Sir Andrew Davidson, Chief Medical Officer, Department of Health for Scotland, will visit the United States and Canada during November and December. He will be attending various public health conferences, and has accepted invitations to lecture at several American Universities.

COMING EVENTS

College of General Practitioners.—Foundation Membership of the College will close at the first annual general meeting to be held on November 14. Details of this meeting and the annual report will be sent to all members three weeks before the meeting. The following lectures on general practice have been arranged by the College. They will take place at 5.45 p.m. at the Society of Apothecaries, 14, Black Friars Lane, London, E.C.4:

- October 8—"Entry into and Setting up in General Practice," by Dr. Geoffrey Barber.
- October 13—"The Family Doctor-Patient Relationship," by Dr. George F. Abercrombie.
- October 22—"The Present Position and Future of General Practice," by Dr. John H. Hunt.
- November 5—"Common Ailments met in General Practice and Seldom Seen in Hospitals," by Dr. Geoffrey Barber.
- November 19—"Medical Ethics and the Pitfalls of General Practice," by Dr. Stephen Hadfield.
- November 23—"The Running of a Surgery and the Doctor's Room," by Dr. Ian Watson.

Charing Cross Hospital Medical School.—The inaugural address will be delivered by Admiral of the Fleet Sir Philip Vian, G.C.B., K.B.E., D.S.O., at the Royal College of Physicians, Pall Mall East, London, S.W.1, on Friday, October 9, 1953, at 3 p.m. The prizes will be presented by Lady Vian, and Lord Inman will be in the chair.

St. Andrews Medical School, Dundee.—The inaugural postgraduate lecture of the new session will be delivered on October 8 by Sir Russell Brain, P.R.C.P. The title is "Consciousness and Unconsciousness."

The Westminster Medical School.—The inaugural address will be delivered by Lord Radcliffe at Church House, Great Smith Street, London, S.W.1, on October 12 at 3 p.m. Mr. H. M. Clowes will be in the chair.

Princess Tsahai Memorial Hospital Fund.—Mr. Richard St. Barbe Baker will deliver a lecture on behalf of the Fund at the Old Library, B.M.A. House, on October 13 at 3 p.m. Mr. St. Barbe Baker will speak about a recent expedition to the Sahara Desert, and Miss Sylvia Pankhurst will report on the progress of the Princess Tsahai Memorial Hospital. Admission to the lecture will be free, but reserved seats (5s.) may be obtained from the hon. secretary, 3, Charteris Road, Woodford Green, Essex.

1953 Bengué Memorial Award Lecturer.—The Royal Institute of Public Health and Hygiene has appointed General A. M. E. Sicé, M.D., the Bengué Memorial Award Lecturer for 1953. The lecture, entitled "The Evolution of Therapeutics in the Course of the Last Few Years," will be delivered in the Lecture Hall of the Institute, 28, Portland Place, London, W.1, on October 14 at 4 p.m. Admission is free, without ticket.

Course on Allergy.—A course on allergy, comprising theoretical lectures and practical demonstrations, will be held at the Clinique Médicale, Hôpital Broussais, 96, rue Didot, Paris, 14, from October 19 to 29. Applications to attend the course should be sent to the above address; the fee is 5,000 francs for the lectures only, 8,000 francs for the entire course.

Professional Nurses and Midwives Conference.—The 38th annual conference will be held at Seymour Hall, London, W.1, from October 12 to 16, under the presidency of Sir William Gilliat. Mrs. Iain Macleod will open the conference on the morning of October 12, and the third Blackham Memorial Lecture will be given that day by the Chairman of the Central Midwives Board, Mr. Arnold Walker.

Royal Air Force.—The 23rd annual dinner of the Royal Air Force Medical and Dental Branches will be held at the Hyde Park Hotel, Knightsbridge, London, S.W.1, on Friday, October 23, 1953. All past and present officers who have served in those Branches are eligible to attend. Tickets (27s. 6d. each) may be obtained from Air Ministry (MA3), Aldry House, Kingsway, London, W.C.2.

Manchester Medical Students' Ball.—The Manchester University Medical Students' Representative Council is holding its annual Medical Ball on October 23 in the Whitworth Hall, Manchester University. Application for tickets (price one guinea for a double ticket) should be made to Mr. M. R. Thompson, social secretary of the council, Medical School, The University, Manchester, 13.

The Yorkshire Association of Graduates of Glasgow University will hold its annual dinner on October 23. The guest of honour will be Mr. W. W. Galbraith, P.R.F.P.S. Potential members of the association are asked to communicate with the secretary, Mr. James Wishart, 33, Manor Row, Bradford, 1.

NEW ISSUES

British Journal of Venereal Diseases.—The next issue (Vol. 29, No. 3) will be available in a week's time.

Thorax.—The next issue (Vol. 8, No. 3) will be available in a week's time.

Issued quarterly; annual subscription £2 2s., single copy 12s. 6d.

British Journal of Ophthalmology.—The next issue (Vol. 37, No. 10) will be available in a week's time. Issued monthly; annual subscription £4 4s., single copy 8s. 6d.

These journals are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Friday, October 2

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Dr. E. Hinden: Tuberculosis in Childhood.

Monday, October 5

INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: Lecture demonstration.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.—5.15 p.m., Manson Lecture by Sir Rickard Christophers: Malaria in the Field.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. Rainsford Mowlem: Role of Surgical Repair in Burns; 6.30 p.m., Mr. Denis Browne: Hirschsprung's Disease.

Tuesday, October 6

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. C. O. Carter: Principles of Genetics.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. A. Lawrence Abel: Carcinoma of the Rectum; 6.30 p.m., Major C. K. Anderson: Blood Substitutes.

Wednesday, October 7

EUGENICS SOCIETY.—At Royal Society, Burlington House, Piccadilly, W., 5.30 p.m., Mr. James Shields: Personality Differences and Neurotic Traits in Normal Twin Schoolchildren.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Normal Histology of the Skin.

INSTITUTE OF NEUROLOGY.—5 p.m., Sir Francis Walshe, F.R.S.: Principles of Clinical Neurology.

INSTITUTE OF ORTHOPAEDICS.—8 p.m., clinical-pathological conference.

MANCHESTER MEDICAL SOCIETY.—At Medical School, Manchester University, 4.30 p.m. Presidential address by Professor John Morley: A Surgical Retrospect; 8.30 p.m., Reception at Whitworth Art Gallery.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. G. H. Algire: Observations on Tissue and Tumour Growth *in vivo*.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. V. H. Ellis: Internal Derangement of Joints; 6.30 p.m., Mr. J. M. P. Clark: Some Aspects of Poliomyelitis.

SOCIETY OF PUBLIC ANALYSTS.—At Burlington House, Piccadilly, W., 7 p.m., discussion to be introduced by Dr. G. Roche Lynch: Destruction of Organic Matter.

YORKSHIRE SOCIETY OF ANAESTHETISTS.—At Leeds General Infirmary, 8 p.m., Dr. W. D. Wylie: Obstetrical Anaesthesia, with Particular Reference to Cases with Cardiac Disease.

Thursday, October 8

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., discussion between psychiatrists and physicians: Psychological Reactions to Physical Disease.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At Beveridge Hall, Senate House, 5.30 p.m., Sir Henry Dale, O.M., F.R.S.: Scientific Method in Medical Research.

● INSTITUTE OF CHILD HEALTH AND INSTITUTE OF NEUROLOGY.—At National Hospital, Queen Square, W.C., 5.30 p.m., Dr. J. Purdon Martin: Terminology, Diagnosis, Classification, and Physiological Considerations.

LONDON HOSPITAL MEDICAL COLLEGE.—At Bearsted Theatre, 5 p.m., Schorstein Memorial Lecture by Sir James C. Spence: Varieties of Clinical Experience.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. D. J. Robertson: Arterio-venous Fistulae of the Extremities; 6.30 p.m., Mr. Norman C. Tanner: Carcinoma of the Stomach.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Sir W. Russell Brain, P.R.C.P.: Consciousness and Unconsciousness.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. Denis Williams: Neurology demonstration.

Friday, October 9

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. O. L. S. Scott: Developmental Abnormalities.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Sir Neil Hamilton Fairley, F.R.S.: Malaria and its Modern Treatment.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Professor Bryan L. McFarland: Reconstructive Surgery of the Hip.

Saturday, October 10

SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At Grove Park Hospital, Marvels Lane, Lee, S.E., 10.30 for 11 a.m., general meeting. "Brain Trust." Speakers, Sir Geoffrey Todd, Dr. James Maxwell, Dr. Thomas C. Wright, and Mr. F. Ronald Edwards.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Collinson.—On September 6, 1953, at Rotherham nursing-home, to Elaine (formerly Micklethwait), wife of John Pexton Collinson, T.D., M.R.C.S., of Burgh-le-Marsh, Lincs., a son—Edward Peter.

Gibson.—On September 7, 1953, to Agnes Macfarlane Stark, M.B., Ch.B., M.R.C.O.G., wife of John Baird Gibson, M.B., Ch.B., D.A., 3, Ewbank Avenue, Newcastle-upon-Tyne—a son.

Rowe.—On August 8, 1953, at Ashleigh Private Hospital, Gosforth, to Sheila (formerly Cowling), wife of Dr. Alan I. Rowe, a son—Simon Innes.

Sloan.—On September 14, 1953, to Mairi, wife of Dr. J. Burnley Sloan, Kelvin Glen, Abbots Way, Highfield, Southampton, a son—Iain Douglas.

Tighe.—On September 11, 1953, at Birmingham, to Nora (formerly Cregan), wife of John Robert Tighe, M.R.C.S., L.R.C.P., a second daughter—Geraldine Mary.

Vella.—On September 20, 1953, at Cannock, Staffs., to Corinna, wife of Dr. J. M. Vella, a daughter.

DEATHS

Andrews.—On August 22, 1953, at his home, Beechmount, Pittville Circus Road, Cheltenham, Glos., Robin Andrews, M.R.C.S., L.R.C.P., aged 53.

Daman.—On September 3, 1953, in a nursing-home, Lincoln, Thomas Walter Alfred Daman, M.B., Ch.B., C.M.

Hardman.—On September 8, 1953, at Ryde, Isle of Wight, John Leicester Hardman, M.R.C.S., L.R.C.P., late of Nyasaland, aged 31.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Gamma Globulin and Poliomyelitis

Q.—How does gamma globulin prevent poliomyelitis? Is it a specific effect depending on the donor having developed antibodies to the particular strain of poliomyelitis virus concerned?

A.—The success of gamma globulin in the prophylaxis or modification of measles is based on the sound assumption that most people have had an attack of measles in childhood, and that the antibodies persist into adult life and are concentrated in the gamma globulin fraction of the plasma proteins. The same assumption has been made in regard to poliomyelitis in the U.S.A., where this infection has been prevalent for the past fifty years, and in fact tests of the gamma globulin prepared from adult donors showed that antibodies to the three main types of poliomyelitis virus were present. It has also been shown that viraemia is a common occurrence in the early stages of poliomyelitis, so that an injection of gamma globulin, containing antibody to the polio virus, at a stage before the virus has become fixed in the nerve cells may be expected—and has proved—to give at least some temporary protection against the infection. In Britain poliomyelitis has occurred in widespread epidemics only since 1947, and it is not yet certain which type or types of the virus are responsible for these recent outbreaks. It would therefore be unwise, and would indeed be impracticable, to use gamma globulin from British donors for the prevention of poliomyelitis in those likely to be exposed to the risk of infection. This matter has been fully discussed in a recent leading article (*Journal*, April 18, p. 874).

Hormones in Cosmetics

Q.—Various cosmetic preparations, such as "skin foods" and certain hair preparations, are said to contain hormones. Have they any useful therapeutic action, or is their use dangerous?

A.—Most frequently these cosmetics contain oestrogens in an ointment basis. The injection of steroid hormones is a recognized therapeutic method of administration, and there is no doubt that the hormone is absorbed into the general circulation. It is possible that the local effect is more concentrated than if given orally or by injection. The effects claimed by the cosmetic sellers, such as "rejuvenation" of skin and abolition of wrinkles, have not been substantiated by any scientific findings. The same is probably true of the scalp hair. This does not mean that oestrogens are not useful under certain recognized conditions—for example, in Simmonds's disease oestrogens are beneficial to scalp hair, restoring its lustre and pigment. In some phases of the climacteric, oestrogens may be indicated.

As to harmful effects, in so far as an oestrogen is a very potent substance even in small doses, and capable of disturbing the rhythm of the menstrual cycle, it is obvious that the use of such preparations may prove harmful quite apart from the controversial question of their potential carcinogenic qualities when administered over long periods. I think it also obvious, from what I have written above, that such preparations should not be used except under the guidance of the patient's physician, who has knowledge of her underlying conditions and of the exact quantities of oestrogen he is prescribing.

There is little doubt that the sale of hormones in shops dealing with cosmetics, and their increasingly widespread

use, is giving rise to considerable anxiety, and that the problem will probably come up for evaluation and guidance under proper auspices. The writer has evidence that disturbing effects are met with, but are usually not reported. He also happened to be a member of a research committee during the war when the question of increasing the milk supply by the administration of oestrogens to cattle was being considered, and the question of the minute amount excreted in the milk was investigated. Contrary to the impression of some clinicians, the very minute amount present in a pint (570 ml.) of milk from an oestrogen-treated cow was sufficient to cause menstrual disturbances in a proportion of a group of female medical students who volunteered to undergo trials for this purpose. The oestrogen for these trials was not administered in milk, but an equivalent amount was given as a tablet.

Repetition of Gold for Rheumatoid Arthritis

Q.—How often can courses of gold for rheumatoid arthritis be repeated? A patient has had gold (1 g. on each occasion) in 1940, 1949, and 1950 with some benefit. Is a further course indicated?

A.—Gold is a cumulative drug, but, provided adequate time is allowed for elimination between courses, there is no reason, in the absence of toxic reactions, why courses should not be repeated indefinitely. In the present instance it would seem to be the correct procedure. It is true that in many cases the benefit produced by the initial courses does not seem to be so well reproduced on subsequent occasions. This has led certain workers to advocate the principle of a maintenance dose every few weeks, more or less indefinitely, instead of courses separated by prolonged intervals. One patient who has been satisfactorily maintained in this way for over fifteen years is known to the writer.

Psychological Factors and Myopia

Q.—Two children, now aged 10 and 11, a brother and sister, have during the last three years suffered from rapid deterioration of their myopia. From the psychological aspect the home environment is highly unsatisfactory. Could this play any part in the deterioration of the children's sight?

A.—Increase in the amount of myopia during the years of active growth is usual, and there is no known method of preventing such increase. The rate of increase varies among different patients, but tends to be greater in those who display myopia during early childhood. Psychological instability would not be likely to aggravate myopia. Children with more than a dioptré of myopia should wear glasses habitually. Otherwise they miss many beautiful and interesting images during their most impressionable years. Parents should never make depressing remarks about the disadvantage of glasses in the presence of their short-sighted children. Such disadvantages are far outweighed by the handicap of blurred vision, because blurred vision tends to produce clumsiness and lack of confidence.

Pock Marks

Q.—What can be done to improve the appearance of a patient whose face has been badly disfigured by smallpox?

A.—The problem of improving the appearance of a face badly disfigured by smallpox or even by acne, which is often just as bad, is a very serious one. The essential difficulty is the pitted surface, and what can be done depends upon the depth and number of the pits. If the pits are single or grouped in such a way that they can be successfully excised, this would be the preferred method; but where they are evenly spread over the face, particularly on the nose, excision is impossible. In such cases, if the scars are not too deep and they do not involve the whole

thickness of the skin, considerable improvement can be effected by sandpapering the entire area. This would be equivalent to removing the surface layers of the skin as though a skin graft had been taken from it. For this operation a general anaesthetic is required. When the skin has healed after this somewhat drastic treatment it presents a smoother and more attractive surface. Much the same effect can be produced by performing a face-lifting operation in which the skin is undermined and stretched. These surgical treatments can be applied only occasionally, and it must be regretfully stated that the vast majority of cases of smallpox are not amenable to any form of treatment whatsoever. Cosmetics and various forms of make-up seem to make the condition more apparent.

NOTES AND COMMENTS

Cyclical Buccal Ulceration.—Dr. KATHARINA DALTON (London, N.22) writes: I note in "Any Questions?" (September 12, p. 634) the history given of cyclical buccal ulceration is typical of the premenstrual syndrome as described by Dr. Raymond Greene and myself in your issue of May 9 (p. 1007). The universally successful treatment of this condition is 50–150 mg. ethisterone daily, or failing this 25 mg. progesterone injections thrice weekly, in the last fortnight of the menstrual cycle. I believe it is the placental production of progesterone during pregnancy that accounts for the almost universal disappearance of this condition during pregnancy.

OUR EXPERT writes: One of the many views about cyclical buccal ulceration is to regard it as a manifestation of the premenstrual or menstrual tension state. It does not, however, respond to treatment as well as do other symptoms of this state, and for this and other reasons the view is not yet widely accepted. On the basis suggested by your correspondent, progesterone, as well as other pregnancy hormones, has been used in treatment for many years, and was advised in the original reply to the question. Ethisterone may be given as a substitute. Dr. Dalton has been fortunate in finding this treatment universally successful, for in the experience of the writer and most other observers it is helpful only in certain cases. Gonadotrophin appears more useful in some cases and oestrogens in others, while many show no beneficial response to any form of sex hormone therapy.

Anaesthesia for E.C.T.—Dr. H. PULLAR-STRECKER (Isleworth) writes: I do not agree with your expert's opinion ("Any Questions?" August 29, p. 520). It is the preparations that frighten the patient. Having a tooth out with no anaesthetic is all right for other people, but not so good for oneself or one's friends. The same applies for E.C.T.

Correction.—In the article entitled "Blood Transfusion Accidents" (August 15, p. 390) it was stated that the British Red Cross Society has donors on its panels available for giving fresh blood of all groups, at all hours, for planned or emergency work. We have been informed by the British Red Cross Society that these emergency facilities are available only from the Greater London Blood Transfusion Service of the British Red Cross Society.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Attitology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated. Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad. ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: Britmedads, Westcent, London. MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 4499. TELEGRAMS: Medisecra, Westcent, London. CARCINOMA OF THE FEMALE BREAST: CONSERVATIVE AND RADICAL SURGERY

BY

I. G. WILLIAMS, F.R.C.S., F.F.R.

Director of Radiotherapy Department, St. Bartholomew's Hospital

R. S. MURLEY, M.S., F.R.C.S.

Surgeon, Royal Northern Hospital and St. Albans City Hospital

AND

M. P. CURWEN, M.A.

Medical Statistician, St. Bartholomew's Hospital

"I have drawn the impression that in dealing with mammary cancer surgery meets with more peculiar difficulties and uncertainties than with almost any other form of the disease. The anatomical types are so numerous, the variations in clinical course so wide, the paths of dissemination so free and diverse, the difficulties of determining the actual conditions so complex, and the sacrifice of tissue so great, as to render impossible in a majority of cases a reasonably accurate adjustment of means to an end" (James Ewing, 1928).

In 1867 Charles Moore, of the Middlesex Hospital, introduced an extensive operation for the removal of a cancer of the breast. Since that time, through the labour of many surgeons, the operation of radical mastectomy has developed, until to-day Haagensen, after careful selection of cases, requires some five hours to ensure a complete dissection. The argument for radical surgery is simple: the only safety for the patient lies in the removal of every cancer cell from her body. By mechanical means the surgeon aims to remove what he cannot control, and there is no doubt that, with selection and extensive operation, survival rate has improved and local recurrence decreased. The advent of radiotherapy had a double effect on the management of the "operable" cancer of the breast: first, it delayed the full study of Beatson's (1896) observations on breast cancer; secondly, its use as a supplement to radical surgery, by improving the survival rate when the disease has extended beyond the breast into the regional glands, has tempted surgeons to operate when the disease is perhaps too far advanced.

It was in 1922, at St. Bartholomew's Hospital, that Mr. Geoffrey Keynes, at the suggestion of Professor George Gask, began an investigation into the treatment of recurrent cancer of the breast with radium. Impressed by the results obtained, he extended the method to include advanced primary cancer, and, later still, operable cancer, for he was gravely dissatisfied with the results of the radical operation. In a series of papers Keynes (1927, 1937a, 1937b) recorded his experience with

conservative surgery and radium therapy. Primarily he hoped to mitigate or abolish the necessity for so drastic a form of treatment as the radical operation, which has a comparatively low absolute cure rate, and a definite morbidity in the form of oedema of the arm and limitation of movement at the shoulder-joint. As he gained experience Keynes maintained that, if the axillary lymph nodes are involved by growth, dissection of the axilla may be harmful, whilst if they do not appear to be invaded their dissection is unnecessary, provided radical irradiation is carried out in every case.

Anatomical investigation has shown no evidence for the centrifugal permeation of lymphatics by cancer cells. Keynes (1952) points out that Handley's work was done on pathological material taken from patients who had died of the disease, and that an abnormal state of affairs was taken as the basis for a system of treatment which was to be applied to all stages of the disease. It is only when the normal lymph channels are blocked that the cancer cell will seek out abnormal channels, such as those described by Handley. Some surgeons have been concerned lest, by dissecting the axilla, they open up pathways for the dissemination of the disease. It may, however, not be a question of opening up new pathways as much as the removal of normal pathways, leaving only abnormal ones for dissemination.

Death from cancer of the breast is almost always due to metastases transported by lymphatic or venous embolism. The recent work of Richard Handley (Handley and Thackray, 1947; Handley, 1952) has shown that, as well as the axillary glands, those along the internal mammary vessels are frequently invaded and can be regarded as immediate regional lymph nodes draining the breast. The internal mammary glands form one of the routes for intrathoracic and more distant spread, and lie outside the scope of the classical radical operation. In order to be successful, treatment must be carried out before the onset of distant metastases. Even in clinical stage I distant spread has already taken place in about 20% to 30% of patients, but once the axilla is invaded the incidence is much higher. In either stage,

if the addition of radiotherapy to radical surgery improves the results, it must be because irradiation has destroyed (or confined) cancer cells still remaining within the treated tissue. It can be argued that, in clinical stage I, radical surgery is too radical and that the chance of peripheral but still regional lymphatic spread can be met by full post-operative irradiation.

In stage II radical surgery can deal only with about one-third of cases successfully, and in the remainder the disease is already beyond the reach of the surgeon's knife. Keynes maintained that in these cases simple removal of the tumour, which may mean simple mastectomy, with simple excision of accessible lymph nodes and no disturbance of the axilla by dissection, together with full post-operative irradiation, would achieve the same result as radical mastectomy and irradiation without the morbidity of the larger operation. Indeed, if radical mastectomy exposes the patient to the risk of spread by abnormal channels the results of conservative surgery and irradiation may be better than those of more radical surgery. Surgery and radiotherapy balance each other in the eradication of cancer cells within a similar volume of tissue, and the scope of surgery can be decreased provided the radiotherapy is thorough. Actually the scope of radiotherapy is greater, for it can include the whole skin area from clavicle to costal margin and sternum to back. It can embrace the lymph nodes in the internal mammary region, the neck, the axilla, and the pathways and tissue planes in between. It can exert its full action only if anatomy and physiology have not been too seriously interfered with, and in skilled hands it can do this without risk of immediate morbidity.

Ewing pointed out many years ago that the radical operation was, on the one hand, performed too often on comparatively innocent growths, such as encapsulated adenocarcinoma, and localized duct cancers which may be ablated by simple mastectomy; and, on the other hand, on highly malignant forms of the disease which are invariably fatal. The good result in the first type of case is ascribed falsely to sacrifice of tissue, whilst in the other type of case the extreme limits of tissue removal will not save the patient.

The Present Investigation

The unique nature of the material available in the records of St. Bartholomew's Hospital for 1930 to 1939 inclusive suggested that a retrospective inquiry might be of real value in answering some of the problems of mammary cancer. During this decade a large number of cases were treated, chiefly by Keynes but also by the surgical professorial unit, by a method which was at that time considered highly unorthodox. In view of the continued dispute about the merits of radical and more conservative treatment there seemed to us to be a real advantage in comparing the results of these different methods of treatment during the same period of time, when conditions were more or less uniform. It must be recognized, of course, that certain problems may be answered only by a planned research, such as one in which alternate cases are allocated to different treatment groups. Nevertheless, it would hardly be justifiable to do this unless one had substantial evidence, such as we believe is provided by the present material, that the ultimate results are much the same for different methods of treatment.

Objects and Scope of Inquiry

We set out to analyse the results of treatment of all the new cases of primary carcinoma of the female breast seen at St. Bartholomew's Hospital during the years 1930-9

inclusive, but excluding cases sent on for radiotherapy after operation elsewhere. The main objects of the analysis were: (1) To endeavour to assess the relative merits of radical surgery and conservative surgery, together with radiotherapy in the treatment of cancer of the female breast. (2) To find out what part radiotherapy plays in the treatment, its effect on local recurrence rate, and its effects on survival. (3) To determine the morbidity of treatment, with special reference to oedema of the arm and the possible influence of radiotherapy. (4) To decide whether the radical operation justifies itself in terms of survival and morbidity. (5) Finally, if different methods of treatment have their special indications, to try to find out how the doctor may decide the best method for each particular patient.

From the total number of cases registered in the follow-up department, 182 patients from previous years with recurrent tumours were excluded, as were 102 cases operated on at other hospitals. In addition there were 60 cases for which the records were incomplete, and it was impossible to determine whether or not they should have been included. In all, 1,044 cases were available for analysis.

St. Bartholomew's Hospital, in common with other London teaching hospitals, draws its patients from a wide and indeterminate area. The existence of a large radiotherapy centre has probably been the reason for the greater number of advanced cases than is seen in most series, but otherwise there is no reason to suspect any particular selection. Once referred to the hospital, all malignant cases were registered in the follow-up department.

Follow-up and Method of Inquiry

Of the 1,044 cases all but 30 (2.9%) were followed up, either by frequent examination at the out-patient department or by postal inquiry, until May, 1951, or the time of their death. This has enabled ten-year survival rates to be calculated for the whole series, and fifteen-year rates for those registered during the six years 1930-5.

Apart from registration in the follow-up department no uniform methods of recording were used, and the only material available for study has been the routine clinical notes taken by students, house-surgeons, registrars, and consultant staff. All the records were scrutinized by two of us (I. G. W. and R. S. M.) during a period of five months in 1952, the most important details being transcribed on to special forms from which Hollerith cards were punched.

Clinical Staging.—Many of the cases had been staged at the time of first diagnosis, but as uniform methods had not always been used all were staged afresh from such information on the clinical condition as was available. The method used was a modification of the so-called "Manchester" system.

Stage I.—The tumour is freely mobile on muscle or chest wall. Ulceration or involvement of the skin must be no larger than the primary tumour and directly in continuity with it.

Stage II.—There are now palpable lymph nodes, considered to be metastases, in the axilla of the same side.

Stage III.—The primary growth is larger, and is now fixed to muscle but not to chest wall. Skin involvement can be wide of the primary tumour but is still over the breast. Axillary glands, if infected, must be mobile.

Stage IV.—The growth has extended beyond the breast and immediate regional lymphatic glands. Fixation of axillary glands or fixation of the primary to the chest wall places the tumour in stage IV.

The distribution by clinical stages for the whole series is shown in Table I.

TABLE I

	Clinical Stages				Unstaged	Total
	I	II	III	IV		
No. of cases	339	302	286	106	11	1,044
%	32.5	28.9	27.4	10.2	1.1	

General Features of the Series

Age.—The age distribution of the whole series was as follows:

Years:	0-24	25-34	35-44	45-54	55-64	65-74	75+	Not Stated	Total
Number	3	37	190	317	298	159	38	2	1,044
%	0.3	3.5	18.2	30.4	28.5	15.2	3.6	0.2	

This follows the familiar pattern with nearly 60% of cases falling into the group 45-64. Over the age of 65 there were perhaps fewer cases than appear in most comparable series—for example, 18.9% compared with 29.0% given by Harnett (1948). The proportion of single women was 21%, and this agrees with other published series. There were three cases of lactation carcinoma, and in four cases

Fig. 1.—Distribution of clinical stages according to age. Eleven cases with stage unknown and one other case with age unknown are excluded.

the disease was diagnosed and treated during pregnancy. Fig. 1 shows the distribution of clinical stages for the different age groups. Of women aged less than 45 about 70% had tumours which were in clinical stages I and II, whereas at all ages from 45 to 75 the corresponding proportion was about 60%. There were only 38 women aged 75 or more, and half of these were in stages I and II.

Site of Tumour.—The site of the tumour in the breast was recorded in all but 26 cases, although the quadrant was not always specified. Fig. 2 shows the percentages occurring in the four quadrants and also of those simply recorded as "upper," "lower," "inner," or "outer." In 8% of cases the tumour was described as central, and 12% of cases the whole breast. Exact comparison with other series is made difficult by the absence of precise definitions. For the purposes of later analysis all inner and all outer tumours have been grouped together, other sites being, for this purpose, ignored. Of the 502 outer-half tumours, 37% fall into stage I and 35% into stage II. The corresponding figures for the 182 inner-half tumours are 46% and 29%. Simultaneous bilateral tumours were recorded in eight cases, giving a slightly lower proportion than has been noted by other observers. For the rest of the series the excess of left-sided

over right-sided tumours was 11%, a figure that agrees closely with those cited by Nohrman (1949). Among these were 37 (4%) in which the other breast was, either previously or subsequently, the site of a carcinoma; but there is, of course, a possibility of confusion between some of these cases and the true simultaneous tumours.

Fig. 2.—Distribution of tumours by site. The narrow sectors indicate the proportions of tumours recorded simply as "upper," "lower," etc. The percentages are calculated from the whole series less the 8 cases with bilateral tumours and the 26 for which no exact site was recorded.

Length of History.—Were it possible to obtain accurate information of the time when the lump in the breast first appeared it might be possible to calculate some sort of index of growth rate, or essential malignancy for each tumour. But, in the nature of things, such information is unobtainable, and all we can give is the length of time for which the patient can remember symptoms. This length of history is naturally correlated with the clinical staging, as is shown in Table II, but not to such an extent that all difference in

TABLE II.—Clinical Staging and Length of History

Length of History (To Nearest Month)	No. of Cases	Distribution by Stages			
		I	II	III	IV
1 month	117	40%	41%	13%	6%
2 months	122	40%	34%	18%	7%
3 months	107	37%	26%	24%	12%
4-6 months	222	39%	28%	25%	8%
7-11 months	230	23%	29%	33%	15%
1 year	118	25%	26%	40%	9%
2 years	93	31%	21%	40%	8%

This table excludes 33 cases with unknown length of history and two other unstaged cases.

staging can be explained in this way. For example, 19% of the 117 patients with only one month's history of symptoms were in stages III or IV by the time that they were seen, whilst of the 93 women who claimed more than two years' history no less than 31% were still in stage I.

Pathological Grading and Staging.—Histological reports were usually available, but it was clear that any attempt to grade the tumours from the reports alone in the manner suggested by Bloom (1950) would not be justified. It was not found practicable to study the original sections. It was, however, recorded whether or not the axillary glands had been invaded, and this will be referred to as the pathological staging. Pathological reports were available in 448 of the 505 cases in which the axilla was dissected, and Table III

TABLE III.—Clinical Staging and Gland Involvement

Stage	No. of Cases with Axillary Dissection	No. of Cases with Histological Reports	Percentage Reported as Having Glands not Involved
I	184	164	71%
II	202	180	23%
III	103	93	17%
IV	13	11	—

This table includes all cases subject to radical or modified radical surgery, other than three unstaged cases.

shows the results according to the clinical staging. It will be seen that for stage I the clinical assessment was upheld by the pathology report in 71% of cases, whilst in the remaining 29% the clinician had been unable to detect an involvement which was later proved to be present. In stage II, on the other hand, there were 23% of cases in which the clinician reported gland involvement which the pathologist was unable to confirm. It is perhaps interesting that whereas, as has been shown, there is an appreciable association between length of history and clinical staging, there is no such clear association between length of history and gland involvement. This may be seen from the following analysis. If we take the 428 cases in clinical stages I, II, and III (omitting the few for whom the length of history was not given), the following percentages are the proportions of cases in each stage with a length of history of six months or more: Stage I, 43% (161); Stage II, 54% (177); Stage III, 64% (90). If these same cases are now divided according to the histological reports we have: Glands free, 51% (170); involved, 52% (258), the figures in parentheses being the numbers of cases on which the percentages are based.

Methods of Treatment

The methods of treatment used in this series are shown in Table IV; there were three main surgical treatment groups: simple surgery, radical surgery, and modified radical surgery.

TABLE IV.—Methods of Initial Treatment for the Whole Series

	With X Rays	With Radium	Without Irradiation	Total
Simple surgery	70	101	58	229
Radical	147	7	184	338
Modified radical surgery	51	70	46	167
Without surgery	114	149	47*	310
Total	382	327†	335	1,044

* Untreated cases. † Includes two cases treated with radium and x rays.

cal surgery. Each of these three groups is further subdivided into surgery alone, surgery with x rays, and surgery with radium. A few of the cases treated initially by simple surgery had more extensive operations at a later date, but the figures in the Table refer only to the primary treatment and not to any subsequent operations or irradiation.

Simple Surgery.—This group comprises 229 cases, 58 being treated by operation alone, 70 by simple surgery and x rays, and 101 by simple surgery and radium. The operation was confined to simple excision of the tumour in 127 cases and the remaining 102 had a simple mastectomy. Two-thirds of the cases were under the care of Keynes or the surgical professorial unit. In the earlier years Keynes tended to do local excision of the tumour, but the occasional occurrence of carcinoma elsewhere in the breast led to his adoption of simple mastectomy in most cases. Ten of the 127 simple excision cases had more radical surgical treatment at a later date; these include one modified radical operation four months after local excision and x rays, and three modified radical and six radical mastectomies from one to thirteen years after simple excision and radium treatment. Even after excluding these ten secondary operations for persistent or recurrent disease it should be noted that more than half the cases in the simple surgery group were treated by the minimum of surgery.

Radical Surgery.—Radical mastectomy with or without irradiation was performed as the initial method of treatment in 338 cases—that is, in 32% of the whole series. Fig. 3 shows that the proportion remained fairly steady throughout the whole 10 years. A study of the case records of those treated by radical surgery and knowledge of the practice of individual surgeons indicate such variations in surgical technique as one would expect among different operators. (The operations were done by 12 members of the consultant staff and their chief assistants and also by the professorial staff.)

Modified Radical Surgery.—This is the descriptive title used for simple mastectomy and axillary clearance without removal of the pectoral muscles. A special group of 70 cases treated by modified radical mastectomy by the surgical professorial unit formed a research series which has been reported by Professor Sir James Paterson Ross (1938). This

FIG. 3.—Crude five-year survival rates for cases registered each year, compared with percentage of cases in clinical stages I and II.

was an almost consecutive series of cases in which mastectomy followed radium treatment after an interval of three months in 50 cases and of six months in the remainder, and the operation was done with the object of providing material evidence of the effects of irradiation rather than as a method of treatment *per se*. This series is too small to permit any definite conclusions about the value of this form of combined treatment. The reasons for performing this operation were not often given in the records of the remaining cases, but sometimes it was done in elderly or less fit patients in whom the radical operation was considered too severe. It is an operation which provides fuller pathological data than simple mastectomy, but it is doubtful whether there is any direct therapeutic advantage.

Irradiation

Radium treatment alone was used initially in 149 cases, but subsequent simple mastectomy was done in 13; radical mastectomy in 7, and modified radical mastectomy in 5. About a quarter of those treated by radium alone were in stage I, but as the diagnosis was not always confirmed by biopsy one must be cautious in assessing the results for radium treatment alone.

Simple surgery and radium were combined in the treatment of almost half the cases dealt with by limited surgery. The technique of radium therapy was that described by Keynes (1929, 1932), and it will not be further discussed here. Radium was combined with radical surgery in seven cases, all of which were treated in the earlier part of the decade under review, when x-ray methods were still being developed.

X-ray treatment alone was reserved chiefly for advanced cases, and only 6% of this group was in stage I. Rarely was the diagnosis confirmed by biopsy. X rays and simple surgery were used less often than the combination of radium and simple surgery, although, in the light of experience, the former method gradually became more popular.

Radical surgery and x-ray therapy, generally post-operative, was used in almost half the radical mastectomy cases. Dosage was in the region of 4,000 r minimum, during a period of four weeks, directed to the chest wall, axilla, and

supraclavicular regions. In 15 cases the treatment was given pre-operatively, the usual reasons being either a large growth or advanced disease. With so many different surgeons at work and in the absence of any well-defined criteria for x-ray treatment, it is not possible to give any clear indication of how cases were selected for irradiation. Towards the end of the period under review some surgeons were tending to refer all patients for post-operative radiotherapy, but in general those irradiated included a higher proportion of less favourable cases. Fig. 3 shows how the combination of surgery and irradiation became increasingly popular, the proportion thus treated being 18% in 1930 and 60% in 1938, although it fell to 48% in 1939.

Untreated Cases.—Of the 47 untreated cases 14 were in stage III and the remainder in stage IV. Only two patients in the whole series refused all treatment.

Assessment of the Results of Treatment

Discussion has raged for many years regarding what is the most appropriate way to measure the results of treatment of cancer of the breast. A whole battery of statistical and actuarial techniques has been introduced, but in spite of this there is still no general agreement on the fundamental question of how long, if at all, life is prolonged by any form of treatment. Greenwood (a pioneer in this field) asserted (1926): "The expectation of life of a woman with untreated cancer of the breast is 3.25 years. The expectation of life of a woman operated on under 'average' conditions is 5.74 years and of a woman operated on under the best conditions is 12.93 years." His analysis may seem somewhat naive to our present way of thinking. At the other extreme we have Park and Lees (1951): "It has not been proved that the survival rate of cancer of the breast using the five-year survival rate as an index is affected by treatment at all."

This is not the place to discuss the statistical problems involved, for we are concerned in this paper only with the relative results of different forms of treatment: in choosing the statistical method most appropriate to our purpose our chief requirements are: (1) that the method chosen should be simple to use and understand; (2) that it should be reasonably sensitive; and (3) that it should allow for any gross bias introduced by selection between the groups.

The method we have adopted is to express our results in terms of five- and ten-year survival rates calculated separately for the different stages and adjusted by Berkson's (1942) method to allow for variations in the age distribution. Fifteen-year survival rates have also been calculated for the 600 cases registered from 1930 to 1935.

Recent observers are agreed that staging, whether assessed clinically or pathologically, is the most important single factor in prognosis. This is clearly demonstrated by Fig. 3, in which are plotted: (i) the crude five-year survival rates for all cases registered in each of the years 1930-9, and for all cases registered in each of the years 1930-9, and (ii) the percentages of stages I and II cases among each year's registrations. It will be seen that the two graphs have an almost identical pattern. (The other graphs plotted on this diagram have been referred to already.) The survival rates for the different stages are so different that little or no useful information can be gained from a study of figures in which no distinction is made between them. Even methods of standardization, such as that recommended by Park and Lees (1951), are open to serious disadvantages.

In using time of survival as an index of the success of treatment it is clear that no satisfactory comparison can be made without taking age into consideration. For example, in 1931 the expectation of life of a woman of 40 was about 32 years compared with only 10 years for one of 70. This difficulty is particularly important in a disease like carcinoma of the breast, where there is a relatively high survival rate even at 10 years. One solution of the problem is to confine analysis to those actually dying of cancer; if all patients lived and died under the care of the hospital where they were first treated this might be the ideal solution, but in practice it leads to difficulties. We have preferred, there-

fore, to use the method first proposed by Berkson and now adopted by W.H.O. (1950)* for the purposes of international comparisons.

For any group of people of known ages it is possible to calculate the number who may be expected to be alive after a given number of years, assuming that they are subject to the normal mortality experience of the whole country as expressed on the Registrar-General's Life Tables. We can therefore define the crude and adjusted rates as follows:

$$\text{Crude rate} = \frac{\text{No. alive and traced after } n \text{ years}}{\text{No. originally registered}} \times 100$$

$$\text{Adjusted rate} = \frac{\text{No. alive and traced after } n \text{ years}}{\text{Expected No. alive after } n \text{ years}} \times 100$$

It will be seen that no allowance is made for the possible survival of any of the untraced cases.

The chief advantage of this method is that it is entirely objective, but one disadvantage is that it is effective only for groups of such a size as to even out chance fluctuations in the number of deaths due to intercurrent disease. The effect of the adjustment is illustrated by the following figures, showing the crude and adjusted rates for two age groups:

		10-year Survival Rates	
		Crude	Adjusted
Stage I cases	Ages 0-44	45%	48%
	" 65-	22%	49%

When comparing treatment groups there was not as much difference as this between the crude and adjusted rates, for there were no very great differences in the age distributions of the groups under consideration. Nevertheless the adjustment is certainly worth making when ten- or fifteen-year rates are being used.

Another problem that has to be solved is that of defining the groups for which survival rates shall be calculated. There are so many factors, such as age, stage, and site, as well as variations in surgical and non-surgical treatment, that it would be impossible from a series of the size available to a single hospital to split up the figures in such a way as to enable the effect of all these factors to be sorted out. In order to get any results at all a fairly drastic grouping has to be accepted—the more so since, as has been said, it has been felt necessary to give all results separately for the four clinical stages. But to ensure that no important effect has been masked by such grouping, we have in most instances examined the figures in greater detail than can be shown here.

In the following analysis no mention is made of the statistical significance of the results. In a retrospective survey of this kind formal tests of significance are often most misleading. Little is known of what selective factors may have been at work, and the very methods of grouping introduce a highly subjective element into the calculations; it is often possible to change a "significant" into a "not significant" result merely by making an arbitrary change in the classification. All we shall do is to present the survival rates we have calculated and draw such tentative conclusions from them as we feel able.

* The formula given by the W.H.O. report is as follows:

$$\text{Corrected survival rate} = \frac{1}{p} \times (\text{crude survival rate})$$

where p is the probability of not dying within a comparable period from any cause other than cancer of the site in question, in a population having the same age distribution as the patients comprising the group. The report points out that for most sites p does not differ appreciably from the probability of not dying from any cause, and although the female breast might be regarded as one of the sites where the distinction should be drawn, we have not felt it necessary when using the adjustment only for internal comparisons. Our definition is equivalent to the W.H.O. formula, but defining p as the probability of not dying from any cause.

The W.H.O. report does not recommend a method of calculating p , and there is some variation of practice in the matter. To calculate the expected number of survivors we have used the values for women of ${}_0p_x$, ${}_{10}p_x$, and ${}_{15}p_x$ derived from English Life Table No. 10 (1930-2) (and kindly supplied by the General Register Office). For our purposes it has been sufficiently accurate to use ten-year age groups for the calculations.

FIG. 4.—Percentages dead and alive based on whole series (1–15 years). (The dotted line indicates the expected survival of a normal group with similar age distribution based on Life Table for 1931.)

Although it is not our object to discuss the overall results of the series, it may be of interest to give them in the form of Fig. 4; this shows the crude survival rates for the whole series (including untreated cases) from one to ten years and for the 600 cases registered between 1930 and 1935 from 10 to 15 years. The numbers recorded as dying of recurrent disease and those untraced are also shown.

Results of Treatment

In presenting results we have compared the survival rates for the different types of surgical treatment—that is, simple, radical, and modified radical surgery—and also those for surgery alone and surgery with irradiation. The number of cases in each of the various subgroups shown in Table IV is generally too small for any comparison of the results obtained, with the possible exception of radical mastectomy. In Fig. 5 the results are shown for five main treatment

the survival rates are almost of surgery.

In assessing these results it should be remembered that the simple surgery group includes 127 cases treated by simple excision of the tumour. Only 10 of these subsequently had a more extensive operation, and the other 117 cases were therefore treated by an operation which most surgeons would regard as quite inadequate. The fifteen-year adjusted survival rates (calculated from the 600 cases registered between 1930 and 1935 inclusive) were 42% for simple surgery, 42% for radical surgery, and 37% for modified radical surgery, the crude survival rates being 28%, 27%, and 26%. We must conclude from these figures that the results for simple surgery are as good as those for radical surgery.

Surgery Alone and Surgery with Irradiation.—Radiotherapeutic technique was developing during the decade in question, and it may be that the selection of cases was not

groups, the various subgroups being ignored. The simple, radical, and modified radical surgery groups include all cases treated by these methods regardless of whether irradiation was also given. The last two groups—surgery alone and surgery with irradiation—include all surgical cases irrespective of the type of operation done. Full details of the various subgroups are shown in Table V to supplement the information given in Fig. 5.

Simple Surgery and Radical Surgery.—Fig. 5 shows that at the five-year follow-up the adjusted survival rates in stage I are slightly in favour of simple surgery, but that this trend is reversed at ten years. Modified radical surgery shows a lower five-year and a higher ten-year survival rate, but there are only 37 cases in this group. In stage II cases identical for the three types

such as to allow the benefits of radiotherapy to be clearly demonstrated. Fig. 5 shows that the five-year survival rates in stages I and II were practically the same for all surgery alone and all surgery with irradiation. The ten-year survival rates were, however, slightly higher for surgery with irradiation in both stages. Fuller details of the subgroups are given in Table V, where it will be seen

that radical mastectomy with irradiation gave slightly better survival rates than radical surgery alone in stage I at five- and ten-year follow-up. The results were also better at ten years in stage II. However, in both cases the numbers were small, and it is impossible to draw firm conclusions.

Value of Clinical and Pathological Staging

It is commonly assumed that pathological staging is superior to clinical staging in the assessment of prognosis, but it would be better to say that the methods are complementary. In those cases in which the axilla is not dissected the staging must necessarily be clinical, and even where the axilla is dissected the pathological examination of the axillary glands is, as Handley (1952) has shown, by no means the last word. The margin of error in clinical staging has already been referred to; but, despite this, there seems reason to believe that clinical assessment of the axilla may offer a more accurate clue to prognosis than might be expected. Table VI shows the five- and ten-year survival

TABLE VI.—Gland Involvement: Five- and Ten-year Adjusted Survival Rates for Cases in Stages I–III after Radical or Modified Radical Surgery.

	Stage I		Stage II		Stage III
	Glands Free	Glands Involved	Glands Free	Glands Involved	All Cases
No. of cases	117	47	42	138	103
5-year survival rate	78%	52%	51%	37%	14%
10-year survival rate	67%	25%	29%	22%	5%

There are not enough cases in Stage III with glands free to enable separate figures to be given (see Table III), but overall rates are included for purposes of comparison.

rates for 447 cases, treated by radical or modified radical mastectomy, in which a pathological report on the axillary glands was available. The cases in clinical stages I and II are subdivided into those with glands free and those with glands involved. The second and third columns of figures in this table represent, therefore, those cases in which the clinician was wrong in his assessment of the axilla.

The lower five-year and ten-year survival rate in stage I with glands involved as compared with stage I cases with glands free is readily understandable. It is, however, less easy to comprehend why stage II with glands free should show the same survival rate as stage I with glands involved. This might be regarded as just a strange anomaly in our figures, but a similar state of affairs is indicated in a table of Smithers (1952), on which no comment is offered in the text.

FIG. 5.—Adjusted five-year and ten-year survival rates for surgical cases (stages I and II only). The figures in parentheses are the numbers of cases from which the survival rates are calculated.

The practical importance of this finding would seem to be that, in those cases in which the clinician believes the axillary glands to be involved, the prognosis may be much the same, regardless of whether the diagnosis is confirmed pathologically. The high incidence of reactive hyperplasia in the axillary glands of breast carcinoma cases is, of course, well recognized by pathologists. The cause of the reactive hyperplasia which produces the enlarged but cancer-free glands is not known, but Professor Hadfield (1952, personal communication) believes that it may be related to the microscopic foci of necrosis throughout the tumour. Whatever the explanation of this interesting finding may be it does seem to be a matter worthy of fuller attention and investigation, for its relationship to a more serious prognosis is not explicable in terms of orthodox pathology.

Apropos of clinical staging, it is perhaps important to recognize that a clinician is more likely to detect a just palpable axillary gland and to examine the patient more carefully if the primary tumour is a large one. It is likely that this factor—that is, the size of the tumour—explains some of the difference in prognosis in these cases, but it will not adequately explain the similar prognosis for stage I cases with glands involved and stage II cases with glands free.

Site of Tumour and Prognosis

Several published reports (Perry, 1925; Truscott, 1947; Smithers, 1952) have recorded lower, but not significantly lower, five-year survival rates for growths in the medial half of the breast.

For our series, as shown in Table VII, the five-, ten-, and fifteen-year survival rates in stage I were much the same

TABLE VII.—Lateral and Medial Tumours: Five-, Ten-, and Fifteen-year Adjusted Survival Rates for Surgical Cases in Stages I and II.

	Stage I		Stage II	
	Lateral	Medial	Lateral	Medial
Whole series:				
No. of cases	159	71	136	41
5-year survival rate	73%	70%	47%	38%
10-year survival rate	52%	53%	29%	25%
1930–5 series:				
No. of cases	94	39	82	19
15-year survival rate	42%	43%	28%	(15%)

for tumours in medial and lateral halves of the breast. In stage II cases, however, the survival rate was slightly lower for tumours in the medial half of the breast; but this is only what might be expected, since a medially situated tumour with axillary glands palpable is likely to be at a

TABLE V.—Adjusted and Crude Survival Rates for Stages I–III According to Method of Treatment

Radium	137	38	75 (66)	56 (42)	49	30 (27)	19 (14)	50	19 (16)	3 (2)			

(a) The following cases are omitted from this table: 106 cases in Stage IV, only one of whom survived 5 years; 11 unstaged cases, whom survived 5 years; 11 unstaged cases.
(b) Survival rates for subgroups containing fewer than 25 cases are not shown.
(c) The crude survival rates are shown in parentheses.

more advanced stage of its development than a laterally situated tumour with palpable glands. Handley (1952) has shown that the internal mammary lymph nodes are invaded in 60% of cases with medial tumours, and in only 19% with lateral tumours, and on this evidence one would anticipate a worse prognosis for those patients with medially situated tumours.

Despite the greater ease with which the medial growth may reach the mediastinum our own figures would suggest that, in the absence of palpable axillary glands, prognosis is no worse for a tumour in the medial half than for one in the lateral half, and this is a point of some importance to the clinician faced with the daily problems of breast carcinoma.

Length of History and Prognosis

It may be asked whether we can demonstrate from our figures that delay in seeking advice worsens the prognosis. This is a most difficult question and one that obviously cannot be answered directly. In so far as longer history is associated, as we have shown, with tumours of a more advanced stage, which undoubtedly have a worse prognosis, then the answer is clear. A more detailed analysis, for which there is not space here, seems to show that for tumours of a given stage (as assessed both clinically and pathologically) the ones with a long history do no worse or better than those with a short history.

Mortality and Morbidity of Treatment

Mortality.—Four out of 338 patients died after radical mastectomy, a mortality of 1.2%. Three of these four deaths were due to massive pulmonary embolism. Of the 167 patients undergoing modified radical mastectomy only one died. One died after simple excision of the tumour and three after insertion of radium needles. Two of these last five deaths were due to massive pulmonary embolism, and two were due to pulmonary infarction following repeated embolism. Of the nine deaths in the entire series seven were therefore due to thrombo-embolic complications, with five deaths due to massive embolism.

Morbidity.—In the course of the analysis the question of treatment morbidity was investigated, special attention being directed to the problem of the swollen arm, limitation of shoulder movement, radionecrosis, and brachial plexus palsy. The first of these complications was the one in which we were most interested, particularly in trying to determine what part extensive surgery and radiotherapy play in its production. The true incidence of some complications may well have been higher than the notes reveal, and the severity of such a complication as oedema cannot be accurately estimated. It is possible that some of the original observers may have been more punctilious in recording the complications after certain methods of treatment. Notwithstanding all these factors, we believe the information collected to be of value.

Oedema of the Arm.—Surgeons are shy to admit responsibility for this complication and the radiotherapist is often blamed. Some surgeons indeed claim that they rarely see this complication after surgery alone. In Table VIII is

TABLE VIII.—Incidence of Post-operative Oedema

	Total No. of Cases	Cases of Oedema	
		No.	%
All surgery	734	87	12

With primary healing	84	20	24
" sepsis or sloughs	65	13	20
" haematoma			

* With or without irradiation.

There were 78 cases with no record of the healing of the radical wound.

shown the incidence of oedema of the arm following different methods of treatment. The three different types of surgical procedure are listed irrespective of whether irradiation was also given, the proportion of irradiated cases being not greatly different in each group. There is no doubt about the significance of the lower incidence following simple surgery. In comparing the results for all methods of surgery alone with all methods plus irradiation the incidence of oedema of the arm is 12% in each group. A further factor of some importance in causing oedema of the arm is sepsis at the operation site; this was emphasized by Halsted (1921) many years ago. Table VIII also shows how the incidence of oedema of the arm was related to healing of the wound after radical or modified radical mastectomy. Oedema was twice as frequent in those cases developing haematoma, sepsis, or slough as those with uncomplicated healing.

Recurrences in the Treated Area

Among the whole series there were 297 (28%) for whom local recurrences were recorded; of these, 53% were in the first year, 74% within the first two years, and 91% within the first five years.

