of whom 12 were given patch tests—three were seen by other doctors, and two were not seen. The patients came from 11 hop-fields situated in all the different hop-growing areas in Herefordshire. There were five men and 17 women. This is of no significance, since there are many more female than male pickers. At one farm, for example, there were 410 women and only 40 men. The ages range from 15 to 71. This agrees with the usual finding that contact dermatitis is rare among children. Apart from two cases in sisters, no family history of hop dermatitis was dis-

covered. Two patients gave a history of contact dermatitis to other irritants. There was no obvious evidence of psychological stress and strain, patients compared favourably with the average run of dermatological patients in this regard. No one wanted to give up picking, in fact the patients were upset if they were forced to do so, and the cry of compensation was not heard once.

Socially patients varied from the poorest caravan dwellers to undergraduates. Secondary infection of the dermatitis was seen in only two cases. The dermatitis was papular and oedematous rather than weeping, and this would help to prevent secondary infection.

The following case histories illustrate typical hop dermatitis.

Severe Dermatitis.—A healthy housewife aged 29 had no previous history of skin trouble other than dermatitis due to hops. She was born in Herefordshire, but lived away and was visiting the county for the hop-picking. Her mother had picked hops during many seasons without trouble. The patient had often been in hopyards for odd days as a child, but had had no sign of dermatitis until the age of 21, when after picking hops for one afternoon she developed a rash on her face, arms, and legs which lasted for three days. She had not visited a hop-yard again until 1952. She started picking on September 10, and by the evening felt a rash under the skin of her face. She picked again on the following afternoon, but the rash became worse and she did not pick again. When seen on September 13 she had gross oedema of eyelids, nose, and lips, with erythema, and an itchy papular eruption on the face, between the fingers, and on the dorsum of the hands, extending up the flexor surface of the forearms to the elbows. Antihistamines by mouth and sedative applications were prescribed. By September 15 the condition was beginning to settle down, and by the 22nd the oedema had subsided completely, the skin was peeling, and there was a slight vesicular eruption on the fingers which disappeared during the next seven days. Patch tests to hop-cone on September 22 and October 25 were strongly positive.

Moderate Dermatitis.—A healthy male undergraduate with no previous history of skin trouble was working as a busheller. He plunged his right arm with the bushel measure into the picker's crib of hops and helped the hops into the measure with his left hand. He started work on September 4, having never previously seen a hop. After eight full days of bushelling he developed an irritable papular eruption on the back of his hands and the flexor surface of his forearms, corresponding fairly accurately to the site of staining from the hop juices. He carried on with his work and the dermatitis was little different when he was seen 10 days later. He then had a slight erythema round his eyes and at the side of his nose. A patch test to hop-cone on his back was strongly positive. He was treated similarly to the previous case and went on with his work until October 3 without much discomfort. On October 6 his skin was almost clear.

Mild Dermatitis.—A healthy female publican aged 45, with no previous history of skin trouble, had been in the hop-yards every year since the age of 1. Her mother had also picked hops for many seasons without trouble. She started picking on September 4, and 11 picking days later developed an oval erythematous area with itchy papules on the dorsum of her right forearm and erythema and slight swelling round the eyes. This persisted for five days and disappeared, in spite of continued picking, without treatment. The site of the eruption on the forearm was the same as a painful area due to tenosynovitis or hop gout. No embrocation had been used, but she had rubbed the area with hop-stained fingers. A patch test to hop-cone was negative on a day when the rash had recovered.

The degree of severity and the number of days picking before the development of dermatitis in 18 cases classified according to their previous history of hop dermatitis or of contact with hops is summarized in Table I. From these results it seems that hop dermatitis is a true sensitization

dermatitis, in that the skin has to be previously exposed to the sensitizing agent and the dermatitis recovers when this is removed (Hellier, 1950).

Cases with a previous history of dermatitis all developed an attack within 48 hours of exposure in the hop-yard. In new cases length of exposure varied widely and did not seem to depend on the type of the subsequent attack. As is usual in contact dermatitis, there seemed to be no reason why these particular individuals should be sensitive to hops.

Prognosis could also be assessed and was in accordance with the view of Hellier (1950) that hardening in contact

TABLE I

dermatitis, as described by Schwartz *et al.* (1947), occurs only in mild cases, while the more severe ones become progressively worse with each exposure.

Apart from the mild cases which recovered during this season, a case of hardening was found in the sister of one of the cases. This woman had picked for three seasons without trouble, but developed moderate dermatitis during her fourth season, mild dermatitis during her fifth season, and this season had picked free of trouble again. One case of moderate severity seen two months after the end of the season still had a chronic eczema of the hands at the site of previous dermatitis. This result may be an alternative to hardening in some patients.

Daily weather reports were obtained from the county observatory to try to correlate the development of new cases with periods of sunshine. This was not possible, but it is probable that the weather over the whole picking season may affect the incidence of dermatitis. September, 1952, was the coldest in Herefordshire for 80 years, the mean daily maximum temperature of 59° F. (15° C.) being without precedent (F. G. Parsons, 1952, personal communication). This may account for the low incidence of severe dermatitis this year. It is hoped to study weather influence in subsequent years.

Possible Causative Factors

To discover the cause of hop dermatitis a search was made for a sensitizing agent. Three possibilities were explored.

(1) **Insecticides and Other Washes.**—The evidence against these is as follows. First, hop dermatitis was described by Badham in 1834. Sulphur was first used as an insecticide for hops in about 1850 (Parker, 1934). All other insecticides were introduced later. Secondly, hop dermatitis is almost unknown among cultivators. One case which was thought to be due to hop pollen was reported by Dr. J. C. Taylor, of Goudhurst. The number at risk must here be taken into account. For example, on a first-class Herefordshire hop-farm employing more than 450 pickers, only 23 people are employed regularly in cultivation, with an additional 15 at hop-tying. Hop-pickers would come into contact with sprays if these were present on hop-cones. The fate of the following sprays was therefore investigated:

(1) Nicotine : this evaporates (A. H. Burgess, 1952, personal communication). (2) Sulphur : this may remain on hops until they are dried in kilns, when it is usually driven off (Burgess, 1952). (3) Bordeaux mixture : correctly applied the hops should be free of copper at picking (Lloyd Hind, 1948). (4) Pestox : contamination with organo-phosphorus compounds may be fatal in a few days (Barnes and Davies, 1951)—these are applied according to regulation to prevent contamination. Sulphur, therefore, is the only one of these insecticides which need be considered.

(2) *Insects on Hops*.—At least 11 caterpillars are found on hops (Theobald, 1925). Of these the caterpillars of the pale tussock-moth, or hop-dog, the vapourer moth, and the dock-moth are hairy and in the caterpillar stage in September. Hop dermatitis often starts on the face, but never round the neck, which is the usual site for caterpillar dermatitis. "Hop-fleas" are present and bite the legs of pickers. The spots caused by these are distinguished easily from dermatitis by the pickers.

(3) *Hop-cones*.—These are the female inflorescence of the dioecious hop-plant and ripen in early September, when they are aromatic and sticky with resin. The aroma is due to hop-oil and the pickers are in contact with this in the atmosphere and also have it on their hands mixed with hop-resin. In view of the importance of hops in the brewing industry, much work has been done on hop-oil and hop-resin, so that in addition to patch tests with hops it was possible to use the different hop products as well. The content of these oils and resins is at a maximum when the cones are ripe in September. The bines are pulled down from the wires and the cones picked off one by one. A good picker can pick up to 20 bushels in a day, and picks for about 30 days each season, from 7 a.m. to 4 p.m. The contact with the hops is therefore a concentrated one.

Results of Patch Tests

Hop-cone.—The cone was bisected and the cut surface applied to the skin away from the site of dermatitis under lint, jaconet, and strapping for 48 hours. A control test, omitting the cone, was used. Severe cases were not tested until the dermatitis had subsided. The results (see Table II) were :

Cultivated hops possibly contaminated with sulphur: eight tested—six positive, one doubtful, one negative.

Escape hops from bine on telegraph pole, no possibility of contamination with sulphur: five tested, all positive.

Controls: 12 used, all negative.

The doubtful and negative tests occurred in patients whose dermatitis had recovered, although picking continued, before the test was read. Oedema was severe around the erythematous positive patch test. From this it seems highly likely that the hop-cone itself is the cause of the dermatitis. In order to exclude contamination with caterpillar hairs and to try to pin down the sensitizing agent, further patch tests were done using hop-oils and hop-resins. The oil would be present on the face and hands; the resin would be on the hands and brought to the face by the fingers.

Soft Resin, Total Resin, Humulone, Lupulone.—These were prepared by Messrs. Bencard. Appropriate control tests were made from material supplied by the Brewery Research Association. Nine patients were tested, all of whom had previously given positive results to hop-cone. Two were positive to all four tests; one was positive to soft resin and total resin; and six patients negative to all four tests.

Hop-Oil.—This was obtained from three sources. *Oil A* (from Messrs. Bencard) on prepared patch tests. This oil was known to be one year old. The nine patients tested were all positive to hop-cone; eight were negative and one was positive to hop-oil. *Oil B* (from Cheltenham Brewery). This also was an old oil. It was applied on lint under jaconet and strapping. Two patients were tested, one was positive and one was negative. The positive patient was one of those who gave positive results with the four resin patch tests. *Oil C* (from Messrs. White, Tomkins, and

Courage) was freshly distilled oil from fresh green hops and was applied on lint as above. Seven patients were tested, six were positive and one was doubtful, possibly due to evaporation of oil before test could be used. Two of these positive patients gave positive results with some or all of the resin patch tests.

Discussion of Results of Patch Tests

Where accurate histories could be obtained it was found that dermatitis started on the face in seven patients, and in three of these the hands were not affected. In three patients the dermatitis started on the hands and spread to the face. In view of this, and the probable variation in incidence with the weather, a volatile agent seemed likely. Hop-oil is such an agent, as it consists of a mixture of essential oils. Fresh hop-oil is known to differ from old oil in that it contains 40% myrcene which is oxidized and disappears in old oil (Lloyd Hind, 1948). From the patch tests it seems possible that myrcene might be one of the sensitizing agents responsible for hop dermatitis. If the sensitizing agent is in fresh hop-oil, it seems surprising that kiln workers do not commonly develop dermatitis. Again the number at risk has to be considered—10 kiln workers in proportion to 450 pickers. In the kilns, also, the fresh hops are not handled by the workers but spread with flat shovels. The hops awaiting drying are kept in sacks and on the drying racks; some of the oil myrcene is lost in the air current used in drying (A. H. Burgess, 1952, personal communication).

If dry hops contain little myrcene they may be less likely to cause dermatitis, as seems to be the case both in breweries (R. Webb, 1952, personal communication) and in the hop-markets. The commercial manager at the Hop Marketing Board (Mr. F. H. Job) gave the following interesting information. Among about 250 people employed he has heard of only one case. These people are constantly taking samples from the pockets of dry hops and testing them by rubbing between the palms, which are then put up to the nose to obtain the full aroma. It seems highly likely, therefore, that the sensitizing agent has been removed in the drying, otherwise cases of dermatitis might be expected frequently among the samplers.

Unfortunately this explanation does not cover the patients who gave positive patch tests to resins. The fact that they were positive to all four tests in two cases might be explained if the substances provided for the tests were not absolutely pure. There is probably no chemical relationship between the constituents of the oil and those of the resins (A. P. Tatchell, 1952, personal communication). The two patients who gave positive patch tests to both fresh hop-oil and resins had severe dermatitis, two of them with rapid development of acute oedema and erythema after a short contact. The patch tests were not part of a general sensitivity, however, as the controls were negative and the tests did not reactivate the dermatitis which had subsided.

It is possible that two sensitizing agents are involved, with fresh hop-oil as the more usual one. On the other hand, the explanation may lie in further elucidation of the chemistry of the hop-cone.

Summary

Hop dermatitis in Herefordshire was studied during the 1952 picking season, which was regarded as a light season for dermatitis.

Accurate estimation of the incidence of dermatitis was impossible, but it was thought that most of the severe cases were seen. The incidence of this type of case in Herefordshire in 1952 was found to be about 1 case in 3,000 pickers.

Daily observations of 450 pickers showed a much higher incidence of mild dermatitis: approximately 1 in 30 of these pickers developed some type of dermatitis.

It therefore seems probable that, while severe cases are rare, mild cases may be fairly common.

Hop dermatitis in some cases tested seemed to be due to a sensitivity to fresh hop-oil, of which myrcene may be the active ingredient. In three cases sensitivity to hop resins was also present. No satisfactory explanation of this is forthcoming at present.

It is suggested that the rarity of hop dermatitis among workers in dried hops is due to the fact that the sensitizing agent is driven off in the drying process. It is concluded that this is just as well, in order that the use of hops may continue. Harrison's words in his *Description of England* in 1577 are still true in 1952: "For if your Ale may endure a fortnight your Beere through the benefice of the hop shall continue a month, and what grace it yieldeth to the taste all men may judge that have sense in them."

We thank the medical practitioners and district nurses of Herefordshire who sent us the patients, and particularly the patients themselves, who were most helpful about patch testing. We also thank Dr. A. H. Burgess, head of hop research, Wye College; Mr. R. Webb, of Cheltenham and Hereford Brewery; Mr. Milner, of Messrs. Bencard; Dr. Bernard Tate; and the Davies family, of Claston, Herefordshire, for much help.

The joint committee set up in 1946 by the National Institute for the Blind and the London County Council to advise on the use of optical aids for the partially sighted has now published its report (*N.I.B. Bulletin No. 19*). The search for a good magnifying lens capable of covering an entire printed page has resulted in the production of special binoculars which fit over the nose. Various types of desk lenses are also described and illustrated. Another method advocated is the projection on to a screen of micro-filmed books, newspapers, etc.; the advantage of books on micro-film over other aids is that greater magnification can be obtained without loss of contrast and with no distortion. Suitable projectors cost about £20. Tests on partially sighted children show that in some cases the use of contrasting colours, such as blue chalk on yellow board, improved the visual impact of reading and writing. At one school a preference for black crayon on white paper was expressed. The report may be obtained from the National Institute for the Blind, 224, Great Portland Street, London, W.1.