In analysing the incidence of local recurrences there are considerable difficulties. First there is the question of definition. We have not always found it possible to distinguish, from the records, between a tumour persisting after conservative treatment and a true local recurrence. In a retrospective inquiry there is clearly no way out of this difficulty. Then there is the problem of how to express the figures themselves. Smithers *et al.* (1952) recommend the use of the "recurrence-free rate," which is the percentage at any time who are alive and have suffered no local recurrence. This method does not, however, take into account the time of onset of the local recurrence, making no distinction, for instance, between two patients, both surviving for five years, one of whom has a recurrence in the first and the other in the fifth year.

Our somewhat tentative solution to this problem has been to devise a ten-year local recurrence index, which is defined as follows:

$$\text{Local recurrence index} = \left(1 - \frac{\text{Total completed recurrence-free years}}{\text{Total completed years of survival}} \right) \times 100$$

In calculating both these totals only the first ten years after treatment are taken into account; recurrence-free years are those between treatment and the onset of the first recorded local recurrence, irrespective of whether it was cured. An advantage of the index is that it is largely independent of the actual survival rate, and it is therefore possible to compare groups in which the proportions of the clinical stages are not the same.

Table IX shows the number of cases of local recurrence recorded after each form of treatment and also the local recurrence index. The high figures for x-ray and radium treatment are no doubt partly due to the confusion of persisting tumours with local recurrences. So far as the other methods are concerned, it will be seen that the lowest

TABLE IX.—Local Recurrences in Stages I-III

indices are for radical surgery, and that the addition of radiotherapy seems to have no appreciable effect.

All this is, however, somewhat speculative, and we should be unwilling to base any firm conclusions on these figures. The method is presented partly with the object of stimulating comment and criticism, for the subject is one that seems to have been neglected. Not only should consideration be given to the theoretical aspects of this problem, but, more important, a large series should be followed up with the specific aim of discovering the usual pattern of local recurrences and their effect on survival. We believe that, while the treatment of local recurrences may rid the patient of an obvious focus of disease, it may not in most cases be a means of prolonging life.

Discussion

The present series represents a group of cases treated long enough ago for us to be able to assess the long-term results. The fact that radiotherapy technique was neither so highly developed nor so widely accepted as at the present time suggests that the results obtained then should be bettered to-day.

The most impressive finding in this series is the remarkable similarity in survival rates following different methods of treatment. All the main treatment methods analysed seem to have been equally effective in stages I and II. It must, however, be frankly recognized that all methods of treatment may have been equally ineffective in prolonging life. While properly applied treatment has great palliative value it is important to ask to what extent treatment has affected survival. The only truly curable cases are those in which there is no distant spread at the time of the initial treatment, and complete eradication of the disease is probably not often achieved.

The advocacy of conservative surgery and radical radiotherapy by McWhirter (1948), although it has not yet met with universal approval, has encouraged many surgeons to take a much more critical view of their results. Some have been slow to appreciate the fact that the best results of radical surgery are due to selection of the most favourable cases, and it has not been easy for such people to accept a less radical doctrine. Great credit is due to McWhirter and the surgeons of the Edinburgh school, who have given the more reluctant amongst us the opportunity of watching a bold experiment. Even greater credit is, however, due to Geoffrey Keynes, who had the courage to adhere to a method of treatment which, 20 years ago, was regarded by most surgeons as totally inadequate.

The advocates of radical mastectomy, while conceding the point that a grossly diseased axilla is not benefited by dissection, believe that a real advantage accrues in those patients with minimal axillary gland involvement. But is this really so? Is it not possible that axillary and internal mammary lymph node involvement are of equally serious significance, and that, despite the seeming accessibility of the former, in neither instance is the disease truly curable? If this is in fact true, it may be the main reason why the results of simple surgery compare so favourably with those of the more radical procedure. The supporters of radical mastectomy may have attached too much importance to the removal of the axillary glands. Does their accessibility justify the assumption that their removal is advantageous to the patient? The possible advantage of axillary dissection in those patients with low axillary gland involvement may be offset by the frequent occurrence of extensive axillary disease which even the most experienced surgeon may not detect before operation.

The definite morbidity of radical mastectomy, and the fact that it seems to offer no greater survival rate, suggest that the time has come to ask whether this operation has more than a limited place in the surgeon's armamentarium. The only possible advantage we have adduced in favour of the radical operation is the lower local recurrence index when compared with simple surgery. However, many of the local recurrences in the simple surgery group occurred in those cases treated by simple excision of the tumour; and modern

radiotherapy and simple mastectomy might show up more favourably in this respect. It might be expected that a method of treatment which gives a low local recurrence index would also show a better overall survival rate. It is, however, possible that local recurrence *per se* is an infrequent source of distant metastases and that the appearance of the latter has been determined quite independently of the former. No firm decision can be given on this matter, and the subject is worthy of further investigation.

In the absence of facilities for modern radiotherapy it may be that the radical operation, confined to the most favourable cases, offers the best chance of cure and of preventing local recurrence.

Although we doubt the value of the radical mastectomy operation it is noteworthy that some surgeons, and more especially in the United States of America, have advocated even more radical operations involving removal of costal cartilages and excision of the anterior mediastinal glands. In our opinion such operations are unjustifiable and may in many cases be positively harmful to the patient. Some of the recent interest in this over-radical surgery has been due to the too literal interpretation of Handley's work by the enthusiastic surgeon. The anterior mediastinal glands are readily accessible to irradiation, and it would seem more reasonable to treat them in this way rather than to remove them by block dissection.

So far as the results of radiotherapy are concerned we are reluctant to draw conclusions from our own material. Owing to variations in technique during the decade in question, it has not been easy to show that radiotherapy increased the survival rate or lowered the incidence of local recurrence, although there are some indications that this was so. A carefully planned research would be necessary to elucidate this matter.

To determine a treatment policy suited to each individual type of case, although perhaps an ideal, is a difficult problem. Points about the case which are readily recognized after operation, and detailed examination of the pathological specimens, are not easily appreciated beforehand. To practise several variations in treatment is not always so easy or so logical as it seems. There are so many unknown factors to be taken into consideration that in these circumstances, and in the present state of our knowledge, a great deal can be said for simple mastectomy and radical irradiation in the majority of cases. Simple excision of the tumour and radiotherapy is a reasonable alternative in many elderly patients, and in some of the most careful clinical examination, supplemented by the necessary diagnostic x-ray investigation, should be continually emphasized as the only way to avoid unnecessary treatment for the patient with distant disease.

Summary

The purpose of the paper is to present an analysis of the results obtained in 1,044 cases of carcinoma of the female breast first seen at St. Bartholomew's Hospital during 1930-9.

Follow-up of all but 30 untraced patients was complete until May, 1951, enabling 10-year survival rates to be calculated for the whole series and 15-year rates for cases registered in 1930-5.

The distribution by clinical stages was as follows: I, 32.5%; II, 28.9%; III, 27.4%; IV, 10.2%; unstaged, 1.1%. Distribution by age and site of tumour was similar to that given in other published series.

Differences in clinical staging are not explicable only in terms of delay in seeking advice. Of cases with more than two years' history 31% were still in stage I, whilst 19% of those with a history of one month or less were in stages III and IV.

Pathological investigation of cases with axillary dissection revealed that the clinical assessment of the glands was wrong in 29% of stage I cases and 23% of stage II

We wish to express our gratitude to Mr. Reginald Vick, Mr. Geoffrey Keynes, Sir James Paterson Ross, and the other members of the staff of St. Bartholomew's Hospital who allowed us to undertake a study of patients who were under their care. Our thanks are also due to Dr. Christine Abernethy and Mrs. Perkins, who have both contributed to the completeness of the follow-up records, and to the staffs of the follow-up and statistics departments, on whom fell much of the routine work.

BY

AND

Consultant in Radiotherapy, London Hospital

The background of the cases must first be examined. The number of cases of breast carcinoma recorded with pleural or lung metastases from 1943 to 1950 was 159, and the number of cases with pleural or lung metastases, verified radiographically, was 127. Of these latter cases, oestrogens were prescribed in 61 and not prescribed in 66. The selection of cases for hormone administration was statistically random but not controlled. When the cases came to be analysed it was found that the proportion of cases of a younger age group was considerably higher in the untreated than in the treated group (Table VI). That this distribution did not influence the results is seen in the same table, where for each group the age of the patient was found to exert no influence on the length of survival. This fact is further commented on later.

TABLE I.—*Months of Survival in Treated and Untreated Cases*

Months Survival	Cases of Pleural Metastasis		Cases of Lung Metastasis		Total	
	T.	U.	T.	U.	Treated	Untreated
1-3	17	31	6	12	23 (5 still alive)	43 (all dead)
4-6	9	10	3	4	12 (4 " ")	14 (" ")
7-11	5	3	2	1	7 (2 " ")	4 (" ")
12+	9	4	10	1	19 (9 " ")	5 (" ")
Total ..	40	48	21	18	61	66

	Treated Group	Untreated Group
Died within 3 months ..	29.5%	65%
„ 4-11 months ..	21.5%	27.5%
Survival over 12 months ..	31%	7.5%
Still alive, 1-11 months ..	18%	—
	100%	100%

Mere survival over 12 months is unusual enough, in cases of lung metastasis, to the clinician who sees large

Fig. 1.—Numbers surviving month by month after diagnosis of metastasis. Untreated group, 66 cases.

FIG. 2.—Numbers surviving month by month after institution of oestrogens for metastasis;

TABLE III.—Regression of Pulmonary Metastases Following Oestrogens

Lesion	Total Cases	Cases Surviving 12 Months	Cases with Radiographic Regression
Lung metastases	21	10	7
Pleural " "	40	9	9
Total	61	19 (31%)	16 (26%)

months or more after oestrogen therapy include 10 out of 21 cases of lung metastases and 9 out of 40 cases of pleural metastases. In the former group 7 out of 10, and in the latter group 9 out of 9, showed radiographic evidence of regression of metastases. Such regression develops after two to four months in the majority, but in some cases there was evidence of new lung or pleural metastases after 12 months. There was evidence of regression of pulmonary metastases also in a further three patients who are still alive but who have not completed 12 months' survival. The total of cases showing radiographic evidence of regression is thus 16 out of 61 cases (26%). When we compare the untreated group we find that, although 5 cases out of 66 survived over 12 months, in no case was there evidence of regression of pulmonary metastases.

The dose prescribed was, in the main, either 2 or 20 mg. of stilboestrol daily, according to the random choice method advocated by the Oestrogen Research Committee set up by the British Empire Cancer Campaign and Royal Society of Medicine.

Table IV shows that of the 39 patients who had taken the drug for three months or more, 57% survived seven months or longer. Of the 22 taking the drug for two months or less, 18% survived over seven months. It would appear from these figures that with more prolonged administration of oestrogens the results are better. In spite of this it must be recalled that it was previously noted that regression of

TABLE IV.—Duration of Oestrogen Administered in Relation to Survival

Duration of Oestrogen	Total Cases	Cases Surviving over 7 Months
Over 3 months	39	22 (57%)
Less than 3 months	22	4 (18%)
Total	61	26

pleural effusion occurred in some cases after administration of oestrogens for two months. It must therefore be assumed that two months is adequate to establish a reaction capable of controlling the disease. It might be relevant to recall at this point that recognizable regression of soft-tissue metastases in breast carcinoma usually occurs after three months' administration of oestrogens (Stoll, 1950).

With regard to the optimal dose of oestrogen, it is seen from Table V that of the 26 cases receiving 2 mg. daily, 35% survived over seven months. This compares with 35 cases receiving 20 mg. daily, of whom 49% survived over

TABLE V.—Dose of Oestrogen in Relation to Survival

Dose of Oestrogen	Total Cases	Cases Surviving over 7 Months
2 mg. daily	26	9 (35%)
20 " "	35	17 (49%)
Total	61	26

seven months. The difference between the two groups is not significant, suggesting that the lower dose is sufficient to exert the maximal possible effect. This is in agreement with the effect of oestrogens on soft-tissue metastasis noted in the previous paper, but does not agree with some other authorities. Walpole and Paterson (1949) noted a better result with 20 mg. of dienoestrol or stilboestrol daily than with 1-2 mg. daily. It must be noted that the oestrogenic potency of dienoestrol is one-fifth that of stilboestrol, and thus the smaller dose of dienoestrol would be equivalent to about 0.25 mg. of stilboestrol daily—a dose which may be quite insufficient.

Effect on Concomitant Soft-tissue Metastases

In 29 of the treated cases there were signs of active growth involving the soft tissues—that is, skin or glands. In only eight of these cases were there signs of regression in these metastases, but five of these survived over 12 months in spite of pulmonary metastases. There is therefore some degree of correlation between the response of the two types of metastasis to oestrogens.

Survival in Relation to Age Group

As noted before, the proportion of cases of a younger age group was considerably higher in the untreated group than in the treated group. In order to assess what possible bias effect this might have on the comparison of the two series, Table VI was planned.

It is seen from Table VI that in the treated group the seven-months survivals in the under 59 and over 60 group

TABLE VI.—Survival in Relation to Age Group; Treated and Untreated Cases

Months Survival	Under 59 Group		Over 60 Group		Total	
	T.	U.	T.	U.	T.	U.
1-3	7	27	16	15	23	42
4-6	7	12	5	1	12	13
7-11	5	3	2	1	7	4
12+	6	3	13	2	19	5
Total	25	45	36	19	61	64*

* Plus two cases, age unknown.

are 44% and 42% respectively. In the untreated group the seven-months survivals are 13% and 16% respectively for the two age groups. There is thus no obvious difference between the age groups in the expectation of life in either treated or untreated groups, and therefore the inequality of the age distribution does not vitiate the value of the control series.

It is of interest to note that in the case of soft-tissue metastases there is generally agreed to be a notable difference between the under 60 and the over 60 age groups in their response to oestrogens. The Royal Society of Medicine symposium in 1944 quoted 14% and 40% regression respectively.

Possible Prophylactic Effect of Oestrogens

In spite of the proved value of oestrogens in the treatment of pulmonary metastases from breast carcinoma, there is no evidence that they exert any protective effect against the development of such metastases even during their administration.

In the period under review 147 patients for whom oestrogens were prescribed for breast carcinoma showed no evidence of pulmonary metastases at the time of prescription. In 41 of these pulmonary metastases developed at a later date (in 15 cases while the patient was taking oestrogens), in 13 within three months of stopping oestrogens, and in a further 13 more than three months after stopping oestrogens. While no prophylactic effect is shown by these figures, there is no suggestion that oestrogens can be incriminated as precipitating pulmonary metastases.

Discussion

Relevant to the regression of pleural effusions in these cases, associated with long-term survivals, it would be useful to discuss the other possible causes, apart from metastases, which might lead to such effusions. The main possibilities are (a) idiopathic effusion—usually tuberculous; (b) effusion as a reaction to irradiation of the thorax; and (c) hydrothorax as a complication of cardiac or renal disease. All these may lead to an effusion which can regress spontaneously.

The differential diagnosis of a malignant effusion depends on certain features. The effusion is said to be blood-stained, but this is not always so, because the fluid may be a transudate following pressure on the pulmonary veins by metastatic mediastinal glands. The presence of neoplastic cells in the fluid is diagnostic, but notoriously difficult to establish. Associated haemoptysis is occasionally noted, and indicates underlying lung involvement; and, indeed, deposits in the lung may often be shown by a radiograph to coexist, or they may develop later. Involvement of the opposite side in the case of unilateral lesions is a more or less inevitable result. The development of spontaneous hydropneumothorax (as seen in two cases in this series) suggests the rupture of a subpleural metastasis in the lungs.

The clinical picture of the patient with malignant effusion is usually typical. A sudden onset of dyspnoea is frequently associated with a very small effusion, the degree of dyspnoea often being apparently out of proportion to the size of the effusion. A malar flush is common and may be due to the cyanosis, but is often associated with a degree of pyrexia. Essentially, however, the diagnosis of malignant effusion is presumptive upon the history of breast carcinoma and must be regarded as such unless proved otherwise.

The possibility of pleural effusion resulting from radiation changes must be considered. Although depending on the technique used for irradiation of breast carcinoma, radiation changes in the lungs are not infrequent. As a rule they develop six to nine months after a course of irradiation and usually lead to lung fibrosis, which may persist unchanged for years. Occasionally a transient patch of pneumonitis may develop, mostly soon after treatment. The site of the changes is typical for the irradiation technique used and

TABLE VII.—Site of Effusion in Relation to Site of Primary Breast Tumour

Site	Cases in Untreated Group	Cases in Treated Group	Total
Ipsilateral	36	33	69 (80%)
Contralateral	8	4	12 (14%)
Bilateral	3	2	5 (6%)
Total	47	39	86

In two cases the side was unspecified.

TABLE VIII.—Survival in Relation to Date of Previous Irradiation in the Case of Ipsilateral Effusions

Months Survival	Months since Last Irradiation of Same Side of Chest				Total
	1-11	12-23	24+	No Irradiation	
1-3	15	8	4	8	35
4-6	7	4	1	5	17
7-11	3	1	—	1	5
12+	1	3	3	5	12
Total	26	16	8	19	69

corresponds to the junction of the supraclavicular and tangential fields in the cases treated in the London Hospital radiotherapy department. Pleural effusion is almost never associated with the lung changes, although in 2 out of the 68 cases of effusion in this series there were signs of apical lung fibrosis antedating the development of the effusion by some months.

In an attempt to clarify any relationship between the pleural effusion and the antecedent irradiation, Tables VII and VIII were planned.

Table VII shows that of the 86 cases in which the primary site of effusion is specified, in 80% the site was ipsilateral to the original breast lesion, in 14% contralateral, and in 6% bilateral. When only 19 previously non-irradiated cases are considered the proportion of ipsilateral effusion is 74%, suggesting that ipsilateral effusion is the common result of malignant metastases.

Table VIII shows that 26 out of the 69 cases of ipsilateral effusion developed within 11 months of irradiation being given to that side of the chest. If pleural effusion is a complication of irradiation one might suspect this group of cases, and, if so, it should provide the cases of regression and long survival. In actual fact, 22 out of these 26 patients did not survive six months, and only one survived over 12 months.

We consider that the most conclusive evidence that the effusions were malignant in this series is the death within 17 months of all the patients in the untreated control series.

A final observation is presented on the radiographic appearance of lung metastases from breast carcinoma. Of the 39 cases in the series, 23 presented with a single rounded opacity or multiple mottling in one or both lung fields; nine with lymphangitis carcinomatosa with reticulation throughout the lung fields and increase in the size of the hilar shadow; five with hilar gland enlargement alone; and two with a localized area of collapsed lung with later evidence of further lung involvement.

Regression of lung metastases from breast carcinoma by the use of oestrogens has been quoted by Paterson (1950). There was regression in two out of seven cases.

Case Histories

There were 10 patients with lung metastasis (apart from the nine cases of pleural metastasis) who survived over 12 months. Their case histories are appended.

Case 1.—Aged 67; post-menopausal. October, 1944, history of left mastectomy 23 years before. Patient attended with carcinoma of the right breast. November, 1944, deep x-ray treatment of right breast. November, 1945, radiograph showed multiple rounded shadows in the left lung field; stilboestrol, 5 mg. q.i.d., prescribed. April, 1946, lung metastases fading and stilboestrol stopped. January, 1947, metastases fading and also left pleural effusion; stilboestrol restarted and continued. June, 1947, increase in effusion and spread of left lung metastases. October, 1947, patient died, 23 months after original lung metastases.

Case 2.—Aged 66; post-menopausal. July, 1948, attended with ulcerated carcinoma of right breast and fixed axillary glands. October, 1948, radiograph showed multiple rounded shadows in both lung fields (Fig. 3); stilboestrol, 0.5 mg. q.i.d., prescribed and continued. January, 1950, deep x-ray treatment of right breast in view of response of lung metastases. July, 1950, partial regression of lung metastases (Fig. 4). February, 1951, patient alive and slightly dyspnoeic on exertion, 28 months after the original lung metastases.

FIG. 3.

FIG. 4.

FIG. 3.—Case 2. Radiograph taken on October 1, 1948, showing multiple rounded shadows in both lung fields. FIG. 4.—Case 2. Radiograph on July 12, 1950, showing partial regression of lung metastases.

FIG. 5.

FIG. 6.

FIG. 5.—Case 7. Radiograph on February 28, 1950, showing multiple rounded opacities in mid-zones of both lungs. FIG. 6.—Case 7. Radiograph on February 2, 1951, showing partial resolution of lung opacities.

Case 3.—Aged 53; post-menopausal. April, 1945, right mastectomy followed by deep x-ray treatment for breast carcinoma. January, 1947, right supraclavicular metastases treated by deep x rays. October, 1947, radiograph showed prominence of both hilar shadows and reticulation in the lung fields, diagnosed as lymphangitis carcinomatosa. January, 1948, stilboestrol, 5 mg. q.i.d., prescribed and continued; deep x-ray treatment given to pelvic metastases. August, 1949, decrease in size of hilar shadows, and lung fields appear clearer, although right diaphragm now raised. January, 1950, patient died, 27 months after the original lung metastases.

Case 4.—Aged 52. October, 1945, right mastectomy for breast carcinoma. January, 1946, radiograph showed rounded shadow at right costophrenic angle; stilboestrol, 0.5 mg., prescribed and continued for 14 months. April, 1946, deep x-ray treatment to mass on right chest wall. March, 1947, deep x-ray treatment to left supraclavicular metastases. July, 1947, shadowing at right base unchanged. In addition there was a right interlobar and left basal effusion, and generalized increase in lung markings. September, 1947, patient died, 19 months after the original lung metastases.

Case 5.—Aged 75, post-menopausal. December, 1945, attended with carcinoma right breast. January, 1946, deep x-ray treatment to right breast and glandular areas. June, 1947, radiograph showed bilateral hilar gland enlargement; stilboestrol, 5 mg. q.i.d., prescribed and continued. February, 1951, radiograph showed clearing of hilar shadows; patient alive 44 months after original mediastinal metastases.

Case 6.—Aged 65; post-menopausal. March, 1948, right mastectomy for breast carcinoma. August, 1948, post-operative deep x-ray treatment to right chest wall and glandular areas. December, 1949, radiograph showed multiple rounded opacities in both lung fields. January, 1950, deep x-ray treatment to right supraclavicular metastases. December, 1950, stilboestrol, 0.5 mg. q.i.d., prescribed and continued. March, 1951, radiograph showed no change in lung shadows. May, 1951, patient alive 17 months after original lung metastases.

Case 7.—Aged 71; post-menopausal. July, 1947, right mastectomy for breast carcinoma. November, 1947, post-operative deep x-ray treatment to right chest wall and glandular areas. February, 1950, radiograph showed multiple rounded opacities in mid-zones of both lungs (Fig. 5); stilboestrol, 5 mg. q.i.d., prescribed and continued for seven months. February, 1951, radiograph showed partial resolution of lung opacities (Fig. 6). April, 1951, patient alive 14 months after original lung metastases.

Case 8.—Aged 59; post-menopausal. September, 1949, attended with carcinoma right breast and fixed axillary glands; radiograph showed rounded multiple opacities in both lung fields. November, 1949, deep x-ray treatment to right breast. February, 1950, stilboestrol, 0.5 mg. q.i.d., prescribed and continued. April, 1951, radiograph showed partial resolution of lung opacities. May, 1951, patient alive 20 months after original lung metastases.

Case 9.—Aged 66; post-menopausal. August, 1949, attended with carcinoma left breast and fixed axillary glands; stilboestrol, 5 mg. q.i.d., prescribed and continued. October, 1949, deep x-ray treatment to left breast and glandular areas. February, 1950, radiograph showed bilateral hilar gland enlargement with extension into lung fields; diagnosed as lymphangitis carcinomatosa. June, 1950, shadowing on right side cleared after four months. October, 1950, testosterone, 800 mg. monthly, prescribed for ulceration of left breast which was not responding to stilboestrol. April, 1951, radiograph showed decrease in left lung infiltration; breast ulceration regressing on testosterone. May, 1951, patient alive 15 months after original lung infiltration.

Case 10.—Aged 47; cyclical. October, 1943, deep x-ray treatment to carcinoma right breast with multiple skin nodules. December, 1944, radiograph showed opacity in

right lower zone, ? nature; this increased slowly in size. July, 1946, stilboestrol, 5 mg. q.i.d., prescribed and continued for 13 months. December, 1947, radiograph showed no new opacities; stilboestrol stopped. June, 1948, radiograph showed multiple opacities in right mid zone, left basal effusion, and radial shadowing suggesting lymphogenous spread; stilboestrol restarted. November, 1948, patient died, 47 months after original lung shadowing.

Summary

A report is made on 61 cases of pleural or lung metastasis secondary to breast carcinoma treated by oestrogens. A series of 66 similar cases which were not treated is used for comparison.

In the treated group 31% of cases survived over 12 months, as compared with only 7.5% in the untreated group. In the treated group 26% of cases showed regression of pulmonary lesions, compared with 0% in the untreated group.

The possibility of a non-malignant aetiology in the cases with long survival is discussed.

The effect of oestrogens in these cases is essentially temporary, and no prophylactic effect against the development of pulmonary metastases can be shown.

TEN YEARS' CLINICAL EXPERIENCE OF MODIFIED LEUCOTOMY OPERATIONS*

BY

WILLIAM SARGANT, M.B., F.R.C.P., D.P.M.

Physician-in-Charge, Department of Psychological Medicine,
St. Thomas's Hospital

It is over 10 years since some of us, evacuated to Sutton Emergency Hospital from the Maudsley Hospital during the last war, decided to approach Mr. Wylie McKissock, of St. George's Hospital, about attempting modifications of the standard leucotomy operation, then being used in America by Freeman and Watts, so as to investigate its possibilities in the treatment of selected neuroses. I had already seen some results of the early full standard leucotomy in Washington in 1938, and it was obvious then that this operation would come to be used in the neuroses, but cuts would have to be modified, if possible, to try to prevent some of the sequelae seen in these patients. A little later on Mr. G. Knight also offered to help in such work at the West End Hospital for Nervous Diseases.

Experimental Work

Our earliest experiments were not as satisfactory as one would have desired. We were able to do some at our own hospital, but in those days permission to perform such operations had to go through varied L.C.C. and E.M.S. administrative channels, and viewpoints could be so conflicting that varied makeshifts had often to be employed to enable them to take place at all, even on the most carefully selected and studied patients.

*Paper given at a meeting of the Royal Medico-Psychological Association on February 12, 1953.

These sometimes had to be transferred for operation officially to the neurosurgical units of voluntary hospitals, where more freedom of action existed, but this meant also that they then had to go straight home, often the end of a fortnight, and be followed up as well as possible as out-patients. However unsuitable this was for research purposes, recent developments have made an earlier work well worth while, for it has enabled us to have interesting follow-ups of up to 10 years' duration in cases of neuroses with limited cuts, and as the atmosphere has become progressively more favourable to this work about 80 neurotic patients have now been operated on at Sutton (recently renamed Belmont Hospital) out of the many thousand admissions there, and ten months have been spent before or after operation, necessary, in studying the individual cases in hospital. In the past four years it has also been possible to work with Mr. Harvey Jackson at St. Thomas's Hospital on the use of other modified forms of operation in the neuroses and to explore their value in yet another field—the so-called "psychosomatic" disorders. We can hope that some of the results obtained (Sargent, 1951) will make this work at least as acceptable in the next 10 years as the use of modified procedures has come to-day in the ordinary neuroses.

I think English clinicians may truly claim to be among the early workers in this field. Dax (1949) and Radley (1949) were beginning to experiment with modified cuts in cases of psychoses in 1942, as we were in cases of neuroses. By 1944 Slater and I were already able to say, as a result of our early findings, that "for each patient the minimum of brain tissue must be destroyed at will produce the desired clinical effect," and that the operative skill of the surgeon is required to ensure that the operation is not so extensive and destructive as to produce unnecessary and undesirable sequelae. It is also possible to outline some of the more obvious clinical indications and contraindications resulting from our earlier work (Sargent and Slater, 1944; Sargent and Stewart, 1947).

The "Post-leucotomy Syndrome"

However, at the end of the war it still seemed generally accepted in America that extensive cuts and post-operative confusion were necessary in order to obtain satisfactory results, and workers, such as Rylander (1948) in Sweden and others in this country (Ström-Olsen and Tow, 1949), were still subjecting cases of neuroses to full and often posterior "standard" operations. Such operations were taking a quite needless toll of a neurotic patient's remaining personality. Unfortunately, it is the published and understood findings of some of these workers that still provide the major ammunition for the hostile criticisms of this operation in the medical and lay press alike. As a result, it is generally necessary to reassure neurotic patients and their relatives that such methods have been abandoned as a routine measure for many years now at centres specializing in neuroses in England.

An independent follow-up study of 30 patients operated on at Sutton eighteen months to eight years previously (Sargent and Minski, 1951) showed, in fact, that no so-called "post-leucotomy syndrome" common to the group as recognizable as such, and the view was expressed that the findings of others in this respect were possibly due to persistence of previous personality defects or disease symptoms, or because the cut had been made too far posteriorly in other anatomically undesirable areas. Rylander (1952) has also confirmed that, with undercutting of the lower quadrants only, no undesirable personality changes were found in a careful follow-up of his patients. Without hesitation or equivocation, one can now say that it is wrong

to subject the ordinary run of neurotic patients, and many psychotic patients for that matter, to a routine full standard operation till modified procedures have been tried first.

Modifications of Procedure

Since 1942 it has been possible to work with four British surgeons on various modified procedures and to see the work of many others in the U.S.A. All sorts of modifications have been attempted in selected patients, including full sweeps involving both the upper and lower quadrants of the frontal lobe done further forward, and section of the lower quadrants only, first used by McKissock in 1943.* Transorbital leucotomy was done on one of my patients while I was in the U.S.A. in 1948, and I saw the results in other cases. In the same year an open "rostral" type of leucotomy was also carried out by Mr. Guy Odom at my request at Duke University, and Mr. McKissock has been doing both open and closed rostral and medial quadrant operations at Belmont Hospital in recent years. In the past four years at St. Thomas's, special attention has again been paid to section of the lower quadrants by Mr. Harvey Jackson in the neuroses and psychosomatic states. Deteriorations resulting from full cuts have been seen for comparison from time to time and when the operative results from other workers have been examined, or complications have occurred, and also when a surgeon has obviously misplaced the cut in too posterior a manner—a greater or less risk that must still unfortunately be reckoned with in all decisions on whether or not to operate in a particular case by any particular method.

It is no longer as easy to believe those who have suggested that the thing that really matters is the quantitative amount of brain damage done in the prefrontal lobe rather than its actual site. My own clinical impressions increasingly support Fulton's (1952) work on animals, that the more you keep to the region of the inferior medial quadrant the safer you are. The further one ventures from this area the more likely is one to run into undesirable sequelae, though the farther forward the damage the better. Especially with broad foreheads, cutting the fibres in this area by a lateral approach may be difficult unless special techniques are employed, and many patients still showing tension after an apparently full cut may be, in fact, those in whom important fibres in this quadrant have unfortunately been missed. Many reoperations on this quadrant may have to be performed in the future when this fact is more generally realized.

Quantitative factors in the cut are also very important, but I believe it will be finally shown that to obtain the best clinical results with the minimum of undesirable sequelae in neuroses the site of the operation is more important still. This may be the reason why Freeman's new deep frontal cut, using the transorbital route (Freeman and Watts, 1950), is apparently achieving many successes in the U.S.A., since it produces its maximum damage in just this lower medial area of the frontal lobe. There are also far fewer psychotic patients than is generally supposed who need to pay the price of a full posterior cut for their release from a mental hospital, though the deliberate production of emotional blunting is necessary in some. Greenblatt and Solomon's (1952) findings in the U.S.A. with what is termed "bimedial leucotomy" should be carefully studied in this respect.

Clinical Selection of Patients

The use of these limited cuts has, of course, entirely transformed the clinical possibilities of leucotomy. One can now promise the properly selected patient that, barring accidents, he will certainly not come to great harm, though total relief of distressing symptoms may not be as dramatic

*One of these patients operated on then, at the age of 68, is still enjoying a hale, hearty, and happy old age at 78, without any recurrence of his chronic tension state and attacks of severe recurrent depression. He remains a regular attendant and a sidesman at his church, an equally regular attendant at his bowling club, and recently won two first prizes at three consecutive whist drives.

and certain. With increasing surgical skill and modified operations, these accidents are becoming relatively fewer, and, like death from the operation, because of their increasing rarity need not now weigh too prominently in the final decision. Provided the right clinical indications are present, operations can be performed, if necessary, in intractable psychosomatic states, in anxiety hysteria, and in anxiety and depressive states in obsessive personalities. Such patients will also often do much better than severe obsessives where a more extensive operation may be necessary, as in the chronic psychotic, to remove symptoms making life so intolerable. One finding has been consistently true in the past ten years: the more worried you become about subjecting a well-preserved neurotic patient to a modified leucotomy because the basic personality remains good, the better he will do. Your unhappy results will be in those on whom you have recommended an operation more lightly because their personality is not so well-preserved and there is so much the less to lose. Some hospitals get disappointing results because they choose patients from among their worst clinical material rather than their best, even after all other methods have failed to help the patient, and he or she remains totally incapacitated by illness.

When using restricted cuts in the neuroses there are certain principles that still have to be observed to avoid disaster, apart from those already mentioned. One must be constantly on the look-out for schizophrenic features hiding under the presenting picture of an obsessional neurosis. For in partially relieving the obsessional component by operation you may be simply facilitating the emergence of more incapacitating schizophrenic thought disorder. There is no need to be worried by the presence of secondary hysterical features in the total presenting picture, provided they are being released only by underlying anxiety or obsessive tension. The malignant hysteric without anxiety and obsessive features probably does as badly, however, as the chronic hebephrenic. But in long-term follow-ups some good results will occur in chronic phobic states in mixed hysterical and obsessive patients. It is wise to pay special attention to body build, for the results in those of good muscular physique will be generally more satisfactory than in the constitutional asthenic. One should be very cautious in all states of psychopathy, or where paranoid features are deeply rooted in the basic personality rather than being merely part of a recent illness. One need not be too worried by symptoms of ill-temper which are found to be due solely to underlying tension resulting from the illness itself and do not occur when the patient is relaxed. But it is wise to avoid those patients in whom a quick temper is part of their normal constitutional endowment and which occurs without much tension, and in a total setting so frequently seen in the explosive psychopathic patient. In selecting neurotic patients for operation, one must always try to estimate what personality assets will remain if tension and obsessive thinking are diminished. In some patients this may be beneficial and in others harmful to their future social adjustment. If they are already impulsive and lacking in foresight the operation may make them more so, but there are so many other patients totally unable to live at all in the present because of numerous anxious preoccupations with the past and future. These can be made more normal by modified operations.

Finally, in choosing patients for modified leucotomy operations one should have available all other methods, such as psychotherapy, drug abreaction, intravenous acetylcholine therapy, E.C.T., modified insulin, and skill in the use of routine sedation in the hope that operative measures may be avoided. Many of the results obtained at Sutton and at St. Thomas's have been good because all other methods were available for trial first and a long period of preliminary study as an in-patient could be undertaken when necessary.

Psychological Testing

A word should be said about psychological testing as opposed to clinical psychiatric examination in the selection

of patients for these modified procedures and in assessing results. One can only beg competent clinicians not to rely too much on such tests at the expense of their mature clinical judgment, otherwise clinical perspectives can become distorted. The criterion of success or failure is best measured by whether the patient and the relatives are pleased or displeased, and by the subsequent work record and social and ethical adjustments shown. We do the operation for social and personal reasons, and not because a theoretical I.Q. may rise or fall a point or two, or some selective psychological testing shows what may prove to be an unimportant change socially for the patient concerned. I for one have now abandoned routine psychological testing, till further progress is made, in favour of clinical assessment, except in certain circumstances. For instance, it is somewhat useful to check the I.Q. before operation, because those with higher I.Q.s will generally do better than those with the lower ones. A Rorschach test in skilled hands may also detect latent schizophrenic features missed in the most careful clinical examination, which may prove a contraindication in the young obsessional patient. For follow-up purposes I prefer clinical and social assessment to reliance on tests, which so often fail when they are most needed in assessing emotional rather than intellectual alterations that may have occurred.

Problems of Relapse

With the increased use of modified operations one is faced with the important problem of relapse. Recently one has occurred with a reasonably full cut as late as nine years after operation and an intervening period of good health. Some are also occurring four to five years after operation, and others have happened in as early as a month. Relapses occur with all types of operation, but in the case of modified techniques further improvement may often be obtained by reoperation, still without resorting to too posterior a cut. We have had several successes with reoperation when satisfactory improvement has been followed by relapse. Many years may also have passed between operations, but reoperation still helps.

One obsessional patient had his first operation in 1943, confined to the lower quadrants; he was generally improved for three months and then relapsed. It was not until 1948 that he was persuaded to have a more extensive cut, and he has since maintained his improvement. Another patient also had his first operation in 1943, relapsed, and was quickly reoperated upon; he was then able to stay at work till a recent follow-up revealed that he had again relapsed in 1951; the possibilities of his further treatment are now being explored. A patient with chronic tension, with an anterior total sweep at operation in 1947, relapsed in 1951, and had a second operation in 1952, again with benefit, but this time the second operation was confined to the medial quadrants only. I am noticing less tendency to relapse in lower-quadrant cuts done by Mr. Harvey Jackson recently, compared with those attempted in earlier years, possibly because we are now paying more attention to the inner quadrant than formerly. This finding would bear out recent observations by those doing open operations in this area in France, England, and the U.S.A., but we need a longer time to be certain on such points.

Social and Religious Considerations

On these matters, too, one can be most definite after ten years. If anterior and limited cuts are used conventional religious and ethical values are rarely irrevocably lost. Fanaticism on any topic may no longer be as easy to maintain, but more balanced points of view on religious and social issues are again made possible to the patient. Several of my patients have certainly had their religious faith heightened with the healing of their minds and a better ability to think of things beyond their own immediate and intense personal suffering. One patient has had two episodes of religious reawakening after each operation, which has also helped him on each occasion to attain better social adjust-

ANAL FISSURE

BY

E. S. R. HUGHES, M.D., M.S., F.R.C.S.

Assistant Surgeon, Royal Melbourne Hospital, Australia

An anal fissure is a triangular ulcer at the anal verge, extending into the anal canal. The lesion is often associated with severe pain, and when untreated tends to run a course of exacerbations and remissions.

Aetiology and Pathology

The fissure begins as a tear at the anal verge. This tear might be caused by the passage of unusually large or hard faeces (sometimes enema tubing) or may be related to temporary incoordination of the external sphincter, with slow relaxation of the subcutaneous part. The elliptical shape of the superficial portion of the external sphincter leaves vulnerable the midline posteriorly, and hence the fissure is nearly always in this position. The anterior fissure is seen almost exclusively in the female, and is due to the unprotected anterior segment.

A fissure is about 2 cm. long and 1.5 cm. wide, and the apex extends just above the anal intermuscular septum, to overlie the lower border of the internal sphincter. At first the fissure is uncomplicated. The floor contains longitudinal fibres of the corrugator ani muscle. Their presence indicates the shallow depth of the ulcer and a likelihood of healing without surgical intervention. If a skin tag ("sentinel pile") be present, it is small. There is no induration of the base, but the fissure is extremely tender and associated with much sphincter spasm.

This spasm prevents the ulcer from healing. It deepens, and the floor is then formed by circular fibres of the subcutaneous portion of the external sphincter. The skin tag is often large and oedematous; at the proximal end of the fissure the mucous membrane becomes polypoidal. This secondary mucosal polyp is found in a high percentage of chronic anal fissures. The edges of the ulcer are well defined and overlap the floor of the ulcer, so that the true size is concealed. Infection is an important complication of the fissure. The inflammation is localized and may end in suppuration, with abscess formation; this usually discharges into the anal canal to form a blind internal fistula. Much less often the abscess discharges on to the perianal skin, with the formation of a low anal fistula.

Clinical Features

Males and females are affected with equal frequency. The pain is described as burning, shooting, or aching in nature, and is related to defaecation; sometimes the act is extremely painful, but more often the pain begins half an hour after and drags on for another hour or two.

Therapeutic Persistence

I would also like to stress the need for therapeutic persistence and the use of all methods before too deteriorating procedures are finally decided upon or the too ready throwing of one's hand when confronted with difficulties after a modified leucotomy. One patient with a very severe obsessional neurosis had had 15 years of psychoanalysis and supportive therapy on and off before faith was finally lost by both patient and therapist alike in this approach, and a modified leucotomy agreed to. This resulted in some relief of tension but a release of severe paranoid and depressive symptoms. These complications then had to be dealt with by the giving of insulin and E.C.T. A second operation, still confined to the lower quadrants but farther back, relieved further tension, but obsessional thoughts persisted. She is now being treated as an out-patient with intravenous acetylcholine injections and occupational therapy, where some might have decided that after the failure of so much psychotherapy, the first leucotomy, and the complications that ensued there was nothing more to be done; especially as a full operation was thought to be contraindicated in this particular patient because of certain personality traits. If one's operative efforts are not irretrievable it always leaves hope that other measures, short of deteriorating cuts, may be effective which would have failed before. Thus some phobic states may be further helped by intravenous acetylcholine injections after the edge has been taken off the patient's anxiety by modified leucotomy; and treatment with E.C.T. and insulin may become effective in depressives and schizophrenics where it has failed before. We have seen several examples of this. In addition, a reasonably intact personality is still preserved. Time for further psychotherapy can also be gained.

Conclusion

I must finally pay my very grateful tribute on behalf of all psychiatrists here to the many neurosurgeons in England for all the patience and co-operation they have shown us in our often stumbling and hesitant efforts for the relief of mental suffering by a method which is as yet obtaining only a hazardous social and medical respectability. I am certain, however, that a large number of psychiatric patients would echo these thanks. They and their families should be the real judges of our success or failure, and not our own theoretical prejudices and emotionally toned judgments. Psychiatry often creates insoluble difficulties for itself when we leave the patient's bedside and become too involved in speculative philosophical issues. If we are only content to remain doctors, constantly searching for new and better practical ways of trying to help our individual patients, the future of leucotomy is assured—at least until better ways are discovered for the practical relief of so much persistent individual human misery and social incapacity.

Passage of blood with the motions is alarming to the patient even though it is slight in amount; it is usually observed on the toilet paper as well as on the motion. If the patient has associated haemorrhoids their prolapse might be, to the patient, the obvious cause of the discomfort.

The fissure can always be seen without subjecting the patient to the agony of rectal palpation. The buttocks are firmly parted and the anal verge inspected; this in turn is gently opened with the index fingers of each hand. If the surgeon has secured the confidence of his patient the subcutaneous sphincter will relax to reveal the fissure in most of its length and the surgeon can see the floor without difficulty. Palpation must often be confined to the perianal region, searching for evidence of deeper infection, but in the more patulous type of anus it is possible to push the finger upwards along the anterior segment, and, gently turning the finger, palpate the upper end of the fissure for a polyp while the base of the fissure can be felt between the forefinger and thumb.

Proctoscopy and sigmoidoscopy should not be attempted at this stage. Carcinoma of the rectum and sigmoid practically never coexist with an anal fissure, although they are excluded by subsequent sigmoidoscopic examination.

Treatment

The treatment advised will depend upon the type of fissure, the nature of the patient, and the preference of the surgeon.

1. Conservative Treatment

A small number of cases respond to conservative measures. The bowel habit is regulated by adjusting the diet and by prescribing aperients, particularly paraffin oil. Just before the bowel action the patient passes into the rectum a finger lubricated with an ointment containing a surface analgesic, such as cinchocaine 10%. Acute fissures, which are shallow and contain longitudinal fibres in their floor may respond to such treatment, but even in these the outcome is unpredictable. Further, some patients are sensitive to cinchocaine and other such ointments and develop a rash around the anus, whilst others are disturbed by the pain and by the slowness of the cure and seek more active measures.

2. Injection

Injection treatment appeals to many because success, when it comes, is often dramatic. Either the water-soluble procaine hydrochloride or the oily solution "proctocaine" can be used. The effect of the latter is said to last longer, but this is disputed, and certainly complications following its use are seen in cases referred to the proctologist.

The injection is best made with the patient in the right lateral position (for the right-handed surgeon). The left index finger is inserted into the anal canal, and after cleaning the skin a subcuticular wheal is raised with procaine. The needle is then pushed forwards, first on one side of the anal canal and then on the other, and 5 ml. of proctocaine or procaine injected on each side in order to cause temporary

relaxation of the sphincter muscle; 1 or 2 ml. is finally injected into the base of the ulcer. The sphincters promptly relax and enable a second finger to enter the anal canal alongside the first. The muscles are then gently stretched.

Injections in this region are usually acutely painful, so that a failure is the more disappointing to the patient. Injections in such a contaminated area may cause abscess and fistula formation. If proctocaine be injected too superficially a necrotic ulcer will develop.

3. Digital Dilatation

The most popular method of treatment is digital dilatation of the anal canal. The patient is given a general anaesthetic, and the anal canal is gently stretched until two or more fingers can be inserted into it.

Again this simple method may produce a permanent immediate cure. But it is uncertain: an over-vigorous stretch has caused serious damage to the sphincter muscle; whilst one too gently performed is ineffective. Carefully done with local analgesia and combined with dietetic and habit adjustments, it can be recommended for the uncomplicated fissure.

4. Excision of Fissure

Radical cure of an anal fissure entails excision of the ulcer, with division of the subcutaneous sphincter muscle. The patient is anaesthetized and placed in the lithotomy position. The fissure is then excised. A triangular piece of skin is outlined, with the apex at the anus and base outwards and including the fissure ulcer. It is dissected upwards off the underlying tissue. The subcutaneous sphincter is divided in the centre of the wound, and the two ends retract to leave a wound approximately $1\frac{1}{2}$ in. (3.8 cm.) long and 1 in. (2.5 cm.) wide (Fig. 1).

Gabriel (1930, 1952) advises that this wound be left open and be permitted to heal by second intention. This entails a prolonged regime of some weeks before the wound is healed. The surgeon must be careful to keep the wound flat so that pockets will not form. In good hands the results of the operation are excellent, but if the surgeon be less vigilant the scar puckers to leave a tight anus, with the possibility of recurrence.

Suture of the wound cannot be recommended, because the danger of abscess and fistula formation is too great. Moreover, when the wound is sutured there is a possibility of the anus becoming constricted and again favouring recurrence.

The best treatment is to apply a split-skin (Thiersch) graft to the wound after excision (Hughes, 1952). After excision in the manner outlined above, a row of guy sutures are placed in position along either side of the wound (Fig. 2). A graft of split-thickness skin is taken from the leg or arm, applied to a mould of tulle gras and wool (Fig. 3), and then held firmly in the wound as the guy sutures are tied across the back of the mould (Fig. 4). A preliminary course of succinylsulphathiazole before the operation and antibiotic therapy post-operatively controls any tendency for contami-

nation to develop into infection. The antibiotic therapy consists of penicillin "distaqueine" fortified, 300,000 units, and streptomycin 0.5 g. both three times a day for four days. The graft is inspected on the fourth or fifth post-operative day and the mould removed. Any excess skin is removed and a piece of cotton-wool is placed over the grafted area to keep it dry. The patient is discharged on the fifth or sixth day post-operatively with the wound healed.

Goodsall (1892) practised sphincterotomy with good results. He did not excise the ulcer but simply cut through the subcutaneous sphincter. The wound healed by secondary intention. In patients with chronic fissures who are unwilling to undergo operation this process has more to commend it than digital dilatation.

Discussion

An anal fissure is a non-malignant condition of the anus, causing acute discomfort to the patient. He asks for relief, but is reluctant to accept a treatment that demands an absence from work for any prolonged period.

Acute uncomplicated fissures not uncommonly respond to more conservative measures. The patient is advised of the nature of his condition, suitable adjustment is made to his diet to give a bulky but soft stool, and digital dilatation is practised; an injection of local analgesia often helps to break the vicious circle by enabling the surgeon to dilate the anus gently.

Chronic fissures, particularly those complicated by some degree of infection of the deeper tissues, are unlikely to obtain permanent relief by such measures. If an anaesthetic is to be given to the patient, the fissure is best excised so that recurrence is prevented. If there are associated haemorrhoids, these should be removed. After excision of the fissure and division of the subcutaneous sphincter the wound can be left open to heal by secondary intention, but this prolongs the convalescence, demands daily dressings and keen appreciation by the surgeon of the importance of a flat wound until completely covered by epithelium, and still leaves a scar which as it matures might be responsible for recurrence of the fissure. Therefore I favour primary skin-grafting to the wound after the fissure has been excised (Hughes, 1952). The period in hospital and that of convalescence are much shortened, no dressings are required after the grafted area has been inspected, the absence of granulation tissue eliminates fibrosis, and the chances of recurrence of the fissure are slight. The results of primary skin-grafting have been excellent: all 12 cases subjected to excision of the anal fissure combined with primary skin-grafting have had a 100% "take" and all have left hospital within a week of the operation with the fissure removed and the wound healed.

Summary

The aetiology and pathological and clinical features of anal fissure have been briefly reviewed. The acute but otherwise uncomplicated fissure may respond to treatment administered in consulting-rooms, but chronic fissures, particularly those complicated by infection, superficial or deep, usually require more radical treatment. The fissure should be excised, the subcutaneous sphincter divided, and a primary split-thickness skin graft applied. The fissure is removed and the wound completely healed during a stay of six to seven days in hospital.

INTESTINAL PROTOZOA IN MENTALLY DEFICIENT CHILDREN

BY

G. D. BELIOS, M.D., M.P.H., D.T.M.&H.

Deputy Director, Division of Malaria and Tropical Diseases,
Ministry of Social Welfare, Greece; on Scholarship
deputation

AND

W. COOPER

Chief Technician in Protozoology, London School of
Hygiene and Tropical Medicine

(From the Department of Protozoology, London School of
Hygiene and Tropical Medicine)

Specimens of faeces from mentally deficient children in the wards of Harperbury Hospital, Shenley, Hertfordshire, were examined by various methods in order to ascertain the degree of infections by intestinal protozoa.

This paper gives particulars of the methods used and the results obtained in a "pilot" survey which was undertaken during September and October, 1952.

Materials and Methods

The total number of mentally deficient children currently treated at Harperbury Hospital was 56. Specimens of faeces for this survey were secured from 50. All those examined were male. Their age distribution and the duration of their stay in hospital were as follows:

Age	No. of Children	Time in Hospital	No. of Children
5 to 7 years	10	Less than 3 years	8
8 to 10 "	15	From 3 to 5.9 years	21
11 to 13 "	18	From 5 to 8.9 years	18
14 to 17 "	7	Over 9 years	3
Mean age of the group 10 years		Mean duration, 5.36 years	

The children came from the London and Middlesex areas, and none had resided in a tropical or subtropical country. There was some contact between them and outside because they attended school. Intestinal disturbances were not uncommon.

Specimens were placed in new clean waxed cream cartons and carried by messenger to the London School of Hygiene and Tropical Medicine. When received they were usually 3 to 5 hours old, but in a few instances they were from 10 to 12 hours old. Most of the specimens were formed. Each batch was inoculated at once in culture media, then examined directly and after concentration. Particulars of the techniques follow.

Direct Examination.—In addition to the direct films in saline and iodine (double strength Gram's iodine) a third film was made in a drop of 1% aqueous solution of eosin. This procedure (Kuenen and Swellengrebel, 1913), besides improving the efficiency of the direct examination (three films seen instead of the usual two), has some other advantages. The eosin solution has the property of staining everything in the stool pink, except living protozoa. On this pink background the living protozoa (and their cysts) stand out prominently as colourless, pearl-like, refractile bodies which can be recognized very easily even with the 2/3 objective. Moreover, the chromatoid bodies of the cysts of *Entamoeba histolytica* (invisible in the iodine preparation) are much more distinguishable in eosin films than in ordinary saline preparations. Each of the three films of the direct method was examined for about 10 minutes, first under the 2/3 objective and then under the 1/6 (with a $\times 10$ eyepiece).

Concentrated Specimens.—The original centrifugal flotation technique of Faust *et al.* (1939) was modified in order to facilitate detection of cysts of the smaller intestinal protozoa. Tests were made with denser solutions of zinc sul-

phate, the specific gravity of which was increased by steps of 0.02. Finally it was found that the specific gravity of the zinc sulphate solution could be increased from 1.18 to an optimum of 1.28, which corresponds to a 51% solution. This new centrifugal flotation technique can be summarized as follows:

1. Take a piece of faeces the size of a walnut and emulsify it in tap-water, using a pestle and mortar to ensure a uniform suspension.
 2. Strain off large particles by pouring the solution through a copper wire sieve of about 40 mesh to the inch into a bowl (wet the sieve before use).
 3. Centrifuge the emulsion at about 3,000 revolutions a minute for about three minutes to obtain a deposit.
 4. Pour off supernatant fluid and break up deposit with a glass rod.
 5. Half fill the tube with 51% zinc sulphate, stir with the glass rod and complete suspension by gently inverting the tube after closing the mouth with the thumb or cork. Try to avoid the formation of bubbles, as these will interfere with the final "film."
 6. Fill the tube nearly to the brim with the zinc sulphate solution and mix again by gently inverting the tube several times as before.
 7. Centrifuge at about 3,000 revolutions for three minutes and allow the tubes to come to rest gradually without disturbance.
 8. Remove a portion of the film on the top of the fluid by a loop bent to lie in a horizontal position and deposit a loopful on each of two slides.
 9. Add a little 1% eosin to one and Lugol's iodine to the other, mix in and cover with a coverslip.
- N.B.*—Do not delay the dilution in eosin and iodine after the cysts have been exposed to zinc sulphate, as they tend to collapse after about 15 minutes in this strong solution.