RAPID METHOD FOR DETECTION OF BARBITURATES IN URINE AND STOMACH CONTENTS

BY

R. MARSHALL, M.B., M.R.C.P.

Registrar, Medical Professorial Unit, St. Bartholomew's Hospital

Treatment of barbiturate poisoning by analeptics is not without danger, and a rapid method for the detection of barbiturates in urine and stomach contents is of value in doubtful cases. Several "rapid" methods (Griffon and Le Breton, 1938; Denis and Lambrechts, 1940; Merley, 1948; Goldbach and Opfer-Schaum, 1949; Selwyn and Dark, 1950) have been described for detecting barbiturates in urine, but the procedures take from one to three hours.

A micromethod for the detection of barbiturates in urine, cerebrospinal fluid, and blood has been described by Kresbach and Gomahr (1951), and a modification of this method, making it less sensitive but more rapid, has been used for the detection of barbiturates in urine and stomach contents.

Principle of the Method

The acidified urine or stomach washings are extracted with chloroform. This is carried out in one stage, and the volume of chloroform is kept small so that the time required for evaporation is not excessive. Chloroform is used in preference to ether because of the inflammatory nature of the latter. The chloroform extract is dried and decolorized. Activated charcoal is used for decolorization because, although it absorbs some of the barbiturate, it is more effective than any other agent and the loss of some of the barbiturates is not serious. The chloroform extract is evaporated to dryness and the presence of barbiturate in the residue is tested for by its reaction with cobalt nitrate and ammonia vapour.

Reagents Required.—Chloroform; dilute sulphuric acid (approximately 10% w/w); sodium sulphate (anhydrous); a mixture of activated charcoal 3 parts and magnesium oxide 1 part; cobalt nitrate 1% w/v in absolute methyl alcohol; and ammonia solution (S.G. 880).

Procedure

About 50 ml. of urine or stomach contents are acidified with 4 ml. of dilute sulphuric acid and shaken with 20 ml. of chloroform in a separating funnel for one minute. Stomach contents should be strained to remove solid material, although any portions of tablets or capsules which are present should be included in the sample.

After allowing the chloroform emulsion to settle out, the chloroform layer is run off into a 250-ml. conical flask. Enough anhydrous sodium sulphate (5–10 g.) is added to dry the chloroform emulsion, so that, after shaking, the sodium sulphate separates out from the clear or slightly opalescent chloroform. About 0.5 g. of the activated charcoal mixture is added, the resultant mixture being shaken and filtered through a No. 43 Whatman paper into a 100-ml. beaker. The filtrate should be crystal clear. The filtrate is then evaporated to dryness on a boiling water-bath. Towards the end of the process the beaker is tilted so that the final residue is confined to a small area of the beaker.

The residue is rubbed off the bottom of the beaker, using a small piece of filter paper fastened over the rounded end of a glass rod so that most of the residue, which is of a pale yellow colour, is concentrated on an area about 2 mm. in diameter in the centre of the paper. The paper is then removed from the glass rod, flattened out, and a drop of

the 1% cobalt nitrate solution is added to the residue. This is dried by warming over a flame and then the paper is exposed to ammonia fumes by holding it over the mouth of a bottle containing strong ammonia solution. A positive reaction is shown by the development of a reddish-violet colour in the region of the residue. The colour is best seen by transmitted light.

Weak reactions may sometimes be intensified by adding another drop of cobalt nitrate solution. The colour given by a strong positive reaction is fairly stable, but a weak positive reaction tends to fade after a few minutes.

The time required for carrying out this procedure is less than 15 minutes.

Results

Tests were carried out on solutions of the common barbiturate derivatives in urine. The solutions were made up from powder or from the commercial tablets; the derivatives used, together with the results obtained, are shown in the Table.

Results of Tests

Barbiturate Derivative	Concentration per 100 ml. of Urine		
	2 mg.	1 mg.	0.5 mg.
Soluble barbitone ..	++	—	—
phenobarbitone ..	++	++	—
Amylobarbitone sodium ..	++	++	+
Quinalbarbitone ..	++	+	—
Butobarbitone ..	++	++	+
Pentobarbitone ..	++	+	—
"Allonal" ..	++	++	+

++ = Positive. + = Weak positive.

The use of a larger volume of urine made weak positive reactions rather stronger, but strong positive reactions were not appreciably affected. The urine of patients having therapeutic doses of barbiturate derivatives were also tested. The urine of patients having barbitone or soluble barbitone (0.3–0.6 g. daily) gave a positive reaction in every case, the urine of patients having phenobarbitone (0.03 g. thrice daily) gave a weak positive reaction in four specimens out of ten tested. The shorter acting barbiturates could not be detected in the urine of patients receiving therapeutic doses. In none of the barbiturate-free urines tested was a false positive reaction obtained.

Comment

From the point of view of detection the barbiturate derivatives can be divided into two main groups. First, the "long-acting" barbiturates such as barbitone and phenobarbitone, which are excreted in the urine in considerable quantities and can be easily detected even after therapeutic doses; and, secondly, the "short-acting" barbiturates, which are for the most part metabolized and are excreted in the urine in small quantities only.

If poisoning is due to one of the longer-acting barbiturates it should be easily detectable in the urine. The shorter-acting barbiturates, even though producing coma, will probably not be excreted in the urine in sufficient quantities to give a positive reaction with a rapid method of detection such as is described here, and in these cases the barbiturate is more likely to be detected in stomach washings.

The first 500–1,000 ml. of stomach washings should be saved separately for detection of barbiturates. If these first washings are diluted with the rest of the water required for complete stomach washout, then the subsequent detection of barbiturate is more difficult.

Summary

In cases of suspected barbiturate poisoning it is of value to confirm the presence of barbiturates in urine or stomach contents before treatment is begun.

A method is described whereby barbiturates can be detected in concentrations of the order of 1–2 mg. per 100 ml. of urine. The time required for performing the test is less than 15 minutes.

Medical Memorandum

Peripheral Neuritis Following Tetraethylthiuram Disulphide Treatment

Tetraethylthiuram disulphide ("antabuse") has been in use since 1948 for the treatment of alcoholism. No case of peripheral neuritis has been fully reported, although three cases were mentioned as occurring among 120 alcoholics treated with the drug (Child *et al.*, 1951).

CASE REPORT

A man aged 40 had been drinking since the age of 16. His job as a waiter gave him ample opportunity to indulge, and so by 1948 he was consuming two bottles of gin a day. This state of affairs continued until his admission in July, 1952. The medical history was negative apart from gonorrhoea at the age of 21. Examination showed him to be a small man with an aggressive, mildly hostile, and suspicious manner. No physical abnormality was detected; the blood pressure was 146/94. His intelligence was a good average, there being no sign of intellectual impairment. The blood Wassermann reaction was negative and the sedimentation rate normal. Van den Bergh and thymol turbidity tests were negative. Plasma proteins were normal.

On August 8 he was given 1.5 g. of tetraethylthiuram disulphide; this was followed by 0.5 g. daily. An alcohol/tetraethylthiuram-disulphide test reaction was carried out six days later without any untoward effect, and the patient left hospital on October 15, continuing to take the drug and remaining abstinent. At the end of November he noticed tingling sensations in his toes, with numbness, which progressed to involve the anterior third of the feet. Examination revealed a loss of sensation to light touch, pin-prick, and vibration over the anterior third of both feet, together with some diminution in the ankle-jerks. He had to give up his work because of the symptoms. On December 18 he stopped taking the drug because he felt it might have been responsible for his symptoms, since when there has been a gradual improvement in his condition.

COMMENT

Although the development of peripheral neuritis in alcoholics is to be expected, the development of the condition in this case seems to have followed 16 weeks' treatment with tetraethylthiuram disulphide while the patient was abstinent. During his stay in hospital his nutritional intake was good and he gained 10 lb. (4.5 kg.) in weight.

Tetraethylthiuram disulphide can lead to a variety of toxic symptoms, chiefly tiredness, headache, and mild ataxia. Electroencephalographic changes have been reported (Guild and Epstein, 1951). Several authors describe toxic confusional states following its use (Bennett *et al.*, 1951; Guild and Epstein, 1951; Martensen-Larsen, 1951). Such reports would indicate that considerable caution should be exercised in giving tetraethylthiuram disulphide over long periods of time, for it seems possible that the nutritional deficiencies occurring in alcoholics may increase the susceptibility of these patients to the toxic effects of the drug.

My thanks are due to Dr. D. L. Davies, physician, Bethlem Royal and Maudsley Hospitals, for permission to publish this case.

F. B. CARATAN, M.D., M.R.C.P., D.P.M.,
Senior Registrar, the Maudsley Hospital, London, S.E.5.

Reviews

TREATISE ON OTOLARYNGOLOGY

Diseases of the Throat, Nose, and Ear. Edited by F. W. Watkyn-Thomas. (Pp. 880; 367 illustrations (including 22 coloured plates). £5 10s.) London: H. K. Lewis. 1953.

In a sense this work is based on Herbert Tilley's textbook of 30 years ago, but, as the editor points out in the preface, "the whole outlook in the field has changed beyond recognition." So that, though some of Tilley's observations still stand, the whole book has had to be rewritten and brought up to date; further, a section on the ear has been added. So good are all the articles that scarcely any criticism can be found.

The book is in five parts. The first is novel in that it describes special methods of treatment, plastic surgery, fractured nose, and physiotherapy. The last section includes a clear description of the system of exercises introduced by Cooksey to overcome post-operative vertigo.

The second part is devoted to the larynx, hypopharynx, trachea, oesophagus, and endoscopy. It is all sound and practical, and made easily readable by division into short chapters. Of special interest is the point that electromyography can help to distinguish between fixation of the crico-arytenoid joints and paralysis of the cords. The coloured illustrations of the various lesions of the cords are good and clear, though glowing with a curious pink tinge. For carcinoma of the cord laryngo-fissure is preferred to irradiation, and the discussion on laryngectomy is full of common sense. This operation and that of Owen for pharyngotomy are excellently described and illustrated. The author's wide experience is evident in the chapter on endoscopy, and he favours general anaesthesia for oesophagoscopy.

The third part is on the oropharynx and nasopharynx. The well-worn subject of removal of tonsils and adenoids is truly dealt with, indications being described as "absolute" and "considered"; perhaps the impression given is that the tonsil is the source of all evil. In conjunction with the pathologist and the expert on irradiation the difficult matter of malignant disease of the nasopharynx is made clear. The fourth part is on the diseases of the nose and accessory sinuses and is of a very high standard. The author has a heavy task, but has carried it out with striking success. After an account of the anatomy, physiology, and examination of the nose, a chapter is devoted to local analgesics, which gives many practical hints and instructions on their use. There is a chapter on allergy by Professor Lucas so skilfully written that this most complicated subject appears comparatively simple. In the following four chapters acute and chronic inflammations are clearly described, as is epistaxis and its rarely needed surgical treatment. The author of the chapters on sinusitis has made the pathology and diagnosis of the condition in the various cavities as clear as may be. There is a separate and first-rate chapter on the treatment, which is illuminated by many admirable illustrations.

The fifth part is on the ear and is a tour-de-force on the part of its author (the editor). It is a most complete and up-to-date account of this vast subject, written in a scholarly style, and it is evident that the author has a complete and clear grasp of the pathology of infections of both middle and inner ear. The chapters on hearing are excellent, and include all the most recent research on audiology; theories on hearing are fully discussed, and Helmholtz's favoured for several reasons. The whole field of middle and internal ear deafness, with acute and chronic inflammations and the various types of operation, are all there clearly illustrated. The author discusses otosclerosis, and emphasizes that histological otosclerosis is four to eight times more frequent than deafness from that disease. There is no description of the fenestration operation, but good diagrams of the various openings made at it. In considering chemotherapy, the author insists that as much consideration must be given to

ordering a course as that given to advising operation. Causes of aural vertigo are discussed and Atkinson's work on histamine reactions reviewed. Complications of middle ear suppuration are also described. Accounts of two complications are put into other hands. These are facial paralysis, fully and expertly discussed by Miss Collier, and intracranial abscess by Professor Lambert Rogers. He gives an excellent account of the neurosurgical approach and its technique, with appropriate illustrations.

This treatise should be in the hands of all who wish to specialize in otolaryngology.

W. M. MOLLISON.

THE DISK IN GENERAL PRACTICE

Disc Lesions for the General Practitioner. By James Cyriax, M.D. Foreword by R. Barbor, M.B. (Pp. 37. 5s.) London: Cassell and Co. 1953.

This little book provides both a challenge and a warning. It purports to show the general practitioner not only how to take a careful history and make a thorough examination in order to localize the lesion, but also in many cases how to treat by manipulation a host of lesions that were formerly called lumbago, sciatica, pleurodynia, fibrositis, and the like—all this with few ancillary aids besides his wits, his hands, and an examination couch.

Enthusiasts like Dr. Cyriax are apt to build mansions of theory on slender foundations of evidence. That disk protrusions, whether of nucleus pulposus or annulus fibrosus or both, occur and cause symptoms and signs are now generally accepted facts. That it is possible to distinguish between the protrusion of a ruptured annulus and the oozing out of the substance of nucleus pulposus is not so easily acceptable. Yet on this distinction depends the decision whether to manipulate or not. Again, as most protrusions will reduce spontaneously with rest in a suitable position, and as manipulation is to be used only when symptoms persist, it will be only in severe attacks of pain that manipulation will be required. It is precisely in these severe attacks that there is most danger to the spinal cord if the manipulation is unsuccessful. Dr. Cyriax is an acknowledged expert as well as an enthusiast, and in his hands, especially as he advises against the use of an anaesthetic, the patient runs little risk, but the comparatively inexperienced general practitioner will need to be careful. Most general practitioners have experience of patients who were not improved even by the most expert manipulators and of others who were treated for some time before their disease was found to be due to something quite other than disk protrusion.

It is only fair to say the author is fully aware of the dangers and gives warning of them, so that many general practitioners may well accept the challenge and open up new and delightful fields of exploration and treatment. The book is condensed, which does not make for easy reading, and some of the phraseology is obscure, but doubtless it is not meant to be more than a stimulus to inquiry and endeavour.

C. W. WALKER.

DISPOSAL OF THE DEAD

The Disposal of the Dead. By Professor C. J. Polson, M.D.(Birm.), F.R.C.P., R. P. Brittain, M.B., B.L., LL.B.(Glasgow), and T. K. Marshall, M.B., Ch.B.(Leeds). (Pp. 300. £1 1s.) London: English Universities Press. 1953.

The law of burial, a dry subject, has already received attention, notably by Fellows, and is accessible. But the larger subject of disposal of the dead, which includes embalming, cremation, transport, burial, and exhumation, has been tackled for the first time—and with success—by Polson and his staff at Leeds. This new book achieves a remarkably comprehensive survey of these macabre subjects while contriving at the same time to be more than factual. Indeed, Brittain's scholarly vignettes of the history of embalming, cremation, and burial rites, and Polson's eye for apt illustration from case reports, combine to leaven the subject with much interest, even some humour. The result is a most

readable yet plainly authoritative reference book which registrars, coroners, public health authorities—and, not least, undertakers—will find of inestimable value.

Polson's interest in the funeral director is timely, for England is slower than the U.S.A. (curiously not mentioned in the index) to appreciate the advantage of intelligent collaboration with the undertaker. The somewhat elementary sections on anatomy for the embalmer and on his stock-in-trade are excusable on these grounds.

The duty to ascertain both the fact and cause of death is an onerous one, and Polson spares no pains to give it due weight. His emphasis, particularly plain in his own contributions, is on accurate practical guidance. He has the ability of the good teacher to recognize his pupils' uncertainty, and careful reading found no avenue inadequately explored.

This valuable addition to the somewhat scanty literature on the disposal of the dead is a practical, authoritative guide which should be at the elbow of the doctor, registrar, and undertaker, and will undoubtedly attain the status of a standard reference book on the subject.

KEITH SIMPSON.

THE SUPRARENAL CORTEX

The Suprarenal Cortex. Edited by J. M. Yoffey. Proceedings of the Fifth Symposium of the Colston Research Society held in the University of Bristol, April 1-4, 1952. (Pp. 232. £2 2s.) London: Butterworth Scientific Publications, 1953.

The world is a vast place, even in this jet era, and if the busy scientific research ants are transported by this or that foundation to this or that steroid mound, who can fail to appreciate the clean impressive publications with familiar chapter headings that record for all time the unequivocal calibre of their cordial confabulations? This present volume is a magnificent compendium of up-to-the minute knowledge by modern masters. C. H. Li, of Berkeley, California, writes on the preparation and properties of A.C.T.H., and the theme is continued by Dixon, Stack-Dunne, and Young, of Cambridge University, and concluded by the Morris group of the London Hospital. J. M. Yoffey, of Bristol, who did so much to organize the symposium and who has edited with great skill, discusses the structural background of the suprarenal cortex and supports the view that the zona reticularis is an actively functioning and morphologically independent zone, probably concerned with the production of androgens and responding readily to stress.

F. Verzar, of Basle, Switzerland, considers the nature of adrenal cortical secretion and the mechanism of the influence of cortical hormones on metabolism. Marthe Vogt, of Edinburgh, carries forward her pioneer work on the control of the secretory activity of the adrenal cortex. She concludes that the perfused adrenal carries out its synthetic activity efficiently but at a steady rate, and that the only physiological mechanism found to accelerate its secretion is the addition of A.C.T.H. to the perfusing fluid. Zuckerman, of Birmingham, thoroughly discusses with his usual, or rather exceptional, perspicacity the adreno-genital relationship, and among other thoughts implies from experimental evidence that secretory elements of the gonads are able, under certain conditions, to serve as accessory adrenal tissue, and that the adrenal cortex reciprocally can act as tissue "not dissimilar from the secretory tissue of the gonads." Folley, of Reading University, discusses the unsuspected role the adrenal cortex is now seen to play in lactogenesis, indicating the use of the lactating-mammary-gland slice for metabolic studies. Marrian, of Edinburgh, discusses with care and profundity the use and fallacies of urinary adrenocorticoid steroid assays, a valuable presentation which was further elaborated at a recent conference of the British Endocrine Society. It is the opinion and experience of the reviewer that the use of chromatography applied to suitable clinical material, dynamically studied by periods of cortisone and A.C.T.H. administration and after bilateral adrenalectomy, is perhaps qualifying the scepticism of some about the potential value of the chemist to the clinician—and, may we add, vice versa.

It may be that studies on blood will prove even of greater value. A. J. Robinson, of the Merck Institute, U.S.A., considers the role of the adrenal gland in infection; animal and experimental findings have shown the dangers, sometimes lethal, of A.C.T.H. and cortisone, even when symptomatic improvement results, but it is also known that the adrenals enlarge during infections and that adrenalectomized animals are sensitive to infections. Robinson's finding that small doses of cortisone may aid resistance to infection is in keeping with the latter considerations.

Hoagland, of Massachusetts, considers the influence of adrenal steroids on personality disorders. Cameron, of University College, London, produces important histological evidence on the tissue response to A.C.T.H. and cortisone. Krohn, of Birmingham, discusses steroid hormones and skin grafting; Dwight Ingle successfully achieves a holism with "the role of the adrenal cortex in homeostasis"; Heller, of Bristol, introduces the important theme of the adrenal cortex and water metabolism; Broster, of London, is refreshingly pragmatic in the "surgery of the adrenal gland"; Astwood, of Boston, draws on clinical experience of high order to discuss the effects of cortical steroids and A.C.T.H.; and Kersley, of Bath, considers the response of rheumatic disease. And the exhausted reviewer ponders on whether Will Mayo's advice to him to specialize on only one endocrine gland was more in keeping with the limitations of the human intellect than the fine tradition of remaining a general physician, come what may.

S. LEONARD SIMPSON.

CELL PHYSIOLOGY

Symposia of the Society for Experimental Biology: No. 6. Structural Aspects of Cell Physiology. (Pp. 357; illustrated. £2 5s.) Cambridge: The University Press, 1952.

Although it has lost its former Grecian gaiety the symposium* is becoming increasingly popular. To some extent it solves the rather pressing problem of those engaged in the application of the basic sciences to medicine who find it impossible to keep abreast of the scattered and highly technical literature of modern physiology. While no longer a drinking-party, the symposium is still a "party," and the 21 papers published in this volume were read to the company of biologists who held their party at Bristol in 1951, presumably under the guidance of a symposiarch. The programme was a skilful blend of fundamental problems in cell physiology, and, as might be expected, the nature of the cell membrane and the problem of permeability and secretion were introduced in full measure. Professor Danielli discussed the broad problem, and was followed by B. Katz, who elaborated the accepted principle that the nerve impulse is conducted along the cell membrane of the axon. John Runnström, of Stockholm, discussed cell surface in relation to fertilization. M. M. Swann, seeking an explanation for the intimate relation between mitosis and cell cleavage, believes that this is conditioned by the release from the chromosomes of a catalytic substance. Other papers relating to the cell surface dealt with cell membranes in relation to cell division, and the action of anaesthetics on amoebae. More closely related to medical problems were papers on the cellular fate of injected antigens and the behaviour of viruses within cells. An account of the role of the nucleus and cytoplasm in intracellular synthesis and morphogenesis by J. Brachet, and another on ultra-violet absorption by living cell nuclei by P. M. B. Walker and H. B. Yates, introduced two broad problems having considerable current interest.

The papers in this series are difficult to read without some general knowledge of the physical sciences, but, taken as a whole, they show the extent to which these sciences and their special techniques are being brought to bear on a large range of biological problems.

INSULIN AND GROWTH

The dwarfing effect of hypophysectomy in experimental animals has long been known, and largely owing to the inspiration of Herbert McL. Evans, who was elected a Foreign Member of the Royal Society two years ago, a protein named variously growth hormone, somatotrop(h)ic hormone, and somatotrop(h)in was isolated from the tissues of the anterior pituitary gland of oxen in 1945.¹ This pituitary growth hormone is remarkably active in inducing growth in hypophysectomized rats, but so far has had meagre success in cases of human dwarfism of apparently pituitary origin. Indeed, many endocrinologists are beginning to doubt the hitherto accepted view that "pituitary" dwarfism does arise at all frequently as the result of a deficiency of growth hormone.

In recent years the idea has been gaining ground that pituitary growth hormone needs, for its complete action, the co-operative secretion of insulin by the pancreas. Whether growth hormone directly stimulates the secretion of the extra insulin, and if so by what mechanism, are still matters for debate, but it is certain that under clearly defined conditions the growth-promoting action of growth hormone depends on the availability of insulin. Thus the experiments of Milman, DeMoor, and Lukens² showed that the administration of growth hormone to a depancreatized cat caused no anabolism of protein unless insulin was simultaneously given, and the retention of nitrogen induced by the growth hormone was not maximal unless a substantial dose of insulin was given in addition to that needed by the animal in the absence of growth hormone. Young³ has recently reviewed the relationship between the growth hormone, the pancreas, and diabetes, and the view first put forward by him in this *Journal* in 1939⁴ is now widely

accepted. According to this the action of growth hormone in inducing growth depends at least in part on the ability of the pancreas to secrete extra insulin, and, if the pancreas cannot produce enough insulin, then the growth hormone causes diabetes instead of promoting growth,^{5,6} since growth hormone directly or indirectly so acts on the tissues as to induce a diminished sensitivity to the hypoglycaemic action of insulin, a phenomenon which has been particularly investigated in Cori's laboratory.⁵

If the action of growth hormone depends on the secretion of extra insulin by the pancreas, and if the diminished sensitivity to insulin's hypoglycaemic action is not essential to the growth-promoting action of growth hormone, then it might be possible to induce growth in the hypophysectomized animal by the administration of insulin alone. In this issue of the *Journal* Mr. James Salter and Dr. Charles H. Best report at page 353 experiments on hypophysectomized rats which fulfil this expectation and which have already been briefly reported elsewhere.⁶⁻⁸ The dangers of spontaneous hypoglycaemia in the hypophysectomized rat and the hypersensitivity of this animal to the hypoglycaemic action of insulin are so well known that many workers have hesitated to investigate such a possible growth-promoting action of insulin therein. But Salter and Best have succeeded where many feared to try, and they report that a slow-acting insulin in gradually increasing doses induces somatic growth, including growth of the skeleton, in hypophysectomized rats, while untreated control animals grew not at all. The insulin-treated rats ate more than untreated control animals, and this was undoubtedly of importance in causing the growth; but in 1951 Maassen⁹ reported that insulin-treated normal rats grew faster than pair-fed control animals, so that food intake alone is unlikely to be a limiting factor. Indeed, it seems probable that insulin exerts a much more important action on protein building in the body than has hitherto been suspected.

At a Ciba Foundation Colloquium last year Conn¹⁰ reported some comparable results in the human being. The subject was a 17-year-old male pituitary dwarf with diabetes mellitus, who appeared to be suffering from panhypopituitarism as the result of a calcified craniopharyngioma. When he was given insulin with constant food intake there was nitrogen retention of 1½ g. a day, though Conn concluded on the basis of the observed changes in electrolyte balance that insulin induced a form of nitrogen retention different from that produced by growth hormone.

We have therefore the interesting and paradoxical situation that growth hormone cannot induce growth in the absence of insulin, while insulin can induce a

form of growth in the absence of growth hormone. The possibility that, clinically, dwarfism results from a relative insulin deficiency, not sufficiently severe to induce diabetes but insufficient to support growth, is obviously one to be considered. Another is whether gigantism can ever result from hyperinsulinism unaccompanied by pituitary overfunction. That the actions of insulin and of growth hormone on growth are not identical in every way is clear from the results both of Salter and Best and of Conn, and it is perhaps unlikely that acromegaly ever develops as the result of hyperinsulinism.

Since insulin mimics growth hormone in inducing growth, it is perhaps not entirely unreasonable that growth hormone might mimic insulin in possessing hypoglycaemic activity. Indeed, an insulin-like activity of growth hormone has been observed both *in vitro*^{1,2} and *in vivo*.⁵ Dr. J. H. Ottaway, in an article we publish at page 357, now brings forward evidence that the insulin-like action of growth hormone observed *in vitro* is due to the liberation by growth hormone of insulin held in an inactive state in the blood or tissues. If this finding is generally supported it will simplify the situation a little, though the physician may well regret the passing of the day when the idea of a growth-stimulating hormone seemed to be straightforward, while insulin was simply the anti-diabetic hormone. But the vicious circle of the endocrine system will provide more shocks, both for the experimentalist and for the doctor at the bedside, though the pattern ultimately revealed may have that simple elegance which usually lies at the basis of Nature.

TREATMENT OF ACUTE POLIOMYELITIS IN HOSPITALS

A year ago we published in "Any Questions?" an answer¹ to an inquirer who wanted to know whether it was advisable to admit patients with infantile paralysis to the general wards of a hospital. Our expert concluded his reply by advising that "the interests of the patient should take priority over the theoretical risk involved in sending the patient to a general rather than an isolation hospital." A lively correspondence arose from this question and answer, and in an informative letter Dr. A. H. Gale² presented evidence to show that the danger of cross-infection in general wards might be something more than theoretical. In fact he was inclined to the view that in the present state of knowledge it would be wise to admit patients in the acute stage to hospitals for infectious diseases. Other correspondents quite

rightly pointed out that some infectious diseases hospitals were more suitably staffed and equipped to nurse patients with poliomyelitis, even when respiratory paralysis was present, than neighbouring general hospitals. Dr. W. Ritchie Russell,³ in a later contribution, made the essential recommendation that, irrespective of the type of hospital, "the doctors in charge should make sure that their knowledge is up to date, that the nursing staff are properly trained, and that the best possible equipment is available."