TABLE I.—Protozoa found in Faecal Specimens from Mentally Deficient Children

* Revealed by Heidenhain's haematoxylin staining of a wet-fixed film.
E.c. = *Entamoeba coli*. E.h. = *E. histolytica*. E.n. = *Endolimax nana*. I.b. = *Iodamoeba butschlii*. G.i. = *Giardia intestinalis*. C.m. = *Chilomastix mesnili*. Ent.h. = *Enteromonas hominis*.

Each of the two slides of the concentrated specimen was examined for 10 minutes, bringing the total time devoted to the examination of every specimen, either positive or negative to approximately 50 minutes. A certain number of faecal specimens were examined more than once by the above methods.

Cultivation.—As soon as the specimens were received they were inoculated in culture media—Dobell's HSre medium, or modified Tanabe's medium for intestinal flagellates, or Rao's (1951) modified liver infusion agar medium. A loopful of sterile rice starch was added to the culture tubes upon inoculation, and the whole work was performed under sterile conditions. Cultures were examined after 24 hours at 37° C., and in some instances after 48 hours. Sub-inoculations and isolation of colonies of protozoa were made only in exceptional cases.

Permanently Stained Preparations.—These were made in a few selected cases. The staining methods used were Heidenhain's iron haematoxylin and Mallory's phosphotungstic haematoxylin, as modified by one of us (W. C.) (see Hoare, 1949). Dry preparations were made of some flagellates from cultures, and these were stained by Leishman's and/or Giemsa's method.

Results of Direct Film and Concentration

Table I gives detailed results of the general one-stool examination in direct film and after concentration, cultivation, and staining of permanent preparations. Cysts of four species of amoebae and two species of flagellates were detected during this survey. No active forms either of amoebae or of flagellates were found. Of the 50 specimens

examined, 30 were positive for one or more species of protozoa in the direct film (60%). After concentration the number of positive specimens increased to 33 out of the 49 examined (67%). In no case did the direct examination reveal anything that the examination of the concentrated specimen did not, and often the latter technique changed a doubtful into a certain result.

Table I shows the following incidences: *E. coli*, 29 (58%); *E. histolytica*, 16 (31%); *E. nana*, 10 (20%); *I. butschlii*, 9 (18%); *G. intestinalis*, 7 (14%); *C. mesnili*, 3 (6%); *Ent. hominis*, 10 (20%).

The importance of the concentration technique is shown even more by the increased number of species of protozoa detected (Table II).

TABLE II

No. of Specimens Positive for	Direct Film	Concentration
1 species of protozoa ..	21	11
2 " " " " " "	10	10
3 " " " " " "	0	9
4 " " " " " "	1	2
5 " " " " " "	0	1
Average No. of species of protozoa per positive specimen ..	1.4	2.2

The relative efficiency of direct film examination, as compared with concentration, is given in Table III. (The figures in parentheses represent percentages of the first column when the figures of the third are taken as 100%.)

TABLE III.—Number of Specimens in which Cysts were Detected

	Direct Film	Concentration
<i>E. coli</i> ..	18 (64%)	28
<i>E. histolytica</i> ..	9 (60%)	15
<i>E. nana</i> ..	5 (50%)	10
<i>I. butschlii</i> ..	3 (33%)	9
<i>G. intestinalis</i> ..	6 (100%)	6
<i>C. mesnili</i> ..	0 (0)	3

Cultivation

(a) No. 33 (Table I) showed trophozoites of *E. histolytica* (not found before).

(b) Nos. 3, 4, 23, 29, 32, 36, 38, 45, and 49 showed active forms of small flagellates which could not be identified with certainty. In order to identify them in at least one instance, a culture of No. 2 in Dobell's HSre medium, showing small flagellates, was subinoculated in the same medium, and for some time, until the organisms were numerous enough to enable us to make permanent preparations. They were also examined under dark-ground illumination, and were eventually diagnosed as *Enteromonas hominis*.

(c) Nos. 2 and 42 showed, in addition to the "small" flagellates mentioned above, trophozoites of *E. histolytica*. No. 42 had been negative previously for this organism. It should be noted that Nos. 4 and 29, which were found negative when examined by other techniques, proved positive after cultivation, thus increasing the overall incidence of protozoa found during this survey to 70% of the specimens, and the proportion of specimens showing *E. histolytica* was raised by these cultural methods to 34%. *Blastocystis hominis* was a very common contaminant of the cultures.

Permanent Preparations

Permanently stained preparations were made of about one-fifth of the specimens obtained, using one or more of the staining methods mentioned. Only when examination was prolonged for over 30 minutes (under the 1/12 objective) was it possible to detect species of protozoa not found previously. Thus *G. intestinalis* cysts and *E. nana* cysts were added to the previous results of Nos. 33 and 46 respectively. The size of the *E. histolytica* cysts was not measured as a routine, but most seemed to be of the small variety (7 μ to 12 μ).

Discussion

This small survey did not pretend to find out the true incidence of infection of intestinal protozoa, which would have required the examination of repeated specimens. However, specimens from twelve children were examined twice, from two children three times, and from a further two children four times; three additional infections of *E. histolytica* were thereby discovered, bringing the apparent total incidence of this species to 40%. This figure is probably the highest recorded in the United Kingdom, where in persons who had never resided abroad it has varied from 1.6% (Morton *et al.*, cited by Hoare, 1950) to 10% (Dobell *et al.*, cited by Hoare, 1950). In a group of men of the R.A.F. previously stationed in India, some of whom had given a past history of dysentery, Rickards (1949) estimated a true incidence of from 21.99 to 36.65% (*E. histolytica*). High rates are usual in institutions for mental deficient, and even higher rates than the present ones were found by Tobie *et al.* (1951) in Wassaic State School, Wassaic, New York, U.S.A., where the following incidence (direct film and concentration combined) was determined: *E. coli*, 76%; *E. histolytica*, 59%; *E. nana*, 65%; *I. butschlii*, 61%; *G. intestinalis*, 38%; *C. mesnili*, 40%.

The importance of *E. histolytica* with respect to public health remains doubtful in the absence of clear knowledge of the pathogenicity of the species. It is suggested that the high incidence of this parasite (and others) in patients in mental institutions, as compared with that in the general population, is probably due to close contact between people with unhygienic personal habits.

Conclusions and Summary

A pilot survey for intestinal protozoa was carried out with faecal specimens from mentally deficient children in Harperbury Hospital, Shenley, Hertfordshire, during which, besides direct examination and cultivation, a new concentration technique was used.

The results of this survey showed a very high infection rate among these children, most of whom were found to harbour from one to as many as five different species of intestinal protozoa. The rate of infection with *E. histolytica* was found to be 40%, but it is believed that its incidence may be even higher.

A rare species of flagellate, *Enteromonas hominis*, was isolated in culture media from one specimen and maintained by subinoculation in Dobell's medium.

This work was done under the guidance and direction of Professor P. C. C. Garnham, Director of the Department of Protozoology, to whom we are indebted for the facilities provided for this investigation. We are also indebted to Dr. E. D. Taylor, medical superintendent, Harperbury Hospital, for the supply of specimens of faeces and epidemiological information on the mentally deficient children of his hospital.

At the end of March this year there were 9,413 blind persons on the registers of the local authorities in Scotland, the highest figure ever recorded. The increase over last year of 294 people is accounted for almost entirely in the 70-years-and-over age group, which now comprises 44% of the total. The total number of children under 16 registered as blind was 184, 27 of whom were new registrations.

HYPERCALCAEMIA AND IMPAIRMENT OF RENAL FUNCTION IN GENERALIZED SARCOIDOSIS

BY

C. E. DENT, M.D., M.R.C.P.

F. V. FLYNN, M.D.

AND

J. D. N. NABARRO, M.D., M.R.C.P.

(From the Medical Unit and Department of Clinical Pathology, University College Hospital, London)

Patients with generalized sarcoidosis occasionally show evidence of impaired renal function. In most of the cases reported in the literature this has been associated with marked hypercalcaemia (van Creveld, 1941; Schüpbach and Wernly, 1943; Klinefelter and Salley, 1946; Westra and Visser, 1949; Longcope and Freiman, 1952). The pathological mechanisms underlying these disturbances remain obscure, and we have recently had an opportunity of studying a case with these two complications and of observing the effect on them of cortisone therapy.

Case Report

A married man aged 23 was first seen in July, 1950. He complained of vague dyspepsia, which he had had for three months, and also admitted to the loss of 16 lb. (7.3 kg.) in weight and to nocturia up to four times a night. The only abnormality noted on physical examination was a moderately enlarged gland in the right axilla. The chest x-ray film showed bilateral hilar gland enlargement and miliary mottling in the lung fields. He was admitted to hospital and various investigations were carried out. No tubercle bacilli were found in the sputum, urine, or gastric contents. The Mantoux test was negative at 1/100. The urine contained a few pus cells and hyaline casts, the concentration-dilution range was 1010 to 1006, and the maximum urea concentration was 1.49 g. per 100 ml. The blood urea was 60 mg. per 100 ml, and the urea clearance (C_m) 65% of average, normal. An intravenous pyelogram showed no abnormality. The plasma albumin was 3.8 g. per 100 ml., globulin 2.5 g. per 100 ml.; the serum flocculation tests were positive; and the E.S.R. was 58 mm. in one hour (200 mm.). A diagnosis of pulmonary sarcoidosis was made and the patient was discharged to out-patient supervision.

In June, 1951, he started to get attacks of pain in his right loin; these became increasingly severe, and from April, 1952, were accompanied by haematuria. He was readmitted to hospital for further study. Physical examination revealed a few enlarged glands in the right axilla, and there was early calcification of the corneal limbus of both eyes. The chest x-ray film still showed enlarged hilar glands and further mottling of the lung fields. A straight x-ray film of the abdomen showed a "mulberry calculus" in the right renal area; x-ray films of the skeleton were normal. The urine contained numerous pus and red blood cells, and was sterile on culture; the concentration-dilution range was 1010 to 1008, and the maximum urea concentration 1.4 g. per 100 ml. The blood urea was 60 mg. per 100 ml. and the urea clearance (C_m) 47%. The E.S.R. was 46 mm. in one hour (100 mm.). The plasma albumin was 3.5 g. and the globulin 4.6 g. per 100 ml.; the electrophoretic pattern showed an increase of γ -globulin. The serum calcium was 14.3 mg. per 100 ml., plasma inorganic phosphorus 4.2 mg. per 100 ml., and serum alkaline phosphatase 11.1 (K.-A.) units per 100 ml. The urinary calcium output was 350 mg. in 24 hours on an ordinary ward diet containing about 1 g. of calcium. Estimations of serum and C.S.F. calcium were performed on specimens obtained nearly simultaneously; the

serum contained 13.8 mg. and the C.S.F. 5.1 mg. per 100 ml. The Mantoux test was negative at 1/100. Biopsy of a gland in the right axilla showed the typical appearance of sarcoidosis.

It was decided to study the effect of cortisone on the radiological appearance of the lung fields and on the calcium metabolism and serum proteins. In view of the relationship between sarcoidosis and tuberculosis and of the danger of activating tuberculous lesions with cortisone, it was also decided to give streptomycin during this period. Preliminary determinations of the blood streptomycin levels after various doses were made in view of the impaired renal function. The dose chosen was 1 g. of streptomycin a day. This was started on May 10 and continued until July 13, periodic blood-level determinations being made during this time. After a preliminary nine-day period on a low-calcium diet (170 mg. a day) cortisone, 150 mg. daily in six-hourly doses by mouth, was started on May 11. During the preliminary period on the low-calcium diet the serum and

Chart of the case, showing effect of cortisone therapy and variation of dietary calcium on serum and urinary calcium, serum globulin, and renal function.

urinary calcium fell. Reduction of the serum level continued while the patient was on cortisone, despite an increase of the dietary calcium after 10 days. The lowest figure obtained was 10.1 mg. per 100 ml. The urine calcium also fell further when the patient was first given cortisone with a low-calcium diet, but there was a slight temporary increase when the calcium intake was raised. The plasma inorganic phosphorus fell to 2.2 mg. per 100 ml. The alkaline phosphatase was unchanged. There was some reduction of the serum globulin, an improvement in renal function, and the Mantoux test became positive (Pyke and Scadding, 1952). (These changes are shown in the Chart.) The sedimentation rate showed no significant change. The course of cortisone was continued for 23 days and all diets given during this period had a low-sodium content.

X-ray examinations of the chest during the treatment showed steady improvement, and by the end of the course there had been marked clearing, which has persisted (August, 1952).

Surgical opinion advised exploration of the kidney and removal of the stone, and this was done on June 26 by Mr. D. R. Davies. The stone was found to be almost pure calcium oxalate. A renal biopsy performed during the operation showed evidence of very mild chronic pyelonephritis but no characteristic sarcoid lesions or evidence of calcification.

The patient's recovery from operation was uneventful, but subsequently he started to get pain in the left side; the serum calcium level had risen to 12.6 mg. per 100 ml. before

his discharge from hospital and his urinary calcium output remained over 300 mg. per 24 hours despite moderate restriction of the calcium intake.

Discussion

This patient had "band keratitis" and a renal calculus, clinical manifestations of hypercalcaemia and of hypercalciuria respectively. Calculi, almost always of calcium oxalate, have occasionally been reported in patients with generalized sarcoidosis (van Creveld, 1951; Albright and Reifstein, 1948; Longcope and Freiman, 1952), and corneal calcification is apparently equally rare (Haldimann, 1941; Cogan *et al.*, 1948). The origin of hypercalcaemia has not been satisfactorily explained, although three suggestions have been put forward: that it is due to the disturbance of plasma protein; that it is a manifestation of parathyroid overactivity; or that it results from bone destruction by sarcoid deposits. It is unlikely that the extra calcium is bound to the additional globulin, because the serum calcium and globulin levels (as determined by the present crude methods) do not vary in parallel (Harrell and Fisher, 1939; van Creveld, 1941; Albright and Reifstein, 1948). Under normal circumstances albumin and not globulin is the protein chiefly concerned in calcium binding (Gutman and Gutman, 1937), and if the extra calcium were all bound to protein hypercalciuria should not occur. Parathyroid hyperplasia has been found in some cases of sarcoidosis with hypercalcaemia (Westra and Visser, 1949; Longcope and Freiman, 1952), but in others exploration has shown the glands to be normal (Albright and Reifstein, 1948; the patient reported with a low plasma inorganic phosphorus level, and this also makes it unlikely that there is primary parathyroid overactivity.

The most probable explanation of the hypercalcaemia is that it is due to active destruction of bone from widespread involvement by sarcoid deposits. This would be comparable to that found in some cases of myelomatosis. Radiological changes in the bones in sarcoidosis are usually confined to the hands, and generalized bone rarefaction is rare, although van Creveld (1941) and Schüpbach and Wernly (1943) have reported cases in which it was present. Radiological evidence of generalized rarefaction is found only when there has been a negative calcium balance for many years, and sarcoidosis is a self-limited process in which hypercalcaemia has seldom persisted for any considerable evidence of rarefaction in most cases does not therefore exclude active bone destruction as the cause of the hypercalcaemia. More direct evidence is provided by the histological studies of Schaumann (1926), who demonstrated widespread osseous lesions and thinning of the bony trabeculae without any radiological changes.

The effect of variation of calcium intake on the serum calcium concentration and urinary output has seldom been reported. Albright and Reifstein (1948) found little change in the urinary calcium with intakes varying from 360 to 2,967 mg. a day. In our patient the serum level and urinary output of calcium fell slightly when he was placed on a diet containing much less calcium (170 mg. a day), although the urinary output remained abnormally large. Klinefelter and Salley (1946) also reported a slight fall in serum and urinary calcium on a low-calcium diet. The fact that the urinary calcium remained fairly high when the intake was only 170 mg., together with the histological evidence of Schaumann, suggests that the hypercalcaemia results from reduction of serum and urinary calcium following cortisone therapy would be consistent with this hypothesis. There was radiological evidence of improvement in the lung condition while cortisone was being given, and it is probable that the bone lesions, if any, were similarly affected.

Impairment of renal function is a rare finding in cases of sarcoidosis; in only two has a post-mortem examination been reported, and little is known about its causation. It

cannot be correlated with the severity of the sarcoid process in the kidney, but seems to have some association with hypercalcaemia. Longcope and Freiman (1952) reported a case in which the patient died of renal failure and the kidneys showed chronic pyelonephritis and tubular calcification. In another patient, dying of miliary tuberculosis, sarcoid lesions, miliary tubercles, and calcified tubules were found in the kidneys (Horton *et al.*, 1939). Our studies clearly indicate the reversibility of the renal function impairment and its lack of association with any permanent structural damage to the kidney. Reversible impairment of renal function is known to result from a number of biochemical disturbances, of which hypercalcaemia is one. Long-continued elevation of the serum calcium leads to permanent renal damage with tubular calcification and hyalinization of the glomeruli; transient hypercalcaemia, on the other hand, leads to a temporary impairment. The improvement in renal function in the patient reported here was more rapid than is usual, for example, after vitamin-D overdosage. The renal biopsy performed a few weeks after the serum calcium fell to normal showed no evidence of calcification, but, in view of the report by Björnboe and others (1952) of the disappearance of tubular calcification within three weeks of discontinuing treatment in a case of vitamin-D intoxication, this does not exclude the presence of tubular calcification before the cortisone administration, and there is always the possibility that the renal biopsy may not have been typical of the whole kidney.

Hypercalcaemia in sarcoidosis is of importance for three reasons. First, it may lead to impairment of renal function, which, however, rarely progresses to uraemia; secondly, calcium oxalate stones may form in the renal pelvis; and, thirdly, if it occurs in the absence of x-ray changes in the lungs or of hyperglobulinaemia it may be attributed to hyperparathyroidism and lead to an unnecessary neck exploration. Renal calculi and band keratitis with hypercalcaemia, hypercalciuria even on a low calcium intake, normal bone x-ray films, and a normal serum phosphatase may be found in "hyperparathyroidism without bone disease." In this condition the plasma inorganic phosphorus is usually reduced, but it may be normal if there is impairment of renal function—that is, in Albright and Reifstein's (1948) "hyperparathyroidism - without bone disease - with renal failure." The differential diagnosis can therefore be very difficult. Howard *et al.* (1949) have reported that in sarcoid with hypercalcaemia the C.S.F. calcium is elevated, whereas in hyperparathyroidism it is normal. The C.S.F. calcium estimations in our patient were performed in duplicate in two laboratories and do not support this claim, but our studies do suggest the possible value of cortisone in differentiating between the two conditions, though we have not yet had an opportunity of investigating the effect of this hormone on the serum calcium level in a case of hyperparathyroidism. A similar reduction in serum calcium concentration in a case of sarcoidosis treated with cortisone has been observed by Professor G. M. Bull (personal communication).

Summary

Hypercalcaemia and impairment of renal function may occur in generalized sarcoidosis. A case is described in which the effects of variation of dietary calcium and cortisone therapy were studied. Clinical, radiological, and biochemical improvement followed the administration of cortisone. There was reduction of serum calcium and serum globulin, and renal function was much improved.

It is suggested that hypercalcaemia and hypercalciuria result from active bone destruction due to generalized sarcoidosis, and that in some cases the impairment of renal function is a consequence of the continuing disturbance of calcium metabolism.

A renal biopsy performed after cortisone therapy showed no sarcoid deposits or tubular calcification.

The differentiation of sarcoidosis with hypercalcaemia from hyperparathyroidism is discussed.

We wish to thank Miss D. P. Tuck for the preparation of the special diets; Mr. V. K. Asta for the chart; and the Medical Research Council for the cortisone used in this study.

ADDENDUM.—Since this report was prepared we have had another opportunity of studying the patient under constant normal dietary intake of calcium with and without cortisone. This time no change in serum proteins was observed, but again the cortisone reduced the serum calcium level to normal, improved renal function, and greatly improved the patient's well-being. This has now been repeated on three other patients with similar results. It appears that the improvement can be maintained for some months at least on a reduced dose of cortisone. It is hoped to publish these results later when a longer follow-up has been obtained. A recent paper by Shulman, Schoenrich, and Harvey (*Bull. Johns Hopk. Hosp.*, 1952, 91, 371) on the general effects of cortisone on patients with sarcoidosis briefly mentions changes in calcium levels and in renal function which are very similar to those we have described above.

SPLENIC VENOGRAPHY

Great interest has lately been taken in the surgical treatment of cirrhosis of the liver (Berman *et al.*, 1951; Reinhoff, 1951; Leger *et al.*, 1952; Hunt, 1952) and portal hypertension (Whipple, 1945; Blakemore and Lord, 1945; Blakemore, 1951; Walker, 1952; Hunt, 1952). Valuable information may be obtained by needle biopsy of the liver in cases of hepatic cirrhosis. The procedure is sometimes difficult owing to the hardness and smallness of the liver and to the presence of ascites. Portal hypertension is usually determined by noting the pressure in one of the tributaries of the portal vein. Cavernomatous changes in the portal vein and obstruction in its prehepatic part or in the splenic vein may be made out by injecting a radio-opaque dye in the tributaries. In all these cases the abdomen has to be opened to carry out the investigation. Moreover, a surgeon must be sure that the splenic vein is patent and that the veins are large enough before attempting spleno-renal anastomosis. If useful information could be obtained

without laparotomy by a procedure which is safe it would be welcome. Splenic venography was done by Dreyer and Budtz-Olsen (1952) in 11 cases without any untoward incident. They suggested, among other things, that the method might be useful in finding out the site of block in cases of portal hypertension.

We carried out splenic venography in two control cases, in two with portal hypertension, in three cases with cirrhosis of the liver, and in seven cases of splenomegaly of unknown aetiology.

Method

The patients fasted overnight. Half an hour before the procedure 50 mg. of pethidine hydrochloride was injected. The patients lay supine on the x-ray table. The left ninth intercostal space in the mid-axillary line was chosen as the

FIG. 1.—Splenic venogram showing iodoxyl in spleen, splenic vein, upper part of a superior mesenteric vein, portal vein, and intrahepatic branches of portal vein.

FIG. 2.—Most of the dye has left the spleen and accumulated in the right lobe of the liver.

site for injection of the radio-opaque dye. The part was sterilized and the space up to the splenic capsule was anaesthetized with 2% procaine hydrochloride solution. About 5 ml. was needed. Then 20 ml. of a solution of "iodoxyl" (N-methyl-3:5-di-iodo-4-pyridone-2:6-dicarboxylic acid) was taken into a 20-ml. Record syringe to which a lumbar puncture needle was attached. It was pushed in medially and slightly downwards. The engagement of the needle in the spleen could be felt. The patients were asked to hold their breath at the end of inspiration until the whole amount was injected. An assistant held the lower pole of the spleen in cases in which it was enlarged.

The dye was injected as quickly as possible and a picture was taken when 15 ml. of dye had been injected (Fig. 1). That amount took about five seconds to inject. The next picture was taken five seconds later, when the full amount of the dye had been injected (Fig. 2). The needle was taken out and the site was sealed. At first we used a fine lumbar-puncture needle (children's size) attached to a 20-ml. all-glass syringe. It required great force to inject the dye into the splenic pulp. Later on, an adult lumbar-puncture needle attached to a Record syringe was used, when it became easy to inject the dye in five seconds. If the spleen was enlarged the needle was pushed for about 5 cm. from the skin surface. In cases without splenic enlargement this

distance varied between 3 and 4 cm., depending on the thickness of the parietes. The patients were kept in bed for 24 hours and the pulse, respiration, and temperature were noted every hour. Sensitivity to iodine was not tested.

Reactions

If we exclude the first patient, who neither fasted nor had a sedative before the injection of the dye, there were practically no untoward reactions. Most of the patients complained of some pain over the spleen which lasted for about 10 minutes. There was no obvious alteration in pulse, respiration, and temperature. To note the amount of bleeding we drew out ascitic fluid in two cases of cirrhosis of liver before and after venography. In both cases only the second specimen contained blood. The patients were up and about from the next day and took their usual diet. The first patient vomited immediately after the injection of the dye, had a rigor, and was febrile for several days. He is now quite well. The cases are summarized in the Table.

Discussion

In a normal splenic venogram the splenic vein and the portal vein and its branches for some distance inside the liver are visible. A small portion of the superior mesenteric vein near its entry into the splenic vein may sometimes be made out (Fig. 1). The dye leaves the spleen very rapidly (Fig. 2). A small remnant may, however, be seen inside the spleen even an hour after the investigation. It usually appears in the urinary bladder within 30 minutes of the injection of the dye. In cases of obstruction of the splenic vein the portion of the vein beyond the obstruction will not appear, as shown by Dreyer and Budtz-Olsen (1952). In portal hypertension due to greatly increased pressure in the portal circulation the blood flow may be reversed and the dye may enter the inferior mesenteric vein, its tributaries, and the left gastric vein (Fig. 3).

In cirrhosis of the liver, as the obstruction to the portal vein is inside the liver, the intrahepatic branches of the vein

are either not made out or faintly seen, depending on the degree of obstruction, and the extrahepatic portal vein and the splenic vein become markedly dilated and tortuous (Fig. 4). The inferior mesenteric and left gastric veins may not be demonstrated unless the portal hypertension is great. Hence the degree of prominence and tortuosity of these veins in the splenic venogram will be a measure of the extent of portal hypertension. Case 5, who was admitted to hospital for operative treatment of cirrhosis of the liver, had a contracted liver with a granular surface. The portal pressure was 300 mm. of saline, and immediately after ligation of the hepatic and splenic arteries it fell to 225 mm. There was no injury to the spleen due to venography.

In our cases of splenomegaly of unknown aetiology there was no clinical evidence of portal hypertension, the liver-function tests were within normal limits, and liver biopsy did not show cirrhotic changes. Owing to the huge splenic enlargement the splenic vein has to carry a large amount of blood and becomes dilated and tortuous. The portal vein and its intrahepatic branches also become dilated. In these cases the dye will be poorly concentrated, and the venogram will show dilatation and tortuosity of the splenic and portal

FIG. 3.—Tortuous splenic and inferior mesenteric veins. Extrahepatic portion of portal vein and left gastric vein can be seen.

Summary of Cases

Case No.	Age and Sex	History of Bleeding	Veins over Abdominal Wall	Venous hum.	Spleen	Liver	Ascites	Liver-function Tests	Liver Biopsy	Clinical Diagnosis	Splenic Venogram

veins (Fig. 5). As there are no cirrhotic changes, the intrahepatic branches of the portal vein can be made out, though faintly owing to dilution of the dye. Inferior mesenteric and gastric veins are not seen, as there is no associated portal hypertension. In Case 14, who underwent splenectomy, the portal venous pressure was 120 mm. of saline. Often some of the dye gets underneath the capsule of the spleen, probably owing to adhesions between the spleen and the parietal wall; but in the case of splenomegaly in which splenectomy was done no such adhesions were found. In this case also no injury was noted in the spleen due to venography.

In experienced hands splenic venography is usually safe. Rarely the dye may produce vomiting and rigor, as is sometimes seen when carrying out intravenous pyelography.

FIG. 4.—Markedly dilated splenic vein. Extrahepatic portion of portal vein faintly seen, but the intrahepatic branches are not visible.

FIG. 5.—Tortuous and dilated splenic and portal veins. The intrahepatic branches are dilated and the dye is poorly concentrated in them.

Overnight fasting and the use of pethidine hydrochloride usually prevent these complications. Though pethidine quiets the patient and removes his apprehensiveness, he remains co-operative and holds his breath during injection of the dye. There is some bleeding due to puncture of the spleen, which, however, stops spontaneously. The needle should be pushed for some distance inside the spleen and the dye injected into the splenic pulp. There is far less chance of rupture of the spleen than when the dye is forcibly pushed immediately underneath the capsule. The possibility of excessive bleeding and of rupture of the spleen, though very remote, should be kept in mind, and the procedure carried out only in a hospital where emergency splenectomy could be done.

Most of the patients complained of pain over the spleen immediately after injection of the dye. It lasted from five to ten minutes. It is probably due to spasmodic contraction of the spleen, set up by the large amount of foreign substance inside the splenic pulp. If there is associated spasm of the splenic vein the dye is retained longer inside the spleen.

Summary

Splenic venography was done on 14 cases without untoward incidents.

Though there is slight haemorrhage from the spleen the procedure is safe.

The venogram shows the size and patency of the splenic and portal veins.

The intrahepatic branches of the portal vein are visible in a normal venogram, but, depending on the degree of obstruction, they are either absent or are faintly made out in venograms of cases of cirrhosis of the liver.

In portal hypertension the inferior mesenteric and left gastric veins may become visible and their prominence and tortuosity may be a measure of the degree of hypertension.

In splenomegaly without portal hypertension or cirrhotic changes in the liver the splenic and portal veins are dilated and tortuous and are fainter in outline than in normal cases. In these patients and in cases of cirrhosis of the liver the splenic and portal veins are sometimes so dilated as to resemble a loop of intestine (see Fig. 4).

ADDENDUM.—Since the submission of the paper for publication we have carried out splenic venography on four cases of cirrhosis of the liver, two of nutritional oedema, and three of splenomegaly of unknown aetiology without any untoward incident. The conclusions drawn in the paper have been corroborated.

We are much indebted to Dr. A. K. Dutta Gupta, Principal-Superintendent, Nilratan Sarkar Medical College, for giving us the facilities for carrying out this investigation. Our thanks are also due to Dr. S. Mitra, the Registrar, and Drs. M. Gupta, G. Chanda, and G. Melhotra, the house officers to the associate professor of medicine, and to Drs. M. Mukherjee and R. Roychoudhary, the radiologist and assistant radiologist respectively of the Nilratan Sarkar Medical College Hospital, for their help and co-operation.

On Thursday last a plaque was unveiled on the wall of an old people's home in the King's Road, Chelsea, to commemorate the association of Sir Hans Sloane with the district. Sloane was born in Ireland in 1660. He studied medicine in Paris and Montpellier and graduated at Orange in 1683. He became a fashionable London doctor and a Fellow of the College of Physicians and of the Royal Society. In 1687 he sailed to Jamaica as physician to the Duke of Albemarle. From there he brought back a large number of plants and animals which formed the basis of his famous collection of specimens and books. As a physician he was as well known for his charity as for his professional skill, and devoted part of his salary to establishing a dispensary for the poor. He was elected secretary and later President of the Royal Society, and in 1716 he was made a baronet. He did not live permanently in Chelsea until 1742, but it was there that he died in 1753. In his will he left his famous collections to the nation, and they were housed in a building on the site now occupied by the British Museum.

Medical Memoranda

Unusual Case of Rupture of Spleen

The following case of traumatic rupture of the spleen was treated recently at Cardiff Royal Infirmary.

CASE REPORT

The patient, a lusty young miner aged 28, was admitted on a Saturday evening complaining of upper abdominal pain and of dyspnoea. Twenty-four hours before admission he had been knocked down by a cyclist. When the accident happened he had just left a public-house where he had drunk "about ten pints" (5.7 litres) of beer. He had not been concussed but was unable to remember on which part of his body he had been hit. He had immediately got up, and had exchanged suitable imprecations with the cyclist, and had then walked four miles (6.4 km.) to his home. He had gone to bed and had been woken from sleep by upper abdominal pain which interfered with his breathing. This had persisted up to the time of his admission to hospital. On examination the most striking finding was a respiration rate of 40 a minute with the alae nasi moving vigor-

ously. There was no cyanosis, pallor, or sweating. The pulse rate was 92 and the blood pressure 130/80. The skin was warm even on the extremities and the skin circulation was brisk. The abdominal wall did not move freely on respiration and there was muscle guarding and tenderness to deep palpation all over the abdomen. Marked tenderness, muscle rigidity, and persistent dullness to percussion were present in the left upper abdominal quadrant. Left shoulder pain was absent, nor was it produced by raising the foot of the bed for 10 minutes with the patient lying flat, after the manner suggested by O'Connell (1951). A diagnosis was made of incomplete rupture of the spleen. An hour or so after admission the abdomen was opened by an upper left paramedian incision. The peritoneal cavity contained a quantity, estimated at 1 to 2 pints (570 to 1,140 ml.), of fluid blood and some clots. On retracting the left edge of the wound the lower pole of the completely ruptured spleen (see photograph) was seen lying quite free and unattached on the front of the greater omentum. It was simply picked out of the abdomen. The main mass of the spleen was lying in its normal position with the hilar vessels intact. The surface of rupture was covered by clot, and at the time of operation haemorrhage from this surface was certainly not brisk. Splenectomy was completed without difficulty and the patient made an uneventful recovery. Two pints (1,140 ml.) of blood was transfused during and immediately after operation. Histological examination of the spleen revealed no abnormality.

COMMENT

That rupture of the spleen not uncommonly presents in a clinically covert manner is, of course, well known. The pathological explanation is that haemorrhage is arrested or

retarded by blood clot. Conditions favourable to the formation of a localized clot, such as tearing of a small hilar vessel or partial or subcapsular rupture of the spleen, are generally present. The interest of the case reported lies in the fact that the same mechanism was effective in retarding haemorrhage in a patient whose spleen had suffered injury severe enough to amputate and to dislocate its lower pole.

I am indebted to Mr. J. B. Haycraft for permission to publish this case history.

D. H. JENKINS, M.S., F.R.C.S.,
Senior Surgical Registrar, Cardiff Royal Infirmary.

Rupture of Spleen in Infectious Mononucleosis

Spontaneous rupture of the spleen is rare except in districts infested with malaria. Among recorded diseases associated with spontaneous rupture are arteriosclerosis, arterial degeneration, sarcoidosis, lymphatic leukaemia, and glandular fever or infectious mononucleosis.

In the records of the United States Army Institute of Pathology infectious mononucleosis accounts for 7 out of 44 cases of spontaneous rupture of the spleen, and is second in frequency to malaria, which was responsible for 22.

CASE REPORT

A man aged 23 was seen on February 6, 1952, as an acute abdominal emergency of 24 hours' duration. He complained of upper abdominal pain of a continuous nature since 5 a.m. on the previous day. The pain was felt in the left hypochondrium and the epigastrium, and there had been some distension in this region. Vomiting had not occurred, but he had had several attacks of nausea on the previous day. There was no history of trauma. He had not eaten a meal for over a week. His bowels were normal up till the previous day, when an attack of diarrhoea occurred. His urine was "strong," but otherwise normal. He had no cough and no backache. For the past two months he had been off-colour and claimed to have lost 28 lb. (12.7 kg.) in weight during this time. Seven days ago he had had a quinsy which had cleared up on sulphathiazole, 1 g. four-hourly for five days. Two days ago he had an attack of severe abdominal pain which doubled him up and lasted 15 minutes. Pain also occurred in the left supraclavicular region for a short period. There was no other significant past history.

On examination the patient was seen to be pale and a little wasted. His temperature was 100.6° F. (38.1° C.), pulse 100, respirations 28, blood pressure 145/90. The throat showed slight inflammation, but no peritonsillar abscess or membrane. The abdomen was distended, especially in the upper part; no visible peristalsis. On palpation there was slight tenderness and guarding all over. No masses were palpable. The spleen was not palpable. On percussion the abdomen was tympanitic, except that on percussing along a line from the left axilla to the umbilicus there was a band of dullness 2 in. (5 cm.) wide just above the costal margin. It was continuous with cardiac dullness medially, and faded away laterally. On auscultation there was complete silence in the abdomen. Per rectum definite tenderness was found in the rectovesical pouch. Routine palpation in the axilla, groin, and neck revealed a few lymph nodes that were hardly worthy of attention and were indistinguishable from old septic glands. The chest and heart were normal. On the physical signs a diagnosis of "blood in the peritoneal cavity? cause?" was made.

Laparotomy was performed under gas, oxygen, and ether (Dr. Roberts). A right paramedian incision was made. As soon as the peritoneum was incised blood welled out. On exploring the abdomen the spleen was found to have two tears on its convex surface, surrounded by a large volume of blood clot. The incision was extended with a left transverse cut dividing the right rectus muscle, and splenectomy performed. All blood was removed from the abdomen. No other abnormality was detected. The abdomen was closed without drainage.

After operation a routine blood count showed: red cells, 3,050,000; Hb, 64% (8.2 g.%); colour index, 1.08; white cells, 22,000 (N. polymorphonuclears 47%, lymphocytes 39.5%, monocytes 13%, N. metamyelocytes 0.8%); one normoblast seen in counting 200 white cells; anisocytosis; platelets normal in number; many atypical lymphocytes present; ? glandular fever. A review of the case was then made and glandular fever seemed to be the correct diagnosis.

The Paul-Bunnell test showed:—first post-operative day: patient 1 in 24, control nil; seventh post-operative day: patient 1 in 96, control nil; fourteenth post-operative day: patient 1 in 24, control nil.

The patient was given aureomycin, 2 g. at once, and 0.5 g. six-hourly for four days. He made a satisfactory convalescence, and was discharged home on the sixteenth day in good health, when the white-cell count had fallen to 11,300 (N. polymorphonuclears 41%, eosinophils 6%, lymphocytes 43%, monocytes 10%).

The following pathological report on the ruptured spleen was received. "Microscopical Report:—Spleen (18 by 10 by 4.5–6.5 cm.; 580 g.). There was a large double cruciate tear on the medial surface (upper pole). Capsule entirely stripped from convexity of spleen ? following subcapsular haemorrhage. Pulp semi-fluid due to autolysis resulting from the usual failure of fixative to penetrate splenic tissue in bulk. (The peripheral 0.5 cm. of pulp was well fixed.)" "Provisional Histological Report:—The splenic pulp is unusually cellular. Most of the cells are mononuclears, including lymphocytes, lymphoblasts, and atypical larger cells. Plasma cells are present. There is an unusual proportion of polymorphs in the pulp. Some sinuses are distended with atypical mononuclears. Similar cells have infiltrated the capsule to a slight extent. There is a fresh subcapsular haemorrhage. The follicles are small and widely spaced, germinal centres are practically absent. Spleen: rupture (infectious mononucleosis)."

When seen 12 weeks after discharge the patient was quite well and the white blood cells numbered 8,400 per c.mm. (monocytes 10%). Many of the lymphocytes were atypical.

COMMENT

In 1922, before infectious mononucleosis as a separate clinical entity was recognized, Friesleben described spontaneous rupture of a spleen in a patient who was probably suffering from this disease. Since then a number of cases have appeared in the literature (King, 1941; Ziegler, 1944; Davis *et al.*, 1945; and Smith and Custer, 1946).

Usually some history of minor trauma prior to the rupture is obtained. It may be straining at defaecation, twisting in bed, or a definite slight blow. Signs of rupture may follow at once or appear in a few days, either suddenly or after symptoms suggesting intermittent bleeding. Rupture mostly occurs after the fourteenth day of the disease, suggesting that the changes in the spleen require this time to produce enough fragility in the organ for spontaneous rupture to occur. Ziegler described one fatal case, and four of Smith and Custer's seven patients died.

Histology.—The capsule is infiltrated with lymphocytes and large mononuclear cells, and there is oedema of the capsule and the subjacent pulp. The trabeculae are infiltrated with mononuclear cells to a greater degree than the capsule. A varying degree of dissolution of the trabeculae is present. Splenic pulp is increased in bulk and the pattern is blurred. The blood sinuses contain mononuclears which are often densely packed. Follicles are few per unit area, are small, and lack germinal centres. The histological pattern is thus typical enough to enable a diagnosis to be made.

I am indebted to Mr. B. T. Rose for permission to publish this case.

Pregnancy following Haematosalpinx

Pregnancy following haematocolpos and haematosalpinx is rare enough to justify recording the following case.

CASE REPORT

The patient was referred to Mr. V. B. Green-Armytage at the age of 17, after she had had a year of monthly pain, which was thought to be due to the delayed onset of menstruation. Mr. Green-Armytage, who has kindly supplied details which he has allowed me to record, states: "When seen, she had a typical haematocolpos and haematometra together with right and left iliac fossa pain suggesting overflow into the tubes. So the abdomen was opened. She had a bilateral haematosalpinx, and the distended uterus was sitting on the top of a mountain of haematocolpos. An assistant incised the anatomical vaginal defect and then I slowly milked the blood in the tubes into the uterus and away it went. There was just over one and a half pints of fluid (750 ml.), and I was interested to find on either side that a certain amount of the retained blood in the tubes was able to leak out of their fimbrial ends into the peritoneal cavity. Later I confirmed the patency of the tubes with carbon dioxide insufflation and salpingogram, and was able to give a good prognosis when she married."

Another gynaecologist who was present at the operation writes: "I well remember the haematocolpos, haematometra, and haematosalpinx which had further become haematoperitoneum. Vividly I recall the mahogany staining of the great omentum at laparotomy."

The patient was married in December, 1948, and became pregnant in February, 1951, at the age of 29. The only obstetric abnormality was some hydramnios. Labour started spontaneously at 42 weeks. The first stage lasted 18 hours and the second one hour. After an episiotomy, a 9½-lb. (4.3-kg.) baby girl was born spontaneously and thrived.

COMMENT

Because of its comparative rarity congenital vaginal atresia with its complications is only briefly described in most textbooks. However, in the Tropics the condition is by no means uncommon, and Mr. Green-Armytage's great experience there, together with the outcome in the above case, adds much weight to his opinion that laparotomy should be carried out in cases complicated by haematosalpinx.

Bernstein and Walter (1939) reported 19 cases of haematometra and thought that drainage from below is effective, thus avoiding a laparotomy. Curtis and Huffman (1950) stated that where there is haematosalpinx the tubes are usually closed. They believed that abdominal exploration should be reserved for those cases in which a pelvic mass remains after evacuation of the haematocolpos. In their review of 50 cases of congenital vaginal atresia, Christie Brown and Brews (1930) reserved laparotomy for those cases which had distended Fallopian tubes. They pointed out how undue abdominal pressure during examination could lead to tubal rupture, making salpingectomy and sometimes hysterectomy necessary.

When the tubes are found to be distended at laparotomy they should be emptied with care by milking blood into the uterus. If this is not possible, incision of the haematosalpinx (salpingostomy) would seem preferable to resection.

I have not been able to find in the literature a success similar to that in the above case, although in the opinion of Christie Brown and Brews the prognosis with regard to subsequent fertility in treated cases of haematocolpos is excellent. It is probable, however, that there have been similar cases, and it would be interesting to hear of them.

Reviews

GASTRIC ACID SECRETION

The Biochemistry of Gastric Acid Secretion. By Professor Edward J. Conway, M.D., D.Sc., F.R.S. American Lecture Series. (Pp. 185; 37 illustrations. 47s. 6d.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

Professor E. J. Conway has written a stimulating and provoking book on one of the topics of great current biochemical and medical interest. It is a striking illustration of the unifying value of biochemical concepts that Conway discusses the mechanisms whereby the yeast cell can, under certain conditions, reduce the external pH to as low as 1.5 in considering the mechanism of HCl secretion in gastric mucosa, and is able to ascribe the production of acid in both instances to a K⁺ and H⁺ exchange. But, as he points out, "It is likely that the true analogy between the parietal secretion and the secretion of acid by yeast lies between HCl in the one and succinic acid in the other, the corresponding anions existing already in the cells." Conway puts forward cogent evidence to suggest that, with respect to gastric secretion, there are serious difficulties in assuming that the H⁺ ion donor is a metabolized acid and concludes that the donor is a reduced heavy metal catalyst operating in a redox cycle across a membrane. He considers the energetics for such a scheme, and elaborates the principle into the "redox pump" theory of the manner in which a cell performs osmotic work.

Conway considers that, in gastric secretion, the restoration to the active parietal cell of H⁺ ions removed in the oxidative phase of the redox cycle occurs through the ionization of carbonic acid, and the existence of carbonic anhydrase in the parietal cells is here of especial significance.

In discussing the ways in which the concentration of acid in the parietal secretion or in the gastric juice may be decreased Conway accepts the theory, put forward by Fitzgerald and Murphy in 1950, that urease, present in the mucosa, may be of significance in producing ammonia from urea and may be of functional significance in protecting the mucosa against acid. This view is, however, criticized by others on the grounds that the urease is not in fact of endogenous origin, but such criticisms do not affect the validity of Conway's opinions as a whole. The value of urea therapy in the treatment of ulcer cases with dyspepsia resistant to the usual treatment is advocated and discussed in the light of these views.

Conway's hypotheses have by no means been accepted by everyone concerned in researches of this kind, but here we have a lucid and readable discussion of the author's views on work that is one of the growing points of biochemistry. To those who wish to read an account of an individual viewpoint in a field of controversial interest by a modern biochemical polymath this book can be confidently recommended, and for the doctor who wishes to savour something of the excitement of fundamental research in a field of medical importance no better *hors d'œuvres* could be found.

F. G. YOUNG.

SCIENCE OF NUTRITION

The Work of Sir Robert McCarrison. Edited by H. M. Sinclair, with additional introductory essays by W. K. Aykroyd and E. V. McCollum. (Pp. 327. 30s.) London: Faber and Faber. 1953.

This book contains a selection from the writings of Sir Robert McCarrison and a prologue made up of three essays, one by Dr. W. R. Aykroyd, who was for many years McCarrison's successor as director of the Nutrition Research Laboratories at Coonoor, another by Emeritus Professor E. V. McCollum, and a third written by the editor, Dr. H. M. Sinclair, and Mr. Selwyn Taylor. Much of the work reprinted is from books now mainly out of print or from journals not always easy to obtain.

The value of McCarrison's contribution to the science of nutrition, seen after an interval of fifteen to twenty years, is, in Aykroyd's words, "abundantly evident, and little importance need be attached to the occasional errors of an enthusiastic pioneer exploring new territory." A feature of this record is the contemporary interest of many of the conclusions drawn from McCarrison's own experimental work and observations. In an appreciation of McCarrison's studies Mr. Taylor concludes, "I know of no one else alive to-day who has contributed so much that is new to so many varied aspects of the goitre problem." McCarrison also recognized the special value of work on applied nutrition and summed up the situation in India in the following observation, which is as relevant to-day as when it was written many years ago: "Indeed the greatest of all problems in India at the present time is the adjustment of the population to its food supply. It is one that is capable of solution only by the people themselves: by the exercise of self-help; by the jettisoning of old habits and customs unsuited to modern economic conditions; by improvement in methods of agriculture, animal husbandry, and industry; and, above all, by restraint in reproduction."

We may join in the pleasure expressed by Professor McCollum in following McCarrison "through two decades toward the distant watch-fires of truth to express high regard for him as a man as well as an investigator," and at the same time share in this happy tribute to McCarrison on his recent seventy-fifth birthday.

B. S. PLATT.

RADIOACTIVE ISOTOPES

Radioactive Isotopes: An Introduction to their Preparation, Measurement, and Use. By W. J. Whitehouse and J. L. Putman. (Pp. 424; 154 figures. 50s.) Oxford: At the Clarendon Press. 1953.

The doctor of medicine in the world to-day, and more particularly to-morrow, cannot afford to forget the physics of his premedical training. Radioactive isotopes have come to stay and will be further developed for therapy and for various forms of investigation both at the bedside and in the laboratory. As a corollary, their production poses a problem in industrial and public health.

This new British publication is written by two physicists associated with the Isotope Division at the Atomic Energy Research Establishment at Harwell. "It is intended," they state, "primarily for the use of scientific workers who, while they may be experts in their own field of study, have no specialized knowledge of radioactive theory and technique." What need will it fulfil for the doctor of medicine?

The first three chapters are basically an exposition of the physical theory necessary. Chapter IV gives a useful account of the production of radioactive isotopes chiefly in the pile but also by cyclotrons. Chapters V and VI concern the detection and measurement of the radiations directly by particle counters and indirectly by virtue of the ionization produced; Chapter VI is perhaps rather ambiguously headed the "Gross Effects of the Radiations." With all this the modern medical practitioner in hospital, and especially his alter ego in medical research, needs to be acquainted. This volume will be a useful addition to his personal or departmental library. To his colleague, the hospital physicist, the work may well have a place on the bench. It is well supplied with tables and graphs, most, it is true, to illustrate the text, but many useful for day-to-day reference.

The last two chapters on "Some Applications of Radioactive Isotopes" and "Manipulation of Radioactive Material" can be helpful to both in the design of experiments and of routine work; neither is meant to be comprehensive but only illustrative.

The Oxford University Press have issued this book with their usual high standard of production, and they and the authors are to be congratulated on the absence of errors. (The reviewer is not competent to check much of the algebra.) Of necessity this has entailed delay, and the book reflects the state of knowledge at the end of 1950. It is too advanced for the beginner (for example, basic

definitions like those of the curie and roentgen do not appear till chapters V and VI respectively) and not sufficiently comprehensive to be a sole work of reference for the moderately initiated. Nevertheless, it should compete successfully with, and complement, several similarly not complete and earlier manuals published in the United States.

J. F. LOUTIT.

SOCIAL MEDICINE

Social Aspects of Disease. By A. Leslie Banks, M.A., M.D., F.R.C.P., D.P.H. (Pp. 373. 20s.) London: Edward Arnold. 1953.

At first sight this book by the professor of human ecology at Cambridge appears to be a small textbook on general medicine in that a chapter is devoted to each system. But deeper digging reveals that the author has considered the main afflictions of mankind and achieved order and clarity by his systematic and systemic approach. The work is intended for ancillary workers in the medical and medico-social services, by which is meant, no doubt, health visitors, almoners, and workers in voluntary organizations. But Professor Banks hopes that the book will also interest doctors and medical students—a modest hope which will certainly be fulfilled.

The detailed discussion of each disease is concise and well done. It is always a difficult task to write satisfactorily for both lay and medical readers. The bias here is a little towards the medical side, which from the doctor's point of view is a good thing, although in consequence some of the matter may be found a little too technical for others. There seems to be an occasional lack of proportion in the space given to difficult diseases. For example, plague is considered at about the same length as bronchitis. Plague is the more dramatic; bronchitis is now far more lethal and presents a grave social problem which surely needs much more space than two pages. Those who live and work in public health in the north, where mortality is more than 20% higher than that of the country as a whole, would have welcomed more consideration of the effects of climate and atmospheric pollution. But these are mild criticisms, heavily outweighed by the general and particular excellence of the book.

Random sampling of the index demonstrates that the indexing is of the same high and careful standard as the writing. The binding, paper, and printing are good, and better than one may reasonably expect at the price. This book is recommended to doctors who appreciate the importance of relating therapeutic medicine to social conditions—and I would hope that this applies to all doctors.

C. METCALFE BROWN.

A GREAT DENTIST

Dr. Howe and the Forsyth Infirmary. By Rollo Walter Brown. (Pp. 188. £1 2s. 6d.) Harvard: University Press. London: Geoffrey Cumberlege. 1953.

Between 1842 and 1854 four sons were born to the wife of William Forsyth, a prosperous Scot whose business was near Boston, Massachusetts. All four sons became rich, but only two married, and neither had any progeny. Yet they were fond of children and wanted their money to benefit the little ones, so, on the advice of a certain Dr. E. A. Johnson, they gave or left their money to found a large and palatial dental clinic—the Forsyth Infirmary. This clinic became the model for others in many parts of the world, and owed much of its success to the energy, ability, and initiative of Dr. Percy Howe, whose life-story is recounted in this book.

Percy Howe was a successful dental practitioner up to the age of 50, though he had an independent mind and, as best he could, carried out a certain amount of research in his spare time. When the Forsyth Infirmary was opened Howe was attached first as research worker and later as director, a post which he retained till he died at the ripe age of 85 in 1950. Under Howe's guidance the Infirmary became a centre of research and dental education whose

influence spread far and wide. Among those who were attracted by Howe's work were Sir Arbuthnot Lane, Sir James Mackenzie, Sir Arthur Keith, and, at a later date, Lady Mellanby.

Howe was years ahead of his time in many respects, but particularly in two. First, he realized, as Sir John Tomes had realized in this country 60 years earlier, that dentistry was a part of medicine and should have a course of training comparable to that required by the medical student. Secondly, he clearly appreciated that general diseases had an effect on the development and structure of the teeth, and therefore he advised that doctors and dentists should work more in collaboration and know more of each other's work.

Howe became attached to Harvard Medical School, and at the invitation of President Conant helped to found the Harvard School of Dental Medicine. There is no doubt that he helped to raise the status of dental education in America. His advice to dental students deserves to be quoted: "The best medicine for all who are buried in a profession is to find refreshment in other fields. They should make the acquaintance of eminent men. They should know good poetry and good prose, and they should learn how to write."

It is difficult for a writer who is neither a dentist nor a doctor to get the proper perspective in writing the life of such a man as Howe, but Mr. Rollo Walter Brown has succeeded in giving a good picture of Howe's personality. Incidentally, he has also given vivid vignettes of the brothers Forsyth. Listen to John Forsyth giving advice to a young girl: "Now don't put off too long doing the things you think you'll enjoy. Look at all these fine books I kept buying and meaning to read some day. But I waited for the day when I'd have lots of time. And now I fall asleep reading the newspaper."