These and other points are discussed and practical advice given in a commendably concise report⁴ of the Committee on Poliomyelitis of the Royal College of Physicians. The committee agrees that there is a need for strict isolation of patients with poliomyelitis, but believes that "adequate safeguards properly carried out" reduce the risk of infection to a minimum. "As a general rule," the report continues, "cases of poliomyelitis should be admitted direct to hospitals that have been specially equipped for the treatment of the acute stage along the lines suggested." It follows that regional boards, besides making provision for the care of sporadic cases, should have plans prepared for dealing with epidemics, but "there is scope for variation of the details of the plans in different regions."

The committee recommends that the immediate supervision of patients in the acute stage of the disease should be by registrars or senior registrars who have had at least a short course in the care of acute poliomyelitis. House-officers should also have had some special training, "so that one competent doctor can be summoned to a case at very short notice." A vital requirement in the treatment of some patients is the maintenance of a free air-way, and anaesthetists or E.N.T. specialists should be available by night or day to give their assistance. The team of consultants who may be called in to give advice should include neurologists, general and infectious diseases physicians, paediatricians, orthopaedic surgeons, and thoracic surgeons who have a knowledge of acute poliomyelitis. Even though consultants are now spread out more widely than they used to be, this list will still look formidable in areas of the country remote from medical centres. The committee itself adds the warning that too many specialists may confuse the management of the case.

No one with experience of treating poliomyelitis has to be reminded of the importance of skilful nursing, and the special training of nurses in hospitals

¹ *British Medical Journal*, 1952, 2, 349.
² *Ibid.*, 1952, 2, 516.
³ *Ibid.*, 1952, 2, 1204.
⁴ Second Interim Report of the Committee on Poliomyelitis, Royal College of Physicians, London: "The treatment of Poliomyelitis with special reference to the nursing and medical facilities required in hospitals which admit cases of acute poliomyelitis."

selected for the treatment of poliomyelitis must go hand in hand with the training of the medical staff. There are many nurses in infectious diseases hospitals, large and small, who have gained invaluable experience of nursing patients with poliomyelitis in past epidemics, and in addition to these the committee recommends that a panel of nurses who volunteer to treat patients in the acute stage should be prepared in all regions. When their services are required they should be released from other work immediately. Collaboration between the medical staffs of special departments—especially the E.N.T., anaesthetic, and thoracic surgery departments in a hospital or hospital group—should lead to arrangements for the transfer of nurses from the special departments to assist with the care of complicated cases of poliomyelitis.

The committee's report concludes with a list of the special requirements, including equipment, which the diagnosis and treatment of poliomyelitis in the acute stage now demand. No doubt regional hospital boards have made ready to meet any epidemic of poliomyelitis that may occur this year, but the publication of this report should stimulate them to re-examine their plans in the light of the latest knowledge about this disease.

REDUCTION OF POST-OPERATIVE PAIN

Most abdominal operations are followed by pain for the next few days, but too often the surgeon seems to overlook his patient's feelings—or so at least it appears to a sensitive and intelligent patient—and to regard pain as the unfortunate but unavoidable sequel to any intra-peritoneal manipulation. He is content for the most part to leave its relief to his houseman's cautiously administered opiate and to the balm that comes from time alone.

Many recall only too vividly the recurring windy spasms that follow even the simplest of laparotomies. This pain, which is mainly visceral in origin, cannot readily be blocked at the periphery and is, at least in part, unavoidable. But it can be lessened to some extent by planned incisions which afford easy access, by intelligently applied retraction, by gentle handling, and by avoiding the too early use of aperients and enemas.

But it is in the relief of pain in the wound itself that we can hope to achieve something better, and this endeavour is surely worth while. For, apart from the patient's wish for a comfortable recovery, there are

other and even more urgent considerations. We are only too familiar with the patient who lies immobile in bed awaiting with bravely borne, but all too evident, apprehension the tearing discomfort that accompanies his suppressed and quite ineffectual bouts of coughing. He submits with reluctance to the enthusiastic cajolery of the physiotherapist and grudgingly consents to getting on his feet early, which he finds calculated to boost his surgeon's morale rather than his own. If there is any virtue in these post-operative measures, we must surely do everything we can to make it easy for our patient to co-operate.

Morphine remains the stand-by as a pain reliever, but unfortunately it depresses the respiratory centre and the cough reflex. It is this and the other undesirable central effects of the opiates which have led to a continuing search for alternative methods of relieving pain. Crile¹ used to inject a solution of quinine and urea hydrochloride round the wound, and slowly acting anaesthetics in oily solutions have had their champions since.²⁻⁴ But, in addition to difficulties in the handling of these viscous solutions, their use is not free from the hazard of tissue necrosis and abscess formation. More recently several non-oily saturated solutions of anaesthetic agents have been introduced. These, on coming into contact with body fluids, are precipitated as micro-crystalline depots which yield an effective concentration of the drug locally for a long time.⁵⁻⁷ Such is "efocaine,"⁸ the use of which has recently been reported in this *Journal* by Roualle,⁹ and with some enthusiasm. Such solutions have the disadvantage of being non-diffusible, so that a precise blocking of nerves at some distance from the wound is more likely to succeed than any local infiltration. The local instillation three-hourly of procaine through fine polythene tubes introduced into the parietes at the time of operation has been suggested as an alternative, but this method necessitates a careful operative technique and an exacting post-operative routine.¹⁰

All local injections are proscribed in the presence of infection, a limitation to which the administration of procaine intravenously is not subject. This drug has been used both in a drip infusion^{11,12} for the relief of post-operative pain and in a single injection as an indirect method of encouraging coughing in cases of atelectasis.¹³

Despite such attempts to relieve the discomfort of the post-operative period, there is little indication that they have attracted enough attention, and certainly no particular method has yet been widely adopted. Surgeons and anaesthetists alike could with good reason continue to apply themselves to this problem, which concerns not only the patient's comfort but also his health after operation.

BREAD IN THE GUT

The laxative effect of wholemeal bread has been known since the days of Hippocrates and Galen. That such bread passes through the gastro-intestinal tract quicker than its white counterpart can be demonstrated by incor-

porating in the food "markers" such as carmine or charcoal to colour the faeces. We do not know where the speed-up actually occurs. McCance, Prior, and Widdowson¹ have tried to find this out by following radiologically the passage through the bowel of meals consisting largely of wholemeal (100% extraction) and of white bread (70% extraction). They gave six normal subjects a small quantity of barium sulphate mixed with a large quantity of bread and by radiography watched the transit of this mixture through the gastro-intestinal tract. This technique of observing the passage of the food through the bowel is not new, having been employed some fifty years ago in the early days of radiology. Large quantities of radio-opaque substances were then used to outline the gastro-intestinal tract. But McCance and his colleagues used as little barium sulphate as possible, consistent with good radiological delineation of the gut, so that the barium sulphate would have only a slight effect on the passage of the meal through the gastro-intestinal tract. About three-quarters of the total daily calories was provided by the bread, the remainder being derived from small amounts of bacon, eggs, cheese, meat, butter, and preserves. The subjects were screened or radiographed every half-hour for eight hours after the bread and barium sulphate meal, the further progress of which was studied by examining the subjects radiologically every day until the barium sulphate had been evacuated per rectum. Both salivary and gastric secretion were greater on the brown bread diets, and brown bread was evacuated from the stomach and passed through the small intestine more rapidly than white bread. The residue from the brown bread was greater than that from the white bread in the ileum and colon, and it left the latter 24 hours sooner.

Why a meal of brown bread should leave the stomach more rapidly than one of white bread is not known with certainty; probably increased salivary and gastric secretion may be contributory. The radiological appearances in the small gut suggested that the absorption of the white bread was more rapid and complete than that of the brown. This has already been shown by chemical balance tests.² It is probably the "filling" effect of the hydrated celluloses and hemi-celluloses in the brown bread rather than its mechanical irritation that accounts for its quicker transit through the small gut. The quicker transit through the large gut and quicker expulsion of the brown bread residues from it was probably due to the increased bulk of the faeces. While these radiological studies and the chemical balance studies of McCance and Walsham² show that the passage of white bread through the gut is slower than that of brown bread, and that a greater portion of it is digested in the sense that it leaves less residue, this does not prove that white bread is any more nutritious than brown or vice versa. Even if white bread does remain in the gut longer than brown and appears to be better digested, it is a moot point whether this compensates for the removal of a very high percentage of nutrients in its preparation. In the processing of white flour a third of the protein, two-thirds of the essential

amino-acids and riboflavine, practically all the vitamin A, and 80% of the iron, nicotinic acid, and aneurine are removed, as well as other members of the vitamin B complex. The slightly improved digestibility of white bread becomes rather academic in the light of these figures. For persons whose economic circumstances permit them to eat a good mixed diet it probably matters little whether they eat white or brown bread, but for those whose staple food is bread the colour is important.

INHERITANCE OF RHEUMATIC FEVER

The aetiology of rheumatic fever remains unknown. There is good but indirect evidence that infection, perhaps repeated infection, plays a part. There is also reasonable support for the hypothesis that there are inherited differences in susceptibility to the disease. The suggestion that the infective agent is the haemolytic streptococcus is based in part on the parallelism of the mortality rates from scarlet fever and rheumatic fever in Britain and North America and in part on the frequency with which an attack of streptococcal tonsillitis precedes an attack of rheumatic fever by two to three weeks. During the war Macdonald¹ made use of the fact that both scarlet and rheumatic fever were notifiable in the Royal Air Force to show that the morbidity rates for the two conditions were closely related.

Morbidity is related to social class. This is clearly shown in the figures for Sheffield, where the disease was made notifiable in 1947. The morbidity ratio increases from 48 in children in Social Class I to 147 for children in Social Class V. Hewitt and Stewart² have recently analysed the information collected about the home conditions of these children and a control group to see if they could discover what it was that was responsible for the class difference. It was apparent that neither family income nor income per head was the operative factor. The condition of the home, too, was not important. There was little relation to the degree of statutory overcrowding. But there was a significant relation to the number of people living in the household. Since both large families and more than one family in a household are more common in Social Class V, this might account for much of the difference between social classes. The explanation may well be that the more people there are in the household the greater the chance that infection will be brought into the home. A complementary finding is that the risk of developing rheumatic fever increases greatly at the age of 5, when children first go to school.

The evidence for differences in inherited susceptibility is also somewhat indirect. Several studies, including a recent investigation from Northern Ireland reported by Cheeseman and Stevenson,³ show a mild degree of familial concentration for rheumatic fever. In the Northern Ireland surveys 3% of about 800 brothers and 7.8% of about 750 sisters of the index cases show clinical evidence of rheumatic fever. The real risk of

brothers and sisters developing the disease must be higher than this, since many of them are still young and might develop the disease; moreover, this simple method of counting the proportion of the brothers and sisters affected, apart from the index case, usually underestimates the risk. If repeated infection is important in causing rheumatic fever, then caution is needed in interpreting a familial concentration as being due to genetic resemblance. But a striking feature of this and the earlier family studies was that the risk to the brothers and sisters was doubled if one of the parents had also been affected. This might perhaps be due to infection persisting in the affected parent and being transmitted to the children, but it seems much more likely that it represents an increased genetic susceptibility. Some confirmation of this is supplied by the few available series of twins. In the Northern Ireland series the one monovular pair were both affected, but one only of each of the nine binovular pairs was affected. In another similar series, that of Wilson and his colleagues,⁴ the two monovular pairs were both affected whereas only one member of each of the three binovular pairs was affected. Nevertheless, rheumatic fever is certainly not entirely genetically determined, for several instances are known in which only one of a pair of monovular twins had the disease.

DIAGNOSING THE SEX

Sexual characteristics in insects are determined entirely by chromosomal constitution and are apparently uninfluenced by hormones. Gynandromorphs are most commonly seen in butterflies of the family Lycaenidae (the blues and coppers). Abnormalities in cell division may give rise to females with areas of the characteristic male blue on their predominantly brown wings, or in more extreme cases an insect may be male on one side of the body and female on the other. In mammals the situation is different. The well-known freemartins in cattle show that hormones may greatly influence sexual development *in utero*, while partial sex reversal in post-natal life is too well known in man to justify further description. But there is no evidence that hormones can override chromosomal constitution entirely. If this were so one could produce a functional female with a large X chromosome and the very much smaller Y chromosome, and a functional male with two X chromosomes. Given a normal mate, the latter would produce only female offspring.

The result of the mammalian Y chromosome being much smaller than the X is that females have somewhat more chromatin than males in every cell in the body. Barr, Bertram, and Lindsay¹ found in female cats a minute chromatin granule in contact with the nucleolus in the anterior horn cells; it was absent in males. Outside the central nervous system a slightly different picture was found. Here female nuclei were distinguished by a chromatin mass in contact with the nuclear membrane. These differences are present before gonadal differentiation occurs and were not influenced

by gonadectomy or hormonal treatment. The authors attribute the bodies to the relative excess of chromatin in XX cells. Moore and Barr² showed that differences of this nature were not confined to the cat, although they are apparently absent in rodents and in the rabbit.

Moore, Graham, and Barr³ have now found that human skin shows this sexual difference in nuclear structure. They also studied two cases of pseudo-hermaphroditism. The first appeared to be predominantly female, and her skin showed the characteristic female nuclear structure. Clinical examination of the second case disclosed predominantly male characteristics, and skin biopsy again gave a consistent picture. The so-called true hermaphrodite has either an ovo-testis or an ovary and a testis. It may be that they represent a chromosomal mosaic corresponding to the insect gynandromorph, and it would be interesting to learn the nuclear structure in such cases.

It is to be hoped that these findings will be tested in other laboratories. If confirmed they can hardly fail to be of benefit in the study of intersexuality and may cast light on other problems.

MILK ASPIRATION PNEUMONIA

Mononuclear pneumonia has been of increasing interest in recent years. Cases of atypical pneumonia of all sorts have been reported from many countries, and when these have been fatal the lung histology has often shown monocyctic, rather than polymorph, infiltration. The similarity between these "primary atypical pneumonias" in adult life and the often minimal lung lesions found at necropsy in infants has led to the supposition that in the latter the cause is also a virus. The possible part played by mucus causing mechanical obstruction has been considered by Robertson and Morle^{1,2} and Emery.³

Moran⁴ was struck by the difficulty in distinguishing microscopically virus pneumonia in infants from that caused by aspiration of milk. In a series of experiments in which varying amounts of feeding mixtures, cow's milk, and human milk were introduced into rabbits' tracheas, Moran was able to reproduce the lesions found in babies who had aspirated milk—namely, acute pneumonia, abscesses, granulomas, giant cell reaction, and fibrosis. The reaction was usually mononuclear. Although the lesions bore some resemblance to those of lipid pneumonia, they could be produced with milk from which all fat had been removed. The introduced material was seldom recognizable after a week. Perhaps the most surprising finding was the rapidity with which the respiratory tract reacted to the milk, exudation of red blood cells, granulocytes, and macrophages being found almost immediately, and certainly within ten minutes.