ZACHARY COPE.

GROWING UP

Attaining Womanhood: A Doctor Talks to Girls About Sex. By George W. Corner, M.D. Introduction by Dr. Eustace Chessier. (Pp. 102; 14 figures. 6s.) London: George Allen and Unwin. 1953.

Attaining Manhood: A Doctor Talks to Boys About Sex. By George W. Corner, M.D. Introduction by Dr. Eustace Chessier. (Pp. 87; 16 figures. 6s.) London: George Allen and Unwin. 1953.

In these books Dr. G. W. Corner, pre-eminent as a scientist, leaves his backroom laboratories and assumes the roles of father and mother to the adolescent. He brings with him his natural charm and lucidity as well as unsurpassed knowledge of the physiology of reproduction, and wisely keeps as far as possible to the scientific side, leaving the reader to infer the morals from the story. The intended readers are girls aged 12 years and over, and boys presumably of similar age. The great difficulty is terminology, a matter on which Dr. Corner himself comments. He has avoided childish language and instead uses technical terms throughout—defining each when first used. Nevertheless, one gets the impression that the young will find it hard to read with understanding, or without frequent recourse to a dictionary.

The girl's book contains a section on the male and the boy's book a section on the female, and several of the chapters and illustrations are common to both. Parents with mixed families may therefore wonder why they should have to obtain two books when with slight modification one might have sufficed. There is in any case something to be said for making no distinction between the sexes where instruction of this kind is concerned.

The subject matter is as might be expected—comparative anatomy and physiology, ovulation, spermatogenesis, menstruation, conception, and childbirth, with reference to such matters as sex attraction and behaviour, masturbation, and venereal disease. It is all admirably done, and those parents who prefer their children to learn the facts of life from books rather than from themselves will find these among the best of their kind. None could be more authoritative.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 10 1953

TREATMENT OF BREAST CANCER

For half a century the operation of radical mastectomy has been the orthodox treatment for early cases of carcinoma of the breast. From time to time minor modifications have been introduced and the indications for carrying it out have varied within narrow limits, but by and large the solution of this therapeutic problem has been substantially that suggested by Moore¹ in 1867 and pressed with such vigour by Halsted² from 1889. But for some years the value of this procedure has been seriously questioned. An early sceptic was the late Professor Gask, of St. Bartholomew's Hospital, at whose instigation Mr. Geoffrey Keynes undertook to treat cases of carcinoma of the breast by the implantation of radium needles. This treatment was applied alone or in conjunction with a much modified surgical extirpation. Later Professor McWhirter treated a large series of cases of early cancer by simple mastectomy followed by x-ray therapy to the axilla.

So firmly established had the practice of radical mastectomy become that even to question its value smacked of *lèse majesté*, and those who had the courage to look for other methods had to face, not only the barriers of reasoned resistance, but an array of prejudice which lifted the discussion out of the cool atmosphere of scientific argument and plunged it into a cauldron seething with emotion. In our opening pages this week we publish a report by Mr. I. G. Williams, Mr. R. S. Murley, and Mr. M. P. Curwen, of St. Bartholomew's Hospital, on a series of 1,044 cases treated by different methods, including a series treated by Keynes and a comparable series submitted to radical mastectomy. This series of cases is discussed and analysed with all statistical safeguards, and the most striking of the conclusions is that, in terms of survival, there is not much to choose between radical mastectomy and procedures entailing a more modest surgical removal. These writers point out how morbid conditions, particularly oedema of

the arm, are much more common after radical mastectomy, and we may naturally question whether this distressing price is worth while paying if the achievement in terms of survival is negligible. Recently McWhirter³ has announced his ten-year survival rates, and these compare favourably with most of those published after more radical methods of treatment.

However, before relegating the operation of radical mastectomy to the category of a useless but spectacular piece of surgical virtuosity, there are certain considerations to be weighed. A comparison of the value of two different treatments can, it is true, commonly be made only by a statistical analysis. No amount of armchair pathology can support a method which is found to fail in practice. The difficulty, so far as the ordinary observer is concerned, is that the science of statistics has become vastly elaborate, and the exclusion of disturbing variables is an advanced mathematical exercise. Consequently a statistical analysis presents a structure so intricate, so specialized, and so formidable that this complicated erection has to be taken to pieces by an expert before a flaw can be detected in some small piece of the mechanism, upon which the whole working depends. The unprejudiced observer may therefore be pardoned if he views with some reserve statistical arguments alleging that one method of treatment is better, as good as, or worse than another in its effect upon survival rates. While the statistical instrument may be the one which must be used to measure these comparative differences, possibly this instrument is as yet insufficiently tempered to fulfil the difficult task which it is called upon to perform.

At a meeting this year of the Association of Surgeons the treatment of carcinoma of the breast was discussed. In the opening address Mr. Hedley Atkins warned his audience that the claims of rival schools of therapy which they were about to hear were unlikely to differ very much. He pointed out that a large proportion of patients with this disease would be dead within three years whatever was done. Another large group would survive five years or more in the absence of all treatment. It was only in a small fraction that, in terms of survival, it mattered what kind of treatment was given. If this third group was very small, the differences between any two methods of treatment would be very small also and might require the most careful statistical survey to reveal them. But he rightly added that very small differences in percentage survivals are of supreme importance to the individual patients who survive. Moreover, in the statistical field there is no series before or since which over-

¹ *St. Bart's Hosp. Rep.*, 1867, 3, 133.

² *Surgical Papers (Halsted)*, Baltimore, 1924, 2, 3-50.

³ Meeting of Association of Surgeons in April, 1953.

⁴ *British Medical Journal*, 1938, 2, 1071.

shadows that magnificent achievement reported by Gordon-Taylor⁴ using radical mastectomy alone, in which his ten-year survival rates were 84% of stage-I cases and 29% of stage-II.

Although morbid sequelae are the bugbear of radical mastectomy, this operation has no monopoly in this respect. Oedema of the arm will occur, though less often, after deep x-ray therapy alone and not uncommonly appears before any treatment has been given at all. Furthermore, if a patient who has had a radical mastectomy performed and has subsequently received x-ray therapy is asked which of these two methods of treatment upset her the more, she will nearly always say x-ray therapy, and that quite emphatically. What modern statistical research has done is to shake surgeons out of a certain complacency about the results which they are entitled to expect from the operation of radical mastectomy. It has revealed alternative methods of treatment in a favourable light and has created a more eclectic attitude towards the problem. The days are gone when radical mastectomy is prescribed wholesale for all early cases of carcinoma of the breast.

Two questions need to be answered. First, is there a stage in many cases of cancer of the breast when, apart perhaps from a few stray cells which may lie for ever dormant within the embrace of the body defences, the growth is confined to the breast and to the glands in the axilla? Secondly, is the proportion of these cases sufficiently large to justify the risks of unpleasant sequelae in selected instances in order to cure them? If the answer to these two questions is yes—and it is so in the minds of many reasonable and experienced workers—then radical mastectomy still has a place, even if a limited place, in the treatment of cancer of the breast.

Perhaps long before this difference of opinion is settled its relevance will be as obscure as that of the humoral and Brunonian disputes of long ago. Neither surgery nor x-ray therapy will be the final answer in the treatment of this disease. Increasingly our hopes are set on the work of the endocrinologist, the virologist, and the experimental pathologist. In a paper at page 796 of this issue of the *Journal* Drs. B. A. Stoll and Frank Ellis review the effect of oestrogen therapy on pulmonary metastases. These workers demonstrate statistically what has been the universal impression, that in women well past the menopause the administration of oestrogens may produce a striking improvement in pulmonary deposits. Although the beneficial effects are only temporary, this palliation may be prolonged for some years. The increasingly favourable reports which are

coming in demonstrate the effectiveness of these materials in some cases of advanced cancer, and are a further pointer to the direction in which future investigation will lie. In the meantime a willingness to understand and to use all the weapons that are to hand, clumsy though they may be, and a freedom from prejudice in favour of any exclusive or uncompromising practice, will serve our patients best.

SMOKELESS ZONES

In 1935, Charles Gandy, a Manchester barrister, proposed the principle of smokeless areas as a method of reducing smoke pollution in our industrial towns. The National Smoke Abatement Society, of which he was chairman for many years, approached the Manchester Public Health Committee, which in consequence caused the central area of the city to be surveyed in 1938 as a preliminary step to the creation of a smokeless zone. The outbreak of war held up this scheme, and it so happened that the area was heavily damaged by air attack. After the war the area, 105 acres in extent, was again surveyed, and it was found that the premises within it, consisting mainly of offices and shops and only a few dwelling houses, had more than 2,000 open fireplaces, most of which were fuelled by bituminous coal. The heating system of many of the buildings had already been modernized, and coal had been replaced by electricity, gas, or coke. This central area was therefore deemed to be suitable for an experimental smokeless zone.

There are no statutory powers of general application for the creation of smokeless zones, and the Manchester City Council had to obtain the necessary power, which it did by the Manchester Corporation Act, 1946. This pioneer legislation empowered the city council, among other things, to create a central smokeless zone, and made provision for the creation of other unspecified smokeless zones within the city boundary, subject to conditions including the approval of the appropriate Ministry. The central zone came into being on May 1, 1952.

Subsequently, some 14 towns obtained similar powers by means of local Acts, and other Acts are pending—for example, for the City of London. The City of Coventry created the first central smokeless zone of 30 acres on March 1, 1951, by virtue of its Corporation Act, 1948. In order to establish a

⁶ Clemo, G. R., *ibid.*, 1953, 2, 670.

smokeless zone in a developed area a local authority must proceed by private Bill—an expensive and lengthy procedure. A model clause for inclusion in private Bills for this purpose has been prepared by a committee of Parliament, and it would appear that the time is now ripe for supplementary legislation to permit any local authority to propose smokeless zones and so avoid the heavy expense of promoting private Bills. It is an expense contemplated by large authorities with proper hesitation, and an impossible burden on small authorities with meagre resources.

In a smokeless zone the emission of smoke from any building therein is prohibited and there are prescribed penalties for breach of the order. Smoke includes the visible and tangible products of incomplete combustion; it does not include deleterious gases such as sulphur dioxide. Protection is given in most local Acts against unreasonable action by local authorities, and local authorities are always required to contribute to the expenses incurred in making premises smokeless. There is no control over railway locomotives or of some mining processes—a freedom which is much abused.

The creation of a smokeless zone is not without its difficulties. First, it is essential to obtain the support of public opinion. Secondly, persuasion and diplomacy are required to convince owners and tenants of premises within the proposed zone that it will be a good thing for the community and themselves. Thirdly, expert advice must be freely available in order that the conversion of fuel-burning appliances will be the most suitable for particular conditions. Fourthly, patient explanation must be given to demonstrate that efficiency and economy go hand in hand and that smoke, besides being a nuisance, is in itself a waste of expensive fuel. There are other serious difficulties in relation to industrial operations, but none of them is insurmountable.

The results in Coventry and Manchester have been most satisfactory. Dr. Metcalfe Brown,¹ medical officer of health for Manchester, has been so impressed with the success of the first year's operation of the central zone that he has already recommended an extension marginally of the zone. The city council has approved, and, subject to the consent of the Ministry, the existing zone will be increased to 235 acres in extent on October 1, 1954. There is still plenty of Manchester left to be made smokeless in due course.

Manchester is the nucleus of a congested industrial conurbation of nearly 3,000,000 people. At first sight, to create a smokeless zone of a mere 105 acres in the centre of such a mass of smoke-producing

premises would appear to be a somewhat naive and quixotic gesture, with little hope of practical effect. But that effect has been achieved. The centre of Manchester is already clearer; there is a host of smokeless chimneys; the haze of smoke outside the zone contrasts markedly with the absence of visible smoke within the zone. The Press has commented favourably on "the hole in the fog." Business houses within the zone have written to the newspapers expressing appreciation of the results; commercial firms outside the zone have asked for extensions to include their premises; public opinion is strongly in favour.

At the annual conference of the National Smoke Abatement Society, which was held at Glasgow on September 30 to October 2, Dr. T. Morrison Clayton, medical officer of health for Coventry, referred to four categories of actual or potential smokeless zones. These were (1) industrial areas with heavy atmospheric pollution; (2) industrial areas with moderate pollution where redevelopment is planned; (3) residential areas in process of development; and (4) the environs of airports. Category (1) areas can be dealt with only by statutory legislation; areas in categories (2) and (3) and possibly (4) can be dealt with in the absence of special powers, for a planning or housing authority can usually apply conditions in relation to new buildings which would be difficult or undesirable to apply to existing buildings. Wade² has discussed the smokeless housing estate now in process of development by the Nottingham City Council—an excellent example of a residential area being developed (category 3). This scheme when completed will provide some 5,500 houses, 1,650 of which are already occupied. Each tenancy has a condition that no smoke will be emitted from the house and that all appliances using any solid fuel shall be fired by smokeless fuel. This is the largest smokeless area in this country. Coventry, Manchester, and Nottingham together have shown that smokelessness can be attained both at the centre and at the periphery of industrial centres.

Reduction of atmospheric pollution needs the support of the medical profession. There is a mass of evidence on the relationship between smoke and ill-health; for example, Goodman, Lane, and Rampling³ state, "There is no doubt at all that smoke associated with fog has a serious effect on the elderly and the chronic bronchitic in precipitating a mortal bronchopneumonia." Their data on chronic bronchitis demonstrate that the death rates from bronchitis in men aged 45–54 are highest in the regions of Newcastle, West Riding of Yorkshire, Liverpool, South-east Lancashire, and Birmingham. It is not a mere

coincidence that the atmosphere of these regions is heavily polluted. The presence of benzpyrene in city air has been reported by Waller⁴ and Doll,⁵ and by Clemo⁶ at a recent meeting of the British Association. The need for reducing the smoke menace is emphatic and clear.

THE RETURNED PRISONER OF WAR

The family doctor, consulted by a repatriated prisoner of war, may find that experiences during internment have had deep psychological as well as physical effects, and that the former are likely to be of special importance during the period of resettlement. The Serviceman never expects capture, and the violent change, affecting every detail of his life, strains all his bodily and mental resources. He is extremely depressed on capture. Weary, hungry, and longing for rest and security, he may be treated harshly and cruelly. The daily routine in which he had an established status has vanished. The customary habits are interrupted, and his individuality is lost. He is just one more prisoner, and his survival is of no interest to his captors. But this stage soon passes. He acquires new habits of life, accepts the grim situation, hopeful that somehow he will find means of escape. The group life of the camp, the irritations, the short tempers, the hard conditions, the monotonous and often insufficient food, the indefinite nature of his internment, are offset by efforts to score off his captors, to outwit them, and by a growing comradeship. The circumstances of his past life become idealized, and he pictures the future in rosy colours. Captivity, anyhow, will not last for ever; when he gets home he will live as he has never lived before. These dreams of the future are a necessary and valuable compensation.

Many soldiers, particularly professionals, experience a sense of guilt on capture. The notion that he may be regarded as an unheroic figure, since he is no longer fighting, can lead the prisoner to expect a loss of caste in the eyes of those at home. Men captured after a tough fight and when every round of ammunition has been fired are free of this thought. The feeling of guilt is always intensified by thoughtless letters from home criticizing the prisoner for his capture and mentioning his newly found safety.

Some of these returned prisoners at the difficult period of repatriation are now seeking their doctors' help. In the excitement of returning to his family, and with the prospect of realizing his dreams, the repatriated man has probably forgotten the inevitable changes that time has worked in his home and his friends. His family have been forced to deal successfully with life without him. His children or his

brothers and sisters have developed new interests. Should his wife have left him, he faces a catastrophic situation. The gulf between fantasy and fact is often extremely painful. The limited imagination of his family fails to picture the utterly different life he has led and is unequal to the strain of surrounding the returning soldier with sufficient sympathy. When the early days of home-coming have passed, the Serviceman may get the impression that in some way he has failed. The thought of personal guilt is repressed, becomes unconscious, and is projected. Then there come scathing remarks about politicians, employers, and those who in the security of home have become prosperous. The returned prisoner often has difficulty in resuming the daily financial responsibilities from which he was for a time free. In addition, his working skills may be impaired. In this atmosphere he may become aggressive, apathetic, or depressed, and perhaps alcoholic. Some even drift into crime as offering more excitement and a short cut to affluence. The problem of housing often intensifies the depression and resentment. Psychoneurotic symptoms—a fear of confined spaces, of crowds, of social occasions—may appear, and a tendency to exaggerate physical symptoms.

The doctor does not see those who grapple successfully with their difficulties. But the wise course with the man who consults him is to attend to his physical ailments and assure him at the same time that he is a normal person whose difficulties are in large measure due to the problem of resettlement. If the patient is unresponsive to simple measures, if he remains tense and maladjusted and suffers from insomnia, it is wise to call in a psychiatrist. Every man who has been a prisoner, even for six months, will be affected by it to some degree, and those who have been interned for two years or more will suffer more severely and their resettlement will be correspondingly difficult. Prisoners in Japanese camps during the second world war, and some in Korea, were always hungry. Food became the chief topic of conversation in prison camps and prison hospitals. Hunger overshadowed other instinctive tendencies, and sexual thoughts and activities faded. Abdominal symptoms are often mentioned by such prisoners on repatriation; they are concerned about bowel movements, and complain of vague abdominal pains. Digestive troubles are to be expected with the change of diet—for example, from rice to Service rations. Extreme cold was common in Korea, but usually the staple diet of Indian corn, although lacking in variety, was adequate. Considerations of this kind should be taken into account and a straightforward explanation of the symptoms given with firm reassurance that with

treatment the trouble will quickly settle down. A quite unnecessary dread of impotence often follows the diminution of sexual interest. Again and again repatriated prisoners assert that they have suffered physiological harm and that they will never be the same men again. This fear of impotence often leads to sexual incompetence on repatriation. The origin of the fear and the fact that it is common should be explained, and the assurance that it is groundless should be given and can be given with confidence. Neurosis is rare among returned prisoners of war, and was almost unknown in the survivors of Japanese prisoner-of-war camps. Most of those released from Japanese internment were in sound physical and mental health, for the weaker had not survived. Even so, many were anxious about their health.

The difficulties of resettlement rather than the hardships of internment are likely to be the precipitating factor in neurosis. The physical complaints of young repatriated men can usually be treated on familiar medical lines, but psychological symptoms may be persistent. The doctor should avoid comments on imaginary illness and avoid also the words prisoner of war, or prisoner, for they are unpopular with ex-prisoners. No reference should be made to the circumstances of capture, and even when the patient mentions the subject discussion should be brief. The doctor asked to support a claim for a disability pension should be sympathetic but cautious. A pension has inevitable charms, but its effect on character may be detrimental. The patient must be encouraged to take up his civil life without delay. At every employment exchange there is an official whose special task is to advise on any employment problem, and to give information on the training schemes available for men who want to learn a trade or to enter a profession. The period of resettlement need not be unduly difficult. It is a transitional period when timely advice and informed common sense can modify unprofitable attitudes of mind towards illness and towards society.

ANAL FISSURE

The general practitioner is commonly presented with cases of fissure in ano most of which respond quickly and satisfactorily to simple treatment. It is perhaps not well enough known that simple measures, properly supervised, will relieve the distressing symptoms of this common condition. Only a small minority of patients with anal fissure ever require operative treatment, such as that described by Mr. E. S. R. Hughes at page 803 of the *Journal* this week. Many of them would not need such radical treatment if they were properly managed in the first instance.

The most painful fissures are commonly the smallest and earliest ones. Contrary to widespread belief, a

sentinel pile is not often seen in association with a fissure, and the linear acute fissure can be diagnosed without subjecting the patient to a painful examination. As Mr. Hughes rightly emphasizes, it is essential to secure the co-operation of the patient and to examine him gently and reassuringly. Once the fissure is seen, it is possible to anaesthetize the raw surface quickly and efficiently with 10% amethocaine or cinchocaine ointment. It can be best applied by firmly twisting a small pledget of wool on to an orange-stick, dipping the wool in the ointment, and then gently inserting it into the anus and in contact with the fissure. Within a few minutes the doctor can pass a finger gently and painlessly, and the very fact that he can do so greatly helps to secure the patient's confidence.

After the initial examination the patient is provided with 3% amethocaine ointment and a metal or plastic dilator. The ointment should be gently applied to the site of the fissure once or twice daily (and invariably ten minutes or so before a bowel movement) and the dilator then passed. Patients vary in their ability to grasp the importance of this treatment, and it is essential for the doctor, or a suitably trained nurse, to explain the procedure carefully and to supervise the patient daily at first. The properly instructed patient can then be seen at intervals, and his condition will generally be relieved in two or three weeks. Occasionally treatment is needed for a longer period, but, with attention to detail, rarely will this simple regime fail.

Skin sensitivity, as Mr. Hughes points out, sometimes occurs with local analgesic ointments, but it is less frequent if 3% instead of 10% ointment is applied. Some doctors administer only a 1% ointment, and certainly, once the patient's initial anxiety and sphincter-spasm are relieved, there is a good case for using a weaker preparation. If the patient is taught to apply only a small amount of ointment precisely to the fissured area, and if a simple lubricant is used on the dilator, the chance of skin sensitization is still further reduced.

Most proctologists will agree with Mr. Hughes's opinions on injection treatment and digital dilatation of the anus under general anaesthesia. When we come to that small but hard core of cases with chronic and complicated fissures which really need operation, there are arguments for and against the orthodox operation of excision and the one advocated by Mr. Hughes. There is no doubt that the site of excision needs careful supervision, both while epithelizing and shortly afterwards. During the latter period the epithelium is unstable and the underlying scar tissue is still rather rigid. Nevertheless it is remarkable how soft and normal the anal margin becomes. The theoretical advantages in applying an immediate skin graft are considerable, and those who practise the technique carefully will be satisfied with the results. Surgeons with experience of skin grafting will need no reminding that the after-care of cases treated in this way must be no less careful than that accorded to the granulating area after simple excision. There is, perhaps, no need to adjudicate on the relative merits of simple excision and excision with primary grafting, for each method has a place in treatment. Some will feel that there is no place for skin-

grafting a small area, but where larger areas of skin have to be excised there would seem to be much merit in applying a graft.

SPLENIC VENOGRAPHY

Portal hypertension which has caused haemorrhage from the oesophagus or upper part of the stomach has been successfully treated by anastomosing the portal vein or one of its tributaries to a systemic vein.^{1,2} The obstruction to the portal blood may be either intrahepatic, as in cirrhosis of the liver, or extrahepatic, commonly due to obliteration of the portal vein or its replacement by tortuous varicosities (portal cavernoma), and it is not easy pre-operatively or sometimes even at operation to distinguish between the two conditions. The distinction is important practically, because in extrahepatic obstruction only a spleno-renal shunt is likely to be possible, whereas in intrahepatic obstruction a spleno-renal or porto-caval anastomosis might be carried out. Boulvin *et al.*³ first showed that it was possible to outline the splenic veins by splenic puncture and injection of a radio-opaque substance into the spleen, and later Dreyer and Budtz-Olsen⁴ used the same method in eleven cases.

In this issue of the *Journal* Drs. N. R. Konar and A. N. Sen Gupta report at page 810 the results of splenic venography in fourteen cases and indicate the dangers and possible uses of this method of investigation. Under local analgesia a lumbar puncture needle is inserted in the ninth left intercostal space and pushed into the splenic pulp; 20 ml. of a radio-opaque dye is injected as quickly as possible. Films are taken just before and 5 seconds after the completion of the injection. The radio-opaque substance leaves the spleen rapidly and passes via the splenic vein into the portal vein, outlining both these vessels and sometimes their tributaries. Obstruction of the splenic vein or extrahepatic obstruction of the portal vein can be shown clearly by this method.⁴ In portal hypertension due to cirrhosis, the splenic and portal veins appear dilated and tortuous, but a similar appearance may sometimes be seen in patients with considerable splenic enlargement and increased splenic blood flow without portal hypertension. No serious ill effects after splenic venography have been encountered in the small number of cases reported so far, and the procedure seems to be reasonably safe. The chief dangers are haemorrhage into the substance of the spleen or laceration of its capsule with bleeding into the peritoneal cavity, and splenic venography, by this method should not be used unless all facilities for carrying out an emergency splenectomy are available.

Diagnostic splenic puncture is rarely performed in Britain because of the risk of tearing the spleen, and the same caution should be observed in carrying out splenic venography. The reported number of cases in which it has been used is very small, and it must still be regarded as being in the experimental stage. However, in cases with gastric and oesophageal bleeding due

to portal hypertension it may supply the surgeon with valuable pre-operative information about the site of the obstruction and may indicate which type of anastomosis is most likely to help.

UNIT FOR SPASTIC CHILDREN

Just a year ago, on October 15, Lord Horder formally opened the Swindon unit for spastic children. In an interesting account of it that has recently appeared¹ Drs. J. B. Stewart and J. Urquhart, the medical officers of the unit, describe how it came to be founded. In 1951 it was known that there were eighteen spastic children in the district, but only one of these was accepted for admission to a special school for spastic children. The reasons for refusal were because the children were too young, too severely handicapped, or not sufficiently intelligent. There seemed no hope for the remaining seventeen children. These children, with fourteen others who were subsequently referred by paediatric and orthopaedic consultants, were all examined in the department of physical medicine of Swindon Hospital. Both parents of each child were asked to attend the examination, and the situation was carefully explained to them and their active co-operation was invited. A parents' association was formed, and when they found at last that interest was being shown in the plight of their children their enthusiasm and appreciation became embarrassing. Regular visits on one morning a week were arranged, and it soon became apparent that once more a gleam of intelligence could be detected in these unfortunates whose brains had been so severely damaged and who appeared to be afflicted beyond hope of help.

The authors appealed to the hospital management committee and to the local education authority in order to enlarge the scope of the work. They suggested that this could be done through the provision of a schoolroom in the department of physical medicine and by the appointment of a teacher. The authorities agreed, and provided the necessary funds for the unit. Ten of the spastic children were regarded as suitable for treatment and education in the new unit. The others were sufficiently well to be educated in ordinary schools or were too young to need more than treatment without education. Special school furniture was made in the department, and the teacher was given an opportunity of studying her pupils when they were being treated by the physiotherapists. A speech therapist was appointed for one session a week. The active co-operation of the parents was considered an essential in the training of the children. After a trial period of half-time schooling a programme of a full day of work and treatment was established and a mid-day meal was provided.

Those who have seen this unit at work are convinced of its value and of its success. It encourages the parents and treats the spastic children, and above all gives them a chance to acquire some education which otherwise might well have been denied them. The success of the Swindon unit offers an example and a challenge to those in other areas.

CLINICAL PATHOLOGY IN GENERAL PRACTICE THE PUBLIC HEALTH LABORATORY SERVICE

BY

M. T. PARKER, M.B., Dip.Bact.

Director, Public Health Laboratory, Manchester

There is a growing demand from general practitioners for direct access to the laboratory. Since the Public Health Laboratory Service already provides the practitioner with assistance in the diagnosis of infectious diseases it may be appropriate to discuss the scope and usefulness of this service.

Some practitioners make much more use of the laboratory than others. A number of severe infections have now become rare, many respond to various of the new drugs, and difficult cases can usually be transferred to hospital without delay. Therefore many practitioners find it possible to carry on with little or no help from the laboratory. Others make regular use of the facilities provided, and believe that this enhances the quality and interest of their work. They realize that they have a responsibility to prevent disease as well as to cure it, and that outbreaks of infection cannot be controlled unless their existence is promptly recognized. They find that the identification of the organism causing an infection often enables them to make more intelligent use of antibiotics. The regular use of the laboratory assists them to form and control their clinical judgment and to assess the results of their treatment. The interest of the work is increased when they can obtain assistance in the investigation of new and unusual conditions.

There is a tendency to belittle what is called "postal pathology," in which the pathologist does not see the patient either in his bed or in the laboratory, but if laboratory facilities are to be widely available some such practice is inevitable. It leads to undesirable results only when the practitioner uses the laboratory as a slot-machine to deliver mechanical answers to a few questions, and when the pathologist reports with a rubber stamp. Much of the work of the P.H.L.S. is of a "postal" nature, but this does not prevent a good deal of valuable co-operation between the practitioner and the pathologist. The practitioner must have enough knowledge to request the appropriate investigation at the right time, must have been trained to collect specimens efficiently, and must provide the pathologist with sufficient information to allow him to assess the significance of his findings. The pathologist does not content himself with mechanical reporting, but takes every opportunity to discuss his results with the practitioner, usually over the telephone, but occasionally in the laboratory or at the bedside. He welcomes inquiries about appropriate investigations for particular cases and encourages visits to the laboratory to establish personal contact.

It is often desirable to transmit specimens to the laboratory by some means quicker than the post. In suitable cases relatives can be detailed to take them to the laboratory or to put them on a bus or a train. Many public health departments have collecting centres for specimens, and in some populous districts the P.H.L.S. organizes "specimen collection rounds" with calls at a number of such centres. The practitioner should con-

sult the nearest public health laboratory or health department about the arrangements available in his area.

Nature and Scope of the Services Provided

There are 60 area and regional laboratories of the P.H.L.S., and in areas in which a laboratory has not yet been established arrangements have usually been made for the work to be done at the local hospital laboratory. The laboratories provide help in the diagnosis, prevention, and control of infectious diseases in the following ways: (1) with the general practitioner, by assisting in the diagnosis of suspected cases; (2) with the medical officer of health, by taking part in the investigation of established outbreaks and in the routine control of water, milk, food, and other environmental factors; and (3) on a national scale, with the central reference laboratories of the service, and with the Ministry of Health, by making observations on the spread of disease.

The diseases with which the service concerns itself are those that can be transmitted from man to man and from animals to man. The diagnosis of venereal disease is the one exception to this rule. Although this is generally the responsibility of the hospital laboratory service, arrangements differ from one area to another, and in some places the public health laboratories continue to carry out this work. Certain bacterial diseases, such as coliform infections of the urinary tract, are not strictly infectious. Their investigation is also the concern of the hospital laboratory service. It is best to make inquiries locally if there is any doubt about the correct laboratory for any particular specimen. Public health laboratories provide outfits for the collection of specimens, but do not pay the postage on packages returning to the laboratory.

The local laboratories of the service carry out a wide range of bacteriological investigations. In addition, they avail themselves of facilities at the reference laboratories for the more unusual and difficult tests.

Respiratory Infections

Sore Throat.—In the past, the main purpose of sending a throat swab to the laboratory was to exclude the presence of diphtheria. Now that this disease is less common, more attention can be given to identifying other causes of sore throat. However, the exclusion of diphtheria is still a matter of importance. It is unlikely that this country can be kept permanently free of the disease, even if the present level of immunization is maintained, and there is a danger that recrudescences might not be recognized promptly. Diphtheria in immunized persons is often clinically atypical, and the examination of the throat swab may be of most value in those cases in which the disease is not seriously suspected. Most laboratories issue a provisional report by telephone on the morning after the receipt of a swab, unless it arrives very late in the day. This report will state whether diphtheria bacilli, haemolytic streptococci, or Vincent's organisms are present, and will usually indicate whether they are few or many. On the following day the cultures are re-examined for diphtheria bacilli. A small proportion of previously negative cultures are then found to be positive, but fortunately this occurs rarely in clinical cases of diphtheria. On the second day, also, the haemolytic streptococci will have been grouped and the final report will be issued by post. When submitting a swab, the practitioner should include a brief account of the illness, and state

whether antibiotics or sulphonamides have been given. If diphtheria bacilli are found in the absence of typical symptoms, the laboratory will carry out a virulence test. The giving of penicillin locally or systemically may result in a false negative result for diphtheria. Small numbers of haemolytic streptococci are found in the throats of 10% of normal people in winter, but large numbers are usually present in streptococcal sore throat. Only a few may be present if the swab is badly taken (from the mouth rather than the fauces), or if specific therapy has been employed. A small proportion of swabs from undoubted cases of streptococcal infection, even of scarlet fever, will be negative. Haemolytic streptococci of groups A, C, and G are pathogenic for man, and the other groups can be disregarded as causes of upper respiratory infection. All are penicillin-sensitive. Vincent's organisms are found in large numbers in association with a well-defined clinical type of throat infection, and also occasionally in some blood diseases and in glandular fever. Small numbers may be present in the normal throat. The interpretation of a positive result is therefore a matter of clinical judgment. The laboratory does not usually mention the other types of bacteria present in throat swabs, as none of them is known to be associated with any particular disease of the throat. Swabs from about 50% of cases of sore throat are negative for any recognized pathogens.

Nose and Ear Infections.—All organisms grown from swabs of nasal and aural discharges will be mentioned in the report, with the exception of *Staphylococcus aureus* and non-pathogenic types of *Neisseria* in the nose, as any or all of them may be of clinical significance. As treatment will probably be directed to their elimination, it is usual to perform antibiotic sensitivity tests.

"Pneumonia."—Requests for bacteriological examinations in connexion with uncomplicated cases of lobar pneumonia are rarely made nowadays, as prompt response to chemotherapy is the rule. However, culture of the sputum may be very valuable if the case is unusually severe, clinically atypical, or does not respond to treatment. In addition to pneumococci, the examination may reveal *Staph. aureus*, Friedländer bacilli, or *Haemophilus influenzae* in large numbers, and in such cases the sensitivity to antibiotics should be determined. Sputum examination in more chronic conditions may result in the detection of an unexpected case of tuberculosis or fungus infection. Since the remarkable change in the prognosis of lobar pneumonia more attention is being given to the so-called atypical pneumonias. In addition to a routine sputum culture, the practitioner may request an examination of the patient's serum for various antibodies. Two of the diseases detectable by this means are of animal origin (and therefore preventable) and one is susceptible to antibiotic treatment. Serological tests for the following diseases are now in routine use: (1) "primary" atypical pneumonia, which is associated with cold agglutinins and the agglutination of streptococcus MG; (2) Q fever, a rickettsial disease which in this country is probably transmitted from cattle to man in milk or in dust; (3) infection with viruses of the lymphogranuloma-psittacosis group, which follows contact with many species of birds and is susceptible to aureomycin treatment; and (4) pneumonia following a recent influenza A or B infection.

Tuberculosis.—The laboratory will examine sputum, pus, urine, cerebrospinal fluid, and other materials for tubercle bacilli when requested, or when the history or pathological findings suggest the advisability of doing so. First, a microscopic search will be made, either on untreated or on concentrated material. There is usually little doubt that the acid-fast bacilli present are tubercle bacilli, though many strains of saprophytic mycobacteria are morphologically indistinguishable from tubercle bacilli. The laboratory ensures that its collecting receptacles are free from such saprophytes, and doctors obtaining specimens should take similar precautions. In some materials, such as urine, saprophytic mycobacteria occur commonly, and here a

positive microscopic finding should be confirmed by culture or animal inoculation. Few pathologists like to report "Tubercle bacilli present" on a microscopic examination of any material, and most prefer the phrase, "Acid-fast bacilli present." However, they will generally make it clear when they consider that confirmation of the microscopic findings is necessary. Practitioners should not hesitate to ask for confirmation when the clinical condition and the result of microscopy appear to conflict. Culture and guinea-pig inoculation are also used to detect small numbers of tubercle bacilli when the microscopic examination is negative, but the result is not available for three to six weeks. The laboratory should be left to decide which of the two tests to employ.

Whooping-cough.—A correct diagnosis of whooping-cough is usually made by the practitioner or the patient's mother. Laboratory help is valuable in the atypical case, particularly where symptoms are modified by vaccination. Since chloramphenicol appears to be effective only when given within a week of onset, it is important to establish the diagnosis of an atypical case if there is an infant among the family contacts. The pernasal swab—a fine flexible wire swab which is passed backwards along the floor of the nose—is the most convenient and effective means of collecting material. Unfortunately it takes three to four days to complete the bacteriological examination. With present methods 80 to 90% of cases give a positive result in the first two weeks of the disease. The number of positives will be increased by taking two swabs, one through each nostril. Specimens should reach the laboratory on the same day unless a special transport medium is used.

Gastro-intestinal Infections

Diarrhoea with or without vomiting and fever is due to a variety of agents, including the dysentery bacilli, the salmonellae (including *S. paratyphi B*), staphylococcal enterotoxin, certain strains of *Clostridium welchii*, and, in infants, some serological types of *Bacterium coli*. Though it is often possible from the clinical picture to suspect the nature of the infection, bacteriological examination alone can reveal this with certainty. Failure to establish a bacteriological diagnosis seldom does much harm to the patients, as most recover during or some time after a course of treatment. However, there are great variations in severity from case to case of the same disease, and a mild attack of dysentery or salmonella infection may be followed by a severe or even fatal infection among the patient's associates. Bacteriological examination may reveal an unexpected connexion between a number of cases and lead to the identification and elimination of a source of infection. Although fairly rapid transmission of faeces specimens to the laboratory is desirable, most pathogens survive well enough to make postal specimens highly effective in acute cases. In the occasional case in which amoebic dysentery is suspected, a specimen should be examined within a very short time of being passed: it may be possible to arrange for the patient to defaecate at the laboratory. Rectal swabs are useful in some circumstances, as they can be conveniently and quickly collected. Some laboratories provide a special apparatus, but a moistened throat swab is quite effective if it really reaches the rectum. In acute cases of diarrhoea the results are good, but in convalescent cases and in typhoid fever they are inferior to those of faeces culture. Rectal swabs must reach the laboratory within a few hours. In most acute salmonella and dysentery cases a provisional report may be given on the day after the specimen is received. A final negative report is usually given at 48 hours and the exact identification of a pathogen may take longer.

Unexplained Pyrexia

There are a number of febrile conditions in which the laboratory can be very useful. The blood can be examined for evidence of typhoid fever, Weil's disease, undulant fever, glandular fever, infectious endocarditis, and a number of

other diseases. The laboratory will supply outfits for the collection of blood for culture and for serological tests, together with a sterile syringe. Many practitioners find it convenient to keep such an outfit in readiness. The pathologist will always be pleased to give advice on the appropriate investigations in cases of unexplained pyrexia.

Infections of the Central Nervous System

The practitioner may not often be called on to investigate infections of the central nervous system, as such cases are usually admitted to hospital at an early stage. Investigation usually begins with a general examination of the cerebrospinal fluid to exclude pyogenic and tuberculous meningitis. In cases of lymphocytic meningitis there are various valuable serological tests, including those for lymphocytic choriomeningitis, canicola fever, and mumps infection.

Skin Infections

Bacteriological examination may be of value in some skin diseases. In unusual or intractable pyogenic conditions, a culture and sensitivity test, together with a search for the focus of infection, may be useful. The examination of scales or hair from suspected cases of ringworm may help in prognosis and may indicate a possible animal source of infection. Swabs from suspected cases of anthrax, especially among those not known to handle dangerous materials, may be of vital importance in securing early treatment.

Other Activities of the P.H.L.S.

Supply of Sera, Vaccines, etc.—The service takes no part in the supply of therapeutic sera, but holds stocks of certain prophylactic and diagnostic agents. It supplies vaccine lymph direct to the practitioner, and diphtheria prophylactics indirectly through the local health departments. It keeps stocks of scarce prophylactic agents such as typhus vaccine, rabies vaccine, gamma globulin, and anthrax anti-serum, but typhoid, plague, and cholera vaccines are obtained from commercial sources. The laboratory staff will be pleased to advise about immunization procedures, but will not, as a rule, carry out inoculations. Skin-testing reagents, including Frei antigen, brucellin, Trichinella, and hydatid antigens, are available for suitable cases.

Field Investigations.—The service is constantly engaged in investigations into the source and mode of spread of infectious diseases, and in field trials of prophylactic agents. Although many of these activities are carried out in co-operation with the public health authorities, much help is obtained from general practitioners, and some schemes would be impracticable without their participation. Many practitioners are taking part in the scheme for the early diagnosis of influenza and others are collaborating in trials of whooping-cough vaccines. Those who encounter new or unusual types of infectious disease will find that the laboratory staff are anxious to assist in their investigations.

The general practitioner has direct access to the public health laboratory for the submission of specimens and for advice on the prevention and control of infections and on general problems of immunity. He will find many opportunities for useful collaboration with the laboratory, both in the solution of day-to-day problems and in the acquisition of new knowledge.

Next article on Clinical Pathology.—"Dispatch of Specimens," by Dr. Martin Hynes.

Refresher Course Book.—The first collection of articles in the Refresher Course for General Practitioners (fully revised) are available as a book containing 55 chapters, price 25s. Copies can be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

EUROPEAN HAEMATOLOGY CONGRESS

[FROM A SPECIAL CORRESPONDENT]

The Fourth Congress of the European Society of Haematology was held in Amsterdam from September 8 to 12. Over 500 members and about 250 guests attended from at least 28 countries.

Six main topics were chosen for discussion and over a hundred papers were presented. Immuno-haematology was dealt with first, the chief contributions being by J. V. Dacie (London), J. J. van Loghem, jun. (Amsterdam), C. Gasser (Zurich), J. F. Ackroyd (London), S. Moeschlin (Zurich), W. Dameshek (Boston), and M. M. Hargraves (Rochester, Minn.). Amongst the subjects discussed were the antibody patterns and clinical syndromes of acquired haemolytic anaemia, the mechanism of drug-induced and idiopathic purpura and granulocytopenia, and the significance of the L.E. cell. Further information was available on the characterization of the antibodies of acquired haemolytic anaemia, but there was nothing new concerning its aetiology or treatment. Recent work on anti-platelet and anti-leucocyte agglutinins indicates that many cases of drug-induced or idiopathic thrombocytopenia or granulocytopenia may have a pathogenesis comparable to that of acquired haemolytic anaemia. Dr. Dameshek in his usual challenging style went so far as to suggest that Henoch-Schönlein purpura was an immunovascular disease.

Barbiturates and Porphyrinuria

The metabolism of haemoglobin and erythropoiesis were the next main topics. The chief contributions were by H. Bénard (Paris), C. Rimington (London), and J. Waldenström (Malmö). By the use of tracer techniques in particular it has been shown that haemoglobin synthesis continues in non-nucleated erythrocytes, particularly during active blood regeneration. On the purely chemical side Professor Rimington presented new work on the mechanism of formation of porphyrins from porphobilinogen. Barbiturates can cause porphyrinuria in experimental animals, and there appears to be evidence that this can happen in man also, particularly where latent porphyria exists. The same may be true of lead intoxication.

The metabolism of iron and iron-deficiency anaemia were next discussed, and the remarkable elucidation of the metabolic pathways that can be obtained by using ^{59}Fe was clearly demonstrated. C. V. Moore (St. Louis) made a plea for the abandonment of the title idiopathic as a description for certain iron-deficiency anaemias: in his view iron-deficiency was always due to blood loss, to deficiency of iron in the diet, or to failure to absorb it. Haemochromatosis and the siderosis due to transfusions were next considered, and finally vitamin B_{12} and the megaloblastic anaemias. The main papers were given by L. Heilmeyer (Freiburg) and C. C. Ungley (Newcastle).

Treatment of Acute Leukaemia

On the third day of the Congress three main topics were dealt with: acute leukaemia, lymph-node puncture, and the platelets. W. Dameshek (Boston) reviewed the treatment of acute leukaemia; in his experience the most promising therapy was a combination of A.C.T.H. and aminopterin. With this regime he had had 25 successive remissions lasting from four weeks to two years in cases of acute lymphocytic leukaemia in children and young adults. Some patients had had up to four remissions. The principal papers on lymph-node puncture and blood platelets were given by A. Pavlovsky (Buenos Aires) and S. van Creveld (Amsterdam), respectively.

The last topic discussed was that of blood coagulation. R. G. Macfarlane (Oxford) described his conception of the formation of blood thromboplastin, the main point being that the so-called accelerators are thought to be participants in the reaction which produces thromboplastin and not accelerators of the reaction of thromboplastin with

prothrombin. P. Owren (Oslo) reiterated his well-known views and nomenclature. F. Koller (Zurich), however, appeared to accept the Oxford view in large part; using a modified thromboplastin generation test, he had been able to demonstrate the presence of yet another coagulation factor, Factor 10. N. Rosenthal (New York) put forward evidence for a new (third) variety of haemophilia. The final paper was given by P. Nolf (Brussels), whose work on blood clotting, carried out many years ago, antedated to some extent some of the new advances. There seemed to be no new important advances in the treatment of haemophilia.

Where Congresses Sometimes Fail

Dr. S. I. de Vries, President of the Dutch Haematological Society, and his Secretary, Dr. M. C. Verloop, and the other members of the organizing committee are deservedly to be congratulated on the organization of the Congress. Without doubt it was a success, both socially and scientifically; it was probably at least as successful as any that have been held. However, a few reflections and minor criticisms are perhaps permissible. As in most congresses, there were too many papers, and not all the work presented was new. There was too little public discussion: as this was held after an hour or an hour and a half of papers there is little wonder that saturation point had been reached. Finally, the technique of presenting papers could and should be improved: some papers were excellently given, others by no means so well. Particularly before an audience of many nationalities there can be no excuse for a rapid oration illustrated by most complicated small-scale diagrams and tables. It is essential to present simple diagrams and abbreviated tables made with type of the largest possible size and to emphasize the main points of a diagram or table with a pointer. When this was done even those with an indifferent knowledge of German or French (or English) were able to understand what the speaker was talking about. All in all, though, it was a very enjoyable congress. The Dutch are surely a most generous and genial people.

VASCULAR SURGERY

[FROM A SPECIAL CORRESPONDENT]

The second congress of the International Society of Angiology was held at the Novo Hospital Escolar in Lisbon from September 18 to 20. The opening session dealt with aneurysms. Professor E. HOLMAN (San Francisco) discussed the care of traumatic aneurysms and arterial injuries. In the second world war popliteal arterial ligation had been followed by gangrene in 70% of cases. Arteriovenous fistulae had been treated by quadruple ligation and only exceptionally by restoration of continuity. Most of the patients were afterwards found to suffer from arterial or venous insufficiency.

The Lessons of Korea

During the Korean war the picture had completely changed, and restoration of continuity was now the rule. One surgeon reported 82 cases of arteriovenous fistulae with successful reconstruction as against only three failures, and similar results were reported from other Korean war hospitals. The reasons for the spectacular improvements were: better control of infection by antibiotics; improved technique in handling vessels; availability of blood and blood substitutes in unlimited quantities; training of surgeons in vascular techniques; evacuation of wounded soldiers by helicopters; and availability of homografts stored in Gross's solution at 4°C.

Professor Holman stressed three important rules in the modern treatment of vascular injuries. The first is that the main artery should always be controlled as a preliminary measure, if necessary through a separate incision, when dealing with any wound in which a major arterial injury is suspected. The second is the importance of maintaining

the blood pressure at normal levels by repeated blood transfusions following operations of arterial repair. Finally and most important, "Do not wait. Prompt intervention and reconstruction is the rule." Professor Holman's lessons from the Korean war, and the figures which he quoted, many of which have not yet been published, were of absorbing interest. The emphasis on large transfusions is a fruit of the work of the Medical Research Council investigators, R. T. Grant and E. R. G. Reeve, and of Simeone and his colleagues in the U.S. Army, which showed that "shock" in the old sense is rare or non-existent, and that its symptoms are really due to unrecognized or underestimated blood loss. The American Army system in Korea of training large numbers of young surgeons in the methods of vascular repair has paid handsomely in the good figures achieved, but perhaps the most startling lesson lies in the last principle that Professor Holman enunciated. Prompt intervention in arterial injuries is quite contrary to the conservatism which was the best practice under the circumstances of the two world wars.

Mr. D. J. ROBERTSON (London) described a series of 32 patients with congenital arteriovenous fistulae of the limbs. In 18 the disease was of a localized type and often suitable for surgical treatment, but in the remaining 14 it was diffuse and less easily treated, amputation being necessary in some cases. He warned against the bad and often disastrous effects of proximal arterial ligation. Dr. A. BLAKEMORE (New York) described the results of treating aneurysms by excision and restoration of continuity with a tube of Vinyon-N plastic cloth, a method which showed promise. Sections obtained later showed that the tube became lined with tissues resembling intima. Prostheses such as these, should they prove successful on more protracted trial, would offer obvious advantages over stored homografts.

Dr. F. GERBODE (San Francisco) discussed the uses of blood-vessel grafts in repair of major vessels. Stored arterial homografts were best reserved for use in older patients, as little was yet known about the long-term changes which might occur in the grafts. In young patients it was best to use vein autografts whenever possible.

Surgery of the Mitral Valve

Professor E. HOLMAN, in opening the discussion, said that too little credit had been given to Sir HENRY SOUTAR, of London, for his pioneer operation on the mitral valve many years ago.¹ Dr. E. S. HURWITT (New York) showed a film illustrating the action of the mitral valve in the dog. The sphincter-like action of the annulus was clearly responsible for a great proportion of the closure. The slackening of the chordae tendineae during closure and their pulling effect on the edges of the cusps during opening were beautifully demonstrated.

Dr. F. GERBODE (San Francisco) discussed the indications for surgery for mitral stenosis. The majority of cases never required operation, but during the third or fourth decade of life deterioration due to myocardial changes, shortening of the chordae, or narrowing of the orifice might make operation necessary. It should never be done prophylactically. In those patients in whom disability had necessitated operation the mortality rate had been ten in the first hundred. With greater experience this figure became lower. The main indication for operation was progressive disability in the absence of major physiological defects of other valves. Age itself was no longer a contraindication. Originally the limits were set between 20 and 40, but recently older patients had been treated with success. Previous embolism or auricular fibrillation were not contraindications. Nor was a mild degree of mitral regurgitation, but this was often difficult to diagnose, and in many cases no pre-operative signs existed. Patients with predominant regurgitation were unsuitable for valvotomy. Clinical examinations and plain radiology were the most important elements in diagnosis. Cardiac catheterization and angiography were necessary only in a minority of cases.

A number of surgeons from European centres reported results and described indications in general agreement with

Dr. Gerbode. Professor A. M. DOGLIOTTI, of Turin, reported a mortality of less than 7% in 150 cases. In the last 50 cases only one death had occurred. His indications for operation included some patients with less severe disability than those in Dr. Gerbode's series, and in general it was evident that each surgeon's mortality figures depended upon the degree of illness of the patients included. Dr. C. P. BAILEY (Philadelphia) had a very large experience of this type of surgery and advocated operation in many milder types of disease, including those in Classes I and II in the American Heart Association's classification. Dr. D. E. HARKEN (Boston) had an experience of 500 operations. In favourable cases his mortality rate was less than 3%, and he discussed methods of reducing post-operative morbidity and complications.

Late Results

Mr. R. C. BROCK (London) spoke of the late results of mitral valvotomy. He described the morbid anatomy of the diseased valve. It was possible for digital dilatation to enlarge the central opening to give a 1 to 2 cm. gap. This would produce a temporary relief of symptoms, but recurrence would take place unless the vital "critical areas" of adhesion which he described were broken down. The limit to improvement of function was set by the degree of deformity and fibrosis of the valve. If this was severe the valve would never work again even if the adhesions were cut. To make certain that a proper valvotomy had been done it was necessary to feel the papillary muscles and the chordae tendineae with the finger. In order to make it possible for long-term results to be studied scientifically and for different series to be compared an exact record of the state of the valve before and after valvotomy should be made. Four grades were suggested for this. Although it was really too early to consider late results on a detailed statistical basis, Mr. Brock gave some interesting general figures. Of 135 cases operated on personally and available for review one to five years after the operation, three had died and three had deteriorated during the time of observation.

Mitral Regurgitation

The treatment of patients in whom mitral regurgitation predominated over stenosis was a far more difficult problem. Dr. C. P. BAILEY described his experiences. The first operation tried was a modification of the Murray sling, in which a sling of pericardium was passed across the mitral orifice to act as a sort of flap valve. The mortality rate (38% in 57 cases) was prohibitive and the operation had to be given up. Attempts to improve the efficiency of the valve by placing a purse-string around the chordae proved fatal in two patients. His present operation consisted in opening up the adherent part of the valve orifice as in the stenotic cases and suturing the gaping inefficient part with a strip of pericardium passed by a special method. He had done 86 of these operations with a mortality of 27%. The improvement in the survivors was as good as in the cases operated on for stenosis. Dr. P. CHALNOT (Nancy) showed a film of experimental operations in dogs, in which a plastic ball was placed on the ventricular wall so that it helped to occlude the mitral orifice during systole. The animals survived provided the prosthesis was accurately placed. Dr. D. E. HARKEN had used this type of operation in man, but it had been disastrous. A sphere was the wrong shape; if a cylinder was used success could be achieved, and 25 patients had been treated with only three deaths. He showed a film of the operation.

The congress ended with papers on general subjects. Dr. H. B. SHUMACKER (Indianapolis) described a method of closing inter-atrial septal defects by invagination of a pocket of pericardium which had been used with benefit in an 11-year-old boy. Attempts to close interventricular defects had failed, largely because the patients were in extremis before operation. Mr. D. J. Robertson (for Mr. J. B. KINMONTH, London) described the lymphatic circulation in patients with lymphoedema. Outlining lymphatics at operation with dyes had shown that the lymph trunks were dilated, tortuous, and incompetent, resembling varicose veins. There

was no evidence that obstruction existed. Benefit could be obtained from lymphangiectomy. Dr. E. J. WYLIE (San Francisco) described his experiences with thromboendarterectomy in 50 patients with isolated areas of arterial thrombosis between the level of the lower abdominal aorta and the popliteal artery. Sixteen had re-clotted. There were nine deaths. These figures did not dispel the feeling of disfavour with which the operation is regarded in England, and it was interesting to learn that Professor dos Santos, who originated it, was now pessimistic about its results.