Clearly this work will be of much interest to all concerned with the respiratory pathology of infancy. Immediate thoughts will be that not all mononuclear pneumonias in babies are necessarily of virus origin, and that one cannot be too careful when feeding infants.

REFRESHER COURSE FOR GENERAL PRACTITIONERS SPECTACLES

BY

J. H. DOGGART, M.D., F.R.C.S.

Surgeon, Moorfields, Westminster, and Central Eye Hospital; Ophthalmic Surgeon, Hospital for Sick Children, Great Ormond Street

Some general practitioners are endowed with enough special knowledge of ophthalmology to decide whether their patients need spectacles and, if so, to carry out the tests whereby the proper strength of glass can be ascertained. Such an arrangement has obvious advantages, but those who aspire to enter general practice find the time for training all too short. If they have a year to spare after serving as casualty officer, house-physician, and house-surgeon, most of them will be inclined to seek extra experience in obstetrics, paediatrics, or other branches of medicine closely linked with general practice. Only a minority will find time to familiarize themselves with refraction and ophthalmoscopy. Nevertheless all qualified practitioners who attend families, schools, factories, offices, and Service units are responsible for advising examination of their patients' eyes. They seldom need to concern themselves with the merits of rival examining techniques, but they must see that refractive defects are investigated and appropriate prescriptions given. Most of them have a healthy objection to their patients being saddled with unnecessary glasses.

Functions of Spectacles

Before considering some of the questions which frequently arise concerning spectacles, it is appropriate to emphasize what are the main purposes which these appliances can fulfil. First and most obvious is the provision of clear images. Thus to a patient afflicted with several degrees of myopia (short-sightedness) all objects more than a few inches away will appear misty, unless his refractive error is counteracted by concave spectacles. Secondly, spectacles are an important item in the treatment of squint and other disorders of ocular muscle balance. In such cases it will often happen that the glasses incidentally permit clearer vision, but sometimes the opposite will obtain. For instance, a hypermetropic (long-sighted) child suffering from accommodative squint often finds that objects seen through the appropriate convex lenses appear less well defined than they did with the uncorrected vision, until enough time has elapsed for adaptation to the new spectacles. Thirdly, spectacles may be used as a means of protection against uncomfortable or dangerous influences. Anti-glare glasses for use in bright sunshine are increasingly demanded. Other types of spectacles have been devised as a shield from infra-red rays or noxious vapours in certain industrial processes, as well as from flying particles and other occupational hazards.

Refraction not a Closed Compartment of Knowledge

Although retinoscopy, which is the main objective means of estimating refractive error, could be learned in a few weeks by the exercise of intelligent application, many processes besides retinoscopy are needed before a correct decision can be reached with regard to spectacles. Questions of age, aptitude, and occupation must be considered, and the interpretation of subjective tests is not always easy. Then again, refractive errors are often associated with, and may even arise from, certain constitutional diseases—for example, diabetes. A technically competent retinoscopist ignorant of ophthalmoscopic signs will inevitably order

glasses for patients incapable of benefiting thereby. Let us therefore agree that *no spectacles (other than mere protective appliances) should be prescribed until the ocular fundi and media have been thoroughly surveyed*. We have already seen that there are many other relevant considerations besides the actual state of the eyes, but at least that state must be determined before entertaining the possibility of spectacles. It will now be convenient arbitrarily to divide patients into three categories: (1) those up to the age of 14 years; (2) those from 14 to 40 years; and (3) those over 40.

Patients under 14 Years

Children with a large amount of refractive error, especially if they are myopic, will require spectacles to enable them to see clearly; and, although failure to supply the necessary glasses will not directly damage such children's eyes, it must be remembered that other serious disadvantages are entailed. To live in a world where every inanimate object looks misty, and every human face is a featureless blur, must grievously retard the growth of knowledge and will in many cases produce clumsiness and lack of confidence. The presence of a large refractive error will often remain undetected until a child begins to walk about, and perhaps until he begins to look at picture-books or goes to school. At this point it will be relevant to pose the question: *How early in life are glasses feasible?* From time to time one sees 1-year-old infants wearing spectacles, and occasionally these appliances are given to babies within a year of birth, but I believe that none should be prescribed for patients under 2 years old. Admittedly cases arise in which there are arguments in favour of spectacles for children under 2, but such arguments are outweighed by the obvious difficulties and disadvantages of wearing glasses so early in life.

Spectacles in children are often an essential item in the treatment of squint, and especially in the accommodative variety of convergent squint associated with hypermetropia. Astigmatism is often combined with hypermetropia in such cases, and many will exhibit a different level of refractive abnormality in the two eyes. *How often should children for whom glasses are necessary be retested?* It is a good thing to arrange that re-examination should be performed once a year, but there will be many children who will need to be reinvestigated at shorter intervals. When spectacles are being used as a major item in the treatment of squint and other forms of ocular muscle imbalance, their strength may from time to time require modification, even if there has meanwhile been no change in the basic refraction.

Should children wear their glasses constantly? Yes, if the unaided visual acuity is very defective. Another reason for constant wear is the presence of accommodative squint. In such cases it may later be possible to relax the rule, reserving the glasses for close work only. Children suffering from slight myopia may be able to get on comfortably without spectacles for most out-of-school activities, and wear them for seeing the blackboard, looking at films, etc. All prescriptions should clearly indicate whether or not the spectacles should be worn constantly.

Light metal frames are as a rule most suitable for children, and in the early years frames will best be supported by the sides of the nose. For 2-year-old children the ear-pieces usually have to be joined with a tape tied at the back of

the head. Unsplinterable lenses are advisable up to the age of about 8 years, and of course for older children as well when the spectacles are going to be used for cricket.

Patients of 14 to 40 Years

Adolescents with rapidly advancing myopia may for a few years need an annual test, but this interval can be considerably lengthened in the great majority of patients aged 14 to 40 years. It is quite wrong to assume, as many people do, that spectacles need to be changed at fixed intervals. Some people's refraction remains remarkably consistent for ten, fifteen, or even twenty years. Those who display greater variation do not necessarily change at a constant rate. In the course of a given year they may alter more than twice as much as they do during the preceding or succeeding period of three years. Adolescents should perhaps be re-examined biennially, but adults can usually go for longer than two years if their eyes are otherwise healthy, and if they have not recently been exhibiting rapid change. Five years may usually be allowed to elapse before such grown-up people come for another test. If there should be a considerable change before that time, the patient will probably notice new visual symptoms, and thus be prompted to seek earlier examination.

The role of spectacles in the treatment of muscle imbalance is relatively small among adolescents and adults. Therefore few of them will choose to wear glasses constantly unless their visual acuity is thereby sharpened. Young people with only moderate hypermetropia usually prefer to reserve spectacles for close work, because their accommodational reserve still enables them to see far objects clearly. As they approach the age of 40 they will become increasingly dependent upon spectacles for clear definition at all distances.

What are the chief symptoms which suggest that spectacles may be required? The cardinal symptom is blurred vision, which will be experienced by all those suffering from gross refractive errors. Myopia even in small degrees interferes greatly with the detailed appreciation of distant objects. Small amounts of hypermetropia may incite no symptoms in children and young adults. Indeed moderate hypermetropia is physiological in the early years of life, and requires no treatment unless it is associated with a disorder of ocular muscle balance. Another important symptom is proneness to ocular fatigue. Thus, for instance, a patient suffering from hypermetropia, especially if it were linked with astigmatism, might find that words on a page tended to run into each other, and that the act of reading became uncomfortable after a few minutes.

Headache is undoubtedly a possible symptom, but it must be emphasized that most headaches are not due to refractive errors. Patients are often sent for superfluous eye examinations "to exclude refractive error as a cause of their headache." When abnormality of refraction does substantially contribute to headache, it will often be found in association with ocular muscle imbalance, and the patient usually complains that his headache is provoked by long spells of close work. Headache unrelated to concentration of gaze is unlikely to be of ocular origin, and in many instances the history will supply a clue. Thus, for example, headache arising from congestion of the accessory sinuses may exhibit a regular time-cycle, or may show characteristic aggravation from temperature changes. Incidentally it is worth remembering that considerable refractive errors often come to light during the routine testing of people who have never complained of headache.

Patients over 40 Years

Those who are free from hypermetropia, myopia, and astigmatism will retain their distant visual acuity in middle life, assuming that their eyes are otherwise normal; but few of them on reaching the age of 50 can still thread a needle unaided or read small print by artificial light. Indeed, many of them require convex glasses for near work while they are in their forties. Some put off the day of yielding to

spectacles, lest they become too dependent upon these artificial aids. They should be told that they are engaged in a losing battle, because in fact the reserve of accommodation (focusing power) dwindles from childhood onwards. If it were a question of the ciliary muscle waning in strength, the need for reading glasses might well be postponed by dint of extra effort. The main reason, however, for accommodational failure is progressive rigidity of the human lens, which grows like an onion by successive superimposed layers, so that contraction of the focusing muscle no longer produces the alteration in curvature requisite for close work.

If their eyes are in other respects normal, presbyopes do not need to be tested every year. Until they reach the age of 60—by which time their accommodation is almost entirely gone—there is increase in the relative convexity of their spectacles is likely to be needed at intervals of two to five years, but wide variations occur between different patients, and even the same patient will often vary the speed of his refractive change at different epochs. Important alterations in refraction after the age of 60 are as a rule associated with changed relationship between the density of the nucleus (core) and cortex (outer layers) of the lens.

At the age of about 45, habitual wearers of spectacles find that their distance correction is no longer suitable for reading. Some of them will see small print better without their glasses. Let us imagine, for instance, a patient aged 55, with 2.5 dioptres of myopia. He will be able to see the 6/6 line of distant test-types with the aid of his glasses. If he had been free from distant refractive error, he would probably by this age have needed a pair of +2.5 spheres for near work, but this correction is exactly counteracted by his 2.5 dioptres of myopia. Therefore he will not need special reading glasses. He simply takes off his spectacles whenever he wants to scrutinize near objects.

With the exception of that minority of myopes who can manage without reading glasses, presbyopic patients suffering from other refractive trouble cannot use their eyes efficiently for all purposes unless they obtain either bifocals or else more than one pair of glasses. One often meets people reluctant to face that alternative. When the advantages of bifocals are explained to them, they are apt to expatiate on the failure of a friend to become adapted to this device. On the other hand, they resent the inconvenience of using two different pairs of spectacles. Sooner or later they must decide which of the two plans will suit them better, because one fact is inescapable: no single strength of glass will enable them to achieve their best visual acuity both for near and distant objects when once they have entered the presbyopic stage.

Patients over 60 seldom take happily to bifocals, because (a) they are less swiftly adaptable to a new form of appliance, and (b) the difference between their distance and near correction is well-nigh maximal, so that they are more likely to feel confusion when they look down through the lower—for example, the reading—part of the glass on stepping off a kerb or descending a staircase. This last disadvantage can be prevented by arranging for a continuation of the distance correction below the reading portion of the glass, but even so it is often too late for the patient to get accustomed to bifocals. Therefore it is advisable to begin bifocals at or before the age of 50, if the patient requires a distance as well as a near correction. Even if the distant vision is normal, bifocals are worth considering. Plane glass can be supplied for the upper part of the spectacles, and then a presbyope need not keep pulling off his glasses every time he wants to look up from his notes. Nor need he sit with his reading glasses sliding half-day down his nose. Bifocals are particularly valuable to presbyopic artists, medical men, barristers, and administrators occupied with interviews. Such people have need of a device enabling them rapidly to alternate between the scrutiny of far and near objects.

Trifocals are another useful type of spectacles for certain occupations. Between the near and distant correction is an area occupied by a lens of intermediate strength, whereby

a clear view can be obtained of objects about one metre away—for example, a music score. A certain amount of intelligent concentration is needed before the patient can fully appreciate bifocals, and naturally this generalization applies with even greater force to trifocals. Moreover, it goes without saying that accurate frame measurements and skilled fitting by the optician are especially important when spectacles incorporate more than one kind of correcting lenses. Numerous other special devices are available for people engaged in exacting tasks—for example, philately, watch-repairing, or the inspection of electric-bulb filaments.

Fallacies and Misconceptions about Spectacles

So many disquieting myths are apt to circulate concerning the visual function, not only among the lay public, but sometimes within our own profession, that it may be worth while to end with a few denials:

It is almost impossible to damage the eyes by long hours of reading and sewing, even if great fatigue is experienced at the time.

Spectacles worn by mothers and nursemaids do *not* make children squint.

Migraine is *not* due to refractive errors, and cannot be cured by the provision of spectacles.

Most headaches are not due to eye trouble.

Myopia *cannot* be cured by orthoptic exercises, or by electrical treatment, or indeed by any known method of therapy.

Refresher Course Book.—The first collection of articles of this series (fully revised) are available as a book containing 55 chapters, price 25s. Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

BLOOD TRANSFUSION ACCIDENTS

The following statement on blood transfusion accidents is published at the request of the Consulting Pathologists Group Committee.

The war that spurred the development and perfection of radar, turbojets, and penicillin, and thus helped us have television, Comet travel, and potent antibiotics, left us with well-organized blood-donor panels whose continuing vital gifts, no longer required for wounded, are used for the needs of the sick. Blood is now provided for all medical, obstetrical, and surgical emergencies, and most hospitals have a blood bank or obtain blood from the bank of a near-by hospital within the group; these banks are supplied by the National Blood Transfusion Service. More recently the British Red Cross Society has stated that donors on its panels are available for giving fresh blood of all groups, at all hours, for planned or emergency work.

Benefits of Blood Transfusion

In addition to the immediate saving of life, blood transfusion, like improved anaesthesia, has made major thoracic surgery more easily possible and other major surgical procedures more safe. Again, apart from the operation period, those anaemic from chronic blood loss are now prepared for a necessary operation in shorter time; while, in the newborn, erythroblastosis is fairly regularly treated by replacement transfusion. Thus we have reached a point when we can say that the benefits of blood transfusion are as great in peace as in war.

The great boon that blood transfusion is may not be fully appreciated by the public: those who have benefited and

their relatives know, and that most generous and unselfish group, the donors who perform a great public service, they know; but to the general public a blood-donor session and the giving of blood in hospital are things remote. It is thus the more regrettable that a large newspaper-reading population should be introduced to the subject of blood transfusion by headlines that high-light almost every fatality. The incidence of such fatal cases is thus grossly exaggerated and needless alarm thus spread. The true incidence of death resulting from accidents in blood transfusion is not known for the whole country, but in one large hospital in the London area it has been of the order of one death in a period of six years, in which 13,000 bottles were transfused.

The Element of Risk

However, it must always be borne in mind that there is a risk attaching to blood transfusion and that every step must be taken to minimize the chance of causing death in the attempt to save life. Thus, since the risk has been stated as similar to that of uncomplicated appendicectomy, similar consideration should be given to, and plans made for, a blood transfusion as would be given to the question of opening an abdomen for appendicectomy. Always there should be regard for the need as evidenced by the haemoglobin level or the known blood loss.

There is an increasing demand for blood which tends more and more to exceed the supply; this suggests that there may be a certain measure of over-prescribing, which adds to the risks undergone by some patients and acts to the detriment of others who are really ill and require a life-saving transfusion. The three points at which a patient about to be transfused is placed at risk are in the *prescribing* of the transfusion, in the *grouping and matching*, and in the *giving*.

The request for blood ought always to be directly equated to the need. Thus it appears unjustifiable to place any patient at risk for one pint of blood; such cases would do well with a plasma substitute, because only blood volume can be involved when the loss is so small. In healthy young women with slight loss of blood from abortion, miscarriage, or at term the natural recuperative powers must neither be forgotten nor superseded.

Grouping and Matching

The blood bank at each hospital should be under the care of the hospital pathologist, whose responsibility it is to ensure that (i) the grouping of the patient and the matching of blood are done only by experienced technicians, resident pathologists, and/or resident housemen who have been trained and are thoroughly experienced in the methods, and (ii) satisfactory arrangements have been made for care of the bank and grouping and matching at night and at week-ends (see circulars R.H.B. 51/89 and H.M.C. 51/82). In this connexion hospital management committees should arrange that technicians, when on call, should be transported or given travelling expenses and paid for this emergency work.

For maximum safety in grouping and matching two things are essential—adequate time in which to do all the tests and the full relevant history of the patient. Most laboratories now have a special request form to be completed when blood is wanted. This form contains space for details of previous transfusions and any reactions to them and also for the obstetric history in so far as it relates to jaundiced babies and stillbirths. This information determines the additional serological tests that may have to be made.

It is not yet generally known that for the actual grouping and matching of blood for transfusion to be done thoroughly up to four hours may be required. The tests are no longer made on slides or tiles and in three to five minutes. The increasing frequency of transfusion of patients makes more than ever necessary full time for the interaction of cells and sera in ABO- and Rhesus-grouping and in compatibility testing. Thus two hours is the time of incubation (in tubes,

to avoid evaporation of the small quantities used); only by this means can A-group readings, Rh-grouping (anti-D), and the possible presence of immune iso-antibodies be clearly determined. Equally necessary is the matching of recipient's serum with donor cells suspended in saline at room temperature and, in parallel, suspended in 20% bovine albumin at 37° C. for a minimum of two hours and read microscopically. Another essential procedure is to make and stain a film of blood when a sample for matching is taken from the bottle; this permits detection of the rare instance of massive contamination with bacteria that flourish at 4° C. without causing visible change in the blood.

These methods are probably not yet fully adopted by all pathologists, but they ought to be, for only by using them can it be said that every possible precaution against misgrouping and mis-matching has been taken. In emergency, with suitable proved high-titre grouping sera similar procedures can be used and the time cut to 15 minutes for each test, but it must be clearly understood that while there is fair accuracy with the shorter method there still is risk of error. It may be mentioned that impatience on the clinical side has caused junior resident pathologists to make mistakes, some of which were fatal. Thus full understanding and co-operation on all sides are very necessary.

Giving the Transfusion

In the giving of the transfusion the matched blood should be handled as little as possible and used with the minimum of delay. Here, unless there is a simple yet rigid system of check, check, and counter-check, accidents can easily occur: already too many have. A good arrangement is that used in the hospitals of the North-east Metropolitan Region. Each bottle of matched blood has a coloured (according to the group) tie-on luggage label which bears the donor's bottle number and/or name, recipient's full name and ward, the date of matching, and the signatures of the persons who matched and checked the blood. A centrally situated refrigerator or cold-room (controlled at 4° C. to 6° C.) should be provided for such matched blood because ward refrigerators are too unreliable and the blood may be frozen or forgotten (if not used). The central matched-blood refrigerator should have a record of the contained blood in a book or on a sheet, giving as a one-line entry the patient's (recipient's) name and ward and the donor's name and/or bottle number, and each bottle removed should be signed for and the time and date of removal entered.

Blood should only be removed immediately before use, and only by a member of the medical staff, preferably by the houseman or anaesthetist who is to set up the transfusion. Neither the removal of blood from the refrigerator nor the administration (including the follow-on of bottles) should be allowed to be a duty of the nursing staff. On rare occasions it may be necessary for an orderly or nurse to collect blood from the laboratory as soon as matched, and then the messenger should take to the laboratory a note bearing the full name, age, and ward of the concerned patient (recipient), for names are too readily confused in verbal messages, especially over the telephone. Mistakes of this kind that proved fatal are on record.

The details on the luggage label tied to the bottle should be checked (a) with the bottle number, and also with the donor's name and/or bottle number and the recipient's name and ward, in the refrigerator-register entry at the time of removal, and (b) in the ward or theatre, with a nurse or other person as witness before the blood is given. The doctor should ensure that the patient named on the luggage label is the concerned patient about to receive the blood. Check, check, and re-check is common in laboratory procedures—for example, in reporting Wassermann reaction results—and it is surely not too much to expect the same when administering intravenously a "substance" to which there is no "antidote." Axiomatic though it is, it must be stated that blood matched for a patient is for that patient and none other.

Emergency Transfusions

In grave emergency, when compatibility tests cannot be done, unmatched blood reserved in the central refrigerator for emergency use in theatre, in the maternity wards, or by the maternity flying-squad should be used—group O Rhesus-negative blood for women and for men who have had previous transfusions, and group O Rhesus-positive blood for men who have not been transfused. But even in such cases it is essential that a sample of the patient's blood (as for the Wassermann reaction) be secured *before transfusion* is begun in order that the patient's own group can be determined later and the patient's serum used for further matching.

All this may read like a counsel of perfection, but these precautions can easily be taken, and in fact all the serological tests, the request forms, and bottle labels for identification are in universal use and many of the local blood-bank arrangements have been in operation in the North-east Metropolitan Region for almost two years—various procedures obtaining earlier were reviewed, discussed, some discarded, and the best retained. While domestic blood-bank rules may vary from place to place the general principles remain unaltered: those enunciated above have been evolved as the result of local near-accidents and from the reported fatalities.

Manifestly experience so dearly bought should never be purchased twice, yet there is danger that it may be paid for thrice or more unless pathologists and clinicians co-operate and, with the help of senior administrative medical officers of regions, close this sorry account.

Preparations and Appliances

TUBO-UTERINE IMPLANTATION REAMER

Mr. V. B. GREEN-ARMYTAGE, consultant gynaecologist, Hammersmith Postgraduate Hospital, writes: In the operation of tubo-uterine implantation for tubes occluded at the cornua, secondary to septic abortions, etc., it has been found that the punch previously advocated by myself¹ is too long and hence apt to wobble or slip from the fingers when making the necessary tunnel at the cornu, in line with the interstitial part of the tube. To remedy this I have devised, with the help of Messrs. Allen and Hammersley, a shorter, sharper, cheaper and steadier reamer here illustrated, with a lumen of either 7 or 9 mm., which combats all difficulty in these otherwise hopeless cases. Moreover, in order to assist the tube in adjusting itself to the smooth-cut channel, I thread the implanted tube from the fimbria through to the vagina with the finest of polythene tubing, which is pulled out in three to four weeks.

REFERENCE

¹ British Medical Journal, 1952, 1, 1222.

The Earl of Feversham has accepted the invitation of the Royal Sanitary Institute to act as president of the Health Congress which is to take place at Scarborough on April 27-30, 1954. An attendance of about 2,300 delegates and others is expected. Lord Feversham was chairman of the committee of inquiry into the voluntary mental health services which produced the Feversham Report in 1939.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Treatment of Acute Malaria

SIR,—I have read with much interest the excellent and balanced leading article on antimalarial drugs (*Journal*, August 1, p. 266). I have two minor criticisms to make. Chloroquine may act more quickly than quinine as a schizonticide (though I doubt if the difference is sufficient to be of great significance), but it is much more expensive—a point of no small importance in impoverished communities. Most of us will agree that there is little risk of precipitating blackwater fever with quinine therapy unless the patient has previously used quinine irregularly as a suppressant. Those who, like myself, experienced three malaria seasons in Macedonia in the 1914–18 war and have repeatedly seen the dramatic action of this drug when given intravenously to comatose cases will be unwilling to admit that it is completely outmoded by the synthetic schizonticides until these have been tried out in similar circumstances. As a suppressant, of course, it is both ineffective against a severe challenge and dangerous because of its tendency to predispose to blackwater fever. The second point is the statement that proguanil “is the only drug known to be a true causal prophylactic in *P. falciparum* infection.” In the last sentence of a recent paper Sir Gordon Covell¹ writes, “The action (of pyrimethamine) appears to be that of a true causal prophylactic against this species of parasite,” and from the data he gives this conclusion appears justifiable.

My main object in writing this letter is to comment on the article by Sir Gordon Covell and others (p. 258) and to suggest, in the light of ideas which have crystallized since his experiments were planned, a possible explanation of the discrepancy between Covell's results with pyrimethamine against the Madagascar strain of *Plasmodium vivax* and Coatney's results using the Chesson strain.

It has been conclusively shown that pyrimethamine, like proguanil,² acts on the asexual parasites of *Plasmodium* in the blood stream at the time of nuclear division.^{3,4} This observation is in conformity with its known action as an antagonist to one of the folic-folinic acid series, and no doubt has some relationship to the observation made by Jacobson⁵ on the action of aminopterin (a folic acid antagonist) on the dividing nucleus of cells in tissue culture. It is not unreasonable to postulate that, if pyrimethamine does in fact destroy the exoerythrocytic forms of the parasite, it acts by the same mechanism—that is, by interfering with nuclear division. The Chesson strain of *vivax*, used by Coatney, is an “early-relapsing” race of the parasite. By giving pyrimethamine over a period of 8 to 10 weeks an effective concentration of the drug is ensured at the time when the exoerythrocytic forms of this parasite, prior to producing erythrocytic infection, reach the vulnerable stage of nuclear division. Hence the so-called “suppressive cure” which Coatney achieved by this method and reported at the annual meeting of the American Society of Tropical Medicine and Hygiene (proceedings in the press). A glance at Covell's chart on page 258 reveals a very different picture. From this it is clear that the exoerythrocytic forms of the Madagascar strain can remain latent for 30 to 40 weeks. There is no reason to suggest that recurring schizogony of these parasites takes place in this interval, and, in the absence of such division, pyrimethamine is without effect when given at this time. Hence the relapses which occurred in Covell's patients. The remedy in infections with the late-relapsing strains of *vivax* might be to give a weekly dose of pyrimethamine between the tenth and twentieth weeks after the primary attack and again

between the thirtieth and fortieth weeks, but this suggestion is feasible only where the habits of the particular strain as regards relapse have been accurately defined. The important point, as brought out in your leading article, is that if further evidence confirms that pyrimethamine destroys exoerythrocytic forms it will, when taken prophylactically, prevent late relapses of benign tertian malaria.—I am, etc.,

London, N.W.1.

SIR,—With reference to Sir Philip Manson-Bahr's letter (*Journal*, August 1, p. 284), I should like to assure the writer that I do not find myself “in a quandary regarding the effective drug treatment of malaria,” and that I do not advocate a proposal of “back to Methuselah” in the sense that synthetic antimalarials should be discarded in favour of quinine.

In my opinion the drugs of choice for the treatment of an acute attack of malaria in a non-immune subject are chloroquine, amodiaquine (“camoquin”), or mepacrine. I would use quinine only if none of these was available. As Sir Philip recalls in his letter, it was the routine use of mepacrine among our troops in prophylaxis as well as in treatment which banished malaria as a dominant factor in the war in the Far East. In the experience gained at Horton over the past 23 years, mepacrine administered in adequate loading dosage (a minimum of 6 tablets of 0.1 g. on the first day) generally has a more rapid action on *Plasmodium falciparum* than has quinine. This was particularly noticeable in the case of a European strain of this parasite with which a series of experiments were carried out in 1931.¹ With this strain quinine was not only less rapid in action than mepacrine, but was also entirely ineffective in the production of radical cure. Two of the patients in this series developed blackwater fever, and in each case quinine was considered to have been the exciting cause. Chloroquine and amodiaquine have an advantage over mepacrine in that while they are at least as rapid in action they do not produce yellow discoloration of the skin.

The sole object of my letter (*Journal*, July 4, p. 41) was to emphasize that, although both proguanil and pyrimethamine have been shown to be highly effective in the prophylaxis of malaria, neither of them is suitable for the treatment of an acute attack in a non-immune subject without reinforcement by some more rapidly acting schizonticidal drug.—I am, etc.,

Horton, Surrey.