THE NEW ACADEMIC YEAR

MINISTER OF HEALTH AT KING'S COLLEGE HOSPITAL

The opening of the 124th session at King's College Hospital Medical School, Denmark Hill, took place on October 2, Sir WILLIAM GILLIATT presiding. The Minister of Health, Mr. Iain Macleod, attended and presented scholarships and prizes to 24 recipients. THE DEAN (Dr. Vernon Hall) said that the Minister had agreed that the medical school needed about 150 beds for teaching purposes additional to those available in the King's College Hospital group, and that these beds should be under the clinical control of the school's teaching staff. Agreement in principle had also been reached between the regional hospital board, the Camberwell Hospitals Management Committee, and the medical school for the use of beds in Dulwich Hospital for this purpose. But the Ministry had still to decide who was to meet the not inconsiderable cost of these beds. Moreover, this scheme of association, while welcome, was not, in the opinion of their teachers, the final solution. Every teaching hospital needed a large medical staff in the interests of undergraduate education, and only by having more beds under its control could the board of governors make the fullest use of its medical staff and thereby reduce the cost of patients' treatment. Further, until the parent hospital could provide more beds the school could not proceed with its plans for the provision of professorial units in some of the clinical teaching departments.

The State and the Teaching Hospitals

MR. IAIN MACLEOD began his address by quoting passages from the speeches made by Sir Lionel Whitby and Sir Richard Livingstone at the recent First World Conference on Medical Education, and he took as his theme "the philosophy of the first-rate" as expounded by the latter speaker.¹ The Minister said that, although he was not conversant with the content of the medical curriculum nor with the techniques of medical education, he was very much concerned with what industry would call the "end product," and, for good or ill, he was by far the largest employer of those who emerged from the schools. Five years after the inception of the National Health Service might be a good time to consider the relationship between the university, the teaching hospital, and the Ministry. Medical schools were now entirely free within the university sphere to determine the method and content of medical education in the same way as the other schools of universities. In accordance with the well-established principle that the State should not interfere with university education, Exchequer assistance was given through the Universities Grants Committee, with which the universities dealt direct. Mr. Macleod added that many people felt that the hospital system could be improved by the general application of the block system of grants. That was a point to be considered by the Guillebaud Committee.

The Minister went on to ask whether the number of students entering the medical profession was adequate to the needs of the community. The figures for entrants in

¹ *British Medical Journal*, August 29, p. 454.

1951-2 represented no very great increase on those for 1938-9. This was not due to any lack of demand for such facilities. The reason was partly that there had been no recommendation for an increase, and partly that the medical schools felt that they were not therefore called upon to incur risks to their standards which would be involved by a large increase in numbers. It was a very difficult balance to strike, because, while too few doctors were a threat to the health standards of the community, too many doctors might well constitute a threat to the standard of medical education itself. It did not appear from the figures that the introduction of the National Health Service had in any way prejudiced entry into the medical profession, although it had been necessary from time to time to take some steps in order to secure what seemed to the Ministry their correct distribution. This had been done so far as general practitioners were concerned through the Medical Practices Committee. An attempt had also been made, not wholly successfully, to meet the difficult position that had arisen in the senior registrar group, upon the solution of which depended the future of a stable and established consultant and specialist service.

They must not lose sight, Mr. Macleod continued, of the dual function of the teaching hospitals—namely, to provide hospital service and also to provide clinical facilities for education. There might be a real risk in the demand by the school for clinical facilities for specialisms and research, to the detriment not only of the hospital service but of the normal clinical facilities for undergraduate medical education. It was of great importance that the Medical Research Council, in collaboration with the Ministry and other interested bodies, had taken steps to put clinical research on a proper footing, with special financial arrangements by the Treasury under the aegis of the new clinical research boards. Thus it was hoped that the partnership between the schools and the National Health Service would present no difficulties in the future.

Although owing to the introduction of the National Health Service the hospitals were freer from financial worries, there were those who regretted that with the substitution of the Ministry for the board of governors as the final arbiter in so many matters of policy some intimate relationship had been lost. Mr. Macleod thought that it was possible to overestimate this, and he liked to think that in this respect matters were getting happier all the time. In the same way, in another field, that of general practice, the picture presented in the valuable report on the survey recently carried out by the British Medical Association, although not unfavourable, was, Mr. Macleod believed, less happy than the picture as it would be now (the survey was made in 1951). The situation was getting steadily better.

A vote of thanks to the Minister was proposed by Sir CECIL WAKELEY, P.R.C.S., and seconded by Dr. F. S. COOKSEY.

ROYAL FREE HOSPITAL SCHOOL OF MEDICINE

The prize-giving at the Royal Free Hospital School of Medicine took place in the Beveridge Hall of the Senate House of the University of London on October 2. The DEAN (Dr. Katharine Lloyd-Williams), who presided, referred in her report to the recent First World Conference on Medical Education. She had found it most stimulating and interesting, but even six years' training could do no more than lay the foundations on which true medical education was based. She then referred to distinctions obtained by Royal Free students, and paid a tribute to the staff. There then followed the prize-giving.

The Student's Debt to Society

Miss G. E. M. JEBB, former Principal of Bedford College, gave a brief inaugural address. She stated that she knew nothing about medicine nor about science, and what she had to say referred to students in general. Anyone venturing upon a university career found himself a member of a large group or society with a certain status and privilege, but also

with special duties and problems. All students in every grade and branch of learning had one thing in common, that they were in a position of economic dependence. This was a thorny subject. Economists divided society into producers and consumers, and the university student was in the rather embarrassing position of remaining a consumer at a time when most others of his age were already pulling their economic weight as producers. For some time he must depend on the activities of others to sustain him.

Another way of looking at the situation, Miss Jebb went on, was that the student represented an economic investment; he was working for a future, undergoing in many cases a long and severe training, with the expectation of becoming a very effective producer for the community. At present some 30% of students were wholly supported either by their parents or from private funds; the remaining 70% were to a greater or less extent supported from public funds, State or local. While young persons of the present day were most reluctant to be a burden on their parents, there was not the same sensitiveness with regard to the national exchequer, and in this as in other directions people looked upon public funds as an unlimited source from which to draw. Students were in a sense highly privileged persons, and the higher their privilege the more need was there to recognize their obligations. The larger the expansion of the Welfare State, the greater the need for a rising standard of what she called economic morality. The student would be a worthy "investment" if he set out upon his career conscious of his obligations and determined to make an ample return to the community in the service for which he had been trained.

A vote of thanks to Miss Jebb was accorded on the motion of Dr. H. E. DIMSDALE, seconded by Dr. L. M. DICKSON.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Orthopaedic Care in Poliomyelitis

SIR,—We have read with some dismay a document just circulated by the Welsh Regional Hospital Board to every consultant asking "to make sure that the arrangements for the admission and treatment of cases of poliomyelitis in their regions are up-to-date and efficient," and reporting a meeting several weeks ago of 35 physicians, otolaryngologists, and anaesthetists, together with representatives of the Welsh Board of Health, the regional hospital board, and a number of co-opted members, which recommended that teams should be set up throughout Wales for the treatment of acute poliomyelitis, comprising a physician, E.N.T. surgeon, anaesthetist, neurologist, and physiotherapist.

Throughout the whole of this lengthy document and its attached memoranda and reports, and throughout the whole of its recommendations, there is never one single mention of the orthopaedic surgeon, who, of course, has the responsibility of looking after these patients for the rest of their lives and cannot do it well unless he starts from the beginning. No orthopaedic surgeon was invited to attend the conference. There was no proposal to include an orthopaedic surgeon in any of the teams—only a physiotherapist, who, bless her heart, would not get far among the otolaryngologists and anaesthetists who are to treat poliomyelitis. No view was sought from any orthopaedic surgeon; there was only a report from Dr. Ritchie Russell's medical registrar.

Orthopaedic surgeons, who are necessarily tolerant, have applauded the recent enthusiasm of some physicians and neurologists in the management of poliomyelitis, especially since the recent epidemic in Denmark, which showed so high an incidence of bulbar palsy (though, let it be noted,

a high incidence also of limb paralysis), even when recent observations and writings have sometimes tended to suggest that only physicians or neurologists are really capable of treating acute poliomyelitis. But when enthusiasm becomes so fanatical that every consultant in one region of the Ministry of Health, and indeed in the whole of one country—Wales—is advised that no orthopaedic surgeon need be consulted on the advisory committee, or appointed to any of the special teams, and that a physiotherapist will suffice to aid the neurologists, otolaryngologists, and anaesthetists in the treatment of poliomyelitis, it is time to remind ourselves that when this was last done, ten or twenty years ago, we had great disasters and many horrible deformities, which could have been prevented but were relieved only after years of surgical treatment.

The British Orthopaedic Association recognizes at once the vital and imperative part that physicians, neurologists, and other specialists must play in the treatment of poliomyelitis in its acute stage. It knows too that the lifelong treatment of patients with residual paralysis succeeds best when orthopaedic management starts early, because only then is the serious and insidious deforming potentiality of poliomyelitis controlled. It asks only—and not for reasons of courtesy but only in the interests of good preventive treatment—that consultation and collaboration should begin from the beginning.—I am, etc.,

London, W.C.2.

REGINALD WATSON-JONES,
President, British Orthopaedic Association.

Poliomyelitis and Inoculation

SIR,—In your annotation (*Journal*, September 19, p. 669) no direct reference was made to suspended whooping-cough vaccine. Dr. James Grant (*Journal*, August 15, p. 394) describes the introduction of the subcutaneous injection of this substance after an epidemic of poliomyelitis had ceased. Following consultation with the manufacturers and local health authorities, I have used the suspended pertussis vaccine throughout the past summer. In view of the guarded advice given by the Ministry, I would be glad of the opinions of others on the use of this latest method during epidemics.

It would also be of interest to know if there has been any correlation between painful lesions, elsewhere than in the pertussis-injected muscles, and paralysis. From the practical point of view such lesions could not be avoided in persons exposed to and infected with poliomyelitis. Yet much could be achieved if the precepts of Brehme and Leuterer were adopted. They advocate heavy sedation in the pre-paralytic stage to prevent activity of the anterior horn cells. The following recently observed case seems to support their argument. A child of 7 years of age was confined to bed for five days with a fever associated with slight meningism. On the sixth day there was fibrositis of the left shoulder muscles, and two days later an abductor paralysis developed. This child had lain on her right side in bed, holding a comic in the left hand, for quite long periods every day. Only heavy sedation would have prevented the child from this type of activity.

In the interests of clinical research in general practice and the need for improved prophylaxis, certain problems require urgent consideration. First, the general practitioner must have an agreed set of criteria upon which to base a decision to treat a suspect case with full sedation while under observation at home. Secondly, some guidance is needed as to the type of drugs to use and the duration and mode of administration. It would be of help to the general practitioner if some guidance were given on the type of case which should have hospital treatment. For instance, should a patient exhibiting localized muscle pains, together with the other criteria, be sent to hospital?

As a basis for discussion I would suggest that the following criteria would justify a presumptive diagnosis of pre-paralytic poliomyelitis. These symptoms are based on recent experience of a number of cases which were not sent to hospital. It is not considered necessary to submit this

type of case to lumbar puncture. (1) Fever with meningism as evinced by inability to touch the knee with the forehead. (2) Absence of diagnostic signs or symptoms of any other disease after a period of, say, six days has elapsed. That is to say, if at the onset there is no otitis media, classical tonsillitis, or respiratory infection, the case should be considered as pre-paralytic poliomyelitis in conjunction with the other criteria. (3) Headache. (4) Occurrence during the summer and autumn, especially when paralytic cases have been notified. (5) Failure to respond to antibiotics given as a therapeutic test. (6) The occurrence of localized persistent muscle pain, following the muscle ache which is present in the neck and limbs at the onset.

It would, in my opinion, be a helpful research if such cases were notified at the end of six days' observation. In this way some cases due to other diagnosable conditions would be eliminated.—I am, etc.,

Hornchurch, Essex.

I. H. J. BOURNE.

Cancer and the Public

SIR,—The Ministry of Health has sent a circular letter to all local health authorities on the subject of health education in relation to cancer (see *Journal*, October 3, p. 783). This action by the Ministry is an extremely serious matter for every family doctor in the kingdom.

In the first place, cancer is not a matter of health: the province of the M.O.H. is preventive medicine, and cancer cannot be prevented by public health measures. Cancer is the province of the family doctor, and I (for one) am not prepared to share my responsibility with a committee presided over by the M.O.H. The circular letter from the Ministry is the thin end of a very dangerous wedge. In the second place, it is extremely disturbing that the Ministry should have acted without any regard at all to the fact that half the family doctors who replied to a recent questionnaire made it clear that they are not in favour of public cancer education (*Journal*, July 18, p. 148). In the third place, it is only about two years ago that the Marie Curie Memorial Foundation was allowed to question the district nurses about our cancer patients without our knowledge, and very damaging statements were made and published without our being given any opportunity to refute them. Once bitten, twice shy.

Fourthly, I see no reason at all why the Ministry could not wait until the results of the present experiments in cancer education can be studied. I believe there are three different experiments in operation at the moment—in Manchester, in Leeds, and in York. I am sure that the only safe course is for every family doctor to make it quite clear now that he will have nothing to do with the Ministry's schemes until all this research has been completed and the results examined.—I am, etc.,

Wetherby, Yorks.

R. L. KITCHING.

Reduction of Post-operative Pain

SIR,—The letter from Mr. J. B. Oldham (*Journal*, September 5, p. 570) is a timely warning that the new long-acting local analgesic agents must be used with more circumspection than their aqueous counterparts; as in the case of alcohol, phenol, and "proctocaine" their injection into the paravertebral region may very occasionally be followed by paraplegia or other undesirable sequelae, apparently as a result of tracking along the nerve sheaths. In the case of "efocaine," I believe that the neurological lesions are more likely to be due to the 78% propylene glycol solvent, which is strongly hypertonic, than to the anaesthetic base. I would suggest that its use in this area should be confined to emergencies such as arterial occlusion or intolerable pain, and that its injection should be preceded by a preliminary dose of aqueous local analgesic which would serve to indicate or exclude any misplacement of the needle, and incidentally supply some fluid to counteract the osmotic

well encouraged by the Army authorities. One commanding officer put the local bazaar out of bounds to troops who had not been inoculated, on the ground that there was typhoid in the bazaar and only men protected by the vaccine could go there safely.

Later, improvements in standardization, and perhaps the use of strains that made more even suspensions than the earlier ones, which were carried out in the Royal Army Medical College, eliminated most of these troubles, and perhaps if more work had been done in the early days on prevention of reaction the general adoption of the vaccine would have been quicker. But after-wit is a very cheap commodity.—I am, etc.,

L. W. HARRISON.

London, S.W.1.

Industrial Health and the Universities

SIR.—In case your leading article, entitled "Industrial Health and the Universities" (*Journal*, August 29, p. 480), should inadvertently give the impression that the future, financial or otherwise, of the Newcastle Department of industrial Health is in question, we feel that we should place the following facts before you.

When the Newcastle-upon-Tyne Division of the University of Durham accepted a grant from the Nuffield Foundation with which to found a department of industrial health, it had in mind a department which would interest itself primarily in work upon practical local problems within the field of industrial health, rather than a department which would promote either additional teaching or industrial health services. All the money spent in the first year of its work came from the Nuffield grant. The grant from the Nuffield Foundation is a diminishing one, and the expense of running the department has risen, so that in the year 1952-3 it cost eight times as much as it did in its first year. Of this sum, university money met 63%, industrial sources 23%, and the Nuffield grant covered the remaining 14%.

More than half the academic staff of the department hold permanent appointments. Of the remainder, one holds a three-year contract from an outside source, and three hold annually renewable posts, two of which are also financed by outside money. For the rest of this quinquennium the department will, like all the other departments in the Medical School, have to cut its academic coat according to its cloth. In future quinquennia it may expect to receive its due share of whatever funds are available for the purposes of the Medical School.—We are, etc.,

R. B. GREEN,

Dean of Medicine.

R. C. BROWNE,

Nuffield Professor of Industrial Health.

University of Durham
Medical School,
Newcastle-upon-Tyne.

Sweating in Shock

SIR.—In his answer to the question: "Why do shocked patients sweat?" your expert ("Any Questions?" August 29, p. 520) explains that the sympathetic overactivity which accompanies shock gives rise to sweating because the sweat glands are innervated by the sympathetic nervous system. He goes on to describe this involvement of the sweat glands as "teleologically unfortunate." This, Sir, raises a most interesting question. To dub this association as teleologically unfortunate is equivalent to saying to Nature: "You have arranged this wrongly. It would have been better if you had done it in another way." This attitude, surely is a negation of the idea of natural selection. Natural selection should ensure that no teleologically unfortunate arrangement survives (though of course vestigial organs may give trouble before they are finally extinguished); and I feel that any apparent inappropriateness of a natural system should be ascribed to an imperfection in our understanding of it rather than to an imperfection in Nature.

I am often reminded of my ignorance about the cause of sweating during anaesthesia—when it is often apparently unassociated with vasoconstriction—and I feel that we must try to find some more satisfying explanation.—I am, etc.,

RONALD WOOLMER.

Bristol.

POINTS FROM LETTERS

Treatment of Acute Malaria

Dr. I. GORDON CAMERON (Nairobi) writes: The *Journal* of August 1 has just come to hand, with the illuminating letters from Sir Philip Manson-Bahr (p. 284) and Dr. R. Y. Taylor (p. 285) on the prophylaxis and treatment of acute malaria with special mention of pyrimethamine ("daraprim"). May I say how heartily I agree with both writers. . . . Recently I described in the *East African Medical Journal* (1953, 30, 255) a case in which the patient was treated with four times the manufacturers' recommended dose of pyrimethamine and relapsed within 14 days, almost dying of malaria. My stand-by for the past 27 years has been quinine, and it mattered not whether the attacking plasmodium was benign, malignant, or quartan—the patient recovered. One had relapses—no matter; but one had no deaths.

Poliomyelitis and Wrapped Food

Dr. H. DALE BECKETT (Bridgend) writes: It is striking that in those countries where food hygiene is considered important the incidence of poliomyelitis is greatest. Scandinavia and the United States have for many years been subject to the scourge, and for the past few years we, who have recently taken to buying more wrapped bread than ever before, suffer badly too. The old argument that used to be heard against the policy of pasteurizing milk, that a number of subinfective doses may produce immunity, must again be considered.

The Anxiety State

Dr. R. MACDONALD LADELL (Scarborough) writes: It was a pleasure to see the anxiety state so ably dealt with by Dr. E. A. Bennet (*Journal*, September 5, p. 554). It seems to me, however, that Dr. Bennet could have gone further in his task of acting as liaison between the expert and the G.P. The conscientious practitioner may be left somewhat frustrated by the careful and circuitous approach advocated. I believe that the approach can be much more direct so that, with experience, the cases in need of specific reassurance and a word of advice can be detected and dealt with in a matter of minutes. The adolescent youth may complain of heart or lungs, but if the doctor goes straight to the point he will find that the actual worry concerns the possible physical and mental effect of "losses." When masturbation has become obsessive it is always because it has become linked with anxiety. It is then used for comfort as a child sucks a dummy. The youth who has been fighting a losing battle because he believes he is over-sexed and that he has lost his will-power is able to break the vicious circle once the subject has been rescued from the emotional bias which commonly obscures it. The adolescent girl who suffers and resents the domination of her parents is apt to be regressive in the same way, and will be correspondingly grateful if her "secret sin" is dealt with on a matter-of-fact plane. . . . Dr. Bennet would seem to suggest that the phobias can be classed with other anxiety states as regards first-aid treatment. I do not think this is so, although some of the causes of anxiety I have mentioned may be intensifying the phobia. A phobia is symbolic, and, as Dr. Bennet says, the reason is hidden in the unconscious. Such patients should therefore be referred to the expert.

Experimental Hypnosis

Dr. G. AMBROSE (London, W.1) writes: Professor A. Kennedy in his latest review of hypnosis (*Journal*, September 5, p. 546) uncovers some pertinent points confronting hypnotherapy in this country. Students can find no facilities for acquiring the art of hypnosis. Doctors mastering the technique find little scope for their knowledge, for sooner or later they may come up against ignorance and prejudice from their fellow practitioners. However, the solution seems simple. Teach the subject in medical schools, open clinics staffed by competent medical hypnotherapists, give adequate facilities for research, and produce a learned society attracting the best brains in the country. All this has already been accomplished in America.

Alcohol-induced Pain

Dr. H. PULLAR-STRECKER (Isleworth, Middx.) writes: Alcohol-induced pain in Hodgkin's disease as discussed by Dr. Jan G. de Winter (*Journal*, September 12, p. 604) and other chance observations of the kind may eventually help those engaged in study and prevention of alcoholism to find a physiological means of protecting their patients. There are quite a number of substances causing distaste (or disinclination) for alcohol or a dislike of it. Of these, hydrogen sulphide is particularly interesting (*Brit. J. Addict.*, 1949, 46, 47), since it appears to produce a "natural" distaste for alcohol, in contrast to the enforced dislike produced by tetraethylthiuram disulphide ("antabuse").

Obituary

R. H. CROWLEY, M.D., F.R.C.P.

Early days in the medical branch of the old Board of Education are recalled by the death of Dr. R. H. Crowley, formerly senior medical officer of the Board, at Tewin, Hertfordshire, on September 25 at the age of 84.

Ralph Henry Crowley was born on February 11, 1869, the son of the late Mr. Alfred Crowley, of Croydon, and was educated at Brighton Grammar School and at

(Elliott and Fry, Ltd., London)

Oliver's Mount School, Scarborough. Receiving his medical training at St. Bartholomew's Hospital, he qualified M.R.C.S., L.R.C.P. in 1893, taking the London M.B. in the same year. He proceeded to the M.D. in 1895, was elected a Member of the Royal College of Physicians of London three years later, and became a Fellow in 1930. After qualification he held the appointment of house-surgeon to out-patients at the Hospital for Sick Children, Great Ormond

Street, and later became school medical officer under the Bradford education authority, which post he held until 1909, when he began his long association with the Board of Education. He married Miss Muriel Priestman, of Bradford, in 1902, and had two daughters.

We are indebted to Dr. ROBERT WEAVER for the following appreciation: When Sir George Newman died in 1948 many well-deserved tributes were paid to his work as the first Chief Medical Officer of the Board of Education. The school medical service owed him a very great deal. Behind the scenes in those days the unspectacular work was being done by Dr. (now Dame) Janet Campbell, Dr. Alfred Eichholz, and Dr. Ralph Crowley, and they brought to the task that practical experience of school medical problems and handicapped pupils which Newman lacked. Bradford had appointed a school medical officer as far back as 1893, and this post was held by Crowley when, in June, 1909, he was invited to join the recently established medical branch of the Board of Education. In 1924 he was appointed to the newly created post of senior medical officer of the Board, a position he held until he reached retiring age in 1933.

When the Ministry of Health was established in 1919 Newman became Chief Medical Officer of that Ministry as well as of the Board of Education, but the duties of the former post were so onerous that he had of necessity to leave the school medical service very largely in Crowley's hands. If there was one part of that service which Crowley wished to see developed above all others it was research. He realized what opportunities there were for clinical investigations in the schools and school clinics, and anyone who showed signs of wanting to do such work was sure of his whole-hearted encouragement and support. He had a great deal to do with the original investigations carried out directly on behalf of the Board—inquiries into problems of vision and hearing, mental defect, anthropometric data, and so on. His concern was not entirely with medical problems; he was as interested in the educational as in the physical development of the child, so that there was never any possi-

bility of the school medical service being for him a mere organization for the ascertainment and cataloguing of defects.

Crowley seemed to be the perfect example of a healthy mind in a healthy body. It was impossible to imagine him ever being bored or depressed; his enthusiasms were boyish in their intensity, and to the very last day of his service with the Board he retained that keenness which was so characteristic of him. He always appeared to be much younger than his real age.

There can seldom have been anyone less self-seeking than Crowley. Official honours made no appeal to him, and when he had to make a decision his own interests were never considered. He gained the abiding affection of all who worked under him, for they knew they could trust him implicitly.

LEWIS G. GLOVER, M.D.

Dr. Lewis G. Glover, a former treasurer of the Royal Medical Benevolent Fund, died at his home at Hampstead on September 25 at the age of 85.

Lewis Gladstone Glover was born at Highbury on April 9, 1868, the youngest son of Sir John Glover, a well-known shipowner. He was educated at Highgate School and at St. John's College, Cambridge, gaining an exhibition and graduating B.A. in 1889, with a first-class in the Natural Sciences Tripos. From

Cambridge he went to St. Bartholomew's Hospital and took the degrees of M.B., B.Chir. in 1892, proceeding to the M.D. three years later. After resident appointments at the Royal Hospital for Diseases of the Chest and the Victoria Hospital for Children, he became ophthalmic house-surgeon at St. Bartholomew's and thereafter retained a keen interest in ophthalmology.

He then studied for a further six months at various clinics in Vienna. On his return to this country Glover settled in general practice at Hampstead, in the days when Hampstead General Hospital was staffed by general practitioners, of whom he became one of the most active. In 1898 he joined the late Dr. Ford Anderson in partnership. Glover retired in 1929, after more than thirty happy years of strenuous practice.

Meanwhile he had been a councillor in the Hampstead Borough Council and chairman of its public health committee. He became mayor of the borough in 1936 and was re-elected for a second term of office in the following year. A member of the British Medical Association for some fifty years, he served the Association both at Headquarters and locally with enthusiasm. He acted as one of the secretaries of the Section of Medical Sociology at the Centenary Meeting of the B.M.A. in 1932, and from 1934 to 1938 he was a member of the Central Council. He represented his Division at six Annual Representative Meetings and was chairman of the Division in 1922. He was also treasurer and later vice-president of the Metropolitan Counties Branch. Between the years 1932 and 1951 Glover was a member of a number of central committees, with the charities committee and the medical war relief fund committee heading the list for length of service. He was a foundation member and past president of the Hampstead Medical Society, and for many

years he was honorary treasurer of the Royal Medical Benevolent Fund. In the first world war he was in medical charge of the Artists Rifles Officers Convalescent Hospital at Hampstead. He was devoted to St. Bartholomew's Hospital, of which he was a governor. A devout Christian, for more than half a century he was a pillar of the Lyndhurst Road Congregational Church, and for many years was medical adviser to the London Missionary Society.

Glover was the beau-ideal of the general practitioner. Able, highly qualified, keeping himself up to date and in touch with all the worth-while changes in medical practice, he was kindness itself to his patients, always genial and, while scrupulous in details of treatment and diet, never hurried: his memory is treasured by many old patients. He was an accomplished flautist, delighted in the piano, and in his youth was an enthusiastic rider of the old "penny-farthing" bicycle. He was one of the first doctors in London to use a motor-car, a Darracq of 1903.

In 1897 he married Mildred, the daughter of his uncle, Dr. James Grey Glover, of Highbury, to whom he was devoted. This union of fifty-six years was a most happy one, and there were two children, a daughter (Mrs. Abercromby), who practises as an otolaryngologist in Liverpool, and a son. To them we offer our deep sympathy.—J. A. G.

C. B. GOULDEN, O.B.E., M.D., M.Chir., F.R.C.S. We record with regret the death of Mr. C. B. Goulden at his home at Shepreth, Cambridgeshire, on September 20 at the age of 74. For some years he was surgeon-oculist to the Household of the late Queen Mary.

Charles Bernard Goulden was born on August 20, 1879, the eldest son of the late Mr. H. J. Goulden, a publisher and bookseller of Canterbury. He was educated at St. Edmund's College, Ware, and at Downing College, Cambridge, where he graduated B.A. in 1900. He completed his medical training at the Middlesex Hospital, winning the Freeman Scholarship and the Leopold Hudson Exhibition, and took the degrees of M.B., B.Chir. in 1904, in which year he also obtained the diploma of F.R.C.S. He proceeded to the M.Chir. a year later and to the M.D. in 1914.

Goulden was house-surgeon at the Middlesex Hospital in 1903-4 and at Moorfields from 1904 to 1907. His first consultant post, which he held from 1909 to 1919, was as ophthalmic surgeon to Oldham Royal Infirmary. He joined the R.A.M.C. in the first world war, and was on the staff of the ophthalmic centre at Boulogne, where he worked with Sir William Lister, J. F. Cunningham, and M. H. Whiting until he was posted as ophthalmic surgeon in charge of the centre at Rouen. For his services there he was mentioned in dispatches, and in 1919 he was appointed O.B.E.

His exceptional ability was so much appreciated by his colleagues during the war that in 1919 he was elected to the staffs of the London Hospital and Moorfields, and at the latter he became dean of the medical school. From 1937 to 1948 he was surgeon-oculist to Queen Mary's Household, and in the last war he served as ophthalmic consultant to the Ministry of Health. He was also consultant in ophthalmology to the Ministry of Pensions and consultant ophthalmic surgeon to the London Hospital, the Queen Alexandra Military Hospital, Millbank, St. Vincent's Orthopaedic Hospital at Eastcote in Middlesex, and to the Hostel of St. Luke, as well as to Moorfields.

He was president of the Ophthalmological Society of the United Kingdom from 1944 to 1946, president of the section of ophthalmology of the Royal Society of Medicine in 1948-9, and an honorary member of the French and Mexican ophthalmological societies. When the British Medical Association held its Annual Meeting at Dublin in 1933 he served as a vice-president of the Section of Ophthalmology. He was Montgomery Lecturer of the Royal College of Surgeons in Ireland in 1926 and again in 1932, and was an examiner in ophthalmology for the University of London, the Royal College of Surgeons of England, and the London Conjoint Board. His publications included a textbook on refraction, and a translation, with Clare Harris, of Koby's *Slit Lamp Microscopy of the Living Eye*.

Mr. ARTHUR LISTER writes: The above outline of Charles Goulden's career gives an indication of his scholarship, his professional eminence, and the respect in which he was held by those with whom he worked. He was an acute observer, and a first-class clinician and operator. He was always receptive of new ideas, and he was among the first to bring Gonin's detachment operation to England. But his greatest gift was for teaching, in which a combination of enthusiasm, common sense, simplicity of expression and a power to temper criticism with kindness made him perhaps unique in his generation. Two remarks of his are characteristic: a junior colleague had completed an operation successfully, but more by good luck than good management. His bubble of satisfaction was quickly pricked by Goulden saying, "Yes, but you did not do what you mean to do." When the same colleague committed a technical blunder and asked Goulden if he had ever done the same, Goulden replied, "I have done everything I should not have done." His praise of good work was unstinted, and he delighted in technical excellence.

Though not physically robust, Goulden was blessed with untiring energy. Thus, during the last war, when he was past the age of retirement, he carried on at the London and Moorfields, operated weekly at Brentwood, Chase Farm and Goodmayes, and organized the E.M.S. ophthalmic services with undiminished zest and vigour. His enthusiasm and kindness, his sense of humour without malice, and his interest in a wide variety of subjects made him a most charming and lovable companion. He delighted in music, pictures, and cricket, but especially the first, and he said once that music was his chief interest in life but he did ophthalmology for a living. At Boulogne in the first world war the male voice choir which he organized and trained proved a blessed relaxation to his friends and colleagues during those anxious and sombre days.

His retirement, which he deserved and which he could have enjoyed to the full at his home at Shepreth, was marred by serious illness, but his spirit remained undaunted; the night before a serious operation, after giving vent to a slightly unkind remark, he said with a smile, "Fancy saying that on the brink of eternity." Ophthalmologists all over the world who have listened to him owe him much, and the lives of his many friends are the richer because of him. He is survived by his widow, formerly Miss Norah O'Brien, whom he married in 1911.

Dr. H. H. CAVENDISH FULLER, chief medical officer to the former Railway Executive, died in St. Mary's Hospital, Paddington, on September 30 at the age of 66. Hercules Cavendish Fuller was born in 1887 and was educated at Bishop's Stortford and at Edinburgh University, where he graduated M.B., Ch.B. in 1912. He proceeded to the M.D. in 1931. On the outbreak of war in 1914 he entered the R.A.M.C. and served at home and overseas as medical officer attached to the Royal West Kent Regiment until 1917, when he settled in general practice at Malvern. He was then appointed medical officer to Malvern College, a position he held until 1930, and he also became honorary consulting surgeon to Great Malvern Hospital and medical

referee to the Ministry of Pensions for the Malvern area. Dr. Cavendish Fuller was appointed assistant medical officer to the old Great Western Railway in 1930 and in the following year he became chief medical officer. In addition, he was, until war broke out again in 1939, chief clinical assistant to the National Hospital for Diseases of the Heart, clinical assistant to the British Red Cross Clinic for Rheumatism, Peto Place, and medical officer for Channel Islands Airways. During the last war he was responsible for the medical arrangements for the evacuation of children and for air raid casualties at Paddington. He also held the rank of lieutenant-colonel in the Home Guard. In 1948 he was appointed medical adviser to the Railway Executive, while continuing his duties as Western Region medical officer at Paddington, and a year later he became chief medical officer to the Railway Executive. By a sad coincidence his death occurred on the last day of the official existence of the executive.

Medico-Legal

DIABETES AND DRIVING LICENCES

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

S. 5 of the Road Traffic Act, 1930, provides that on application for the grant of a driving licence the applicant must make a declaration in the prescribed form "as to whether or not he is suffering from any such disease or physical disability as may be specified in the form, or any other disease or physical disability which would be likely to cause the driving by him of a motor vehicle, being a vehicle of such a class or description as he would be authorized by the licence to drive, to be a source of danger to the public."

The specified diseases and disabilities are contained in Regulation 5 of the Motor Vehicles (Driving Licences) Regulations, 1950, and are: epilepsy; any form of mental disorder or mental defect as a result of which either the applicant is certified or duly ascertained as subject to be placed under statutory supervision or the applicant's estate is in the hands of a receiver, curator bonis, or judicial factor; liability to sudden attacks of disabling giddiness or fainting; and inability to read at a distance of 25 yards in good daylight six white letters and figures on a black ground of the size and arrangement prescribed for number-plates.

In the case of other disease or disability than the specified diseases and disabilities, s. 5 of the Road Traffic Act provides that the applicant can claim a driving test, and if he passes it his licence is not to be refused solely on the grounds of the disease or disability. If he has previously passed such a test, a further test shall not be required unless it is apparent from his declaration or from information received by the licensing authority that his previous disease or disability has become more acute or that he has developed a new one. In the case of the specified diseases or disabilities, and in the case of other diseases or disabilities likely to cause dangerous driving unless the applicant has claimed and successfully passed a test, the licensing authority is obliged to refuse to grant a driving licence.

Failure by an applicant to disclose that he suffers from diabetes has been made the subject of prosecution for making a false statement in order to obtain a driving licence. Diabetes is not a disease specified under the 1950 regulations. Whether it is a disease which in the words of s. 5 of the Road Traffic Act, 1930, "would be likely to cause the driving by him of a motor vehicle to be a source of danger to the public" is a question on which different views might well be held. The common-sense answer appears to be that, if the sufferer appreciates the risk of hypoglycaemia and has been told by his doctor how to recognize the imminence of attacks and to avoid them by carrying biscuits or sugar or glucose, his diabetes is not likely to be a source of danger. Law and common sense look as if they are in accord.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in the week ending September 26 (38th week of the year) were as follows: paralytic, 119 (123); non-paralytic, 99 (104); total, 218 (227). This is a decrease of 9 compared with the previous week, the figures for which are in parentheses. This is small, and the autumn fall in poliomyelitis notifications towards the winter levels is slower than might be hoped for.

Week Ending September 26

The notifications of infectious diseases in England and Wales during the week included scarlet fever 786, whooping-cough 2,771, diphtheria 29, measles 492, dysentery 263, paratyphoid fever 13, typhoid fever 6.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest variations in the trends of infectious diseases in England and Wales during the week ending September 19 were an increase of 128 in the number of notifications of scarlet fever, from 505 to 633, and a decrease of 153 for whooping-cough, from 3,708 to 3,555.

Only small fluctuations occurred in the local trends of scarlet fever, with the exception of a rise of 34 in Yorkshire West Riding, from 54 to 88. The largest variations in the returns of whooping-cough were a rise of 57 in the number of notifications in Yorkshire West Riding, from 260 to 317, and a fall of 54 in Southampton County, from 162 to 108. 608 cases of measles were notified, 5 more than in the preceding week, and no changes of any size were reported in the local trends. 25 cases of diphtheria, an increase of 6 on the preceding week, were notified. The chief features of the returns for diphtheria were rises in Lancashire from 4 to 7 and in Durham from 0 to 4.

227 cases of acute poliomyelitis were notified during the week. These cases were 31 more for paralytic and 23 more for non-paralytic cases than in the preceding week. The largest returns were Warwickshire 29 (Coventry C.B. 15, Birmingham C.B. 7), London 22 (Lewisham 4, Wandsworth 3, Woolwich 3), Lancashire 20 (Manchester C.B. 6, Liverpool C.B. 4, Preston C.B. 4), Yorkshire West Riding 16 (scattered through 12 administrative areas), Northamptonshire 15 (Kettering M.B. 14), Surrey 13 (Reigate M.B. 4).

The notifications of dysentery have been almost constant during the past month. 202 cases, 2 fewer than in the preceding week, were notified. The largest returns were Lancashire 35 (Farnworth M.B. 12), London 30 (Chelsea 7), Yorkshire West Riding 30 (Bradford C.B. 10), Middlesex 20, and Warwickshire 14 (Birmingham C.B. 12).

73 cases of diarrhoea and enteritis in children aged under 2 were notified in Eire; 57 of these occurred in Dublin C.B.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 19 (No. 37) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Sir Godfrey Huggins, C.H., surgeon and administrator, became the first Prime Minister of the Federation of Rhodesia and Nyasaland when, on September 7, he accepted the Governor-General's invitation to form a temporary Ministry. The Ministry has the task of setting up a new government machine and of preparing the initial electoral law under which the Federation's first Assembly will be elected. In addition to the premiership, Sir Godfrey Huggins assumed the portfolios of Finance, External Affairs, and Defence. Sir Godfrey received his medical education at St. Thomas's Hospital.

Middlesex Hospital Medical School Dinner.—The annual dinner of past and present students was held at the Savoy Hotel, London, on October 2, with Mr. C. P. Wilson in the chair. In proposing a toast to the hospital and the school the chairman said that the past year had been an eventful one for the Middlesex, and a year which found them as youthful and progressive as they had ever been. H.M. the Queen had agreed to become their Patron, thereby continuing an unbroken tradition of more than 130 years. He paid a tribute to Canada's generosity in making a gift to Britain of a unit of cobalt-60, the most powerful radioactive substance yet known, for the treatment of malignant disease. The unit had been installed at Mount Vernon Hospital, Northwood. (A description of the unit was given in the *Journal* of March 21, p. 669; it was stated to have cost over £25,000.) Sir Harold Boldero, Dean of the Medical School, spoke of his great faith in the new Institute of Clinical Research, and said that he wished them to realize how it had developed from an ideal to a reality. The board of governors had decided willingly to spend a considerable proportion of the endowment fund on research, and it had been agreed that there should be an institute in which practising physicians and surgeons could undertake research requiring laboratory facilities. The difficulty remained, however, as to where this could be situated. A house to the north of the school had come into the market, but the B.B.C., whose need for accommodation was very real, was interested in it also. He hoped it would not be forgotten that the fact that the hospital had succeeded in becoming the freeholders of the property was due to the B.B.C.'s Director-General of the day, Sir William Haley, who had taken the line that the needs of research at Middlesex Hospital were paramount. Dr. C. G. H. Newman, Senior Broderip Scholar, also replied to the toast, and the health of the chairman was given on the proposition of Professor B. W. Windeyer.

Medical Defence Union.—Presenting the report and accounts (*Journal*, August 29, p. 504) at the annual meeting of the Medical Defence Union last month, the president, Dr. S. Cochrane Shanks, commented on the rising tide of litigation that besets the medical profession. "In the past, a patient might hesitate to sue a voluntary hospital or a doctor who gave his services free." It was not the case now, he said. The three defence unions were at present negotiating with the Ministry on the subject, with the object of defending unwarranted actions together and of settling just claims in amicable agreement. Two committees had been set up by the council of the Union during the last year—one to report on injection routine in operating theatres and the other, in conjunction with the Association of Anaesthetists, on anaesthetic explosions. The first had completed its work.

Hospital Catering.—"It is evident to all, certainly to the hospital population, that there is, here and there, room for improvement in hospital feeding," said Dr. Charles Hill, Parliamentary Under-Secretary to the Ministry of Food, speaking at the School of Hospital Catering in the grounds of St. Pancras Hospital, London, on September 30. Not only was there room for improvement in the more scientific field of calories and proteins and vitamins, but even more in the presentation and serving of food. King Edward's

Hospital Fund for London, in providing the school, Dr. Hill continued, had discovered a valuable and very human way of using some of its resources. He hoped that management committees would take the fullest advantage of the opportunity to send their staffs to the courses of instruction offered. The activities of the school were on display for the many visitors who attended the demonstration. Sample meals for different diets were graded by cost, but had the same nutritional content. In the advisory service department statistics had been worked out for the labour and cost involved in various aspects of hospital catering. This department also offers expert advice on the equipment of kitchens. Refresher courses for the different grades of catering personnel are provided at the school, as well as one-year courses for new entrants into this occupation. Some bursaries are available.

Malaria in Asia.—The permanent elimination of malaria from regions where nearly a quarter of the world's population live was the theme of W.H.O.'s first Asian Conference on Malaria, which ended in Bangkok on September 29. The Conference was attended by delegates from 20 nations. The main conclusion of the Conference, supported by much evidence from local malaria prevention schemes and likely to appeal strongly to governments, is that efficient malaria prevention pays handsome dividends. In one area of Thailand with a population of 280,000 it is estimated that 175,000 man-days of labour were saved after a single year of control work.

Employment of the Severely Disabled.—The Ministry of Labour and National Service has offered local authorities financial help in providing sheltered employment for severely disabled persons. Until now such assistance has been limited to those who are blind. The Ministry offers grants of up to 75% of the capital cost of providing new workshop accommodation and grants towards losses incurred in running them. This should allow the industrial resettlement of any capable of factory work who are not already being assisted either by voluntary agencies or in Remploy factories.

Nuffield Gerontological Research Fellowships.—Because of the high quality of the candidates applying for a Nuffield Research Fellowship for work on the scientific aspects of ageing, the Foundation has decided to award two Fellowships instead of one as originally intended. This has necessitated increasing the sum set aside for this purpose from £25,000 to £51,000. Dr. P. L. Krohn, Reader in Endocrinology at Birmingham University, has been elected to a five-year professorial research fellowship, and Dr. D. A. Hall, Lecturer in Medical Biochemistry at Leeds University, to a three-year research fellowship of less senior status. Dr. Krohn will analyse the causes of ageing. Dr. Hall will study the changes in connective tissue.

Liverpool Medical Institution.—Over 400 members and guests attended the inaugural meeting on October 1, when Mr. J. B. Oldham delivered his presidential address on "The Founders of our Library." Mr. Oldham described the lives of these men who, 180 years ago, started the library from which the Liverpool Medical Institution had arisen, and gave an account of the times and the town in which they lived. Professor N. B. Capon proposed the vote of thanks to the president.

Family Doctor.—The October issue contains articles on "Television for Children" (by C. A. Lejeune), rupture, and infant feeding (by Dr. Ursula Shelley). Other medical subjects discussed are the mechanism of heredity, spectacles, and catarrh. There is the usual batch of medical "Any Questions?" from the lay, ranging from "Can gallstones be dissolved?" to a note on a condition called "Jack Hulbert Jaw." Dr. J. G. Coburn writes on barrier creams and the kitchen sink.

Chair of Surgery at Durham.—Mr. A. G. R. Lowdon, senior lecturer in surgery at Edinburgh, has been appointed to the chair of surgery at Durham University. During the last world war Mr. Lowdon served as a surgeon with the Eighth Army in North Africa and Sicily, and with the British

Liberation Army in Europe. Since the war he has been working with Sir James Learmonth in Edinburgh.

Sir George H. Henderson is retiring this month from his position as Secretary of the Department of Health for Scotland. He will be succeeded by Mr. Harold Ross Smith.

Sir Rudolph Peters, F.R.S., Whitley Professor of Biochemistry at Oxford, received the degree of doctor of science of the University of Cincinnati at a special convocation ceremony there last month.

Distribution of Medical Films.—The British Film Institute and the medical committee of the Scientific Film Association are prepared to make arrangements for the distribution of approved medical films if the owners of the films are unable to do it themselves. Anyone wishing to avail himself of this offer is invited to lend a copy of his film to the distribution officer, British Film Institute, 4, Great Russell Street, London, W.C.2. The film will be viewed by members of the medical committee, and, on their recommendation, a copy will be made and the original returned. The film will then be available for hire from the film library of the British Film Institute, the copyright, however, remaining with the owner.

COMING EVENTS

West End Hospital for Nervous Diseases.—Clinical demonstrations in neurology will take place every Tuesday at 5.30 p.m. from October 13 until December 15 at the Out-patient Department, 40, Marylebone Lane, London, W.1. The demonstrations are open to postgraduates, medical practitioners, and senior medical students.

Guild of St. Luke, SS. Cosmas and Damian.—The annual mass and communion will take place on St. Luke's Day, Sunday, October 18, at 8.30 a.m. in the crypt of Westminster Cathedral.

Medical Society for the Care of the Elderly.—A general meeting will be held at the City Hospital, Nottingham, on October 22 and 23.

Wessex Rabere Club.—The autumn dinner of the club will take place at the Lansdown Grove Hotel, Bath, on October 24. Membership is open to all Bart's men practising in the West Country. Further details may be obtained from the hon. secretary, Mr. A. Daunt Bateman, 11, The Circus, Bath.

British Association of Physical Medicine.—A postgraduate course in physical medicine will be held on Saturday mornings from October 31, 1953, to January 23, 1954, at various London hospitals. The fee for the course is two guineas. Further particulars can be obtained from the honorary secretary of the association, 45, Lincoln's Inn Fields, London, W.C.2.

NEW ISSUES

Abstracts of World Medicine.—The October issue (Vol. 14, No. 4), which is now available, contains abstracts of important papers on both medical and surgical subjects drawn from journals published in some 20 different countries and in all five continents. In addition to the various branches of clinical medicine and surgery, the subjects covered include pathology, bacteriology, pharmacology, and chemotherapy, and there are also sections dealing with medical genetics, industrial medicine, anaesthetics, radiology, and the history of medicine.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; a specimen will be sent free on request.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Sunday, October 11
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Adolph Tuck Hall, Woburn House, W.C.3, 3 p.m., Presidential address by Mr. Albert Davis: Some Obstetric and Gynaecological Curiosities.

Monday, October 12
● **INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.**—At Chelsea Hospital for Women, 4.30 p.m., Mr. R. H. Boyd: Contraception.
LONDON UNIVERSITY.—At University College Hospital Medical School, 5.30 p.m., Special University Lecture in Pathology by Professor E. G. D. Murray (Montreal): Surmise on Some Trends in Bacteriology.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., general meeting. Presidential Address by Mr. E. W. Riches: Significance of Haematuria.
● **POSTGRADUATE MEDICAL SCHOOL OF LONDON.**—4 p.m., Dr. W. S. C. Cope: Treatment of the Rheumatic Diseases with Cortisone and A.C.T.H.
● **ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5.15 p.m., Mr. J. Cosbie Ross: Management of the Bladder in Spinal Injury; 6.30 p.m., Mr. D. H. Patey: Surgery of the Parotid Gland.
● **WESTMINSTER MEDICAL SCHOOL.**—At Church House, Great Smith Street, 3 p.m., Inaugural Address by Lord Radcliffe.

Tuesday, October 13

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor R. W. Russell: Experimental Psychopathology.
CHELSEA CLINICAL SOCIETY.—At South Kensington Hotel, 41, Queensgate Terrace, S.W.7, 7.30 p.m., dinner, followed by a discussion: The McNaghten Rules, to be opened by Sir Ernest Gowers, Dr. Desmond Curran and Dr. Elliot Slater.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. C. O. Carter: Genetics in Dermatology.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL.—5 p.m., Second Dorothy Platt Memorial Lecture by Professor E. C. Dodds, F.R.S.: Recent Knowledge of the Endocrine Background of Malignant Disease.

MANCHESTER MEDICAL SOCIETY: SECTION OF SURGERY.—At Medical School, Manchester University, 8 p.m., Presidential Address by Mr. O. M. Duthie: Retinal Detachment.

● **ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5.15 p.m., Mr. William Gissane: Major Injuries of the Hand—Open and Closed; 6.30 p.m., Sir Harry Platt: Tumours of Bone.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Mr. G. F. Gibberd: Management of Disproportion.

Wednesday, October 14

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. I. Whimster: Developmental Anomalies.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., symposium to be opened by Professor Andrew Wilson: Use and Abuse of Antibiotics.

MANCHESTER MEDICAL SOCIETY: SECTION OF PATHOLOGY.—At Medical School, Manchester University, 4.30 p.m., symposium on Transfusion Problems by Dr. R. F. Jennison and Dr. F. Stratton, followed by a discussion.

MIDLAND MEDICAL SOCIETY.—At Queen's Hotel, Birmingham, 8.15 p.m., annual dinner and inaugural meeting.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor A. C. Frazer: Normal and Defective Fat Absorption.

● **ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5.15 p.m., Professor C. G. Robt: Arterial Aneurysms; 6.30 p.m., Mr. E. T. C. Milligan: Surgery of the Anal Canal.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—4 p.m., Bengul Memorial Award Lecture by General A. M. E. Sicé (Baile): Evolution of Therapeutics in the Course of the Last Few Years (Illustrated).

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., lecture-demonstration by Dr. J. D. W. Pearce: Psychological Medicine.

● **SCHOOL OF PHARMACY.**—At Beveridge Hall, Senate House, 3 p.m., inaugural address by Sir Henry Cohen.

Thursday, October 15

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., Presidential Address by Mr. Cuthbert Andrews: The Industry and the Institute.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. C. J. Poplak: Biological Synthesis.

CHADWICK TRUST.—At Royal Society of Arts, 5.30 p.m., public lecture by Mr. C. J. Regan: Air Pollution.

EDINBURGH CLINICAL CLUB.—At 7, Drumsheugh Gardens, 8 p.m., Dr. Douglas Miller: Common Obstetrical Injuries and their Sequelae.

EPSOM AND SUTTON INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At Cane Hill Hospital, Coulsdon, Surrey, 8 p.m., annual meeting. Dr. Alexander Walk: Royal Commission on Marriage and Divorce; Dr. F. B. E. Charatan: Psychiatric Aspects of Pulmonary Neoplasm.

● **INSTITUTE OF CHILD HEALTH AND INSTITUTE OF NEUROLOGY.**—At National Hospital, Queen Square, W.C.3, 5.30 p.m., Dr. A. P. Norman: Aetiological Factors of "Congenital" Group (Kernicterus, Birth Trauma, Anoxia, Developmental Abnormality).

NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Manchester Royal Infirmary, 5 p.m., presidential address by Mr. F. Ronald Edwards: Recent Trends in Pulmonary Surgery.

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. W. R. Bett: Truants from Medicine (with lantern slides).

● **ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5.15 p.m., Mr. T. Holmes Sellers: Surgery of the Pericardium; 6.30 p.m., Mr. Geoffrey L. Keynes: Parathyroid Surgery.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—7.30 p.m., presidential address by Dr. Norman White.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor O. Wyss (Zurich): Organization of the Respiratory Centre.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. Desmond Curran: psychiatric demonstration.

SOCIETY OF CHEMICAL INDUSTRY: MICROBIOLOGY GROUP.—At Medical Society of London, 6.15 p.m., Dr. E. F. Gale: Actions of Antibiotics in the Bacterial Cell.

Friday, October 16

FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 2.15 p.m., Diagnosis Section Meeting. Dr. J. W. Pierce: Pulmonary Manifestations of Fungus Diseases.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. J. E. M. Wigley: Eczema.

INSTITUTE OF NEUROLOGY.—5 p.m., Dr. Paul Bucy (U.S.A.): Cervical Hypertrophic Pachymeningitis—Diagnosis and Treatment.

LONDON UNIVERSITY.—At Guy's Hospital Medical School, 5 p.m., Professor William Montagna (Brown University): The Architecture, Growth, and Differentiation of Skin.

● **POSTGRADUATE MEDICAL SCHOOL OF LONDON.**—12 noon, Dr. A. Rae Gilchrist: Coronary Sclerosis; 4 p.m., Sir Neil Hamilton Fairley, F.R.S.: Schistosomiasis.

● **ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.**—2.45 p.m., William Meredith Fletcher Shaw Memorial Lecture by Mr. J. W. Bide: Some Manchester Pioneers in Obstetrics and Gynaecology.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—3 p.m., Harveian Oration by Dr. George Graham: Value of Physiology in Medicine.

Saturday, October 17
BIOCHEMICAL SOCIETY.—At Westminster Medical School, 11 a.m., 322nd meeting, scientific papers.