The Backward Child

SIR,—Having left Columbus in the beginning of May and having been travelling during the last month, I have only recently seen my letter on the backward child and Dr. L. Crome's comments on it (*Journal*, April 25, p. 936, and May 16, p. 1108).

Dr. Crome states that the evidence gleaned from his brain-pathological material does not lend support to the theory that lesions in the geniculate bodies present the main cause of mental deficiency. He calls this theory “Dr. Gellner's hypothesis.” However, I never presented such a hypothesis. In the letter to which Dr. Crome refers I wrote that “pathological changes in the above-mentioned ganglia (the corpora quadrigemina and the corpora geniculata) and in their afferent and efferent tracts may play one of the most important roles in the causation of mental defect.” My topographical reference embraces the whole length of the visual and auditory pathways from receptor organ to cerebral cortex. This shows that my hypothesis is not primarily concerned with the actual anatomical level affected by the impairment, but with the circumstance that mainly or even exclusively disturbances affecting to some degree the integrations of the visual or the auditory system will lead to a mental defect. Both

of these exteroceptor systems possess two ganglionic relay stations in the midbrain, subserving apparently different integrative functions and promoting different aspects of visual or auditory reactions and experience.

The distribution of sensory impulses into two main channels in the midbrain, a sensory-somatic and another probably sensory-autonomic one, is demonstrated in the anatomical fact that both the optic and the auditory tracts divide in the midbrain to form two major branches: one ending together with kinesthetic fibres in the corpora quadrigemina, the other ending in the corpora geniculata of the thalamus. The discovery that the hypothalamus projects to the cortex via thalamic nuclei is to-day a well-established fact and by no means my hypothesis. I only hypothesized on the basis of findings of Le Gros Clark and others the existence of a direct hypothalamic connexion to the geniculate bodies. The dichotomy of visual as well as auditory functions in sensory-somatic and sensory-autonomic ones is able to explain satisfactorily most clinical features evidenced in mentally handicapped children. Such a dichotomy is supported by observations in brain physiology which we owe mainly to Pavlov and his school, as Dr. Crome rightly points out, but also to the work of Dusser de Barenne and Warren McCullough. It is likewise borne out by experimental psychology and furthermore by a large number of educational studies.

Dr. Crome writes that in view of his pathological findings it is “impossible to agree” with my theoretical postulates and “hardly necessary to discuss” my theory. I am, however, unable to discern in his letter what he has actually found in his material which contradicts my hypothesis. Apparently he has at present investigated his material in a fairly gross macroscopical way only. Has he thoroughly examined the telencephalon, mesencephalon, and diencephalon in all his cases, and is he furthermore so well acquainted with the normal anatomy of the brain-stem as to be able to detect immediately minor pathological changes in its structure? He has mentioned changes in the optic tracts and the lateral geniculate bodies. But has he observed—to mention only a few—the not infrequent absence of the striae acusticae (which correspond to the optical tract) from the floor of the fourth ventricle or the occasional lack of a tract, usually emanating from the medial geniculate bodies and known as “Gudden's commissura”? Has he in a number of cases missed the bigeminal nuclei which have close connexions with the inferior colliculi or has he even been confronted with a complete absence of the colliculi themselves?

I have witnessed all these and other subcortical changes repeatedly in the necropsies of more than 200 brains, which Dr. Philipp Schwartz investigated while I was working with him in Wrentham State School, Mass. Dr. Schwartz's extensive pioneer work concerning brain injuries in the newborn is well known to brain pathologists. In June, 1951, he summarized his experiences in a lecture, given to a medical audience: “My observations have all but convinced me that we shall find the key to many yet unsolved problems regarding the pathogenesis of mental deficiency in primary pathological changes of the brainstem.”

This statement does, of course, not imply that alterations in the brainstem were the only changes which we found in the cerebrums of aments. I wrote in my previous letter: “These disturbances (of lower levels) will deprive the cortex of necessary sensory-somatic and sensory-autonomic impulses.” In the language of the brain pathologists that means: “Lesions in subcortical areas will produce secondary cortical atrophy with shrinkage of the white matter, reduction in the number of nerve cells in the protective layers of the cerebral cortex, and consequent loss in weight and size of the brain.” These findings correspond exactly to “the most common structural changes” referred to by Dr. Crome.

Many years ago Dr. Stewart described large numbers of similar findings. But he stressed at the same time the enormous frequency of partial optical atrophy in aments. The coincidence of these phenomena can best be explained by the theory of primary subcortical impairment in either the visuo-somatic or the visuo-autonomic sphere. Such an impairment would result in lack of development in the appropriate projective layers of the cortex and in retrograde partial atrophy of the visual pathways. For further evidence Dr. Crome may also consult the excellent publications of Dr. Norman, Superintendent of Stoke Park Colony, Bristol. Dr. Norman found histological changes of the lateral geniculate bodies in a considerable number of his necropsies, by no means—as Dr. Crome—only in the rare cases of microphthalmia. He regards the accompanying cortical changes in most cases as secondary results of subcortical impairment.

Lastly, I completely fail to understand why Dr. Crome accuses my suggestion that the central integrations of our

most important senses are specially related to the development of intelligence. After all, the statement made about 300 years ago by the philosopher Leibniz still holds true: “*Nihil in intellectu est quod non fuerit prius in sensibus.*”—I am, etc.,

London, N.W.3.

LISE GELLNER.

Infections in Childhood

SIR,—May I comment in one letter on three interesting articles in your issue of July 25?

The staphylococcal infections in maternity hospitals described by Dr. John O. Forfar *et al.* (p. 170) are very serious. Yet even to-day there are hospitals where newborn babies are put into crowded nurseries, the cots nearly touching, and are bathed in a common basin. “Drops” and gentian violet are to hand for the sticky eyes and septic fingers which occur without arousing surprise. In such communal living conditions the individual labelling of towels and cot blankets is a rather inadequate ritual. A patient with a breast abscess is usually isolated, but it is rare for her contacts to be swabbed, and her baby may remain in the common nursery. I recently saw a child which had had styes, boils, and whitlows for the three years since it left the maternity hospital with a sticky eye it caught there from other babies. For the last two years the mother too had had boils and was in the nick of time prevented from taking up a job in a baby clinic.

Maternity units could with advantage be much stricter about the spacing of nurseries, the avoidance of common utensils, and the exclusion of dangerously infected persons. Neither patients nor staff should be admitted if they carry such patently virulent staphylococci that they suffer from boils, styes, or whitlows.

Intestinal cross-infections could be reduced; a practical stool for individual bed-pans has now been designed.¹ The faeces of an expectant mother could be examined bacteriologically, perhaps at the time of the last antenatal visit. It is clear from the article by Drs. William McNaught and John S. Stevenson (p. 182) that this should now include a routine search for the gastro-enteritis strains of *Bacterium coli*.

Finally it would have added to the comprehensiveness of Professor Norman B. Capon's interesting review of indigestion in childhood (p. 197) if attention had been drawn to the frequency with which the common “diarrhoeal” infections may give rise to atypical symptoms. Shigellae, salmonellae, serospecific types of *Bact. coli* and giardia may all cause dyspepsia, fever, pains, and headaches, and may be present without diarrhoea; sometimes loose stools do occur, but irregularly at intervals of several days. Symptoms may persist for weeks or only for hours. In the investigation of a case of indigestion it is helpful to have the faeces examined microscopically, culturally and for blood.—I am, etc.,

Respiratory Paralysis in Poliomyelitis

SIR,—At a recent meeting at the Ministry of Health, reported in the *Journal* of May 30 (p. 1216), a discussion took place on a new method for treatment of respiratory paralysis in poliomyelitis, as applied during last year's epidemic in Copenhagen. It was evolved by Dr. B. Ibsen and described by Professor C. H. A. Lassen.¹ Whereas until then artificial respiration was performed in these cases through passive expansion of the thorax from without by an iron lung type of respirator, with or without tracheotomy, the new method provides for artificial ventilation by means of rhythmic inflation of the lungs through an endotracheal tube passed into a tracheotomy opening. The Copenhagen results appear to be very encouraging, the mortality having been reduced from 80% to 40%.

In view of some difficulties and disadvantages of the method which were mentioned by Professor Lassen as well

as by speakers at the Ministry of Health discussion, I should like to suggest a simpler and cheaper way to achieve the same results—that is, the replacement of the apparatus described by Lassen by the Oxford vaporizer, which, in this case, would not be used for ether anaesthesia, but to apply artificial respiration. The method has the following advantages.

The Oxford vaporizer when fitted with a Salt valve (a non-return valve which can be closed during inflation by depressing a spring-loaded button) permits artificial ventilation without rebreathing. As no soda lime is used, there is no danger of aspiration of particles nor of heat retention by the patient, caused by an overheated canister. Besides, 30s. a day per patient, the cost of the soda lime, will be saved. Any small amount of CO₂ which may accumulate in the corrugated rubber tube of the machine by a slight reflux of expired air can be removed by flushing the tube with air once or twice every few minutes—i.e., by compressing the harmonica bag with the Salt valve open.

The Oxford vaporizer can be used either with air alone or with a variable air-oxygen mixture, the oxygen to be led in through the tap provided for it. Instead of giving a fixed 50-50 nitrogen-oxygen mixture as used in Copenhagen, the oxygen content can be adapted to the patient's needs. This will also ease the "weaning" from artificial ventilation back to spontaneous respiration, as one can reduce the oxygen gradually instead of changing it suddenly from 50% of the fixed mixture to the 20% of air. The cost of the nitrogen-oxygen mixture will be saved against the much lower cost of pure oxygen.

Under European conditions air does not require an additional humidifier, while compressed gases are too dry for prolonged use without added water vapour. If much additional oxygen is used, or if the air is very dry, the ether container of the vaporizer should be filled with water and the ether control tap fully opened. The mixture will then be driven over the water and will absorb sufficient moisture to prevent the tracheo-bronchial secretions from drying up. The spring within the harmonica bag will resist the application of too much pressure during inflation, and the slow re-expansion of the bag will ensure a sufficiently long expiratory period.

The apparatus is foolproof. Should added oxygen run out unobserved, the inflated air would still provide for the minimum oxygen requirements. This safety, together with the uncomplicated working of the vaporizer, will allow for the employment of untrained personnel. They have to be taught only to compress the bag a certain number of times per minute, varying with each patient, and to press down and release the button of the Salt valve simultaneously with compressing and releasing the bag. Thus, one medical attendant can supervise a number of patients, adjust the oxygen mixture, and attend to suction, postural drainage, and any other treatment.

No alterations of the Oxford vaporizer are required, apart from providing a Salt valve with each machine.—I am, etc.,

Jerusalem.

. The bellows previously incorporated in the Oxford vaporizer are now available separately as a small hand unit, which was recently described in the *Journal* (July 25, p. 202) by Professor R. R. Macintosh. On the same page Dr. W. W. Mushin described the Cardiff inflating valve, which has been designed for use with the Oxford bellows.—Ed., *B.M.J.*

Post-inoculation Poliomyelitis

SIR.—Statistical inquiry is only one of the methods by which we seek to acquire knowledge, and, moreover, is one that is notoriously full of pitfalls. In medicine, we have always gained much of our knowledge through the traditional practice of clinical observation aided by the application of reason. For instance, it does not require a statistical inquiry to show that streptomycin is a strong potential remedy against tuberculosis. The timely use of the drug in a single case of miliary tuberculosis so alters the clinical state of the patient as to demonstrate its therapeutic value much more clearly and promptly than a survey by questionnaire and a mathematical analysis of the returns of many individual observers.

Doubtless the South Tyneside poliomyelitis epidemic of 1952 would have yielded many more cases of post-inoculation poliomyelitis if intramuscular inoculations of prophylactics had been allowed to continue, but I would not care to expose any child during an epidemic of poliomyelitis to a risk of permanent disability.

The evidence which I submitted (*Journal*, July 11, p. 66) on the relation between inoculation and poliomyelitis was circumstantial. It depended on a comparison of the incidence of paralytic poliomyelitis in two groups of children being validated by other considerations, such as the frequency and sites of paralysis in the two groups of patients, its severity in the inoculated arms as compared with the effects of the natural disease when it implicated the arms, and the time intervals between inoculation and onset of symptoms. For me the clinical facts observed had a cumulative effect which led to conviction. Finally the facts confirmed the clinical experiences of London and Melbourne.

I cannot see any difference in meaning between the statement quoted with approval by Mr. P. G. Gray (*Journal*, July 25, p. 223) that "the main effect of recent immunization is to add an additional paralysis site," and my conclusion that "there was no doubt of the increased risk to a child of developing a paralytic attack of poliomyelitis as a result of intramuscular immunizing injections." Although I cannot follow the implications of the statistical test proposed by Mr. Gray, I would like to point out that his table of immunization sites is not valid for the Gateshead area, where, out of 1,000 consecutive inoculations of prophylactics in 1951, 776 were given in the left arm, 34 in the right arm, 175 in the buttocks, and 15 in the thighs. This distribution of sites of injection is in very close agreement with the sites of maximal paralysis in the 10 inoculated patients who suffered poliomyelitis not earlier than 10 days after the last injection (left arm 7, right arm 1, legs 2), and completely dissimilar to the sites of paralysis in the 60 paralysed patients among the 130 non-inoculated persons who suffered from poliomyelitis. In these, leg paralysis occurred in 42 and arm paralysis in 21.

In answer to Dr. Guy Bousfield (*Journal*, August 1, p. 285) I would like to state that the diphtheria prophylactic involved in the cases of post-inoculation poliomyelitis was A.P.T. (Burroughs Wellcome) as issued officially by the Ministry of Health. The pertussis vaccine used in 1948 was the Glaxo product containing alum, and the combined prophylactic against diphtheria and whooping-cough was either the product now called absorbed diphtheria/pertussis prophylactic (Glaxo) or the Parke, Davis equivalent, both of which contain alum.

On resuming diphtheria and whooping-cough prophylaxis after the poliomyelitis epidemic we adopted the suspended diphtheria pertussis prophylactic (Glaxo), and the local authority medical staff give it by the subcutaneous route.—I am, etc.,

Gateshead.

JAMES GRANT.