APPOINTMENTS

DUMMER, F. H. M., M.B., Ch.B., C.P.H., D.P.H., Medical Officer of Health, Borough of Andover, Rural Districts of Andover, Whitechurch and Kingsclere, Hants.

FISHER, MARGARET L., M.B., B.Ch., House-physician to Neurological and Neurosurgical Department, Hospital for Sick Children, Great Ormond Street, London, W.C.

GRANT, DONALD KERR, M.B., B.S., M.R.A.C.P., House-physician, Hospital for Sick Children, Great Ormond Street, London, W.C.

SOUTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—Lotte Rosenberg, M.D., D.P.M., Whole-time Assistant Child Psychiatrist (S.H.M.O.).

Hampshire Child Guidance Service; B. W. Richards, M.R.C.S., L.R.C.P., D.P.M., Whole-time Deputy Physician Superintendent and Consultant Psychiatrist, St. Lawrence's Hospital, Caterham; G. W. Garland, M.D., M.R.C.O.G., Part-time Consultant Obstetrician and Gynaecologist, Lambeth Hospital; Mrs. Michael Kohnstamm, M.D., Whole-time Assistant Chest Physician (S.H.M.O.), King George V Hospital, Godalming; A. M. MacArthur, M.B., F.R.C.S., Part-time Consultant Thoracic Surgeon, St. Helier, Croydon and Redhill Groups; B. A. Pomryn, M.B., B.S., D.P.M., Whole-time Assistant Psychiatrist (S.H.M.O.), Belmont Hospital; E. P. H. Charlton, M.D., D.P.M., Whole-time Physician Superintendent and Consultant Psychiatrist, Banstead Hospital; G. V. Sybil Aldridge, M.B., B.S., D.C.H., Part-time Chest Physician (S.H.M.O.), Battersea Chest Clinic; Lois E. Hurter, M.D., M.R.C.O.G., Part-time Consultant Obstetrician and Gynaecologist, Lambeth and Wandsworth Groups; F. Denny, M.D., M.R.C.O.G., Part-time Consultant Obstetrician and Gynaecologist, Chelsea, and Fulham and Kensington Groups; C. P. Mills, M.B., B.S., Surgical Registrar, Royal Hants County Hospital, Winchester; Thomas P. Nash, F.R.C.S., Surgical Registrar, Southampton General Hospital; R. Alhadeff, F.R.C.S., Surgical Registrar, Mayday Hospital; A. O. Watkins, F.R.C.S., Surgical Registrar, Princess Beatrix Hospital; Mary D. North, M.B., B.S., Medical Registrar, St. Stephen's Hospital; Margaret H. North, L.R.C.P.&S.Ed., Anaesthetic Registrar, St. Stephen's Hospital; J. Levin, M.B., Ch.B., Anaesthetic Registrar, Fulham Hospital; J. Towers, B.M., B.Ch., D.P.M., Senior Psychiatric Registrar, Graylingwell Hospital; R. H. Boardman, M.B., B.Chir., D.P.M., Senior Psychiatric Registrar, Springfield Hospital; V. N. Bagadia, M.D., and H. K. Rose, L.R.C.P.&S., D.P.H., Psychiatric Registrars, Netherne Hospital; Rosemary M. W. Ince, M.B., Ch.B., Pathological Registrar, Portsmouth and Isle of Wight Area Pathological Service; Diana G. Partridge, M.D., D.C.H., Senior Thoracic Medical Registrar, Croydon Chest Clinic; H. G. Dixon, M.B., B.S., M.R.C.O.G., D.Obst. R.C.O.G., Obstetric and Gynaecological Registrar, Southlands Hospital; M. C. Michelow, M.B., B.Ch., D.Obst. R.C.O.G., Obstetric and Gynaecological Registrar, Redhill County Hospital; Margaret M. Downes, M.B., Ch.B., M.R.C.O.G., Obstetric and Gynaecological Registrar, St. Luke's Hospital; R. D. Nicholson, M.B., B.S., Orthopaedic Registrar, Winchester Group of Hospitals; W. E. J. Bennett, F.R.C.S., Surgical Registrar, St. James Hospital; Mary D. Campbell, L.R.C.P.&S., Anaesthetic Registrar, St. Mary Abbots Hospital; G. Dutton, M.B., B.S., Psychiatric Registrar, Botley Park Hospital; K. W. Cochrane, M.B., B.S., Ch.B., F.R.C.S.Ed., D.Obst. R.C.O.G., Obstetric and Gynaecological Registrar, Epsom and District Hospital; B. A. Gavourin, M.B., B.S., D.Obst. R.C.O.G., Obstetric and Gynaecological Registrar, Mayday Hospital; W. R. Parkes, M.B., Ch.B., Medical Registrar, Fulham Hospital; J. A. C. Brown, M.B., B.S., D.Obst. R.C.O.G., Surgical Registrar, Redhill County Hospital; M. G. Jones, M.B., B.Ch., Surgical and Orthopaedic Registrar, Queen Mary's Hospital for Children; R. W. L. Calderwood, M.R.C.S., L.R.C.P., Orthopaedic Registrar, St. James Hospital; A. Bramley, M.B., Ch.B., B.D.S., and I. H. Heslop, M.B., B.S., F.D.S., Dental Registrars, Rookdown House, Basingstoke; A. G. Pollen, M.B., B.S., and C. H. J. Rey, F.R.C.S., Surgical Registrars, Lambeth Hospital; A. J. Heber, M.B., B.S., Anaesthetic Registrar, Redhill County Hospital.

BIRTHS, MARRIAGES, AND DEATHS

MARRIAGES

Horne-Mackenzie.—On September 30, 1953, at King's College Chapel, Aberdeen, James Landess Horne, M.D., D.P.H., of Maybank, Strathpeffer, to Margaret Marian Mackenzie, M.B., Ch.B., of Croft Mhairi, Tain, Ross and Cromarty.

DEATHS

Farr.—On August 29, 1953, at 5, Burnham Gardens, Bognor Regis, Sussex, Arthur Farr, M.R.C.S., L.R.C.P., late of Kensington, London, W., aged 79.

Kilgally.—On July 14, 1953, in Kenya, Charles Randolph Kilgally, C.M.G., M.V.O., M.B., B.Ch., D.P.H., Surgeon Lieutenant-Colonel, Grenadier Guards, retired, late of Drimcong, Moycullen, Co. Galway, Ireland, aged 93.

King.—On September 3, 1953, near Bath, Somerset, Lorna Susan King, M.B., B.S., formerly of Bromley, Kent.

McHugh.—On September 8, 1953, at his home, 101, Withington Road, Manchester, Louis Joseph Edward McHugh, M.B., B.Ch., aged 78.

MacLennan.—On September 8, 1953, at All Saints' Hospital, Chatham, Kent, Kenneth Falconer Macrae MacLennan, M.B., Ch.B.

Napier.—On September 10, 1953, George Napier, M.B., Ch.B., D.P.H., of Salisbury, Wilts.

Newton.—On August 31, 1953, at 4, Walden Road, Welwyn Garden City, Hertts, Hallé Newton (formerly Marsten), M.R.C.S., L.R.C.P.

Nicol.—On August 30, 1953, Henry Maurice Dunlop Nicol, M.B., B.Ch., of Great Amwell House, Ware, Herts, and 146, Harley Street, London, W., aged 69.

Robertson-Ross.—On September 7, 1953, at "Laurel Trees," West Coker, Som., James Ewen Robertson-Ross, L.M.S.S.A., aged 63.

Taylor.—On September 2, 1953, Maud Taylor, M.D., late of Godfrey's Farm, Radwinter, Essex.

Tensdale.—On August 26, 1953, at his home, West Retford House, Retford, Notts, John Cambridge Tensdale, M.B., Ch.B., aged 75.

Wallace.—On August 22, 1953, at St. Thomas's Hospital, Godalming, Surrey, John Wallace, O.B.E., T.D., M.D., Colonel, R.A.M.C. (T.), retired.

Will.—On September 7, 1953, whilst on holiday, Ella Kennedy Will, M.R.C.S., L.R.C.P., of 1, Winsford Terrace, Edmonton, London, N.

Zuckermann.—On September 29, 1953, Ernst Zuckermann, M.D., of 14, Oxford Street, Nottingham.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Pain on Ejaculation

Q.—A man of 48 has suddenly developed pain in the glans penis on ejaculation. There is no history or evidence of genito-urinary disease. What is the likely cause, and what treatment is advised?

A.—In this case the pain in the glans penis is almost certainly referred from the prostate or vesicles. These structures must therefore be carefully investigated for signs of infection; the secretion expressed by prostatic and vesicular massage should be examined for pus cells, and the urine voided subsequently for the presence of threads. A small concretion in the prostate might also cause pain on ejaculation. If no physical lesion can be found the possibility of the pain being psychogenic must be considered. A husband who is unable to satisfy his wife sexually sometimes falls back on pain as an excuse for this. Diathermy treatment, using rectal and suprapubic electrodes, is often helpful.

Which Barbiturate?

Q.—How do the various official barbiturate preparations differ in action, effective dose, rate of elimination, and toxicity?

A.—This topic often occupies a whole chapter in a modern textbook of pharmacology, but a good and succinct account will be found in the *National Formulary*, 1952.

The duration of action of a barbiturate depends upon its rate of degradation by the liver, absorption by other tissues, excretion by the kidney, on the rate and route of administration, and also upon the dose given. In general the long-acting barbiturates take effect more slowly than the short-acting ones when given orally. It is usual to classify the substances according to their duration of action as long-, medium-, and short-acting drugs. Barbitone and its sodium salt are almost entirely removed by renal secretion, and a single dose may be effective for 12 hours or more. This substance may be detectable in the urine for several days after a single dose. Phenobarbitone and methylphenobarbitone are partly excreted by the kidneys and partly broken down in the liver. All these substances are slowly eliminated and cumulation may occur, especially if renal function is poor. Medium-acting barbiturates such as pentobarbitone sodium and quinalbarbitone sodium are more rapidly metabolized by the liver, while the short-acting thiopentone sodium is probably dealt with by most tissues including liver. The barbiturates mentioned above are official in the B.P. (1953), but of these only phenobarbitone and quinalbarbitone are widely used. The B.P.C. (1949) includes also the medium-acting allobarbitone, amylobarbitone, and butobarbitone, and the short-acting cyclobarbitone and hexobarbitone. The use of the last-named is, however, dying out in Britain.

The actions of barbiturates vary from sedation, for which some like phenobarbitone are specially suitable, to full anaesthesia. With some compounds such as cyclobarbitone most stages between these two extremes can be usefully obtained by varying the dosage. The short-acting thiopentone sodium is commonly given by intravenous injection. Doses used obviously vary according to the effect desired. Phenobarbitone is used as a sedative in doses of 30–120 mg. (½–2 gr.) and barbitone as a hypnotic in doses of 0.3 to 0.6 g. (5–10 gr.). Medium acting barbiturates are often given in doses of 90–180 mg. (1½–3 gr.) for hypnosis; cyclobarbitone is used in double these amounts, while quinalbarbitone

sodium may be useful in doses as low as 45 mg. ($\frac{3}{4}$ gr.) for insomnia or temporary hypnotic action. Patients vary in sensitivity and it is impossible to define dosage accurately. Large doses of the long-acting compounds are unsuitable as hypnotics as their effect persists for too long.

The toxicities of the barbiturates roughly parallel their therapeutic doses, the therapeutic ratio for all being about the same. Phenobarbitone and methyl phenobarbitone have the additional property of depressing the activity of the motor cortex; hence their use in treating epilepsy.

It is relevant to emphasize that, except in full anaesthetic dosage, barbiturates have no analgesic action. For this a suitable analgesic should be used in addition to a barbiturate if an analgesic effect is also desired.

The practitioner is strongly recommended to choose two or three representative barbiturates and to make himself familiar with their particular merits and defects.

Sudden Unilateral Deafness

Q.—What are the possible causes of unilateral tinnitus and almost complete nerve deafness of sudden onset in an adult? The condition developed, with a subjective "bang" in the affected ear, four months ago and has persisted. A vascular lesion of the cochlea is suspected.

A.—The most likely cause of a sudden and complete deafness in one ear without vertigo is some toxic infection of the ganglion cells, such as may happen in mumps or as the result of streptomycin intoxication. A vascular accident is possible, but signs of a vestibular disaster (vertigo and vomiting) would also be present. In certain cases of endolymphatic hydrops (Ménière's disease) the distension of the endolymphatic system may continue unrelieved until the membranous system is ruptured with complete and irreversible loss of function. If a detailed otological examination does not reveal any cochlear function, then the likelihood of any return of hearing is remote, though the tinnitus may continue unabated. If hydrops of the labyrinth is suspected, then there is some slight prospect of improvement in hearing if a strict low-sodium and limited fluid diet is followed.

Treatment of Amoebiasis

Q.—What is the modern treatment of amoebiasis? Is a change of climate likely to make a relapse more probable?

A.—The drugs of greatest value in the treatment of intestinal amoebic infections are emetine hydrochloride and emetine bismuth iodide.

In acute amoebic dysentery it is probably best to commence with two or three intramuscular injections of 1 gr. (65 mg.) of emetine hydrochloride; this usually brings the diarrhoea under control rapidly. Treatment is continued with emetine bismuth iodide (E.B.I.) given in keratin-coated capsules and in doses of 3 gr. (200 mg.) nightly for ten nights. In order to combat the nausea which is commonly caused by this drug, 1–2 gr. phenobarbitone is administered half an hour before the E.B.I. is given. Most patients will then sleep through the period during which the nausea would have been experienced. Injections of emetine may be omitted in the case of cyst-passers who are not suffering from dysenteric symptoms. This treatment has been shown to eradicate 90% of infections, and there is no satisfactory evidence that superior results are obtained with any of the antibiotics or by following the course of E.B.I. with one of oxyquinoline compounds, arsenic, or enemata containing amoebicidal substances.

At the conclusion of the last war treatment was commonly commenced with penicillin on the assumption that secondary infection might thereby be controlled. The results were disappointing, and it is now no longer commonly employed. More recently aureomycin has been used, particularly in America. Encouraging preliminary reports were made, and there is no doubt that the drug will bring an acute attack of dysentery under control; 50% of cases, however, relapse within eight weeks of completion of treatment. Clinical

trials with terramycin are at present being carried out, and it seems safe to say that it is more effective than aureomycin, though it is doubtful whether it is as effective as emetine and emetine bismuth iodide. There is some evidence that resistant cases may respond better to terramycin or aureomycin given in conjunction with emetine bismuth iodide than they do to the latter given alone. Resistant infections in which organisms persist in the faeces in spite of treatment are, however, very seldom encountered. Cases in which stool examination is negative after treatment are not uncommonly erroneously labelled resistant because of persisting bowel symptoms. In these, however, the disturbance is usually of a functional nature rather than the result of persisting infection.

A change of climate is not likely to make a relapse of amoebic dysentery more probable. The only important consideration in this respect is whether the change in climate entails a change in environment leading to a greater chance of reinfection.

Hormone Treatment of Anorexia Nervosa

Q.—Has cortisone or A.C.T.H. any place in the treatment of anorexia nervosa?

A.—In so far as anorexia nervosa is a primary psychopathic state, as its name implies, there would appear to be no specific indication for cortisone or A.C.T.H. It may be that in the later and more severe phases of the disorder there is a secondary disturbance of pituitary and adrenal function, and if the latter could be demonstrated there might be an indication for the use of these hormones. However, it might be thought that in view of their appetite-stimulating effect in non-endocrine states such as rheumatoid arthritis they might be properly used regardless of the primary condition. However, Dr. C. F. Rolland recently reported at a meeting of the Nutritional Society (*Journal*, March 14, p. 613) that such attempts have not been successful and any gain in weight was due to the retention of salt and water. It would therefore appear better to rely on the more conventional methods of removal from the usual surroundings to hospital or nursing-home, reassurance, encouragement and intelligent persuasion, and suggestion.

Dutch Cheese Rind

Q.—Of what is the waxy rind of a Dutch cheese composed? Is it indigestible? My landlady's small boy has developed a taste for it.

A.—The red Dutch cheeses are first dyed with aniline dye and then coated with indigestible wax, usually paraffin. Eating the rind will probably do little harm to the boy, but neither will it do him much good.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

EFFECTIVE ORAL AMINOPHYLLINE

THEODROX

"These charts show the increase in gastric tolerance following the oral administration of Aminophylline with aluminium hydroxide (Theodrox) compared with that of plain aminophylline."

REFERENCES

- (1) Studies with Two New Theophylline Preparations, *Amer. J. med. Sci.*, 224: 627, 1952.

THEODROX provides a dependable method of oral administration of aminophylline in doses large enough to produce blood levels comparable with those following injection.

Previous investigations have shown that good response is obtained from aminophylline only if a certain concentration of the active component, theophylline, is attained in the blood. Because gastric irritation prevents giving oral doses large enough to produce this necessary blood level, the only dependable way of obtaining this end has been to resort to parenteral aminophylline.

Now there is clinical proof that when aminophylline is combined with a specially prepared aluminium hydroxide, the stumbling block of gastric irritation can be virtually eliminated, and massive oral doses can be tolerated to produce consistent blood levels comparable to those obtained by parenteral administration. (1) (2).

Theodrox is supplied in containers of 25, 100 and 1,000 tablets, each tablet containing Aminophylline, B.P. 3 gr. and Dried Aluminium Hydroxide Gel, B.P.C., 4 gr.

Theodrox is also available as Theodrox with Phenobarbitone, each tablet containing in addition $\frac{1}{4}$ gr. of Phenobarbitone B.P.

THEODROX is a trade mark of

When **NIGHT COUGH** disturbs sleep

the prescription of

SYRUP CALCIDRINE

can bring relief!

To control the night coughing which so frequently interrupts the patient's sleep—and the sleep of others as well—many physicians prescribe Syrup Calcidrine. This widely accepted Abbott specialty is a sedative cough syrup, combining the action of calcium iodide and ephedrine hydrochloride with the antispasmodic and sedative effect of Nembutal in a palatable vehicle of syrup wild cherry, tolu and aromatics. Syrup Calcidrine provides an effective sedative and expectorant for coughs due to bronchitis, tracheal infection and inflammation of the upper respiratory tract. Syrup Calcidrine is available in 4 oz. bottles.

Each fluid ounce of Syrup Calcidrine contains:

Calcium Iodide, B.P.C., 1934	...	...	7 grs.
Ephedrine Hydrochloride, B.P.	...	...	3 gr.
Codeine Sulphate, B.P.C., 1934	...	...	2 gr.
Nembutal (Pentobarbitone Sodium, B.P.)	...	...	1 gr.
Alcohol, B.P.	...	...	28 min.
Syrup of Tolu, B.P.	...	...	36 min.
Syrup of Wild Cherry, B.P.	...	...	115 min.

CHRONIC GASTRIC ULCER

A COMPARISON BETWEEN A GASTROSCOPICALLY CONTROLLED SERIES TREATED MEDICALLY AND A SERIES TREATED BY SURGERY

BY

B. F. SWYNNERTON, D.M., M.R.C.P.

Weir Research Assistant, Wandsworth Hospital Group

AND

N. C. TANNER, F.R.C.S.

Senior Surgeon, St. James's Hospital, London

Chronic duodenal and gastric ulcers are usually studied together under the title of "peptic ulcer," but there is evidence to suggest that their aetiology is different. Duodenal ulcer is predominantly a disease of young adults with a thick hypersecreting gastric mucosa, while gastric ulcer is commonest in the middle-aged with a normal or thinning mucosa and is associated with normal or diminished acidity. The treatment of duodenal ulcer is to some extent physiological in that, whether by neutralization, vagotomy, or partial gastrectomy, the effect is to reduce the high acidity. In the case of gastric ulcer, however, the application of the same principles is less rational, although, at present, the only effective form of treatment. These considerations make it advisable to study them separately.

For economic and clinical reasons there has been an increasing tendency towards the use of surgery in the treatment of chronic gastric ulcer. It is no longer possible in larger centres to compare the late results in controlled series, the one treated medically and the other surgically, but some useful information may be forthcoming from an analysis of uncontrolled material.

Present Investigation

The present investigation concerns 498 patients with chronic gastric ulcer. They are divided into two series—one treated medically and the other surgically in the gastro-enterological clinic at St. James's Hospital during the years 1940–6 inclusive. Late information concerning nearly all was obtained in 1952, giving a minimum follow-up period of five and a maximum of twelve years.

There are 262 patients in the medical series, in which the criterion for inclusion was the presence of a gastroscopically confirmed *active* chronic gastric ulcer. In view of the rarity of the combination of even quiescent duodenal ulcer with gastric carcinoma (only two have been encountered in over 2,200 gastrectomies in ten years at St. James's Hospital) and the need for more evidence on the "ulcer-cancer" problem, those patients in whom a previous or concomitant duodenal ulcer was suspected have been omitted. Also excluded are those patients who were submitted to a curative operation within one year of gastroscopic diagnosis. Analysis of this series may be expected to reveal a preponderance of patients with short histories or mild symptoms, of

those who respond rapidly to treatment and relapse rarely, of those who by reason of age or poor general condition are considered to be unsuitable for surgery, and of those who refuse operation.

In the surgical series there are 254 cases. Patients with additional duodenal ulcers or scars are not included. Those in whom the only operation was repair of a perforated ulcer are excluded, since this cannot be regarded as a curative procedure and since the localization of juxtapyloric perforations may be difficult at emergency operation. Because this is a clinic specializing in gastric disorders the surgical series contains a proportion of technically difficult cases which had been referred from elsewhere. For example, the incidence of high lesser-curve ulcers will be greater than is normally found.

Eighteen patients, sixteen men and two women, appear in both series.

Age and Sex

Of the 498 patients 387 were men and 111 were women, a ratio of 3.5:1, which is the usual recent finding, but a reversal of earlier statistical figures. The reason for this change is the great reduction in the incidence of gastric ulcer in young women.

It is not possible to give complete information on the ages at which the diagnosis of gastric ulcer was first made, since in a certain number of cases this was done by x-ray examination of a barium meal previous to the time of gastroscopy. Table I does, however, give some indication, and shows the age distribution of cases at

TABLE I.—Gastric Ulcer: Age and Sex Incidence

Age (years)	Medically Treated		Surgically Treated	
	Men		Men	
	No.	%	No.	%
10–19	—	—	1	1.4
20–29	7	3.7	1	1.4
30–39	17	8.9	6	8.5
40–49	51	26.7	15	21.1
50–59	51	26.7	26	36.6
60–69	53	27.7	17	23.9
70–79	12	6.3	5	7.0
Total	191		71	

Note: Combined figures are not given, since 16 men and 2 women appear in both series.

the start of the investigation, thus serving as a useful baseline. In addition it shows the ages at which patients came to operation.

It is unusual for patients with chronic gastric ulcer to present at hospital before the age of 30, but after this there is a steady increase in numbers until the middle fifties. As might be expected, most of the youngest and oldest patients were treated conservatively. In both sexes the highest operation rate was in the sixth decade and a higher proportion of men than of women were treated by surgery.

Age at Onset of Symptoms and Length of History

The average age at the onset of symptoms was 43.6 years in men and 44.6 years in women. The similarity between the two sexes is clearly shown in Table II, where the series are amalgamated. These figures confirm the fact that, although gastric ulcers may start at any age, they most commonly do so after the age of 30.

In Table III a comparison is given of the length of symptoms in the two series. It must again be borne in mind that in the medically treated series the times given are not necessarily those of the initial diagnosis. Amongst the men one finds that those with short histories tend to be treated medically. Why this does not hold good for women

TABLE II.—Gastric Ulcer: Age at Onset of Symptoms

Age at Onset (years)	Medical and Surgical				Men and Women	
	Men		Women

TABLE III.—Gastric Ulcer: Length of History

Length of History (years)	Medically Treated		Surgically Treated	
	Men	Women	Men	Women
	No.	%	No.	%
Under 1	40	20.9	7	9.9
1-3	25	13.1	14	19.7
3-5	26	13.6	8	11.3
5-10	32	16.8	13	18.3
10-20	31	16.2	12	16.9
Over 20	28	14.7	15	21.1
Unstated	9	4.7	2	2.8
Total	191		71	

Note: The majority of the "unstated" cases fell into the longer history groups. They were recorded as "many years."

is not clear. It would seem that women, if they do not have an operation early in their ulcer history, become adapted to its presence better than men, possibly because they can, for domestic reasons, treat their recurrences more thoroughly. There is a falling off of the operation rates in men with a history of over 20 years. These too will have learnt to "live with their ulcer," and for this reason their appearance at hospital should excite suspicion that recent symptoms which they attribute to their ulcer may be due to other causes (Tanner, 1951).

Sites of Chronic Gastric Ulcer

The impression in this clinic that the high posterior aspect of the lesser curve is the site of predilection for chronic gastric ulcers in women is confirmed (Table IV). There is a pronounced drop in the frequency as the lower stomach is approached, and ulcers in the pyloric antrum and canal

are exceptional. This last observation has been made on several previous occasions (see Ivy, Grossman, and Bachrach, 1951). In men, on the other hand, the distribution of ulcers from the cardia to the pylorus is more even, with the highest incidence in the mid and lower body, and over 10% are found distal to the angulus. The reasons for these differences between men and women are unknown.

TABLE IV.—Sites of Chronic Gastric Ulcer

Vertical			Transverse		
Site	Medical and Surgical		Site	Medical and Surgical	
	Men	Women		Men	Women
	No. %	No. %		No. %	No. %
High body ..	78 19.2	52 43.3	Posterior lesser curve Lesser curve Anterior lesser curve Greater curve .. Angulus .. Pylorus and antrum .. Unknown	119 29.3	53 44.2
Mid body ..	109 26.8	39 32.5		122 30.0	47 39.2
Low body ..	58 21.7	20 16.7		33 8.1	10 8.3
Angulus	74 18.2	7 5.8		1 0.2	1 0.8
Pylorus and antrum	55 13.5	1 0.8		74 18.2	7 5.8
Unknown ..	2 0.5	1 0.8	55 13.5	1 0.8	
			2 0.5	1 0.8	
Total	406	120	Total	406	120

Note: 2 men had three ulcers each. 15 men and 9 women had two ulcers each.

TABLE V

	High Lesser Curve			Mid Lesser Curve			Low Lesser Curve		
	Ant.	Mid.	Post.	Ant.	Mid.	Post.	Ant.	Mid.	Post.
Men	3	31	44	6	53	49	24	38	26
Women	3	20	29	6	16	17	1	11	7

In the body of the stomach the anterior lesser curve and anterior wall of the stomach are comparatively immune to peptic ulceration, while the posterior lesser curve is very susceptible (see Table V). In men the differences in anterior and posterior ulceration decrease as the angulus is approached, whilst in women the high proportion of posterior ulcers is maintained.

Fractional Test Meal

Results of a fractional test meal, using gruel as the stimulant, were available in 342 patients. The peak values of free hydrochloric acid measured as millilitres of N/10 HCl are shown in the Chart.

The highest incidence in men was with free acidity between 40 and 50 ml. (63), and in women 20 to 30 ml. (23). The age of the patient at the time of the test meal makes little difference to the findings, and it is only by gross

grouping that any higher incidence of hypochlorhydria in the older patients can be shown (Table VI).

Amongst the women, in whom the numbers are smaller, the age of the patient seems to be completely unrelated to the test-meal findings. It seems to be the presence of a

TABLE VI.—Chronic Gastric Ulcer: Acidity in Relation to Age (Men Only)

Peak Values ml. N/10 HCl	Men under 50		Men over 50	
	No.	%	No.	%
0-19	15	14.3	34	20.1
20-39	35	33.3	56	33.1
40-59	41	39.0	68	40.2
Over 60	14	13.3	11	6.5
Total	105		169	

degenerate mucosa rather than the age of the patient which leads to the formation of a gastric ulcer, though age indirectly affects the incidence in so far as mucosal atrophy increases with increasing years.

Although there are differences in the fractional test meal findings when they are related to the site of the ulcer in the stomach, they are not great, and it has not proved possible to work out any definite correlation.

Comparison between different series of gastric analyses is well-nigh impossible owing to different techniques used and differing interpretations put upon the results. The results in this investigation are given here, since the gruel test meal is probably the type of gastric analysis most widely used in this country.

Early Results of Treatment

Medical Series

The unceasing flow of papers to the journals shows that there is no unanimity concerning the effectiveness of individual methods of treating gastric ulcers. Suffice it to say that nearly all will heal on rest in bed, regular feeds, and that antacids, which were the general principles adopted in this series. Five men and one woman died during their initial stay in hospital—three of haemorrhage from their ulcers, two of pneumonia, and one of bronchial carcinoma.

The normal procedure is for a patient suspected of having a gastric ulcer to be gastroscopied within a few days of first being seen and then at regular intervals—usually fortnightly. Patients are kept under a strict regime until there is evidence, preferably gastroscopic, that the ulcer is healed. The Schindler gastroscope was used for the earlier cases and the Hermon Taylor gastroscope for the later ones.

Surgical Series

The procedures and immediate results in this series, which includes emergency operations, are shown in Table VII.

TABLE VII.—Surgical Series: Procedure

Procedure	No.	Deaths	Mortality
Local excision	4	3	75.0%
Gastro-jejunostomy	12	3	25.0%
Partial gastrectomy (whole series)	238	15	6.3%
Partial gastrectomy (excluding 1940-1)	175	5	2.9%

Note: Operative deaths are taken as all deaths occurring within one month of operation.

In 1940 and 1941 there were 13 operative deaths (10 following partial gastrectomy, 3 following gastro-jejunostomy), and the figures for these two years account for the high mortalities. All these deaths occurred during the first five months of intensive night bombing on London, and, although the causes of death seemed to bear no direct relationship to the bombing, there can be little doubt that they were due to resistance being lowered as a result of stress (Tanner, 1946, 1951).

Many of these patients were operated on in the penicillin era, and it is of interest to compare the figures

with the more recent results. In the last 350 partial gastrectomies performed by one of us (N.C.T.) before 1953 for chronic gastric ulcer, unaccompanied by duodenal ulcers or scars or by oesophageal ulcers, there have been four operative deaths—an incidence of just over 1%. These include emergency operations for haematemesis, of which there were 38 cases with two deaths.

Surgery in the treatment of gastric ulcer may be expected to carry a higher mortality than for duodenal ulcer, since one is dealing with an older age group. Table VIII shows the correlation between the age of the patient and the operative mortality.

TABLE VIII.—Surgical Series: Age of Patients Dying Post-operatively

Age (years)	No. in Series	Died	
		No.	%
40-	65	2	3.1
50-	107	9	8.4
60-	44	7	15.9
70-79	7	3	42.9

Unless there is some strong indication for surgery, patients over the age of 65 are treated medically in this clinic, and the older age groups contain a high percentage treated by emergency operation for uncontrolled haemorrhage.

Local excision of ulcers was practised only as an emergency operation for those patients in dire straits from uncontrolled haemorrhage. Gastro-jejunostomy was reserved for the feeble and elderly with obstructive symptoms. Partial gastrectomy was the operation of choice both as an emergency and as a planned procedure. The type most frequently performed was the antecolic Polya-Hofmeister (196 cases), with or without a Pauchet extension, depending upon the site of the ulcer. In 1946 the Billroth I type of partial gastrectomy was used more often, and has since become the operation of choice for chronic gastric ulcer, as it is a simpler and perhaps more physiological procedure.

Method of Follow-up

A circular letter containing a questionnaire was sent to the last known address of the patient requesting him to attend at the clinic if possible, or, if unable to do so, to complete the questionnaire. In the event of failure to receive a reply to this and a postcard reminder, or the letter being returned as "unknown," "gone away," or "house demolished," any other addresses of the patient or next of kin were tried. The response was good, but many remained uncontacted. Personal visits were next paid to all possible addresses. It was often found that the house had disappeared as a result of bombing, in which case the nearest intact dwelling was tried. By this means enough information was obtained to trace well over half the missing patients. Householders were almost without exception extremely co-operative, frequently going out of their way to gather information. Where they were unable to give exact details they could often give some help. For instance, the name of the road to which the patient had moved might be known, when reference to the voters' list would give the number. One patient was run to earth working in a public lavatory and another selling newspapers outside a well-known football ground. Some 400 miles of the streets of South London were covered in this part of the follow-up, which also included tracing a series of achlorhydric patients (in press). Where known and still practising, family doctors gave assistance, and for certain cases the medical superintendents and staff of other hospitals were of invaluable help. Local registrars of births and deaths and the Registrar-General provided details of dates and causes of deaths. In addition, particulars of any of the untraced patients who would now be aged over 50 were sent to the latter in case they had died and were identifiable in the records. Insurance House and the Central Pensions Branch of the Ministry of National Insurance were able to help in tracing some of the remainder.

Note: Patients in the medical series who later had resections performed and who are not included in the surgical series have not been followed beyond the time of operation.

Despite the fact that the medical series might be expected to contain the majority of the aged and infirm patients, the death rates in the two series are almost exactly the same. No particular disease in either series predominates. There are too many factors involved for a more detailed statistical breakdown of the causes and rates of death to be of value, but two conditions, gastric carcinoma and pulmonary tuberculosis, require further analysis.

Gastric Carcinoma

Fifteen patients in the medical and 11 in the surgical series have developed carcinoma. In 10 (6 and 4 respectively) the primary growth was probably in the stomach. Brief particulars of these cases are presented in Table XI.

It has often been pointed out that the differentiation between chronic gastric ulcer and gastric carcinoma may be impossible before operation or even before microscopical examination of the specimen. The first two cases are almost certainly such examples, though, in both, operation was advised on account of the possibility of malignancy. In at

least two of the remaining eight cases the carcinoma arose at a different site from the ulcer. It is interesting to note that in at least two, and possibly three, of the cases the removal of the large portion of the stomach, including the chronic gastric ulcer, did not prevent the subsequent development of a carcinoma.

Estimates of the incidence of malignant change in chronic gastric ulcers—"ulcer-cancer"—have come almost entirely from the pathologists, and very strict criteria for the diagnosis have been laid down, culminating in those of Newcomb (1932). If a certain percentage—for example, 3, 6, 10, or more—of gastric ulcers become malignant, it is remarkable that in none of the present cases do we find macroscopic or microscopical evidence of "ulcer-cancer." In the medical series alone the 262 patients have had some 2,000–3,000 years of ulcer history. When may we expect them to become malignant and show the features of "ulcer-cancer"?

Brinton (1864) described ulcerating carcinomata in which ulceration kept pace with growth for many years. According to Palmer and Humphreys (1944) such cases may show all the features of "ulcer-cancer." In a previous study of patients with gastric carcinoma (Swynnerton and Truelove, 1951) the evidence suggested that the histological diagnosis of "ulcer-cancer" was not always supported by the clinical facts. The problem of malignant degeneration of gastric

Medical Series					
1	M	55	4 years	Irregular ulcer high lesser curve; 7 carcinoma. Failed to heal	Refused operation. Died 19 months later of "carcinoma of stomach." No necropsy
2	M	57	6 "	Antral ulcer. Only one examination	Refused operation. Developed ascites. Died 1 month later of "carcinomatosis." No necropsy
3	F	74	50 "	High posterior lesser curve ulcer. Soundly healed after 5 weeks' treatment	Died 6 years later of "haematemesis due to gastric carcinoma." Before death had lost weight and became deeply jaundiced with enlarged liver. No necropsy
4	M	56	9 "	Ulcer at angulus. Healing 2 weeks later	2 years symptom-free, then recurrence lasting 1 year before admission with epigastric mass. Resection of prepyloric carcinoma. No evidence noted of preceding ulcer
5	M	53	16 "	Ulcer at angulus. Only one examination	Readmitted 6½ years later with gastric retention. At operation small localized prepyloric carcinoma, separate from old ulcer scar at angulus
6	M	51	1 week	Mid. anterior lesser curve ulcer. Soundly healed in 6 weeks	4 years symptom-free, then 1 year recurrence of dyspepsia before resection of high ulcerating diffuse spheroidal-cell carcinoma
Surgical Series					
7	M	51	4 years	High posterior lesser curve ulcer	Partial gastrectomy. Histologically chronic peptic ulcer. Readmitted 9 years later with 2 years periodic dysphagia and substernal pain. Carcinoma of cardia resected
8	M	47	13 "	Ulcer at angulus	Partial gastrectomy. Histologically chronic peptic ulcer. Well for 6 years, then pain and diarrhoea for 4 months before death. Necropsy—diffuse carcinoma of stomach remnant
9	M	70	2 "	High lesser curve ulcer	A huge gastric ulcer penetrating and fixed to the liver treated by gastro-jejunostomy. Recurrent dyspepsia for 5 years, when he was admitted with an epigastric mass and nodular liver. Died—no necropsy
10	F	54	2 "	Low lesser curve ulcer	Partial gastrectomy. Histologically chronic peptic ulcer. 3½ years later admitted elsewhere with Krukenberg tumour of ovary and generalized abdominal carcinomatosis. Primary? stomach. Died 8 months later. No necropsy

ulcers is a clinical as well as a pathological one, and there is all too little clinical evidence in the literature. If there is an association between gastric ulcer and carcinoma, it seems to us to be due to a preference of both for the same soil rather than any direct association.

Pulmonary Tuberculosis

Pulvertaft (1952) has suggested that there may be an increased incidence of pulmonary tuberculosis following gastric resection of peptic ulcer. Among the 233 cases in the present surgical series six men have died of this disease—one seven months, three three years, one five years, and the other eight years after operation at the ages of 52, 49, 58, 62, 56, and 63 respectively. In none was the diagnosis recorded at the time of operation, but two patients who had active pulmonary lesions when operated on are still alive after seven and nine years, and their lesions are reported to be inactive. One woman died of Addison's disease 10 years after operation, and another was diagnosed as suffering from pulmonary tuberculosis seven years after gastrectomy.

In the medical series three men have died of pulmonary tuberculosis, in one only of whom was the diagnosis recorded at the time of admission for gastric treatment. The evidence concerning an increased risk of pulmonary tuberculosis following gastrectomy is inconclusive.

Manifest Haemorrhage

At least 139 (27.9%) of the 498 patients have had at some time haematemesis or melaena during the course of their ulcer career, and, of these, 22 (15.8%) have bled on more than one occasion.

Medical Series—Remaining Patients

After subtracting those patients who have died, those who have developed gastric carcinoma, and those who have been lost, there remain 178 on which to base the late results of medical treatment (Table XII). Transient gastric symp-

TABLE XII.—Late Results in the Medical Series

	Men		Women		Total	
	No.	%	No.	%	No.	%
Recurrence requiring gastrectomy ..	46	36.5	11	21.2	57	32.0
Frequent recurrences ..	28	22.2	16	30.8	44	24.7
Occasional recurrences ..	23	18.3	12	23.1	35	19.7
No recurrences ..	29	23.0	13	25.0	42	23.6
Total ..	126		52		178	

toms have not been considered sufficient evidence of recurrence. There must have been symptoms suggestive of gastric ulcer lasting for at least several days at a time before a diagnosis of recurrence was made. Occasional recurrences have been defined as those occurring less frequently than once a year. The seven patients who have died as a direct result of the ulcer are not considered further, since there is no adequate information on the subsequent gastric history in those who died from other causes for comparison.

In three-quarters of the patients the symptoms of gastric ulcer have recurred despite the fact that these cases might be expected to be mild or of recent onset. The large number of deaths should by the end of five to twelve years have eliminated the majority of patients who were not operated on initially because of age or infirmity. Re-examination of the criteria for inclusion of patients in this series does not reveal any obvious factor in the method of selection of cases to account for the appalling results, and one is forced to conclude that medical treatment, though it may heal the ulcer, will keep it healed in less than a quarter of the early or milder cases. These findings are in accord with those of Althausen (1949) for peptic ulcer as a whole.

The cases have been analysed to see if any factors influencing the recurrence rate can be found.

Age of Patient

That the age of the patient at the time of gastroscopic diagnosis is related to the incidence of recurrence is shown in Table XIII. There is a steady increase in freedom from recurrence with increasing age. There are several possible explanations of this finding, of which the most likely is that

TABLE XIII.—Recurrence Rate in Relation to Age of Patient

Age Group (years)	Recurrences					
	None		Occasional		Frequent	
	No.	%	No.	%	No.	%
Under 50 ..	12	15.2	16	20.3	51	64.6
50–59 ..	16	28.6	11	19.6	29	51.8
60+ ..	14	32.6	8	18.6	21	48.8

many of the patients whose ulcers recur frequently will have been operated on before they reach the age of 60. In addition, the older patients will be able to rest and relax more and to pay more attention to diet, etc.

Length of History

It might be expected that those patients with short histories prior to diagnosis would respond well to treatment and relapse rarely. Table XIV indicates that although they

TABLE XIV.—Recurrence Rate in Relation to Length of History

Length of History (years)	Recurrences					
	None		Occasional		Frequent	
	No.	%	No.	%	No.	%
Under 1 ..	14	40.0	7	20.0	14	40.0
1– ..	5	9.3	13	24.1	36	66.7
5– ..	6	23.1	5	19.2	15	57.7
10– ..	3	11.1	6	22.2	18	66.7
20+ ..	11	36.7	4	13.3	15	50.0

Note: In 6 patients the length of history was unknown.

appear to do better than those with longer histories, their chances of remaining symptom-free are still under 50%. The numbers when divided into groups are small, but with a history of between one and twenty years the chances of prolonged freedom are only about one in eight. The results have been analysed in relation to both length of history and the age of the patient. Numbers are too few to yield significant results, but the trend is for patients under the age of 50 to have a higher incidence of recurrences than those over 60, no matter what the length of history. This, as mentioned above, may well be because those patients whose ulcers recur frequently are operated on before they reach an advanced age.

Diet and Alkalis

No coherent picture emerges from a study of the relationship of dieting and taking alkalis to recurrences. Some diet the whole time, some when they have pain, and the remainder never. The position may be summarized by saying that exactly 75% of those who have had no further recurrences have given up dieting, while 61.4% of those with frequent recurrences have stuck to a diet the whole time. Nearly all patients, whether they have had recurrences or not, try to avoid certain foodstuffs or other factors. Fatty foods, including fried fish, chipped potatoes, pastry, bacon, and pork are eschewed by the great majority. Other factors considered by the patients to be a cause of relapse are pickles, condiments, highly seasoned foods, tobacco, worry, and irregular meals. Since most of these are advised against in their diet sheets it is not possible to say whether they avoid them from personal experience.

The position of alkalis is even more involved. Few patients appear to take them prophylactically, but nearly all list them as giving the most immediate relief when symptoms are present. "Doctor's medicine" is usually the chief stand-by, but most take proprietary brands as well, frequently changing from one to another. Even patients who

state that they have had no further trouble keep alkalis to hand. Rest, milk, diet and regular meals, olive oil, liquid paraffin, and belladonna in various combinations were popular for ending attacks.

Most of the replies to the question of what gave the most relief were orthodox, but one man treated his recurrences by starvation, chlorodyne, and 3 pints of beer, another recommended stout, and a woman found that a little whisky taken medicinally was an excellent remedy. One patient had been "cured" by writing to a faith-healer, and two had obtained long remissions from an expensive medicine obtained from a pharmacist "specializing" in stomach troubles.

Surgical Series—Late Results

The late results in the 169 traced survivors have been assessed according to the grading of Visick (1948), which is as follows:

Grade I.—No gastric symptoms (fullness after an extra large meal is allowed).

Grade II.—No pain, mild occasional symptoms easily controlled by care. Care implies limitation of size of meal, rest, and avoidance of certain articles of diet.

Grade III.—Mild symptoms not controlled by care, slight abdominal discomfort. This grade is subdivided as follows: Grade IIIs, satisfactory (both the investigator and the patient are satisfied with the result; symptoms do not interfere with the enjoyment of life or with work); and Grade IIIsu, unsatisfactory (either the investigator or the patient is not satisfied with the result; either the symptoms or the care taken to avoid them interferes with the patient's enjoyment of life or his efficiency at work).

Grade IV.—Not improved, severe symptoms.

The results in the present series are presented in Table XV.

TABLE XV.—Chronic Gastric Ulcer: Surgical Series—Late Results

Grading	Men		Women		Total	
	No.	%	No.	%	No.	%
Grade I ..	74	52.9	11	37.9	85	50.3
Grade II ..	38	27.1	12	41.4	50	29.6
Grade IIIs ..	14	10.0	3	10.3	17	10.1
Grade IIIsu ..	9	6.4	3	10.3	12	7.1
Grade IV ..	5	3.6	—	—	5	3.0

Out of every 10 patients still alive the result has been satisfactory in 8, moderately successful in 1, and poor in 1. There is a small late operative morbidity which must be taken into account when judging the late operative results. One man died five years after partial gastrectomy following reduction of a retrograde jejunal intussusception, one woman two months afterwards following division of bands causing obstruction, and another four years later following operative procedures designed to relieve "dumping." A further three patients have been successfully operated on for obstruction due to adhesions. None of the unsatisfactory results were due to cases of recurrent ulceration following partial gastrectomy. Indeed, despite careful investigation of many post-operative cases in these years, we have been unable to find any case of proved stomal or gastric ulcer following gastrectomy for gastric ulcer. There have been several cases of iron-deficiency anaemia which have responded well to iron. In one case megaloblastic anaemia was given as a contributory cause of death. No patient has been encountered with any gross nutritional deficiencies, although many are below their best pre-operative weight.

Analysis of the late results to determine whether there are any specific factors influencing them shows that amongst the five patients in Grade IV three suffer from severe chronic bronchitis, one from angina pectoris, and the other, in whom there is no obvious associated disease, has been relieved, at any rate temporarily, since the start of this investigation by the type of gastric suspension operation described by Capper and Butler (1951). Of the twelve in Grade IIIsu three suffer from chronic bronchitis, two from cardiac disease, another from chronic sciatic pain, and a seventh

from osteoarthritis. On the evidence it would seem that the disgruntled chronic invalid is intolerant of any post-gastrectomy disability or discomfort.

The age of the patient at the time of operation makes little difference to the late results so far as gastric symptoms are concerned (Table XVI). Neither does the length of history of symptoms before operation affect the results to any significant degree.

TABLE XVI.—Late Results in Relation to Age of Patient. Surgical Series

Age at Time of Operation	Grades I, II, and IIIs		Grades IIIsu and IV	
	No.	%	No.	%
Under 40 years ..	30	93.75	2	6.25
40-49 ..	43	86.0	7	14.0
50-59 ..	58	89.2	7	10.8
60+ ..	21	95.5	1	4.5

Comparison of Late Results

Symptoms due to chronic gastric ulcer tend to be intermittent while the non-ulcer complications following surgery tend to be constant, so no exact comparison of the symptoms in the two series is possible. If Visick Grades I and II are taken as being equivalent to no recurrences in the medical series, Grade IIIs as occasional recurrences, and Grades IIIsu and IV as frequent recurrences the results shown in Table XVII are obtained.

TABLE XVII.—Chronic Gastric Ulcer: Comparison of Results in the Medical and Surgical Series

	Medical Series		Surgical Series	
	No.	%	No.	%
"No" recurrences ..	42	23.6	135	79.9
"Occasional" ..	35	19.7	17	10.1
"Frequent" ..	101	56.7	17	10.1
Total ..	178		169	

Only a quarter of the patients in the medical series, compared with over three-quarters in the surgical series, have had no further trouble. This despite the probability that the medical series contained the majority of patients whose ulcers were initially considered to be mild or of short duration.

Discussion

Absolute indications for surgery are perforation, certain cases of manifest haemorrhage, obstruction due to hour-glass deformity or pyloric stenosis, and suspicion of malignancy, which includes all ulcers on the greater curve and the majority in the pre-pyloric region. Elective surgery is advisable when there is failure to respond to medical treatment or recurrence after a previous course or courses of strict treatment.

The analysis shows that partial gastrectomy is by far the most satisfactory method available at present for the treatment of chronic gastric ulcer. Before it is advocated various factors must be considered. These include the length of history and severity of symptoms, the presence of intercurrent disease, and the operative mortalities. Early operative mortalities will depend to a large extent on local factors, but they have significantly diminished in most parts of the world since the earlier part of this series. Late operative deaths and complications will probably be fairly constant wherever the operation is performed. In the present series the late operative complications are more than counter-balanced by the late deaths directly due to the ulcer in the medical series.

On the figures in the present analysis a strong case can be made out for surgery as soon as the diagnosis is arrived at, except in those patients with very short histories and those with signs of senility or intercurrent disease, especially severe chronic bronchitis. There are few who would be prepared to operate on all such cases, and a full course of medical treatment will relieve a small proportion for at

least a number of years. Recurrence after a strict course of medical treatment should be regarded as an indication for surgery, whether or not a strict post-ulcer regime has been followed.

Summary

The case records of 498 patients with chronic gastric ulcer who were treated in the gastro-enterological clinic at St. James's Hospital, London, during the years 1940-6 inclusive are analysed. Adequate follow-up data concerning nearly all were obtained in 1952.

The patients fall into two series, the one treated medically and the other surgically. In the former there are 262 and in the latter 254 patients, 18 appearing in both series.

The criterion for inclusion was the presence of an active chronic gastric ulcer, which in the medical series must have been seen gastroscopically. Patients with additional duodenal ulcers or scars have been excluded.

The ratio of men to women was 3.5:1.

The symptoms may start at any age, most commonly after 30, the average age being 44. The average age at the time of operation in those surgically treated was in the fifties.

The sites of gastric ulcers differ greatly between men and women. In women the site of predilection is the high posterior aspect of the lesser curve, and ulcers in the pyloric antrum are exceptional. In men the distribution along the lesser curve is more even, with a maximum incidence in the mid and lower body, while 10% are situated distal to the angulus.

The results of a fractional test meal, using gruel as the stimulant, are given. The age of the patient influences the level of acidity to only a slight extent, and it is concluded that the presence of a degenerate mucosa rather than the age of the patient accounts for the findings.

A quarter of the patients in each series have subsequently died. There is no predominant cause of death.

The problem of the malignant degeneration of chronic gastric ulcers is considered. In none of those who later developed gastric carcinoma is there enough evidence to label them "ulcer-cancers," and it is concluded that if an association between gastric ulcer and gastric carcinoma exists it is due to a preference of both for the same type of degenerate mucosa.

The evidence concerning the incidence of tuberculosis following gastric resection is presented. No conclusion concerning this is reached.

In 28% of patients an incident of manifest bleeding occurred during the course of their ulcer histories. In 16% of these there was more than one episode.

In the medical series it is concluded that although treatment will nearly always heal the ulcer it will keep it healed in only a quarter of the milder or earlier cases. A quarter have symptomatic recurrences more often than once a year, and a further third have had subsequent resections performed for recurrence. Some of the factors which may influence the recurrence rates are analysed.

Three-quarters of those who have had no further trouble have given up dieting, while nearly two-thirds of those with frequent trouble have kept to a diet the whole time.

In the surgical series a very satisfactory result has been obtained in 80%, a moderately successful one in 10%, and a poor result in the remaining 10%.

A high proportion of those with poor results have some other chronic incapacitating disease, most frequently chronic bronchitis.

The choice of treatment for those presenting at hospital with a chronic gastric ulcer is discussed. It is concluded that surgery at present offers the best results, but before it is advocated certain factors, including local operative mortality figures, the severity and length of history of symptoms, and the presence of intercurrent disease, should be taken into account.

Mr. Colin Craig has very kindly allowed us to make use of his late results for patients operated on in 1946. We wish to thank the many people who co-operated in the follow-up of patients, and are grateful to the staff of St. James's Hospital for their interest and advice. We are particularly indebted to Miss Kirwin, who, in addition to secretarial duties, suggested ways and means which led to the tracing of many "lost" patients. The cost of the investigation was met by a grant from the Weir Research Fund.

CANCER AND THE COMMUNITY*

BY

PERCY STOCKS, C.M.G., M.D., F.R.C.P.

Cheshire and North Wales Branch, British Empire Cancer Campaign

In considering the scope of this discussion I have assumed that the Section of Preventive Medicine is not directly concerned with treatment, except in respect of diseases whose spread in the community can be reduced by early treatment of patients infective to others. This absolves me from dealing with the rather controversial questions of how far the community might be influenced to seek medical advice at an earlier stage of cancer and what effect that could have upon ultimate survival. Those aspects of the problem are important to the community and interesting to statisticians, whether in Toronto or London, but, while they may affect the fatality of cancer, they cannot, so far as we know at present, affect the incidence or prevention of the disease.

Attitudes to the Cancer Problem

Some will say that since we can do so little as yet to prevent cancer it is unrealistic to discuss it at all in this Section. Such an attitude seems generally to stem from a fixed idea that cancer is a complication of growing old, or a mode of departing from this life, which is inevitable for a proportion of people in the same sense that arteriosclerosis is inevitable, and I propose to deal with some of the misconceptions mixed up with that idea. According to my observations it is the medical people rather than the lay community who tend to the cheerless view that the best we can do is to try to

*Read in opening a discussion in the Section of Preventive Medicine at the Annual Meeting of the British Medical Association, Cardiff, 1953.

improve the effectiveness of treatment, and that it is futile to try to discover causes of cancer which would be capable of elimination. However, if doctors are at all happy about advances in the treatment of this disease the community certainly is not, and I sense a growing feeling of doubt whether the ordeal of treatment is worth while in many cases in order to achieve a short prolongation of life, coupled with some surprise and impatience because so little serious attempt seems to be made, apart from work on animals, to discover causes with a view to abating them. I find, for example, that, whilst only a very small percentage of people decline to furnish details about their environmental histories, many doctors are hesitant, for one reason or another, in furthering this type of research.