Inoculation Technique

SIR.—I read with great interest the valuable article by Dr. James Grant on post-inoculation poliomyelitis (*Journal*, July 11, p. 66).

Since the early days of immunization I have always used the gluteal route, and for this totally different reason. At that time I was surprised at the frequency with which many very young children started to whimper and cry when they were brought to the surgery for their second and third monthly injections. Very clearly they could associate me and my surroundings with a very painful experience, even at this tender age. This set me thinking—was I unwittingly sowing the seed for an increase in the number of highly strung nervous children with their accompanying bed-wetters and asthmatics? I decided I might be, and so changed my methods.

The mother now places her child across her lap face downwards, and the gluteal region is exposed. I now enter the room, make the injection, and quickly disappear. The child howls, is quickly upturned, but sees no one but his mother. He quickly forgets the pain which he thinks she has administered, for that is dwarfed by her constant love and care. So he comes back for the second and third injections with no "memories."—I am, etc.,

Gateshead.

A. MACARTHUR.

Manual Methods in General Practice

SIR.—I would like to reply to the very helpful letters on manual methods in general practice (*Journal*, July 25, p. 222).

Dr. P. Hopkins mentioned the psychogenic backache. This is quite a common trouble, as explained by Dr. J. P. Spillane at the Cardiff Plenary Session on "Fibrositis," and I agree with him, and mentioned the method of examination in my article (*Journal*, July 4, p. 18). I strongly endorse Dr. Hopkins's last sentence referring to examination of the "whole patient and not just the part that hurts." Examination for backache is carried out literally from "head to toe," and for armache from head to finger-tips. This is essential to avoid missing tuberculous caries or secondary deposits in the spine, or a cervical disk protrusion giving rise to pain in the arm. I cannot, however, agree with Dr. Hopkins's estimate that the proportion of total patients seen who require physiotherapy is 5%. First, he has omitted any cases of arthritis of the hip, shoulder, or knee, cases of strain of the coronary or lateral ligaments of the knee, or the chronic sprained ankle. Secondly, he has seen eight cases diagnosed as prolapsed disk in six months. This is hard to believe, since I see many more than that number every week. I note that 50% of his eight cases had operative treatment or plaster-jacket treatment. I can only remark that during the past three years I have not had one case operated on or encased in plaster.

Dr. R. Howard raised the one big snag—namely, payment. A great deal of work is done free by me and my physiotherapist. Not being recognized as a consultant in the National Health Service, I cannot be paid by the executive council and I cannot charge my patients (N.H.S.). I feel the treatment is so necessary that I am content with giving something for nothing.

Dr. T. Hambly's letter points out the weakness in our medical education. I am sure that before this work can be successfully carried out by general practitioners many courses will have to be arranged at St. Thomas's Hospital, under the guidance of Dr. Cyriax, and one general practitioner from every partnership should attend. We owe it to the patients who trust us to give them the best and earliest treatment practicable.—I am, etc.,

Hoddesdon, Herts.

R. BARBOR.

Cerebellar Dysfunction

SIR.—I must thank Dr. J. O. Newman (*Journal*, July 25, p. 223) for his interest in my medical memorandum (*Journal*, July 11, p. 83). I have to inform him that the ataxia so noted in the case report was indeed cerebellar ataxia, which was, of course, what made the case so unusual.—I am, etc.,

Glasgow.

BASIL SELTZER.

Three Testicles

SIR.—I can appreciate the gentle jest of my very old friend Mr. McNeill Love in resurrecting an anonymous mediaeval Pope and recording his alleged reaction to an anatomical conundrum (*Journal*, July 18, p. 145); but it is a pity to let the doctor who certified that the applicant had three testicles remain unhonoured. Medical history would be brightened if my friend could look up the original documents for an addendum to his admirable article on scrotal swellings.—I am, etc.,

London, W.1.

W. J. O'DONOVAN.

Regional Service for Diabetics

SIR.—It will no doubt be of great interest to those concerned with the care and welfare of diabetics to read (*Journal*, July 18, p. 160) that the Central Health Services Council has drawn up plans for a regional service for diabetics, and that the proposed centres will amongst other activities provide for "the training of patients in how to live with their disability."

The British Red Cross Society will be particularly glad to know of this development, for in 1946 the Society, in conjunction with the Diabetic Association, set aside 50 beds for that very purpose in part of the British Red Cross

Society's Auxiliary Hospital, Burley-on-the-Hill, Rutland, which I think I am correct in saying was the first undertaking of its kind in this country. Patients who had but recently been diagnosed as suffering from diabetes were there taught the diabetic way of life, as well as the use and administration of insulin and the preparation of suitable food. In addition to this instruction they had the benefit of meeting others suffering from the same complaint and were helped to regard the unusual as almost the usual, thus conditioning them for an altered life in the outside world and raising their morale. Burley-on-the-Hill was taken over on the appointed day in 1948 by the Ministry of Health, but it continues to give the same encouragement and help to diabetics as was provided originally by the British Red Cross Society.—I am, etc.,

London, S.W.1.

H. A. HEWAT.

Primary Biliary Cirrhosis

SIR.—We would like to comment on the article by Drs. H. G. H. Richards and C. B. S. Fuller on "Primary Biliary Cirrhosis" (*Journal*, July 4, p. 23). The following case report emphasizes the importance of awaiting post-mortem proof before accepting the diagnosis of primary biliary cirrhosis.

A married woman became jaundiced in July, 1951, at the age of 55. There was no relevant previous history. Investigation showed that the jaundice was of obstructive type. Mr. J. D. T. Jones performed a laparotomy, but could find no evidence of extra-hepatic obstruction. Liver biopsy showed biliary cirrhosis. The histological picture was the same as that described by Drs. Richards and Fuller. The patient remained intensely jaundiced until her death ten months after the beginning of the illness. Later both liver and spleen were enlarged together with ascites and a haemorrhagic state. Despite her extraordinary colour she felt well until the terminal phase of her illness. Post-mortem examination carried out by one of us (P.S.T.) revealed bile-duct carcinoma involving the hepatic duct in the porta hepatis. The tumour was only 2 by 1 cm. in dimension. There was also a small nodule 4 mm. in diameter in the cystic duct at its junction with the hepatic duct. The common bile duct was normal.

It is evident, therefore, that biopsy proof of biliary cirrhosis in combination with negative laparotomy findings does not exclude the presence of a small tumour of the hepatic duct.

We are grateful to Mr. J. D. T. Jones and Dr. H. A. Dewar, who had this patient under their care, for permission to publish this case.—We are, etc.,

J. W. PLATT.

P. S. TWEEDY.

Newcastle-upon-Tyne

Dr. Johnson as Scientist and Patient

SIR.—Your report of the B.M.A. Popular Lecture given by Sir Russell Brain on Dr. Samuel Johnson (*Supplement*, July 25, p. 62) prompts me to suggest that the truth behind the odd behaviour of the great lexicographer is to be found in the pages of *Lavengro*, by George Borrow. In chapters 64-7 is a most vivid account, obviously based on fact, of the author's brief sojourn with a country gentleman afflicted with compulsive neurosis. The sufferer confides in Borrow as follows: "Suddenly, I found myself doing that which even at the time struck me as being highly singular; I found myself touching particular objects that were near me, and to which my fingers seemed to be attracted by an irresistible impulse . . . a mysterious dread hanging over me till I had given way to it." As Borrow sympathetically observed to his host, it was the warding off of the "evil chance." I myself well remember an unfortunate school contemporary who, when walking in the street, was frequently compelled to turn round and round—top fashion—to the no small embarrassment of any chance companion. In the same way Dr. Johnson, when escorting poor blind Mrs. Williams, was obliged to leave her floundering while he carried out the gyrations imposed upon him by that dread, inexorable power.—I am, etc.,

London, E.1.

J. P. ENTRACT.

Obituary

G. E. VILVANDRÉ, M.R.C.S., F.F.R.

Dr. G. E. Vilvandré, consulting radiologist to the London Hospital, died at his home at Redbourn, Hertfordshire, on July 26 at the age of 71.

George Ernest Vilvandré was born in Paris on May 12, 1882. It was at his own wish that he was educated in England, and although very fond of his native country he never returned there to live. In 1903 at the age of 21 he became a naturalized British citizen. Deciding to study medicine, he entered the medical school of the London Hospital, qualifying in 1910. After resident appointments at the London and Poplar Hospitals and at the Chelsea Hospital for Women he went into general practice in Staplehurst, Kent. During the 1914-18 war Vilvandré was in France as a medical officer in the R.A.M.C., one of his duties being that of radiologist to the 16th General Hospital and Guildford Military Hospital. It was then that he interested himself in the movement of metal foreign bodies in the brain, a subject on which he wrote. When he relinquished his commission in the Army he also gave up his general practice to work with the late Dr. J. H. Sequeira in the skin department at the London Hospital, where he carried out much of the superficial x-ray therapy and became expert in the radiotherapy of ringworm. Later he took charge of the Poplar ringworm clinic. Rightly he stressed the value of an appreciation of the dose of x rays reaching the skin and the need of accurate estimation of it, both in therapy and in diagnosis. His interest was not confined to radiotherapy, and in the diagnostic department his scientific approach, accurate work, and co-operation with the members of the medical and surgical staff at the London Hospital brought him recognition.

In 1922 Vilvandré was appointed assistant radiologist to the London Hospital, the late Dr. S. Gilbert Scott being his chief. His great interest was in gastro-intestinal work, which at that time was in its fairly early stages. He realized that it was only in the operating theatre and the post-mortem room that his radiological observations could be checked and proved, and so he became a regular attendant in those departments. Working with such men as Sir James Walton and the late Mr. James Sherren, he had all the cases and co-operation he could wish. He did a very great deal to put the radiological diagnosis of gastro-enterological conditions in its present position. Although gastro-enterology was his chief interest, radiotherapy had a definite place in his heart, and it was due to him that the first deep-therapy apparatus was installed at the hospital. In 1930 he became radiologist to the London Hospital, and he was appointed to the consulting staff when he retired in 1942, in which year he was elected a Fellow of the Faculty of Radiologists. He continued in private practice and was radiologist to St. Albans Hospital until he finally gave up work about a year ago.

Vilvandré was well known in radiological circles. He served on the council of the British Institute of Radiology; he was president of the Clinical Section of the Royal Society of Medicine from 1947 to 1949; and he was a prominent figure in the Medical Society of London, of which he was honorary secretary from 1941 to 1943 and vice-president from 1945 to 1947. He was also a foreign correspondent of the Société Médicale des Hôpitaux de Paris.

George Vilvandré was always ready to assist a junior, and anyone who suffered misfortune could depend on him for help and sympathy. This was especially evident in his very great kindness to his patients, particularly to those whom he was treating with x rays. His cheerful presence and kindly advice and help will be remembered by all who worked with him. He enjoyed teaching—he was lecturer in radiology in the London Hospital Medical College—and many generations of students will gratefully remember his informal demonstrations. He leaves a son and a married daughter. He had the great misfortune to lose one daughter, a nurse with the British Forces in the East, by enemy action during the last war.—M. H. J.

KARL BREMER, LL.D., M.B., B.S.

Dr. Karl Bremer, Minister of Health and Social Welfare in the Union of South Africa, died on July 19 at the age of 68.

Karl Bremer was born at Hopefield, Cape Province, on April 27, 1885, and was educated at Wellington and at the Universities of Capetown and Stellenbosch, where he obtained a science degree in 1903 and won the Victoria scholarship which admitted him to London University for a six-years medical course. At St. Bartholomew's Hospital, where he was a student from 1904 to 1908, he was an active member of the Rugby club. He took the London degrees of M.B., B.S. in 1909, and, after holding a resident post at Bart's, he continued his postgraduate studies in Berlin before returning to South Africa. From 1910 to 1918 Dr. Bremer was in general practice at Cradock, Cape Province, and he then became the first medical inspector of schools under the Cape Provincial Administration. Within a year, however, he was back in general practice, this time at Graaff Reinet, also in Cape Province, where he remained until the early 'thirties, when he decided to specialize in diseases of the ear, nose, and throat, finally settling in consultant practice at Capetown in 1934.

Bremer was always interested in politics, and in time he became a prominent member of the Nationalist Party. At Cradock he was for a time secretary of the local branch of the South African Party, and later he became provincial councillor for Graaff Reinet. In 1924 he entered the South African Assembly as the representative of Graaff Reinet. Finding, however, that he could not do justice to his medical practice and to his public responsibilities at the same time, he resigned his seat in 1925. Nevertheless the pull of politics still possessed him, and so, in 1929, he offered himself again as a candidate at the General Election and was elected. He retained the seat at the 1934 and 1938 elections; in the "khaki" election of 1943 he transferred to Stellenbosch, which he won from the United Party candidate after a hard fight. From 1933 to 1949 he was the provincial chairman of the Nationalist Party in the Cape.

Dr. Bremer was an active and forceful politician, though he did not make politics his whole life. When in office he consistently endeavoured to broaden the scope of the Union's health services. In March, 1948, he announced that he did not propose to stand at the then pending General Election on account of ill-health, and in the following July he became chairman of the board of management of the Diamond Producers' Association. In 1949, however, he again returned to politics as a member of the Senate, this time with his

Party in power. The crowning point in his career came in 1951, when he succeeded the late Dr. A. J. Stals as Minister of Health and Social Welfare.

Before the Medical Association of South Africa (British Medical Association) became an independent entity in 1945 Dr. Bremer was an active member of the B.M.A. in South Africa. He was president of the Cape Midland Branch from 1927 to 1929; chairman of the Graaff Reinet Division in 1929-30; and chairman of the Capetown Division in 1937-8. He was elected a member of the South African Medical Council in 1934, in succession to Dr. Stals, resigning from the chairmanship of the council in 1951 when he became Minister of Health and Social Welfare. Earlier this year the University of the Witwatersrand conferred on him the honorary degree of LL.D.

E. L. HENDERSON, M.D., F.A.C.S.

We record with regret the death of Dr. Elmer L. Henderson, a former President of the World Medical Association and of the American Medical Association, at his home at Louisville, Kentucky, on July 30 at the age of 68.