It is sometimes said, generally by young doctors, that cancer is of comparatively slight economic importance to the community, since it is predominantly a disease of advanced life. Comparison with tuberculosis a decade or two ago gave some justification for the view, but it is not true to-day, and it is time that error was exposed. In an address to the British Tuberculosis Association in 1948 (*Tubercle*, 1949, 30, 50) I calculated the years of future "working" life between the ages of 15 and 65 lost to the community in England and Wales through premature deaths caused by respiratory tuberculosis, cancer, and accidents in 1945. It was assumed that if the people who died of one of those causes had not done so in that year, they would have been subject from that time onwards to the ordinary risks of mortality at successive age periods as shown by the 1945 life table rates for the whole population of each sex. The future working years lost as a result of the cancer deaths was 355,000, compared with 435,000 lost through deaths by respiratory tuberculosis and 268,000 lost by fatal accidents. In view of the great fall in tuberculosis mortality since 1945 I have now repeated the whole calculation for the year 1950, using the life table for that year, and the result is shown in Table I. No account is taken of the loss through invalidity prior to death.

TABLE I.—Estimated Loss of Future Working Life Due to Cancer, Tuberculosis, and Accidents in 1950

Cause of Death in 1950	International Numbers	No. of Thousands of Person-years of Future Life Lost between 15 and 65		
		Males	Females	Total
Cancer	140-205	212	220	432
Tuberculosis, respiratory	001-008	143	125	268
Accidents	E800-962	211	61	272

The cancer total has increased from 355 to 432 thousands in the interval because the expectation of life based on 1950 death rates from all causes was much better at each age than in 1945, and because the new definition of cancer takes in leukaemia and Hodgkin's disease; this does not indicate a worsening of cancer mortality for both sexes taken together. For accidents the figure has hardly changed, owing to a balance between the reduction in deaths and the increase in normal life expectation. Accidents and cancer are now equally important for males according to this criterion, but for females cancer produces three and a half times the loss due to accidents. For respiratory tuberculosis there has been a great fall from 435 to 268 thousands, bringing the total much below that for cancer. Consequently, cancer has now become the cause of death which is of most serious economic importance when judged from

this standpoint. It is interesting to note that cancer of the lung and bronchus in 1950 contributed 65 to the 212 total for male cancer deaths, and this figure is of course increasing rapidly every year. Cancer of the stomach contributed 33 thousand years for males, so nearly half the total is due to these two forms of cancer in the case of men.

Possibilities of Reducing Cancer Incidence

Another prevalent idea among doctors, though not in the community as a whole, is that it is of little profit to talk about abatement of cancer until pathologists have established its aetiology through experiment, despite the fact that this thesis has been disproved in the history of other diseases. I was once asked by a group of demographers why we could be any more confident in predicting the future trend of the general death rates at particular ages than we are in predicting the trend of the birth rate. My reply was that whilst the latter is influenced by many conflicting desires and considerations which pull in opposing directions and are affected by the social circumstances of the time, conscious efforts to influence mortality in a free democracy are pulling all the time in the same direction, downwards, and, apart from wars, we can count on that continuing.

Furthermore, experience has shown that when the public conscience has become thoroughly aroused about deaths from a particular cause, that death rate has tended to come down whether or not the pathology was properly understood. Two decades ago no one thought that the national infant mortality rate would ever be reduced below 30 per 1,000; but world-wide interest in the problem accompanied by all-round efforts without much aid from new discoveries resulted in rates of 20 being attained by Sweden and 25 by Holland in 1950, and brought down the England and Wales rate to about 28 in 1952. About 1934 the public conscience became thoroughly aroused about maternal mortality, and the rate began to fall at once and continued to do so for years before the sulphonamides and penicillin came along and nearly finished the job. The trouble with cancer is that possibilities of abating its incidence have as yet hardly been regarded seriously except in respect of a few varieties of so-called industrial cancer whose causes are well established.

The search for connexions between human cancer and the countless chemical substances, natural and artificial, which we ingest, inhale, and absorb in the course of our normal lives has begun, however, and we really owe its inception to the observation of Percivall Pott, a surgeon at Bart's in the eighteenth century, that skin cancers of chimneysweeps arose from irritation by soot; there followed, more than a century later, proof that certain mineral oils were responsible for the epitheliomas occurring in cotton-spinners.

Chemical Promoters and Irritants

The number of different agents which have been proved to be carcinogenic to animals since Yamagiwa and Ichikawa first produced true malignant tumours by applying coal tar to the ears of rabbits in 1915 now runs into many hundreds. In 1922 Passey produced malignant growths by painting the skin of mice with an ethereal extract of soot, and in 1924-5 Kennaway was able to produce carcinogenic tars by methods which led to the conclusion that the carcinogenic agent was a complex hydrocarbon of the aromatic series. In 1927 Mayneord discovered that the carcinogenic tars and oils had a characteristic fluorescence spectrum, and Heiger then found that a chemical substance, 1:2-benzanthracene, gave such a spectrum. As a result of further intensive research Kennaway and Heiger were able to demonstrate for the first time that cancer could be produced by a pure compound 1:2:5:6-dibenzanthracene, and in 1933 Cook and Hewett synthesized 3:4-benzpyrene, a carcinogen present in pitch. More recently Berenblum and others have produced experimental evidence that after application of a

carcinogen certain non-specific irritants could determine whether or not tumours appeared and how long they took to appear.

Furthermore, it has been found that the addition of certain fats to the diet of experimental animals increases the incidence of tumours resulting from application of some carcinogens to the skin, whilst, on the other hand, hydrogenated coconut oil reduces the incidence. This work on non-specific co-carcinogens and anti-carcinogens might possibly open the way to cancer prevention on a large scale without waiting until the whole mechanism is understood. Consider the case of bladder cancer, which we know is produced with rather high frequency in men who work with certain chemicals of precisely known composition, while thousands of people who have never handled those chemicals industrially contract the same condition. Surely it is a reasonable inference that those other bladder cancers are initiated by contact in ordinary life with chemicals closely related to the known industrial carcinogens, and whether they do develop may depend on the action of some other chronic irritant. This form of cancer becomes, therefore, a problem for preventive medicine to investigate and is not merely a problem peculiar to one industry.

Statistical Research on Cancer

A third manifestation of the sceptical attitude to prevention in respect of cancer is the excuse that statistics cannot prove causation, and, since they can be made to prove almost anything, why take any notice of them? When statistics show a death rate to be falling the evidence is usually accepted without question and credit is taken for it by all who can lay claim to a part in that happy event. But if statistics show a rate to be rising for a particular disease it is at once objected that medical certification or changing the fashion in nomenclature made the figures fallacious. The persistence of the old joke about statistics proving anything is convenient, because when statisticians arrive at unpalatable conclusions it can be said that so long as the evidence is solely statistical nothing need be done except wait for "real," that is to say experimental, evidence. If many thousands of people are dying annually from a disease and statistical evidence indicates that the probability is very high that the main cause lies in an article X, it is hardly sensible to sit back and wait, maybe 20 years, for the experimental evidence. Indeed, unequivocal evidence may never be obtained in a case of a disease which takes a very long time to develop in man after application of an irritant or of an initiator. In such a case the responsibility of advising the community is a serious one, and it is idle to suppose it can be evaded by pretending that statistical evidence alone is of no account.

We are faced with such a situation to-day in regard to lung cancer and tobacco-smoking, and, whilst it is fortunate that tobacco is not a necessity of life, the position is complicated by considerations of finance. In my opinion the proper course is to intensify research on the question from every aspect, and meanwhile inform the community of the statistical findings (as indeed has already been done by the B.B.C.), and say what the risk amounts to if what is suspected is correct, so that each individual can decide for himself or herself whether to take the risk or not. Although statistical studies alone may establish the existence of a real connexion between a factor X and a disease Y without revealing the precise reason for that connexion, the probability that in the absence of X there could be a great reduction in Y may be indicated as so high that some may consider that the use of X involves an amount of risk which it is unwise to take.

Whatever may be the final outcome of the tobacco question, cancer of the lung has now come into the field of preventive medicine. Non-smokers can get the disease and the statistics of deaths suggest that smoke from domestic chimneys may be a factor, so the problem to be solved is whether it arises through inhaling or ingesting carcinogenic or co-carcinogenic substances derived from coal or mineral

oil or used in the cultivation or manufacture of tobacco. Perhaps an initiator is present in one of these and a non-specific irritant in another, and statistical studies now in progress may help to answer this question.

Cancers of the oesophagus and larynx are more frequent amongst men in occupations associated with excessive drinking of alcohol, but there are other factors involved, and the sexes are differently affected. Cancers of the cervix uteri on the one hand and of the breast and ovary on the other are associated in opposite ways with marital history. For these and other kinds of cancer, statistics have indicated that environmental factors have some influence on incidence.

Incidence of Cancer of the Stomach

In the case of stomach cancer incidence is closely related to social and urban environment, and it shows other peculiar local variations for which no explanation has yet been found. Death rates in 1921-30 attributed to this cause showed considerable excess in London and aggregates of large towns at early ages, but the excess was not so pronounced after 65. Standardized comparative figures for years 1947-9, based upon the mortality expected by applying age-specific rates for all rural districts of England and Wales to the populations, are shown in Table II.

TABLE II.—Comparative Mortality Figures for Cancer of Stomach in Certain Large Towns in 1947-9 (With Rates for All Rural Districts of England and Wales as Base)

	Males			Females		
	15-	45-	65+	15-	45-	65+
Liverpool	185	156	144	175	128	131
Manchester	218	158	132	124	151	123
London county	155	114	101	135	109	106
Outer ring of Greater London	133	97	97	112	91	100
Birmingham	130	125	120	155	125	116
All rural districts	100	100	100	100	100	100

There has been no diminution of the urban excess previously noted. It is very pronounced in Liverpool and Manchester, and is also considerable in Birmingham, at every age amongst both men and women. In London the excess is evident only at the younger ages, and rates are higher at each age in the centre than in the outer ring. This suggests that some carcinogenic or co-carcinogenic substance, which might be ingested or inhaled in the first instance, is more often encountered in large towns than in rural areas; but we also know that certain rural areas present a large and at present inexplicable excess of mortality compared with other rural districts. I refer particularly to the counties of Wales which touch the sea coast, and will confine attention to the five in North Wales which are now being studied by the Cheshire and North Wales Branch of the British Empire Cancer Campaign with the help of the medical officers of health, the Liverpool and Welsh Regional Hospital Boards, and the University College of North Wales. Comparative indices for cancer of the stomach and breast in North Wales during the 29 years from 1921 to 1949, based as before on the mortality expected from rates in all rural districts at decennial age groups, are shown in Table III. The North Wales counties included are Anglesey, Caernarvon, Denbigh, Flint, and Merioneth; the West Midland group comprises Gloucester, Stafford, Warwick, and Worcester; and the South-east group consists of Kent, Surrey, Sussex East, and Sussex West. In this table, and also in Table II, duodenum is included with stomach.

North Wales showed a rural mortality attributed to stomach cancer about twice the national average at ages under 65, and about 1.8 times the average at ages over 65. Dividing into two periods 1921-39 and 1940-9, the excess is seen to have become only slightly less in the second than in the first period. Cheshire and Lancashire rural districts produced average rates, whilst the West Midland rates were about 11% below the national level, and the South-east

TABLE III.—Comparative Mortality Figures for Cancer of Stomach and Breast in 1921-49 in Aggregates of Rural Districts of North Wales and Parts of England (With Rates for All Rural Districts as Base)

Rural Districts of	Stomach				Breast	
	Males		Females		Females	
	15-	65+	15-	65+	15-	65+
North Wales { 1921-39 ..	184	173	224	203	95	91
{ 1940-49 ..	177	165	210	173	97	95
{ 1921-49 ..	182	169	220	192	96	93
Cheshire and Lancashire, 1921-49	101	97	99	104	95	101
West Midlands, 1921-49 ..	89	89	86	89	105	106
South-east, 1921-49 ..	81	83	73	76	105	100
All England and Wales ..	100	100	100	100	100	100

county rates were around 20% below. By way of contrast, breast cancer mortality in the 29 years showed no important differences between these areas, that in North Wales being 5% below average, and that in the West Midlands 5% above.

Justification for Research into Environmental Factors

Suggestions have been made that doctors in Wales tend to certify cancer of the stomach as the cause of death whenever haematemesis or obscure gastric symptoms make it seem feasible, and often with insufficient justification. No evidence that such a practice is in fact more prevalent in Welsh than in English rural areas has been produced. The relative excess is smaller at ages over 65 than in mid-life; and no compensating deficiency can be found in the group of deaths attributed to those conditions likely to be mistaken for gastric cancer, such as peptic ulcer, cancer of the liver, pancreas, and colon, other diseases of the stomach, and pernicious anaemia. Inquiries from a first sample of 100 certifiers of deaths said to be due to stomach cancer in North Wales show that there was necropsy, biopsy, operation, or x-ray evidence for 50%, compared with 65% of 100 deaths so certified in rural districts of Cheshire and Lancashire, and about 60% in the large towns other than Liverpool. If half the cases in which the diagnosis is unsupported by any of these tests are rejected, the North Wales rates would be reduced by a quarter and the Cheshire-Lancashire rates by a sixth, correcting the ratio between them to 1.8 at ages under 65 and 1.6 at ages over 65.

These preliminary statistical tests justify the Cheshire and North Wales Branch of the British Empire Cancer Campaign in their belief that there exists a real phenomenon to be explained, and in their determination to investigate race and residence, work and workplace, soil, air, and water, food, drink, and every conceivable vehicle of carcinogenic substances, or co-carcinogenic irritants. With this line of approach the community of the research area seem to be very much in sympathy. It is something they can understand and welcome because it holds out some hope of prevention, which from the patients' standpoint would be so much better than cure by surgery or radiation, no matter how skilful or high-powered that may be.

Contribution of Medical Officers of Health to Environmental Studies

At the International Conference in London in 1928, organized by the British Empire Cancer Campaign, Sir George Buchanan gave an address on "Collective Public Effort in Dealing with Cancer," which after 25 years is still very pertinent to the discussion to-day. Speaking of municipal work, he said: "The principle to be followed . . . is to secure the closest possible common action between the municipal health department and the authorities of the general and poor-law hospitals, the university if there is one, the voluntary agencies which support social work, and especially the staffs of hospitals and the medical practitioners as well as the local work of the B.E.C.C. where it is in operation. It is no part of the programme that municipal direction should

be made prominent; it is enough for the health department if it can help. Where the medical officer of health is wanted to take the initiative he will do so; otherwise he is content to be one of the cogs on a useful working wheel. Personally, I may express the view that cancer research has much to gain through his instrumentality. . . ."

I would like to take this opportunity of expressing my profound appreciation of the way in which the medical officers of health of the region in which I am working are, together with their assistants, helping the British Empire Cancer Campaign in just that spirit.

Sir John Robertson, at that time medical officer of health of Birmingham, uttered at the same conference some words on which I will close. "Inquiry by the health authority into the facts surrounding each death from cancer has as much value from an educational point of view as it has from an aetiological." How true this is we are finding out in the study I have referred to; education of surgeons, physicians, radiologists, and health officers about the essential gravity of cancer as a community problem is proceeding as a result of the inquiries in progress, and later it may even penetrate to the university. Whether the scientific results we hope for materialize or not, by such education the community will benefit eventually.

CANCER AND THE COMMUNITY*

BY

RONALD W. RAVEN, O.B.E., F.R.C.S.

Surgeon to Westminster (Gordon) Hospital; Surgeon to the Royal Cancer Hospital

The control of cancer is a world problem and one of the big challenges of the present day. Its magnitude requires an all-out effort to reach a solution. With our present knowledge of the disease a great deal can be done to help, but we must not be satisfied until it is under complete control. The object of this paper is to indicate the effects of cancer on the community and the ways in which the latter can co-operate in the fight for its mastery.

Effects of Cancer on the Community

These are of such severity that the disease can be described as one of the greatest scourges of mankind.

World Mortality.—The death rate from cancer varies in different countries, and the figures shown in the Table were published by the World Health Organization in 1951.

Deaths from Cancer by Country per 100,000 Population

Country	Males	Females
United Kingdom (1950)	205.8	184.0
France (1950)	175.8	169.5
Northern Ireland (1951)	161.3	145.1
Netherlands (1951)	151.4	147.2
U.S.A. (1949)	141.1	136.4
Canada (1950)	129.7	123.1
Israel (1951)	85.5	105.5
Japan (1950)	80.1	74.9

National Mortality.—Reference to the Registrar-General's Statistical Review of England and Wales for 1950 showed that 87,274 persons died from neoplasms, as compared with 72,613 in 1940. During this decade the death rate has fallen considerably from acute infec-

*Read in opening a discussion in the Section of Preventive Medicine at the Annual Meeting of the British Medical Association, Cardiff, 1953.

tive and parasitic diseases, tuberculosis, rheumatism, and respiratory diseases as a result of early diagnosis and advances in treatment, in which antibiotics have played an important part. Workers in public health and preventive medicine have made a big contribution in these and other fields, but the cancer situation remains serious in that the number of deaths in this decade has risen by 14,661 and only cardiovascular disease has a higher national mortality. It is not without significance that the greatest number of deaths are caused by cancer of the alimentary tract, especially of the stomach and colon, and these are rising. If the two conveying tubes, the oesophagus and the rectum, are compared, deaths from cancer are nearly three times greater in the latter organ.

Family and Individual Problems.—About half the total deaths from cancer occur in persons between 45 and 65, when their family and business responsibilities are greatest. The large number of children who die annually from cancer and allied diseases should also be remembered. The development of cancer is one of the worst events that can overtake us, for it means either a major operation, a course of radiotherapy, or both, and the subsequent rehabilitation may take a long time, with necessary follow-up examinations at regular intervals. Life may be resumed with a colostomy or tracheostomy, and when the disease is more advanced plans must be made for a chronic illness with all its repercussions on the life of the family. These things are brought out in the report of the Joint National Survey Committee (1952), of which I was chairman.

The present situation regarding mortality and morbidity is serious, and everything possible must be done to rectify it.

Control of Cancer.—The joint endeavours of the clinical and laboratory workers which are applied to gain this final objective can be considered as a five-point programme. Every member of the community has a responsible part to play.

Research into Causation

Studies concerning animal cancer in the laboratories have brought to light a number of genetic, physical, and chemical factors which cause malignancy. They have also been identified with human cancer; for instance, in the development of certain occupational and industrial forms of the disease exogenous physical and chemical carcinogens are recognized. It is also possible that some spontaneous varieties of cancer may be caused by other unrecognized carcinogens, either exogenous or endogenous, for which a determined search is desirable. Clues might come from a careful scrutiny of the environment and habits of people of various nations, for it is known that the incidence of the disease varies with race, country, and economic status. A more rigorous search for carcinogenic substances should be made in the tissues of patients with various forms of cancer, and it must be remembered that their action may be additive.

There is scope for increasing the amount of clinical research in the wards and of study of carefully compiled clinical records of astute observers. Obvious advantages would be gained by drawing clinical and laboratory workers closer together so that they could discuss their problems and share ideas. It should not be overlooked that some of the fundamental facts in cancer research were contributed by clinicians; for example, our knowledge of chemical carcinogens was built upon the observation of Percivall Pott that cancer of the skin of the scrotum was common in chimney-sweeps. Fundamental planned research in the laboratories concerning the nature of the cancerous change in normal

cells is a long-term project, but in the meantime there are many other problems to tackle whose solution may throw considerable light on the subject.

Prevention of Cancer

The community must recognize that certain varieties of cancer are preventable if the appropriate action is taken. Were further research to reveal that common types of the disease are caused by exogenous carcinogens it would be possible to gain considerable control by their elimination alone.

Precancerous Lesions.—A number of these conditions are well recognized, and more precise information is required regarding their frequency in the community and the degree of increased risk which they entail. These facts would be taken into account in the assessment of the need for cancer-detection centres where precancerous lesions could be dealt with. The association of this work with the prevention of cancer is obvious, and a few examples will suffice. A benign tumour such as an adenoma of the colon or rectum, a papilloma of the urinary bladder, or a duct papilloma or fibro-adenoma of the breast is carefully removed. If a benign melanoma is in a position where it might be injured it should be excised. Patients with familial polyposis of the colon and rectum develop cancer at a relatively early age, and the affected part should be removed before this occurs. Cancer is likely to develop in the colon affected by long-standing ulcerative colitis, so total colectomy is being performed more often in these patients. The association of oral sepsis, syphilis, and leucoplakia with cancer of the mouth has been recognized for a long time, and the incidence of this form of the disease will diminish by their timely treatment.

Cancer and Industry.—Workers in certain industries are exposed to carcinogenic substances which affect the skin and other parts of the body. The effects of mineral oils and tar are well known, and more recently benzidine and β -naphthylamine, used for making dyestuffs, have proved to be dangerous chemicals. Prevention of cancer in these industrial workers includes the isolation and separation of carcinogenic substances from the materials used by them, thus giving a complete safeguard. In the meantime the provision of protective appliances for the skin, adequate washing accommodation, good ventilation of factories, and the formation of regulations for the guidance of workers are of obvious importance.

Lung Cancer and Cigarettes.—As a result of the careful work by Doll and Bradford Hill we can say that cigarette-smoking is a potentially dangerous pursuit, and before starting the habit people should weigh up the increased risk of developing lung cancer in middle and later life. More investigations are necessary to see whether a carcinogen can be isolated from cigarette tobacco.

Lung Cancer and Atmosphere Pollution.—The high death rate from respiratory diseases in residents of the industrial centres of the country has been recognized for many years, and was emphasized during the great fog of London in the winter of 1952. It has been suggested that the continuous exposure of persons to a carcinogen in the atmosphere such as benzpyrene lowers the resistance threshold of the lung to cancer in cigarette smokers. More work is required concerning local atmospheric pollution in the neighbourhood of gasworks and its effects on the respiratory system.

Early Diagnosis and Treatment

The best chance for a patient with cancer lies in early diagnosis and efficient treatment, and my experience proves that it can be cured in many patients. The community has a special responsibility to report to the doctor when any disturbance in health occurs lasting more than a few days. Conditions other than cancer may be the cause of this, and by timely treatment they can be rectified. Some may hesitate to go to the doctor because they fear cancer, so by

wise teaching we must help them to conquer it. Progress is being made in the treatment of cancer, and people can take courage and find new hope. The present methods available include surgery, radiotherapy, chemotherapy, and combinations of these treatments.

Surgery, helped by advances in anaesthesia and antibiotics, has been extended to a number of organs, and radical operations for cancer of the oropharynx and hypopharynx, oesophagus, and lung can now be performed with a great measure of safety. Other operations have become more radical, thus increasing the percentage of operability and survival rates; these include resection of the stomach, colon, and rectum. Radiotherapy, alone or combined with surgery, has made a valuable contribution, especially in cancer of the skin, breast, cervix uteri, and larynx. Radioactive isotopes are helpful in cancer of the bladder and thyroid. Much work is also being done in chemotherapy to find substances to control cancer. Oestrogens retard the growth of cancer of the prostate or inactivate it; when the disease is advanced and the patient has been treated by castration and oestrogens, adrenalectomy may help further. A number of women with cancer of the breast are helped by the withdrawal of oestrogens by oophorectomy or the administration of androgens. I have known several of these patients with advanced cancer live normally for a number of years without any pain.

Rehabilitation of the Patients after Treatment

Following treatment the general condition of patients is usually lowered together with the ability to work. Hospital treatment is unnecessary, but they are not fit enough to go home; this interval must be bridged by convalescent treatment. Homes are therefore necessary for them which are staffed by those who are trained for this special work. The treatment includes rebuilding the patient's nutritional state, correcting any blood deficiency, restoring muscle tone and development. A colostomy or tracheostomy may be present, and patients may require instruction in their management. Following laryngectomy or laryngo-pharyngectomy speech therapy is necessary. Other patients may have an amputation stump which requires attention, together with instruction concerning wearing an artificial limb. Patients must also have an opportunity to reorientate their general outlook, and this programme of treatment requires several weeks to complete.

Care of Patients with Persistent Cancer

At present this is a big problem, but it is hoped that it will diminish in the future as a result of earlier diagnosis and treatment. Many of these patients are nursed at home and much help is required for them and their relatives. This was shown in the national survey report, where a description is given of how this can be done. Special assistance is available from organizations such as the Marie Curie Memorial Foundation and the National Society for Cancer Relief. There are homes where many can be given all the care and treatment required; some can go temporarily so that the family can have a rest. The maintenance of the general health, the nutritional state, and the condition of the blood are important in improving the patient's resistance to the disease. Modern methods for the relief of pain, palliative radiotherapy, and chemotherapy have proved valuable in certain circumstances. These patients often face a long illness, so care is taken to avoid despondency; much can be done to help them, and no impression must ever be given that treatment has ceased.

Cancer Education for the Public

It is clear that the community has its responsibilities in this programme for cancer control, chiefly in connexion with the prevention and early diagnosis of the disease. Before people can play their part they must be advised about

the steps they can take under certain conditions in a way which will gain their confidence.

In 1804 an attempt was made to give people information on this subject, but the mails were so slow that the patients died before it reached them. Since that time a number of surgeons have stressed the need for this work. For example, in 1900, when Wertheim introduced his operation for radical removal of the uterus, a movement was started in Germany to educate women to recognize the early symptoms of cancer of the cervix uteri. The Marie Curie Memorial Foundation has a plan to carry out cancer education on a national scale. The object is to substitute intelligence and optimism for ignorance and fear. It is not enough to tell people what are the early symptoms of cancer; they should also be told how to act in certain circumstances and what can be done to help them. It is recognized that this must be done wisely and by stages until the whole population is eventually covered. An important approach to the public is through the medical officers of health, and already a number have set up education committees to deal with the work. These committees should be expanded to cover the country, and in the first place information given to specified groups, including the district nurses, who number 13,000 in England and Scotland; health visitors, numbering about 6,000; and student nurses, numbering 50,000. The education scheme should also embrace all the social and welfare workers, and by this means a nucleus of informed people will be created through whom the facts can reach the population. Expansion will occur by degrees by taking in other sections until the whole country is covered.

Methods of Teaching

Use of Leaflets.—A series of 12 leaflets setting out the early symptoms of cancer in the chief sites of the body, together with notes on its prevention and treatment, is available at the Marie Curie Memorial Foundation to medical officers of health and others on request for careful distribution.

Lectures and Films.—Groups of people are invited to lectures on cancer which are illustrated by lantern slides, and educational films are shown. Experience shows that these are well attended, and excellent discussions follow the lectures. Special lectures are also given to members of the nursing profession in refresher courses, and, in addition, arrangements are made for groups of district nurses to attend at a cancer clinic so that they can see the results of modern diagnosis and treatment. Talks on the radio can also be developed, and these will reach a large section of the community.

Publications.—Periodically, articles on various aspects of cancer are published for nurses and health visitors to help them in their work. In addition, simple articles published in the lay press are of value to the public.

Presentation.—The subject must be presented in simple language which is easily understood and designed to develop an optimistic outlook and confidence. A complete picture is given, including information on the nature of the disease, the way by which it may be prevented, the early symptom and signs, and what can be done for the patients. The latter includes the help which is available from the various organizations working in this field.

Summary

The effects of cancer on the community are described with special reference to world and national mortality together with family and individual problems. It is shown that the present situation is serious as regard mortality and morbidity. A five-point programme for the control of cancer is described and the part the community can play is shown. An outline of a scheme for cancer education of the public is given.

MODIFIED COURSE OF T. CONGOLENS INFECTION IN MICE GIVEN DIETS WITH MILK CASEIN*

BY

AUDREY A. N. KEPPIE, B.Sc.

Bacteriology Department, University and Western Infirmary of Glasgow

TABLE I.—Composition (g. per 100 g.) of Diets Tested

Diet 1		Diets 2, 3, and 4			
		2	3	4	
Wheat, whole ground	50	Casein (lactic, un-

Dried grass meal	5	Cod-liver oil			0.5
Cod-liver oil	1	Salt mixture†			4.0
Common salt (sodium chloride)	1	Dried yeast powder			1.5
Total	100	Totals	100	100	100

* Ministry of Food special margarine containing 450–550 I.U. vitamin A per oz. and 90 I.U. vitamin D per oz.

† McCollum's salt mixture No. 185 with iron and potassium iodide (0.221 g. per kg.).

Experiment I

Young white Swiss female mice of about 6 weeks of age of the laboratory inbred strain, which had been bred and reared on diet 1, were allocated to one or other of diets 1 to 4, on which they were fed for three weeks before inoculation, and thereafter throughout the course of the experiment. Twenty mice were allocated to each group. The mice were kept in individual glass jars with sawdust litter, which was changed weekly, and with individual water-bottles. The "casein" diets were made up in bulk and kept in the refrigerator. Each mouse was given 5 g. of diet daily.

The inoculum was a 10% mixture in saline of blood at "acme" (see below) from four mice infected with *T. congolense* (Busimbi); 0.5 ml. was injected into each mouse subcutaneously. It may be explained that for over five years in this laboratory *T. congolense* (Busimbi strain) remained fully virulent for mice. The strain was maintained by passage to fresh mice whenever the number of trypanosomes in the blood of an infected mouse first became uncountable. This phase is known as "acme" and the strain derived thereby as an acme strain (Browning, Calver, and Adamson, 1948). The usual course of infection in a previously uninoculated animal is that small numbers of trypanosomes appear in the blood in three to six days, and increase rapidly until acme is reached (five to nine days). Parasitaemia persists up to a week thereafter (acute phase); then

In February, 1952, mice which had been fed on diets with different amounts of milk casein as protein were inoculated with *Trypanosoma congolense* (Busimbi strain). Contrary to expectation, blood films from the animals failed to reveal trypanosomes and the mice did not die. This phenomenon was so unexpected that it was further studied with a range of diets as described in this paper. The results of two further experiments confirmed the original observation and showed that the unexpected result might be attributed to a change of diet.

In the absence of fuller investigation the results were not published. However, since they show a close analogy with the findings of Maegraith, Deegan, and Jones (1952) of the suppression of *Plasmodium berghei* infection in rats fed on milk diets, it now seems desirable to give a brief account of the experiments with trypanosomes.

Five diets were tested: (1) Rowett Research Institute Stock Diet No. 86 (Howie, 1951). This is a cubed diet of a mixture of natural foods giving good growth and breeding performance. (2) Diet containing 30% casein. (3) Diet containing 20% casein. (4) Diet containing 10% casein. (5) Stock diet of bread soaked in milk daily, with a handful of oats weekly. The percentage composition of diets 1–4 is given in Table I.

* This work was done with a grant from the Medical Research Council.

— to +++ = range of numbers of trypanosomes in blood (see text, p. 854). 1 = little; vl = very little.

trypanosomes disappear for about seven days, but reappear in the blood in large numbers and persist as a rule until the death of the animal (chronic phase). Death may take place in the acute phase or in the chronic phase. Animals may survive up to about four months after inoculation, but usually die much before that time.

In the present experiments the blood of each mouse was examined daily by pressing out a drop of blood between a cover-slip and slide and examining a wet film under the $\frac{1}{4}$ -in. (4-mm.) lens of the microscope. In recording the results of blood examination, the numbers of trypanosomes per microscope field were indicated in the following way :

-	=No trypanosomes seen after three minutes' search
+v	=1 trypanosome in over 2 fields
+l	=1 trypanosome in 1-2 fields
+	=1-3 trypanosomes per field
++	=3-15 " " "
+++	=Over 15 " " "

TABLE IV.—Diet 3 (20% Casein). Results of Infecting Mice with Trypanosomes

[illegible]

-- to +++ = range of numbers of trypanosomes in blood (see text, above). l = little; vl = very little.

Results

The results of daily blood examinations are given in Tables II to V. All the mice fed on the four different diets ate their food well and showed no signs of ill-health, having smooth sleek coats and gaining weight throughout the experiment until such time as those which died of the infections were actually dying. The weights of uninfected mice given diets 1 to 4 are shown in Table X.

Diet 1 (see Table II).—Trypanosomes first appeared in the blood (+v, +1, +) of the animals of this dietary group four to six days after inoculation. They reached acme (+++) in six to nine days and persisted in numbers till 11 to 17 days after infection. Trypanosomes were absent from the blood for two to six days. Thereafter the infection, now chronic, continued with more or less constant numbers of trypanosomes in the blood until death or termination of

- to +++ = range of numbers of trypanosomes in blood (see text, p. 85). l = little; vl = very little.

the experiment. All animals were successfully infected. During the 40-day period of observation three mice died at the acute stage and four at the chronic stage of the infection—that is, 7 out of 20 died.

Diet 2 (see Table III).—Trypanosomes first appeared in the blood of 5 of the 20 mice in five to seven days, and of these only three showed the normal course of increase to +++ with relapse or death at the acute stage. Of the remaining 15 mice, six did not at any time show evidence of infection in the blood, and in the other nine the first demonstrated appearance of trypanosomes was from 10 to 26 days after inoculation. In 7 of the 20 mice, trypanosomes in very small numbers appeared in the blood for a very short time, sometimes on more than one occasion, before they reached +++, after which the course of persistent chronic infection always followed till death. During the 40 days 10 of the 20 mice died of infection—only one of these died at the acute stage—and one mouse (No. 127) died of intercurrent infection. The five mice in which trypanosomes had not been demonstrated were reinoculated from a fresh mouse of the acme passage strain, and their blood was examined for a further 15 days, during which time no sign of infection was observed.

Diet 3 (see Table IV).—One mouse (No. 158) died of intercurrent infection at the beginning of the experiment. Five of the 19 mice showed trypanosomes in the blood from six to nine days after inoculation; of these only two increased to +++ at this stage. Of the remaining mice, eight showed trypanosomes in 16 to 32 days, but only four of the eight ever showed a +++ infection or reached the

TABLE VI.—Summary of Data from Tables II-V

Dietary Group (20 Mice in Each Group)	No. of Mice Showing Trypanosomes in Blood Within 9 Days	+ + + Reaching 9 Days	No. of Deaths			Total	No. of Mice in Which Trypanosomes Were Not Demonstrated in the Blood	No. of Mice in Which Trypanosomes were Seen but did not Reach + + + Level
			At "Acute" Stage	At "Chronic" Stage (Up to 40 Days)				
1	20	20	3	4	7	0	0	
2	5	3	1	9	10	5	0

* One of the mice given diet 3 died of intercurrent infection at the start of the experiment.

chronic phase—that is, four mice showed trypanosomes but never at the level of + + +. In 6 of the 19 mice, trypanosomes were not demonstrated. These animals also were reinoculated as described before, but no resulting infection was seen. Seven of the 19 mice died during the 40 days, two at the acute stage.

Diet 4 (see Table V).—Ten of 20 mice showed trypanosomes in the blood in four to nine days, four reached the +++ level and died at the acute stage. Six further mice showed trypanosomes after 16 to 26 days, all of these mice eventually showing 2 +++ infection which became chronic. In four mice trypanosomes were not demonstrated, and these were reinoculated as before. Trypanosomes were not seen after reinoculation. In this group there were 14 deaths—four at the acute and 10 at the chronic stage of infection.

The results of experiment I are summarized in Table VI.

Experiment II

This experiment was done with diet 1, diet 3, and diet 5, which consisted of bread, milk, and oats. Diet 5 was that used for trypanosome-infected mice in this department for many years.

Details of inoculation and blood examination were similar to those in Experiment I. Male mice of the laboratory inbred strain 3-4 months of age were allocated to the three diets, on which they were fed for a period of two weeks before inoculation with *T. congolense* (Busimbi). The period of observation after inoculation was only 23 days in this experiment.

Results

Diet 1 (see Table VII).—Trypanosomes first appeared in the blood of infected animals in four to eight days after inoculation. Acme was reached at 6 to 10 days. The trypanosomes disappeared from the blood on the eleventh to the fifteenth day after inoculation and reappeared in four to nine days after disappearance. All the animals became infected. One mouse died at the acute stage of the infection, but 9 of 10 mice survived to the chronic stage, at which all remained well till the end of the experiment.

Diet 3 (see Table VIII).—In this group only 2 of 10 mice showed trypanosomes in blood films in six to seven days. Of these two, one had demonstrable numbers of

trypanosomes on only one day of examination, while the other, in which trypanosomes persisted over three days, did not reach acme.

Diet 5 (see Table IX).—Trypanosomes first appeared in the blood of animals in this group five to seven days after infection. Acme was reached at seven to eight days. All the animals became infected. Trypanosomes persisted in large numbers in the blood for as long as 18 days after inoculation, when they disappeared for up to five days. Four mice died at the acute stage, but there were no deaths at the chronic stage in this period of observation.

Discussion

In Experiment I all the animals in the group fed on diet 1 followed the course of infection normally observed in this

laboratory with *T. congolense* (Busimbi) (see Table II). The results of the infection in mice given diets 2, 3, and 4, on the other hand, repeated the unexpected result referred to in the introduction of many failures to infect in the normal manner with this strain. Only 5 out of 20 mice on each of diets 2 and 3 and 10 of 20 mice on diet 4 showed trypanosomes in their blood in anything approaching the normal times; and of these numbers only three animals on diet 2, two on diet 3, and four on diet 4 showed the normal acme phase (Table VI). The remaining mice relapsed before the acute stage of infection had been reached, and did not show the usual chronic phase which normally persists for variable but substantial periods of time. In the other animals on diets 2, 3, and 4 trypanosomes were not demonstrated in the blood for up to as long as 26, 32, and 26 days (Tables III, IV, and V), and indeed were not demon-

— to +++ = range of numbers of trypanosomes in blood (see text, p. 854). l = little; vl = very little.

strated at all in five, six, and four animals of the respective dietary groups 2, 3, and 4, even after reinoculation with the blood of a fresh "acme" passage mouse. In mice given diet 2, 3, or 4 infection followed a much milder course than in those given diet 1. This was true in all mice not reaching or dying at the acute stage, as judged by the total numbers of trypanosomes in the blood of the animals over the period of the experiment. When the persistent chronic stage was reached, however, death was often rapid (cf. Table II and Tables III, IV, and V).

The results of Experiment I are supported by those of Experiment II. The mice fed on the casein diet 3 showed only the slightest evidence of blood-stream invasion by the parasites during the 23-day period of observation. The infection followed an acute course in both the natural diets, Nos. 1 and 5, and this course was that normally recorded in this laboratory over many years.

Maegraith *et al.* (1952) concluded that milk probably contains something that can inhibit or restrict the development of the asexual phase of blood-transmitted *Plasmodium berghei* in the rat and the mouse. Another possibility is that milk may be deficient in certain nutrients required by the parasite (*British Medical Journal*, 1952). The second explanation would fit the results observed in the present experiments with *T. congolense* in mice given diets with paramilk casein as the source of protein. It is clear that parasitaemia developed much more rapidly and attained a higher level in mice given diets 1 and 5, which were nutritionally more complex than the casein diets. Moreover, since diet 5 also contained milk, inhibition of parasite growth from the absence of undefined nutrients rather than from an anti-parasitic effect of milk might appear to be the more tenable explanation. It may be of importance to note that the mice made good gains of weight on all diets, especially on diet 4, which contained a high proportion of carbohydrate (Table X).

TABLE X.—Weekly Mean Weights (g.) of Uninfected Mice Given Experimental Diets 1-4

Diet No.*	Age of Mice (Weeks)									
	4	5	6	7	8	9	10	12	17	
1	19	24	29	30	31	32	34	36	39	
2	17	25	30	30	32	32	33	35	35	
3	20	24	30	33	33	35	37	37	37	
4	18	25	32	34	36	37	39	41	44	

* Each dietary group comprised 4 males and 4 females; litter mates were evenly distributed.

Summary

Mice fed on five different diets were experimentally infected with *T. congolense*.

Parasitaemia with acute followed by chronic infection developed as expected in mice fed on two of the diets, which were diets of the type normally employed in laboratories for rearing and maintenance of mice.

In mice fed on three of the diets in which milk casein was the source of protein the parasitaemia was either delayed or prevented.

Since one of the two "normal" diets contained milk but permitted normal development of the infection it might appear that failure of the incomplete diets to nourish the parasite is the explanation of the observed results, rather than that milk itself contains an anti-parasitic agent.

HISTOPLASMOSIS IN GREAT BRITAIN

DESCRIPTION OF A SECOND CASE OF DISSEMINATED HISTOPLASMOSIS; TREATMENT BY ETHYL VANILLATE

BY

Oldchurch Hospital, Romford, Essex

Work in the past few years on human infections by the *Histoplasma capsulatum* has emphasized certain features. Generalized dissemination (disseminated histoplasmosis) is common and usually fatal. Infection confined to the skin is frequent, though, unlike cutaneous blastomycosis, the skin lesion is usually within a short while followed by manifestations of dissemination (Curtis and Grekin, 1947) and is therefore often fatal. Infection can be confined to a single organ or viscus—usually the lung—with at no time evidence of dissemination and often no past history of even mild illness. These cases are identified usually after recovery by a positive intradermal histoplasmin test or by complement fixation.

Only one other case of disseminated histoplasmosis has been reported in Great Britain, and this occurred in 1940 (Derry, Card, Wilson, and Duncan, 1942). A regular soldier aged 30 developed his illness in France in 1940 and the diagnosis was eventually made at necropsy in Great Britain. He had been resident in India in 1932-6 and in the Sudan in 1936-7; this gives a possible incubation period of three years at least (assuming the disease is not indigenous to France).

In the second case, which we report below, the patient had not been out of England for seven years. Symptoms first appeared about a year before admission to hospital, and we must therefore assume either that the disease has an incubation period of at least six years or that he contracted his illness in England. We regard the first of these suggestions as the more probable.

Arblaster (1950) and Crofton (1950) report three cases of pulmonary calcification in England in which the diagnosis of "healed" histoplasmosis was suggested because of a positive histoplasmin intradermal test. All three patients had been resident in the U.S.A. or Canada. Duncan (1945, 1947) isolated an atypical organism from a skin lesion in a man from West Africa.

In 1951 Limerick described the development of a retrocaecal abscess occurring after appendectomy in 1947 in a man aged 35. The abscess cleared up in three weeks with drainage and was said to be due to *H. capsulatum*. No further details are given.

The cases of Duncan, Arblaster, and Limerick, however, do not conform in many ways to the usually accepted criteria and must be regarded as very doubtful. Hutchison (1952) reported a localized laryngeal lesion due to *H. capsulatum* in a fit man of 72 who had lived

in Hyderabad for 30 years and had spent some time in Malaya. He had, however, been resident in Great Britain since 1934 (six years in Sussex and eight years in Dumfriesshire until the diagnosis in 1948). He was fit and well in 1951.

These cases are particularly interesting on two counts: (1) the three patients, not from the American continent, had all been to India; and (2) in view of the prolonged incubation period it is likely that further cases may now be expected to occur in this country in soldiers who had been resident in endemic areas during the war.

Case History

The patient, a man aged 32, had been in H.M. Forces for six years and was discharged in England in 1945. He had spent most of his time at Alexandria and Port Said, but had visited Durban for three weeks, had spent three weeks in Tobruk, and had stayed at Bombay for two months. He visited numerous places in the Near East, including Cyprus, Aden, and Malta, but never went ashore.

He began to complain of peptic-ulcer-like abdominal pain at the end of 1951. On October 14, 1952, he first attended this hospital, and he was seen by one of us (S.L.) on December 17. On examination he was pyrexial, with obvious loss of

FIG. 1.—Granulomatous ulcer inside right cheek.

weight, a large spleen, a large liver, a few small axillary glands, pallor, marked tenderness over the sternum, and two large ulcers in the mouth (see Fig. 1). Examination of the central nervous system was normal; the blood pressure was 125/75 mm. Hg. The ulcers (about 2 cm. in diameter) were situated on the hard palate and the inside of the right cheek. They were granulomatous in appearance, with a raised rolled edge. The patient was admitted to the medical wards.

On December 19 a blood count showed: haemoglobin, 58%; red cells 3,300,000; white cells, 3,000 (72% polymorphs, 1% metamyelocytes, 1% eosinophils, 11% lymphocytes, 8% monocytes, 7% stab cells). A marrow puncture was normal and did not favour the diagnosis of leukaemia. W.R. and Kahn test were negative. It was felt that the only alternative diagnosis now possible was that of disseminated histoplasmosis.

Penicillin in large doses and the local application of an antibiotic to the ulcers was ineffective, and was discontinued after ten days. An x-ray film of the chest on December 29 showed the presence of a small opacity in the right costophrenic angle. Intravenous hydroxy-stilbamidine for ten days was ineffective. On January 7, 1953, his haemoglobin was 54% and the blood count was unchanged. Repeated estimations of plasma proteins, serum bilirubin, thymol turbidity, and cephalin-cholesterol flocculation were unchanged and normal. Blood urea was 26 mg. per 100 ml. A histoplasmin intradermal test was negative (no wheal or

erythema). An electrocardiogram on January 14 was within normal limits.

An x-ray film of the chest on January 21 showed extensive spread of the pulmonary lesion (see Fig. 2). On the 24th small ulcers of the skin were appearing and doses of sulphadiazine were started with no improvement. On the 29th ethyl vanillate was given.

On February 1 he was having great difficulty in keeping down the capsules of ethyl vanillate, and from February 5 it was given in an emulsion. The emulsion was made up to contain 12.5 g. of ethyl vanillate in 200 ml., and this was dripped into the stomach through a Ryle's tube, the gastric drip lasting for 50 minutes and being given every six hours.

On February 9 he said he felt very much better, but was even more wasted. His blood pressure was 115/70 mm. Hg. There had been no improvement in any of his physical signs, and his clinical condition had grossly deteriorated. He died suddenly on the evening of that day.

FIG. 2.—Chest x-ray film two weeks before death, showing extensive bilateral lung involvement.

Post-mortem Findings

The liver weighed 1,552 g., and a large number of pale slightly raised nodules up to 1.5 cm. in diameter could be seen through the capsule. Enlargement of lymph nodes was general, but was especially marked in the abdomen. The suprarenals showed enormous enlargement, presenting as yellowish rounded masses 6 by 6 by 4 cm., on each side deforming the upper pole of each kidney. On section the suprarenals had a cream-coloured honeycombed appearance with some liquefaction. The kidneys and bowel showed no detectable lesions. The spleen weighed 430 g., with a splenunculus the size of a walnut. The lungs each weighed just over 600 g., all lobes showing very numerous white solid areas 1–5 mm. in diameter, sometimes coalescing into larger masses with central necrosis.

Histological evidence of histoplasmosis was found in sections from the liver, spleen, lymph nodes, lungs, bone marrow, thyroid, and suprarenals. Very scanty parasites were detected in sections of skin lesions. In each case distension of reticulo-endothelial cells by large numbers of capsulated yeasts was evident (Fig. 3). Goodpasture's stain gave clearer definition of the parasites than Schiff's periodic acid or phloxine tartrazine. In the suprarenals there was extensive involvement of the cortex as well as the medulla, with a very small outer fringe of unaffected cells.

H. capsulatum was cultivated from the spleen, suprarenals, liver, lung, and bone marrow.

FIG. 3.—Section of lymph node showing endothelial cells engorged with the parasites.

Bacteriology

Examination of the first biopsy (December 29) was so suggestive of histoplasmosis that a second biopsy was carried out (January 21) in order to isolate the parasite. An impression smear (January 21) showed an abundance of oval capsulated yeasts (Fig. 4), and cultures were made on Sabouraud's and glucose agar (pH 7.4) at room temperature and at 37° C. On 1% glucose agar after seven days at room temperature there appeared a profuse growth of small fluffy white colonies adherent to the medium. A few days later typical tuberculate chlamydospores of *H. capsulatum* were found in the centre of the colonies. No growth occurred on Sabouraud medium, and it appears that, from subculturing, this strain grows very slowly at a low pH. On glucose agar, growth was best at room temperature at a pH approaching neutrality. The colonies become brownish, with the appearance of chlamydospores. The chlamydo-

FIG. 4.—Showing organisms with characteristic unstained capsules obtained by direct contact smear from biopsy of cheek ulcer. ($\times 2,000$.)

spores (Fig. 5) are of two types—a large tuberculated thick-walled structure 14–16 μ in diameter and a small smooth pear-shaped form 4–5 μ in diameter. From the mycelial growth cultures were made on sealed blood-agar slants at 37° C., and after a fortnight smooth creamy colonies of the yeast form were produced. The yeast cells were of varying shape, about 2–3 μ in diameter, and about half appeared oval with pointed ends. The yeast form did not

ferment glucose, maltose, saccharose, or lactose after 14 days' incubation at 37° C.

With the use of the slide-cell technique and 1% glucose agar the control cell showed a good growth in six days but no growth occurred in concentrations of 4.2 mg. of ethyl vanillate or greater. Similar tests carried out with "cuprimyl" (tetraethylamine salt of cupric-bis-8-hydroxyquinoline 5:7 disulphonic acid) showed no inhibition in a concentration of 10 mg. per 100 ml.

Discussion

In this case there did not appear to be any evidence of adrenal failure, though a close watch was kept for this both biochemically and clinically; nevertheless the sudden death was very suggestive of this.

The diagnosis of the disseminated disease can in most cases be suspected on the clinical picture: irregular fever, ulceration of the mouth and palate of a peculiarly granulomatous type (Fig. 1), ulceration of the skin, enlargement of the liver and spleen, lymph-node enlargement, developing pulmonary lesions which may show a localized consolidation with or without cavitation (Fig. 2), or, more commonly, generalized miliary opacities in the lungs. Anorexia and much loss of weight, to eventual gross cachexia, are the rule. Abdominal pain and discomfort is common, and intestinal ulceration with diarrhoea not infrequent. The diagnosis can be confirmed, however, only by identification of the organism in the tissues (Fig. 3) and positive culture.

FIG. 5.—Characteristic "cog-wheel" appearance of chlamydospores seen on culture of *H. capsulatum*. ($\times 2,000$.)

Treatment

Clinical experience has shown the complete failure of promanide (promin in U.S.A.), "actidione" (an antibiotic from *Streptomyces griseus*), penicillin, streptomycin, aureomycin, chloramphenicol, sulphonamides, iodides, arsphenamine, mercurials, stilbamidine, and antimonials to affect the course of the disease and its fatal termination, and to this list we would add hydroxy-stilbamidine. Two cases have been reported in which pulmonary resection has apparently resulted in survival for two years and for six months respectively (Hodgson, Weed, and Clagett, 1950).

Ethyl vanillate, obtained by oxidizing lignin in the spent liquor from the sulphur pulp manufacturing process, has been used in disseminated histoplasmosis (Christie, Middleton, Peterson, and McVickar, 1951; Ellis, Scott, and Miller, 1952), being at the moment the drug of choice in treating histoplasmosis and coccidioidomycosis. In concentrations of 10 to 30 mg. per 100 ml., it has a marked inhibiting effect on *Blastomyces dermatitidis*, *Coccidioides immitis*, and *H. capsulatum* (information provided by Messrs. Squibb). However, a difference in susceptibility to ethyl vanillate has been demonstrated for different strains of *H. capsulatum* which may be of significance in treatment. It is, however, rather surprising that the organism in our case did not grow in ethyl vanillate at a concentration of 4.2 mg. per 100 ml., yet, in spite of blood levels well above this for 10 days (see Table), the disease here showed no signs of regression.

Ethyl Vanillate Levels in Blood and Urine (24-hour Collections)

Day	Plasma Vanillic Acid (Corrected for Normal Phenolic Substances in Blood) (mg./100 ml.)	Urine Vanillic Acid (Calculated as Vanillic and Phenolic Substances Excreted (g.))
28/1/53		1.70
29/1/53		0.88
30/1/53	6.8	5.70
31/1/53		16.50
1/2/53		14.40
2/2/53	3.3	5.75
3/2/53	18.6	26.10
4/2/53	15.8	
5/2/53	20.5	11.40
6/2/53		4.83
7/2/53		6.42
9/2/53	21.5	

Blood levels of over 30 mg. per 100 ml. are apt to cause toxic phenomena (coma with or without convulsions), and if the level exceeds 50 mg. the toxic phenomena can be lethal (Christie *et al.*, 1951). To maintain this blood level in an adult requires about 40 to 50 g. of ethyl vanillate daily by mouth, and in a child 0.75 to 2.5 g. per kg. of body weight a day. More recently, Christie (1952) said that ethyl vanillate was the only therapeutic agent of any value in histoplasmosis, though it was not satisfactory.

The patient here described received 45 g. daily from February 2, but part of this was vomited. From February 5 he received and retained 50 g. daily.

Summary

After a brief review of the cases of histoplasma infection previously published in Great Britain the second case of disseminated histoplasmosis to be reported is described. This case was fatal in spite of treatment with 45-50 g. of ethyl vanillate daily. Some information is included on culture of the organism, as in this case it showed certain cultural peculiarities.

We are grateful for the help we received from many sources in the treatment of this case. We would particularly like to thank Dr. A. S. Osborne, of the American Embassy, Dr. W. P. Kennedy, of the Ministry of Health, and Mr. C. B. Sitterson, M.D., of the Institute of Paper Chemistry, Wisconsin, U.S.A., for their advice; Dr. Harvey Blank and Messrs. E. R. Squibb and Sons, New York, U.S.A., for the prompt dispatch to us of ethyl vanillate and appropriate information adequate for the treatment of this case; Dr. R. Forgan, Dr. John Harper, and Messrs. May and Baker, of Dagenham, for their advice and for supplying us with the hydroxy-stilbamidine and "cuprimyl" used by us; Mrs. E. D. Price for her patience and careful secretarial work; and Mr. E. Sheppard for his most excellent photography. Finally, we are most grateful to the nursing staff for the great care with which treatment was carried out, and to Dr. G. H. Cranswick and Dr. P. G. Swann for their many helpful suggestions.

Since this paper was completed we understand that a case of disseminated histoplasmosis in a young woman was transferred to this country from South Africa, where the diagnosis was made. Unfortunately the patient died two days after arrival.

THE MECHANISM OF SYNCOPE
AFTER COUGHING

BY

E. P. SHARPEY-SCHAFFER, F.R.C.P.

Professor of Medicine, London University

(From the Department of Medicine, St. Thomas's Hospital)

Syncope from coughing has been considered a rare condition; thus Whitty (1943) and Baker (1949) could collect only about 100 cases from the literature. Charcot (1876) thought it was a form of epilepsy, and by coining the term "laryngeal vertigo" made it the province of neurology and throat surgery. McCann *et al.* (1949) obtained some continuous records during coughing in two subjects with the syndrome. They believed that syncope was not primarily epileptic but circulatory in origin, and that pulmonary arterial vasoconstriction or pathologically sensitive "vascular reflexes" might be responsible. Correspondence in the *British Medical Journal* resulted in no factual data, but suggested that the condition might be commoner than supposed.

Material and Methods

The patients were 27 middle-aged or elderly males who gave a history of syncopal attacks on coughing. In many it was found possible to provoke an attack by asking the patient to give a few strong coughs. Inhaling cigarette smoke or irritation of the nose was used in a few. Pressures were recorded continuously by capacitance manometers (Hansen, 1949): intrathoracic by means of a water-filled oesophageal tube (Dornhorst and Leathart, 1952); intracardiac by catheter; and intra-arterial and venous by needles or fine catheters. Fore-arm flow was measured with a plethysmograph and recorded on the same photographic paper (Davies, 1953).

Results

The data obtained in the 27 subjects with syncope were compared with similar measurements in about 40 other subjects of all ages and both sexes. There was no qualitative difference in the effects of coughing in the two groups. A single "ahem" produced an intrathoracic pressure rise of 20 to 30 mm. Hg, ordinary coughing in both groups 50 to 100 mm. Hg, and coughing leading to syncope 150 to 300 mm. Hg. The circulatory effects were proportional to the violence and duration of the coughing attacks. All subjects performed the Valsalva manoeuvre. There was no difference in circulatory effects after the Valsalva manoeuvre between those with cough syncope and those without cough syncope.

Continuous records of syncopal attacks were obtained on fifteen occasions, and many minor attacks causing dizziness or "blackout" were also recorded. The subjects coughed in two ways, continuous or intermittent, with different circulatory effects. Both, when violent, resulted in syncope.

Continuous Coughing

The subjects coughed continuously in prolonged paroxysms lasting many seconds without drawing breath. Often the intrathoracic pressure reached 300 mm. Hg and was maintained at this level until a breath was taken or the paroxysm ended. The circulatory effects were essentially similar to those of the Valsalva manoeuvre, but more pronounced owing to the greater rise of intrathoracic pressure. When asked to perform their maximum Valsalva manoeuvre it was found that few could reach and maintain an intrathoracic pressure of 100 mm. Hg. This conspicuous

FIG. 1.—An example of continuous coughing lasting many seconds. The large downward deflection in arterial and superior vena caval pressures during the attack are due to occasional inspirations. Consciousness was lost at the end of the attack, when arterial pressure was lowest. Time marker in seconds in this and subsequent records.

difference between coughing and the Valsalva manoeuvre may result from the greater number of muscles and the more powerful intermittent muscular effort employed in coughing.

An example of syncope from continuous coughing is shown in Fig. 1. Unconsciousness resulted when arterial pressure was lowest at the end of the attack. As in other forms of syncope from acute arterial hypotension (Barcroft *et al.*, 1944; Brigden *et al.*, 1950; Howard *et al.*, 1951; Howarth and Lowe, 1953) the critical level for loss of consciousness was about 50 mm. Hg. Twitching movements and convulsions were common during syncope.

Two subjects were observed to become unconscious, as judged by rolling up of the eyes and twitching movements, during coughing, while intrathoracic and arterial pressures were still greatly elevated. Catheters passed high up the internal jugular vein showed that intrathoracic pressure changes were fully transmitted to the venous outflow of the brain. As can be seen in Fig. 1, the arterio-venous pressure difference across the brain may reach its lowest level during the paroxysm.

Intermittent Coughing

This was the "normal" form of coughing, inspiration following each cough in a fairly regular sequence. It caused large rapid fluctuations in intrathoracic pressure, which will be termed "cough transients." It was followed in all subjects by a fall of arterial pressure. An example of syncope from this form of coughing is shown in Fig. 2. Consciousness was lost at the lowest blood-pressure level.

Physiological Effects of Coughing

Fig. 3 summarizes the changes caused by the Valsalva manoeuvre (or continuous coughing) and intermittent coughing. The data have been published elsewhere (Sharpey-Schafer, 1953). A to B is the period of raised intrathoracic pressure. This pressure is transmitted to the arteries, veins without valves, and the chambers of the heart. In the periphery, venous valves shut and blood accumulates distal to them at a rate which depends on previous vasomotor tone (Howard *et al.*, 1951) and the height to which the arterial supply pressure is raised.

The accumulation of blood in peripheral veins results in a decrease in the filling pressure of the heart and subsequent fall in stroke output. Pulse pressure is decreased in peripheral arteries during the Valsalva manoeuvre or continuous coughing, but large cough transients are the conspicuous feature of arterial records in intermittent coughing. Baroreceptors therefore are exposed to diminished pulsations during the Valsalva manoeuvre and to large

pressure transients during intermittent coughing. In the former case the response is peripheral constriction and in the latter dilatation, as shown in the forearm during the period B to D. These blood-flow changes do not occur in sympathectomized limbs, and are therefore mediated through the vasomotor nerves. The suggestion that these circulatory responses result from decreased or increased stimulation of baroreceptors by rapid transients is supported by recent work on the isolated carotid sinus of the dog (Ead *et al.*, 1952).

There is a further important difference between the Valsalva manoeuvre and intermittent coughing. In the former at point B the intrathoracic pressure falls immediately to the control level; in the latter it is elevated 10 or more mm. Hg (Fig. 3) and may remain so for many seconds during the period B to D. This raised pressure is transmitted to the chambers of the heart and great veins (Fig. 4) and may play a part in the production of post-tussive arterial hypotension by reducing cardiac output below control values, since it can be shown that positive-pressure breathing causes a fall in cardiac output (Werkö, 1947). There was no evidence on measurement of pulmonary arterial vasoconstriction as suggested by McCann *et al.* (1949).

Clinical Considerations

Some knowledge of the causes of this form of syncope has been helpful in the interpretation of symptoms. If normal physiological mechanisms only were involved it seemed unlikely that the condition was rare. The 27 cases investigated were found without difficulty over a period of two years and many others were seen clinically. Indeed, minor symptoms such as dizziness are almost universal among those who cough strongly. The curious rarity of the

FIG. 2.—Arterial pressure record of intermittent coughing. Large arterial cough transients were followed by hypotension and syncope.

syndrome in females may be due, in part, to social taboos which impose the belief that such exhibitions of violence are "unladylike." The case of a Scots woman with typical attacks has, however, been reported to me. Continuous records are not yet available from children with whooping-cough and infants with breath-holding.

FIG. 3.—Diagrammatic representation of the circulatory events caused by the Valsalva manoeuvre or continuous coughing, and intermittent coughing (see text). The changes in left ventricular output were not measured directly but were inferred from the arterial records.

Patients with large quantities of sputum from chronic pulmonary disease rarely show these symptoms. Continuous records during coughing in such patients showed that intrathoracic pressure rose no higher than about 100 mm. Hg, and although the usual circulatory changes were present they were not sufficiently pronounced to interfere with the blood supply to the brain.

The role of smoking, drinking, and bad teeth and other infections is to produce the upper respiratory tickle, which, like some forms of skin itching, needs the utmost violence to assuage. This form of coughing may become a habit. It is easy to see why middle-aged males are the chief victims.

A history of a single cough followed by immediate unconsciousness should be regarded with suspicion. Three of the subjects reported here gave such a history, but proved to have typical attacks of prolonged violent coughing followed by syncope. Questioned after a recorded attack, they still claimed immediate unconsciousness.

Two may have had a short period of retrograde amnesia; the third interpreted 15 seconds as "immediate."

The occurrence of fits during syncope after coughing is likely to be more misleading to neurological than to circulatory workers, who are probably aware that a fit can occur in any normal subject if the blood flow to the brain is sufficiently reduced. If the subject is a known epileptic the full seizure is more easily induced by methods of lowering the blood pressure. Two of the present cases had a history of epilepsy and grand mal after violent coughing.

The appearance of the subject during continuous violent coughing is alarming, and may suggest to the lay and even the medical mind the likelihood of a burst blood vessel,

while the subsequent syncope may indicate that this calamity has occurred. The vessels of internal organs such as the brain, however, are protected from high pressure differences across their walls, since surrounding structures are exposed to the same pressure, and, as explained above, the pressure across these vessels is less, not more, than normal.

It is only in places where veins are in near contact with the outside atmosphere that pressure differences of 300 mm. Hg may be built up. Since surface veins are protected by valves, high pressures are reached only after a period of some seconds. In prolonged paroxysms of coughing nose veins commonly burst, and occasionally veins in the conjunctiva and anus do likewise.

Treatment

Attempts to alter bad habits or causal irritant factors proved singularly unsuccessful in this group of middle-aged men. Explanation of the mechanism was tried with more intelligent subjects, but even these found it difficult to realize that extreme violence was unnecessary and clung to their way of coughing for various fanciful and erroneous reasons.

The investigation, however, showed a method which, while annoying to the investigator, was almost uniformly successful in alleviating the attacks. It was found on the first occasion when measurements were made that an attack could be induced with ease. Subsequently more and more encouragement became necessary to produce the required intrathoracic pressure changes. The subjects learnt by demonstration that it was violence which caused syncope. As one said on the fifth occasion, "I don't see why I should cough myself unconscious any more—to please you, Doctor."

Summary

Syncope from coughing was found to be common and to result from an acute diminution of supply pressure of blood to the brain. Continuous records in 27 cases indicated that normal physiological mechanisms only

FIG. 4.—Upper curve, intra-oesophageal (intrathoracic) pressure; lower curve, pulmonary artery pressure. Both were elevated to the same extent after coughing.

were involved. The violence of the coughing was the determining factor, intrathoracic pressures of 200 to 300 mm. Hg being reached.

Subjects who coughed continuously without drawing breath were shown to have circulatory changes which were exaggerated examples of the effects of the Valsalva manoeuvre. Consciousness was usually lost during the period of acute hypotension following cessation of coughing. Occasionally syncope occurred while intrathoracic pressure was still high, but the arterio-venous pressure difference across the brain was greatly reduced.

Subjects who coughed intermittently also had syncope. Arterial pressure and peripheral blood flow records showed vasodilatation following this form of coughing in contrast to the vasoconstriction which resulted from the Valsalva manoeuvre and continuous coughing.

It is suggested that vasodilatation following intermittent coughing is due to the stimulation of baroreceptors by large arterial cough transients.

Intrathoracic pressure remained elevated about 10 mm. Hg for many seconds following intermittent coughing.

EFFECTS ON BLOOD PRESSURE OF VENTRICULAR ASYSTOLE DURING STOKES-ADAMS ATTACKS AND ACETYLCHOLINE INJECTIONS

BY

E. D. BARLOW, M.B., B.Chir., D.P.M.

Research Fellow, St. Thomas's Hospital Medical School

AND

SHEILA HOWARTH, M.B., B.S.

Senior Research Fellow, Institute of Cardiology, National Heart Hospital

Ventricular standstill may occur spontaneously in cases of heart-block, and during Stokes-Adams attacks consciousness is lost if asystole is sufficiently prolonged. Cardiac arrest also follows the intravenous injection of acetylcholine, with resulting loss of consciousness (Phillips *et al.*, 1952). Observations have been made to determine the peripheral arterial pressure in these two types of case, and the results are reported in this paper.

Blood pressure was recorded continuously in the brachial artery, using a capacitance manometer (Hansen, 1949). The Stokes-Adams attacks occurred spontaneously in a patient with heart-block, who later showed no macroscopic heart lesion at necropsy. Rapid intravenous injections of 50 to 200 mg. of acetylcholine chloride were given as a part of routine therapy to psychoneurotic patients who had no organic circulatory abnormality on clinical examination.

Results

The blood-pressure records in both types of case show a striking similarity. Typical examples are shown in Figs. 1 and 2. Ventricular asystole was always followed by an acute

fall in blood pressure. With prolonged standstill, blood pressure fell rapidly at first, then more slowly, and finally remained constant at about 20-25 mm. Hg. Loss of consciousness was often followed by convulsive movements.

When ventricular contractions were resumed an "overshoot" was seen on all blood-pressure records: systolic and diastolic pressures rose above control levels for a variable number of seconds before the blood pressure returned to normal. An increase in pulse pressure, more striking in the Stokes-Adams attacks, was recorded during the overshoot. The characteristic flush which accompanied restoration of the circulation following the Stokes-Adams attacks was also observed after cardiac arrest from acetylcholine injection.

FIG. 1.—Effects on the blood pressure of a Stokes-Adams attack. Above: Lead II of the electrocardiogram. Convulsive movements produced interference with the record after 16 seconds asystole. Below: Continuous brachial arterial pressure record. Time (top) in seconds. Calibration in mm. Hg.

FIG. 2.—Effect on the blood pressure of cardiac arrest produced by 100 mg. of acetylcholine given intravenously. Period of injection is shown by signal on time marker. Time in seconds.

Discussion

In spontaneous and induced ventricular asystole, blood pressure falls rapidly to syncopal levels. Systemic arterial pressure tends to stabilize during cardiac standstill at 20-25 mm. Hg. This figure does not differ greatly from the standing pressure of 14 to 22 mm. Hg observed by Dowling *et al.* (1952) during asystole induced for 5 to 10 seconds by carotid sinus pressure. These authors, however, did not record a subsequent overshoot in the systemic pressure.

The overshoot may be regarded as a response to the lowered blood pressure. A similar overshoot follows the fall in effective systemic pressure during the Valsalva manoeuvre (Hamilton *et al.*, 1936; Howard *et al.*, 1951), where it has been shown to be due to sympathetic vasoconstriction (Wilkins and Culbertson, 1947). Vasoconstriction has been demonstrated in muscle vessels during the overshoot of the Valsalva manoeuvre (Howard *et al.*, personal communication); but vasodilatation may be present in the vessels of the skin during the overshoot after asystole, since vivid flushing of the face and neck occurs in both Stokes-Adams attacks and after intravenous acetylcholine injection.

The striking similarity between acetylcholine-induced asystole and spontaneously occurring Stokes-Adams attacks suggests that these effects of intravenous acetylcholine injections result from asystole alone.

Summary

During ventricular asystole in spontaneously occurring Stokes-Adams attacks and following rapid intravenous injections of acetylcholine systemic blood pressure fell to low levels.

During cardiac standstill of up to 21 seconds arterial pressure remained constant at 20 to 25 mm. Hg.

An "overshoot" occurred in the blood pressure following the resumption of ventricular contractions in both forms of asystole: systolic and diastolic pressures increased above control levels before arterial pressure returned to normal.

It is suggested that this action of intravenous acetylcholine results from asystole only.

The cases investigated were under the care of the physicians to St. Thomas's Hospital and the National Heart Hospital.

HIATUS HERNIA AND PREGNANCY

A REVIEW OF NINE CASES AND THE LITERATURE

BY

W. A. W. DUTTON, M.B., M.R.C.S.
D.Obst.R.C.O.G.

AND

H. J. BLAND, M.B., Ch.B., D.Obst.R.C.O.G.
Formerly Resident Obstetric Officers, Southmead General Hospital, Bristol

Herniation of part of the stomach through the oesophageal hiatus of the diaphragm is a fruitful source of errors in diagnosis. Although this disorder is being detected more often (Avery Jones, 1952), it is still commonly overlooked.

Hiatus hernia is probably due in most cases to factors operating in adult life. Laxity of the tissues, with deficiency at the oesophageal ring, is common (Harrington, 1945). Hernia at this site is favoured by conditions raising intra-abdominal pressure and by recumbency. Such herniae may be oesophago-gastric or para-oesophageal, termed by Allison (1951) the sliding and rolling types, which may be present together.

The symptoms are protean, and have been well described by Nicholson (1952). Epigastric discomfort and vomiting are common. If the disorder is complicated by reflux oesophagitis there may be intense "burning pain" behind the lower end of the sternum, which may radiate up to the neck. There may be slight dysphagia, and a gastric ulcer may develop near the cardia. Retching of blood-stained fluid may proceed to frank haematemesis and melaena. Stricture may develop at the lower end of the oesophagus.

Review of Literature

Reports of hiatus hernia complicating pregnancy are infrequent. All authors emphasize that symptoms are aggravated by recumbency, worsen in the last trimester, and tend to clear up after delivery. Heartburn is particularly constant. Evans and Bouslog (1940) reported four cases in which this symptom was almost intractable, and Bush (1950) reported a similar case in which radiation of the pain to the ears was a bizarre addition. Vomiting may be severe and often culminates in haematemesis, which has been described by Schnepf (1943), Queries and Minor Notes (1937), Bourgeois and Hood (1949), Simmons *et al.* (1950), and Hahn (1952). Murless (1947) reported two cases of large para-oesophageal herniae causing vomiting and dyspnoea in pregnancy. Penman (1951) added to the literature four cases in which hiatus hernia produced persistent gastrointestinal disturbances during pregnancy.

Vinson (1921, 1923) described nine cases of oesophageal stricture following severe vomiting in pregnancy. Some of the records of these cases suggest that they were due to hiatus hernia. Rennie, Land, and Park (1949) described five cases of pregnant women who developed dysphagia and retrosternal pain in the latter months of pregnancy. Hiatus hernia associated with a short oesophagus and stricture was present in all five cases. In three, active oesophageal ulceration was demonstrated. Allison, Johnstone, and Royce (1943) described a similar case.

Case Reports

The following cases came to our notice during routine duties in 1950-2.

Case 1.—The patient, a 2-gravida, 1-para aged 31, was a thin woman whose previous health and first pregnancy were entirely normal. Her second pregnancy (estimated date of delivery, October 2, 1951) was complicated. Morning nausea and retching began at the sixth week and persisted throughout pregnancy. During the second trimester there were repeated attacks of "burning" pain behind the xiphoid, exacerbated by meals, recumbency, and stooping forward. Symptoms were worse at night and during the third trimester. Vomiting became so frequent that she was admitted to hospital at the thirty-eighth week and treated symptomatically. Her condition fluctuated until September 24, when, with the spontaneous onset of labour, vomiting culminated in a haematemesis. Labour was inert, and copious vomiting resulted in dehydration and ketosis. Intravenous fluids and gastric aspiration were begun, but a second haematemesis occurred which required blood transfusion. After spontaneous rupture of the membranes her condition improved and normal delivery followed. During the puerperium there were no untoward symptoms. On the ninth day a barium-meal examination showed a small para-oesophageal hernia without oesophageal ulceration or stricture. The stomach and duodenum were normal. We have been unable to trace the patient for a follow-up.

Case 2.—A 4-gravida, 3-para aged 32 attended the antenatal clinic at 20 weeks; the estimated date of delivery was January 8, 1952. She was a thin woman and complained of nausea, heartburn, and retching dating from the first month. No abnormality was found on clinical examination. At subsequent visits she reiterated these symptoms, for which a variety of alkaline medicines gave little relief. During the last trimester she emphasized that the heartburn was much worse at night, was better when she got up to vomit, only to recur when she lay down. From the thirty-eighth week the pain was noted to radiate up to the neck, and there was occasional dysphagia. On January 4 she vomited a few ounces of bright-red blood and was admitted to hospital. She responded fairly well, being nursed propped

up and given a light diet. Vomiting was only occasional, and labour on January 8 was uncomplicated, as was the puerperium. On the seventh day a barium-meal examination revealed a simple sliding hiatus hernia. The stomach and duodenum were normal. When seen in September, 1952, she had very occasional heartburn. A barium-meal examination was entirely normal.

Case 3.—A 2-gravida aged 40 was admitted to hospital on April 2, 1951, for a gynaecological operation. On routine questioning about her pregnancies, she stated that during the first pregnancy, 13 years previously, she had suffered from severe heartburn and vomiting from the sixth week. From the seventh month she had had to sleep propped up. So severe was the pain when she lay down. Symptoms cleared up with the onset of labour ("I never had a sick labour"). The second pregnancy, five years later, was "like a repetition of the first." After her pregnancies she kept fairly well until she became obese. In recent months she had experienced several attacks of heartburn, "indigestion," and vomiting relating to posture, being worse when lying down or stooping. She sometimes vomited "lumps like liver." A barium-meal examination revealed a large Type I hiatus hernia with marked regurgitation of stomach contents when in the prone position. Reduction and repair of the hernia was undertaken in the thoracic unit of another hospital. She has since been symptom-free, and was last seen in September, 1952.

Case 4.—A primipara aged 25 was admitted to hospital as an emergency case on February 5, 1952. She was 36 weeks pregnant. Her previous health had been normal. She had had slight morning sickness from the first month of pregnancy. From the fifth month she suffered from recurrent "burning" substernal pains, especially when prone at night, with occasional small vomits. During the month before admission the vomiting, though more frequent (sometimes ten times a day), was not copious. The patient was nursed propped up in bed. A normal diet was fairly well tolerated, but heartburn and vomiting recurred at intervals. A barium-meal examination on February 13 showed a Type I hiatus hernia, without complications. By February 20 the vomiting had become more persistent, and, after failure of medical induction, surgical induction of labour was undertaken. The progress of labour was unsatisfactory; vomiting became very severe, but there was no haematemesis. Dehydration and ketosis necessitated intravenous fluids, and labour was terminated after two hours in the second stage, by episiotomy and low forceps extraction under local analgesia. The puerperium was uncomplicated. She was well and symptom-free in May, 1952.

Case 5.—A primipara aged 25, 36 weeks pregnant, was admitted to hospital on February 15, 1952, as a case of rheumatic heart disease. She had been well until about 20 weeks, when she began to suffer from heartburn, retching, and occasional vomiting, especially at night, relieved by sitting or standing. Between the twenty-eighth and thirty-sixth weeks her exercise tolerance deteriorated, she became orthopnoeic, and she slept propped up at night. Henceforth, the heartburn, retching, and vomiting concerned her much less, although still present. On February 2 chest screening was undertaken, and a barium swallow confirmed enlargement of the left antrum and, concurrently, a small Type I hiatus hernia. Caesarean section under epidural anaesthesia was performed because of severe pre-eclampsia. There were no puerperal complications. A barium meal in September, 1952, failed to demonstrate a hiatus hernia.

Case 6.—A 2-gravida, 1-para aged 34, whose previous health had been good, was admitted as an emergency case on February 2, 1951, being 28 weeks pregnant. There had been severe vomiting during the first trimester in both pregnancies. The second pregnancy was further complicated by epigastric pains, which were particularly severe as pregnancy advanced. Vomiting was almost continuous for four days before admission, when she was noted to be thin and dehydrated, with ketonuria. The vomit was blood-stained. She was nursed sitting up in bed, and given parenteral fluids

and a continuous intragastric milk drip. A barium meal on February 5 showed a large Type I hiatus hernia without complications. She was discharged home symptom-free, and was subsequently delivered at term at another hospital. In July there was still slight indigestion, and a barium meal showed that the hernia was still present but was much smaller.

Case 7.—A primigravida aged 23 was admitted as an emergency case on December 7, 1950, when 35 weeks pregnant. There had been slight nausea and vomiting during the first trimester, and then no complaint until heartburn and vomiting began at 20 weeks. Symptoms were worse when lying down at night, and were relieved by sitting up. After a severe bout of vomiting, she was admitted to hospital. Dehydration required drip therapy, and she was discharged symptom-free on the seventh day. Symptoms recurred, but were mild until January 11, 1951, when she was admitted in labour. Labour was inert, there was continuous post-xiphoid pain, and frequent vomiting of small amounts of stale blood occurred. Intravenous fluids were given, and normal delivery followed. The puerperium was uncomplicated. In May she complained of dysphagia and had lost 28 lb. (12.7 kg.) in weight. A barium meal showed a hiatus hernia with an oesophageal stenosis immediately above it, about 2 cm. in length. This was later confirmed by oesophagoscopy, during which the oesophagus bled easily. The stricture was subsequently successfully resected.

Case 8.—A 2-para aged 40 had her first pregnancy in 1931. It was characterized by severe vomiting throughout and severe nocturnal post-xiphoid pains related to posture. Vomiting during labour had been severe, but was absent in the puerperium. The second pregnancy, in 1943, was like a repetition of the first. In recent years she had become plump, and the post-xiphoid pains had returned; being worse at night and on bending forwards, but were relieved by alkalis, vomiting, or sitting up. A barium meal in July, 1951, revealed a fairly large hiatus hernia.

Case 9.—A primigravida aged 24 was admitted on September 25, 1950, complaining of pains in the right iliac fossa, and persistent nausea and vomiting. Laparotomy revealed a 16 weeks pregnancy; a simple cyst of the right ovary was removed, together with a normal appendix. She remained well for six weeks, then began to suffer from severe nausea and vomiting, especially when lying down and after meals. On readmission on March 3, 1951, she was dehydrated, and 24 hours later she had a small haematemesis. Persistent vomiting necessitated almost continuous intravenous fluids. A barium-meal examination on March 8 revealed a Type I hiatus hernia with probable oesophageal ulceration. Surgical induction of labour was undertaken, but the first stage was inert, and she continued to vomit blood-stained fluid. As the maternal condition was deteriorating labour was terminated by caesarean section after 48 hours. A barium swallow on the twelfth post-operative day revealed marked functional improvement of the cardia, with little tendency to regurgitation of barium. A small tubular hiatal protrusion was still present, but only in the optimum position. There was no evidence of ulceration. In May, 1952, the patient was still complaining of nausea, heartburn, and occasional vomiting.

Discussion

Rigler and Eneboe (1935) have shown that the association of hiatus hernia with pregnancy is common, but they were unable to demonstrate any correlation between gastric symptoms and the presence or absence of hernia.

On consideration of the manner in which hiatus hernia can produce symptoms these findings are unexpected. It is possible that hiatus hernia in pregnancy is often overlooked for a variety of reasons. In current teaching concerning vomiting in pregnancy, neurosis is often cited, and some of the symptoms of hiatus hernia do suggest a functional illness. Further, the vomiting caused by hiatus hernia frequently ceases when the patient rests sitting up in bed, and

may cease to vomit throughout her stay in hospital, thus testing the credulity of her medical attendant.

A radiologist needs skill and experience to demonstrate a hiatus hernia. Resolution is rapid in the puerperium, and attempts to make a post-partum diagnosis may be unsuccessful because of the diminution in size of the hernia, or even its disappearance. Rigler and Eneboe (1935), Bourgeois and Hood (1949), and Schnepf (1943) all commented on this feature, our experience of which has been similar.

It is not intended to claim that hiatus hernia always causes trouble in pregnancy, or that such a hernia is always responsible for heartburn, vomiting, or haematemesis. We have seen cases illustrating the contrary.

It would seem that there is a need for a large-scale investigation to ascertain the role of hiatus hernia in heartburn and vomiting of pregnancy.

Summary

The association of hiatus hernia with pregnancy is described.

Nine cases with symptoms attributed to a hiatus hernia in pregnancy are reported.

The literature is briefly reviewed.

The need for further investigation is recognized.

We wish to thank Dr. J. M. Naish, Mr. W. M. Capper, Mr. P. Phillips, and Professor H. J. Drew Smythe for permission to publish these cases, Professor G. Gordon Lennon for helpful advice and criticism, and Dr. G. R. Airth, who performed most of the x-ray examinations.

In his annual report the Medical Director of the Central Middlesex Hospital, Dr. Horace Joules, states that despite efforts to reduce the surgical waiting-list it still stands at well over 1,000. This number had been somewhat lessened by the co-operation of several other hospitals which had taken over large numbers, but last winter's fog and the subsequent high incidence of influenza had caused such a demand for acute admissions that the number waiting for surgery had risen to its previous height. Dr. Joules said that it was known that several London hospitals had practically no waiting-list, and he suggested that the time had come to evolve some system of transfer of cases for elective surgery between one hospital and another. A committee had been set up to inquire into the out-patient position, and had agreed that any further increase in numbers must be avoided. Closer association between practitioners and the hospital had been maintained by meetings of local health liaison committees and clinical meetings and courses. The opening of a new mass x-ray unit, domiciliary visiting, and the provision of additional beds had ensured early treatment of new cases of pulmonary tuberculosis. The association with the Middlesex Hospital had been strengthened by an agreement to continue undergraduate teaching at the Central Middlesex Hospital for a further 10 years, and by a scheme to exchange senior registrars after they had two years' experience in their own hospital.

TREATMENT OF TETANUS

BY

J. H. MCINTYRE, M.D.

Grey Hospital, Greymouth, New Zealand

In an article on tetanus successfully treated with gallamine triethiodide ("flaxedil") Smith and Thorne (1952) advocate the use of this drug. They state that relaxation is secured on a steady level and that respiratory depression is less marked with gallamine triethiodide than with D-tubocurarine, especially in the conscious subject. It is to be noted, however, that the period elapsing between the infecting injury and the onset of symptoms in their case was at least ten days, so that the prognosis would be relatively good.

Recently we have had in this hospital two cases of severe tetanus in children in which the periods elapsing between injury and the onset of symptoms were under a week, being in one case four days and in the other six days. Both of these children died, one in 24 hours and the other in three days, despite treatment with gallamine triethiodide and the usual treatment with sedation, antitoxin, and antibiotics. Gallamine was not conspicuously successful in either of our cases in relieving spasm, although used in much the same doses as in the case of Smith and Thorne, and, in addition, we found it apt to cause respiratory embarrassment.

Case 1

A girl aged 4 was admitted to Grey Hospital on December 12, 1952. The mother stated that the child had cut her left thumb in the garden on some glass six days previously. She now complained of neck stiffness and was unable to open her mouth. On the morning of her admission facial spasm became apparent. On examination the pulse was 120 and the temperature 98.4° F. (36.9° C.), although this rose to 102° F. (38.9° C.) within a few hours. The mouth could not be opened more than about 0.5 cm. Risus sardonius was present. Some stiffness of the muscles of the back was apparent, and within an hour of admission two spasms occurred. On the child's left thumb a deep infected laceration was seen.

A diagnosis of tetanus was made and 20,000 units of antitoxin was given, followed by a further 60,000 within six hours. Crystalline penicillin in doses of 500,000 units, later increased to 1,000,000, was given six-hourly. As further spasms were occurring an intravenous saline drip was set up and 5 mg. of gallamine was given intravenously and 20 ml. intramuscularly. This caused a temporary cessation of respiration, and mucus had to be removed with a suction apparatus. The pulse remained steady throughout the episode. Oxygen was given by nasal catheter, and the child recovered sufficiently to talk. About one hour later two further tetanic spasms occurred, which necessitated the addition of 1 ml. of thiopentone to the drip, and gallamine was required. Despite this, several convulsions occurred. As additional sedation 30 ml. of alcohol was introduced into each vacoliter, limited to two vacoliters daily. On the third day (December 15) the child had an exceptional severe convulsion and died. Immediate restorative measures failed, as also did cardiac massage for one hour. Through out, the child was "specialised" by the medical staff.

A total of 27 ml. of thiopentone and 350 mg. of gallamine was given in the three days that the child lived. In addition 4.5 ml. of paraldehyde was also given, and intravenous alcohol. Despite this treatment she had convulsions of moderate or less severity, on an average twice or three times an hour. Respiratory embarrassment occurred seven times, and

on occasions artificial respiration was necessary. Oxygen was often required. Mucus in the air passages was very troublesome and required frequent suction. Some 180 mg. of gallamine was given intramuscularly and 170 mg. intravenously; the doses varied from 5 mg. intravenously to 20 mg. intramuscularly. *Clostridium anti* was grown from swabs taken from the wound when was cleaned.

Case 2

On January 22, 1953, a boy aged 7 was admitted to Grey Hospital. He was quite rigid, was unable to open his mouth, and was perspiring freely. He complained of abdominal pain, and the muscles of the back were very rigid and in spasm. His parents gave a history of his having jumped into a spike of wood in the grass four days previously. The wound had healed. The boy was quite conscious; his temperature was 99.2° F. (37.3° C.), and pulse 140. He was given 40,000 units of antitoxin, and as clonic spasms were most continuous a slow intravenous saline drip was set up and 40,000 units of antitoxin and 80 mg. of gallamine were introduced into each vacoliter. In addition 1,000,000 units of penicillin was given four-hourly. Thiopentone, 0.5 ml., was given as an initial sedative into the tubing of the drip. A dose of 80 mg. of gallamine in the first vacoliter and 40 mg. in subsequent vacoliters was decided upon. Later it was found necessary to give additional gallamine intravenously, the dose being relatively small. Later it was found necessary, however, to increase the dose of gallamine to 80 mg. and finally to 120 mg. in each vacoliter.

Atropine sulphate, 1/200 gr. (0.32 mg.) intravenously, had previously been administered, but even so his breathing became very bubbly. A further 1/200 gr. (0.32 mg.) of atropine was given. For the first few hours the convulsions were relatively few, but as time went on they increased in number and severity, so that 10 hours after admission he was having almost continuous clonic convulsions, and anaesthetic doses of thiopentone were required. Although he was in hospital for only some 23 hours before he died, he had numerous mild and many severe spasms. A total of 29.5 ml. of thiopentone and 404 mg. of gallamine was given intravenously in an effort to suppress his convulsions. This in addition to antitoxin, 80,000 units, and penicillin, 1,000,000 units four-hourly. Although his breathing was very bubbly, respiration was not arrested and no artificial respiration was required. The boy died the morning after admission, death being due to sudden heart failure.

Discussion

These two cases do not make impressive reading. They tend to bear out the axiom that tetanus occurring within a week of injury is invariably fatal. In the first instance we had the impression that gallamine caused some respiratory embarrassment, but this was not confirmed in the second patient, who was, however, desperately ill on admission.

Abel (1934), in a study of the path of conduction of the toxin to the central nervous system, indicates that this occurs by way of the blood stream. He also suggests that the tetanus toxin is altered into or liberates in the cord a substance which has a lethal effect on the vital centres.

The dose of sedatives could not be reduced in either of these two cases without causing severe suffering. Penicillin, even in doses of 1,000,000 units four-hourly, did not seem to affect the course of the disease. Antitoxin serum in doses of 80,000 units in the first twelve hours likewise seemed to have little effect.

It can only be concluded that the present methods of treatment of tetanus in cases occurring within a week of injury are ineffective, and that, in view of the fact that 35 cases of tetanus occurred in New Zealand last

year, recourse should be had to the routine active immunization of all children against tetanus.

I bring these cases to the notice of the public health authorities, both in the United Kingdom and in New Zealand, as so often in minor injuries one is in doubt whether the injury requires a prophylactic injection of antitoxin or not. In view of these two fatal cases it would seem to be worth while to include antitetanic inoculation at the same time as routine immunization against diphtheria is being carried out.

My thanks are due to Dr. B. M. Dallas, Dr. E. E. Tilson, and Mr. S. Barclay, the surgeon superintendent—the last-named for his efforts at resuscitation of Case 1. I also thank Mr. B. Heine and Mr. R. D. Lockhart for their constant attention to these cases.

Medical Memoranda

Stasis of the Large Bowel Secondary to Acute Cholecystitis

It is generally recognized that acute inflammation of the gall-bladder may be accompanied by upsets of large-bowel function leading to distension and constipation; the extreme degree to which distension may proceed, simulating large-bowel obstruction, is worthy of greater emphasis than it usually receives, and is well illustrated by the following two cases.

CASE 1

A married woman aged 72 had been operated on four months previously for a strangulated right inguinal hernia, and had made a smooth recovery. Two days before her present admission she had had an attack of vomiting, during which she had been examined at a London teaching hospital but had not been detained. She complained of abdominal pain of two days' duration which was situated mainly in the right side of the abdomen. There was anorexia and she had passed neither faeces nor flatus for three days.

On examination her temperature was 101° F. (38.3° C.), pulse 110, and blood pressure 130/80. The tongue was furred. The abdomen was distended, with maximal and marked distension in the right flank; the caecum was palpable, and above this was a tender mass. Rectal examination was negative. A plain x-ray film of the abdomen showed much distension of the caecum and ascending colon. The diagnosis was thought to lie between an attack of acute cholecystitis and a perforated carcinoma of the ascending colon; in view of the attack of vomiting two days earlier the former was considered more likely.

Operation.—A right paramedian incision was made. The caecum and the ascending colon were distended to at least twice their normal size, but there was no organic obstruction. The distension extended to that portion of the ascending colon which lay in contact with an acutely inflamed distended gall-bladder; gall-stones were present. Cholecystectomy was performed and the abdomen closed with drainage. The patient made an uneventful recovery.

CASE 2

A married woman aged 80 had had attacks of abdominal discomfort associated with distension and relief by the passage of flatus during the past year. She had had abdominal pain for three days; the pain was mainly in the lower abdomen and was described as being "windy" in character. She was constipated and had not passed flatus for three days. Her abdomen felt as if it had become "blown-up." There had been some retching but no vomiting.

On examination her temperature was 98° F. (36.7° C.), pulse 112, and respirations 24. The tongue was moist.

The abdomen was tensely distended, maximally in the sub-umbilical zone, which was very prominent, tight, and tympanitic. Some degree of tenderness was present in the mid-line below the umbilicus. Intestinal sounds were heard. The release phenomenon was absent and Murphy's sign was negative. There was no jaundice. Some constipated faeces were found in the rectum; there was no pelvic tenderness. A plain x-ray film of the abdomen showed distension of the large bowel round to the sigmoid colon distally. The suspicion of an inflammatory lesion was aroused, but in view of the negative Murphy sign it was thought that the appendix would be the seat of the inflammation if the diagnosis of large-bowel obstruction was proved incorrect and an inflammatory lesion was present.

Operation.—A right paramedian incision was made. The large bowel was distended as far as the sigmoid colon, but there was no organic lesion in it. The gall-bladder was acutely inflamed; an area close to its fundus was near to gangrene. Cholecystectomy was performed. The gall-bladder contained numerous small pigment calculi. The abdomen was closed with drainage.

COMMENT

The extreme degree of abdominal distension made this the most prominent physical sign in each of these cases of acute cholecystitis. The presence of marked distension together with constipation in patients aged 72 and 80 years makes one incline towards a diagnosis of large-bowel obstruction. In Case 1 the correct diagnosis was considered, but in Case 2 it was excluded as Murphy's sign, which was specifically tested, was negative. In this case the degree of distension was quite remarkable and was not regarded as likely to be produced by anything save mechanical obstruction, especially as intestinal sounds were heard on auscultation.

Most of the standard textbooks of surgery make passing mention of bowel distension and constipation when discussing acute cholecystitis, but the extreme degree, with its misleading implications, to which this may proceed is not emphasized enough. Kiely (1949), however, includes intestinal obstruction in his differential diagnosis of acute cholecystitis. The larger books naturally make more mention of the condition. Aird (1949) writes: "There is a flatulent distension of the right side of the abdomen after 36 to 48 hours (Wilkie), and sometimes the whole right side is tense." Maingot (1948) also mentions distension of the caecum and ascending colon; his further comment, "While in others the ballooned caecum may suggest a diagnosis of acute retro-caecal appendicitis or obstruction of the large intestine," is particularly apposite in regard to Case 2, in which these diagnoses were considered to the exclusion of that of acute cholecystitis. Finally, Morley (1947) writes: "Owing to the reflex inhibition of intestinal movements there is constipation and considerable distension, most marked in the colon."

Comparison of the Male Toad and Hogben Pregnancy Tests

Numerous papers have been published showing the reliability of pregnancy tests on toads, but none which compared the Hogben test with the male toad test. Although male toad tests are in common use in other countries there seems to be an impression in this country that it is less accurate than the Hogben test. The figures given below suggest that it is equally reliable and has several advantages.

Methods.—Early morning urine is concentrated by Scott's method (1940). Then 2.5 ml. of the concentrate is injected

subcutaneously into a female *Xenopus laevis* toad and 2 ml. into a common British male toad (*Bufo bufo*). Three hours after injection urine is obtained from the cloaca of the male toad with a blunt Pasteur pipette and examined microscopically for spermatozoa. One male toad is tested. The jar containing the *Xenopus* toad is inspected the following morning for eggs. If the result is negative a second toad is injected and the test read on the following day. If this result is positive the negative result on the first toad is discounted (Landgrebe and Hobson, 1949).

RESULTS

Both Hogben and male toad tests positive	181
"Negative" Hogben, "positive" male toad test	200
Positive Hogben, negative male toad test	19
	0

In over 95% of cases both tests gave the same result, and in no instance was the Hogben test positive and the male toad test negative. Of the 19 cases in which the male toad test was positive and the Hogben test was negative, 18 proved to be pregnant. Seven were early pregnancies, and the Hogben test later became positive. Two were late pregnancies, in the fifth month. One case had a history of several miscarriages, but did not abort in the present instance. Eight patients aborted a few days after the test. The nineteenth patient was not pregnant, but had a fibroid; the Friedman test was negative; after removal of the fibroid the male toad test was negative. A Friedman test was done on 6 of these 18 cases, and was positive in all.

The results strongly suggest that the male toad test can detect a lower level of gonadotrophin in the urine than the Hogben test, as shown in very early pregnancy, late pregnancy, and impending abortion, in all of which conditions the urinary gonadotrophin is probably low. The number of impending abortions detected by a comparison of the tests is striking.

ADVANTAGES OF THE MALE TOAD TEST

1. Comparison with the Hogben test shows it to be equally accurate and, in fact, more sensitive.
2. The test can be read in three hours. The Hogben test takes 24 hours, and if the first toad is negative a result cannot be given for 48 hours.
3. Only one toad is required. In a random series of 200 Hogben tests performed in three months in this laboratory, 16 gave a negative result on the first toad and a positive result on the second. That is, an error of 8% would have occurred by using one toad only.
4. Male toads are useful for dilution tests for a suspected hydatidiform mole. Half a dozen toads can be injected at the same time with different dilutions, read after three hours, and the appropriate dilution injected into a rabbit on the same day. The unreliability of the reaction of the *Xenopus* toad and the time it takes to react compare unfavourably with the male toad for this purpose.
5. The cost and trouble of maintaining male British toads are much less than for *Xenopus* toads. Their initial cost is much lower and the necessary equipment much cheaper. The care of the male toad is simple (Law, 1949). As only one toad is used for a test, and it can be used again within a week if necessary, a much smaller stock of male toads than of *Xenopus* toads is required for the same annual number of tests. The male toad pregnancy test is within the scope of the smallest laboratory.

I wish to acknowledge my gratitude to Dr. M. Haines and Dr. H. P. Ferreira for demonstrating the technique of the male toad test.

Reviews

SURGICAL TREATMENT OF CHILDREN

The Surgery of Infancy and Childhood: Its Principles and Techniques. By Professor R. E. Gross, M.D., D.Sc. Drawings by Etta Piotti. (Pp. 1,000; 1,488 illustrations and 567 figures. 80s.) Philadelphia and London: W. B. Saunders Company. 1953.

This is a most important and useful book—and incidentally, as prices go nowadays, remarkably good value for money with its great size and lavish illustrations. No surgeon who treats children should be without it. In it are recorded the methods and results of one who has unrivalled experience in certain directions, and who in addition is one of the greatest of surgical technicians. It is an extremely personal work, the author giving his own opinions and experiences, seldom wasting time in quoting those of other people. The writing is simple and clear, without that polysyllabic pomposity that is the besetting fault of so much American medical writing. There is a notable absence of vague and oracular statements and of unsubstantiated opinions: in fact, the only ones I have noted are in the very small part of the book not written by Dr. Gross himself. The book is inevitably incomplete, since no man can cover the whole of surgery, even if limited to one age group. There is nothing about orthopaedics, about the nervous system, about hare-lip and cleft palate, tonsils and adenoids, or lymphatic glands. This must have caused the author some difficulty in deciding on a title; a difficulty which another great individualist, H. O. Thomas, solved by putting out much of his work as "Contributions to Medicine and Surgery."

On the surgery of the digestive and circulatory systems of the young this book is at present supreme. It is so because of the combination of Dr. Gross's qualities and the American habit of hustling special cases to special centres, in contrast to the British one of treating them locally. The really remarkable results set out could be obtained in no other way than by this concentration of cases under the care of a highly specialized and skilled team. The opinions of Dr. Gross on his own situation are not very easy to make out. He is against adding paediatric surgery to the number of officially recognized specialties; and when we consider the closed-shop mentality and the rather bogus mystique that characterize some of them we see his point. On the other hand, he considers that "our larger communities and many of our academic centres can support a group who are particularly interested in these problems." If this means that there should be paediatric surgeons, but not many of them, and that they should try to set a standard rather than establish a monopoly, the reviewer cordially agrees.

There is a short but sound section on anaesthetics, in which it is interesting to note that the fashionable use of muscle relaxants is strongly condemned and the opinion given that they have no place in the surgery of the young.

Excellent as this book is, there is no doubt that it would be improved by taking notice of work done outside the United States on the rapidly developing section of surgery of which it treats. Those who work elsewhere on similar lines must feel a longing to raise many questions and discuss many points. What, for instance, is the explanation of 20% of failures in that simple ligation of the ductus arteriosus which is found so satisfactory in Britain? Is the reason for not using the "intussusception-prolapse" technique, which we find cuts an hour off the time of recto-sigmoidectomy for Hirschsprung's disease, ignorance of the technique published in England long before the much clumsier device of Hiatt to which the author gives a reference?

If they are not unaware of what is happening in England and Sweden, how is it that in Boston they are satisfied to give a sufferer from hypospadias the power of urinating normally only at the age of 15 years or more? Is there any objection to the conception of the "covered anus"

and the "ectopic anus," which workers here have found so helpful in classifying and treating deformities in this region? Dr. Gross, as a result of much investigation, holds that hormone therapy is useless in treating undescended testicles, but would not this opinion be strengthened by reference to the anatomical work on which it can be securely based? And on the subject of anatomy, why not set out exact indications for the extent of Rammstedt's operation, which may not be needed by anyone of the experience of Dr. Gross, but which can be very helpful to the less expert?

I have read this book with great admiration and benefit—but, it must be admitted, with occasional irritation at its insularity.

DENIS BROWNE.

SPLENOMEGALY

Hypersplenism and Surgery of the Spleen. By William Dameshek, M.D., and C. Stuart Welch, M.D. (Pp. 84; illustrated. \$10.) New York: Grune and Stratton, Inc. 1953.

This book is highly original in its presentation, content, type, illustrations, and binding, but it is a convenient book to handle and a most valuable one to browse through. Its pages are of card and each page gives a diagram or table with a few explanatory phrases. It is really a bound pictorial demonstration of the American Medical Association exhibit on the same subject which was awarded the Billings Silver Medal in 1950. The authors clearly and succinctly demonstrate the anatomy, histology, and physiology of the spleen, and diagrammatically present the evidence for splenic hormones. They list in a table of names and dates the historic development of our understanding, such as it is, of splenic anaemia and other forms of splenomegaly, and they detail and criticize in the clearest possible fashion the nomenclature of those splenomegalies which are accompanied by cytopenia. The symptoms of hypersplenism, as the authors interpret the term, and the results of treatment, with diagrams and coloured photographs of the operation, are presented in the same tabular way, and the authors also consider haemolytic anaemia and thrombocytopenic purpura. There is a fully classified list of the causes of splenomegaly and the method of investigation of splenomegaly is covered too.

Having read the book, one feels that one has attended a lecture, beautifully illustrated by lantern slides, but given by an inaudible lecturer. I have the impression that it would be a difficult book for a student or a general practitioner to study with the purpose of learning about the diseases of the spleen that it covers, but it is an admirable synopsis of facts about the spleen and would provide valuable lecture illustrations for a teacher of undergraduates.

The chief interest of the book is in the technique of its presentation. Anyone interested in medical books or medical education should try to find access to it (its cost is 10 dollars). Among other attributes it possesses that of showing how a complicated case history can be reduced to 100 words and a diagram without loss of accuracy or detail.

IAN AIRD.

CHEMOTHERAPY

The Sulphonamides and Antibiotics in Man and Animals. By J. S. Lawrence, M.D., M.R.C.P., and J. Francis, M.Sc., M.R.C.V.S., with the assistance of A. Sorsby, M.D., F.R.C.S., and P. G. Scott, F.R.C.S. Second edition. (Pp. 482; 38 figures. £2 2s.) London: H. K. Lewis. 1953.

This book is described as a second edition, but since it was previously Lawrence's *The Sulphonamides in Theory and Practice* it is better regarded as a new book. It follows the usual plan of describing first the properties of individual drugs and then discussing their use in the treatment of different kinds of disease. The earlier chapters on the sulphonamides are excellent, and together with the glossary of trade names in the appendix will enable the reader to sift the truth from the present-day flood of advertising matter in this connexion. On the other hand, these drugs are overdone in some parts of the text. It is surely

not worth while nowadays to devote nearly five pages to the sulphonamide treatment of otitis media. They also figure largely in the section on peritonitis, which cites no authority later than 1947.

It must be difficult, particularly for four authors in Manchester, Brisbane, London, and Exeter respectively, to produce an up-to-date book on so rapidly developing a subject, and, although isoniazid has just got in (in the appendix), other recent work is missing, and parts of the book "date" to several years ago. There is also some understandable lack of correlation; aureomycin is "rarely" bactericidal on page 17 and "bactericidal in therapeutic concentrations" on page 146, and *Ps. pyocyanea* on page 154 becomes *Ps. aeruginosa* on page 268. The bibliography runs to 41 pages of references, and much of the text seems a rather uncritical compilation. The reviewer is quoted as having stated that penicillin has reduced the mortality of actinomycosis from 30 to 20%, but the authors do not mention that this referred only to the thoracic form of the disease. (He also, by the omission of an initial, becomes two different people in the reference list.) There is no discussion of synergism and antagonism between antibiotics, and a lack of emphasis on the present inconstancy of bacterial sensitivity, particularly to the newer drugs. It is useless nowadays to prescribe by rule-of-thumb methods, particularly for chronic infections of the air passages or urinary tract. Laboratory tests are an essential guide to successful treatment, and a statement to the contrary made in the preface should have been amplified or explained in the section describing such tests.

It is inevitable that a book on what is now so vast a subject should be incomplete. Despite its omissions, this is a useful work of reference, as well as a generally reliable guide to therapy for the general practitioner, some specialists, and the veterinarian.

L. P. GARROD.

MEDICINE IN THE U.S.S.R.

La Médecine en U.R.S.S. By Dr. I. Lazarevitch. Preface by Dr. Jean Paraf. (Pp. 217. No price given.) Paris: Les Iles d'Or. 1953.

The great merit of this book is its objectivity. Written by a woman doctor of Russian birth but trained in France, it covers every aspect of Soviet medicine and is based entirely on recent official documents. It is impossible to describe here the details of organization, but the general impression left on the reader is that of a gigantic bureaucratic system planned on paper to the last detail but in practice failing in co-ordination and showing more regard for Communist ideology than for either patient or doctor. But there are some principles underlying the plan which indicate—to a Western mind at least—why it cannot work.

The first three chapters are devoted to an examination of what may be called the "Pavlov Creed," which by an official decree must dominate every branch of science, especially medicine. Many university professors have been deprived of their office and publicly denounced because they have shown independence of thought. It appears that certain theories propounded by Pavlov, who died in 1937, have been adopted by the Party as sacrosanct. The effect of this is that there is growing up a generation of medical teachers not free to question these theories, and of practitioners who are not allowed to know that in the view of scientists outside Russia no theory is sacrosanct. Moreover, in the *Meditsinski Rabotnik* of October, 1951 (official journal of the Ministry of Health), appears the following statement: "One of the essential duties of Soviet medicine is to establish the primacy of Russian savants in the different domains of medical science." Many examples are given in the book of the ridiculous claims that have been made in obedience to this decree. They must be seen to be believed.

There are some queer anomalies in the system. For example, the columns of the official medical journal seem to be open to severe criticism of the administration. Again, all doctors on qualification are immediately assigned to posts in various parts of the vast Soviet territory. There is no question of choice, and frequently the doctor on arrival finds the place very uncongenial and quite often no

arrangements have been made for his accommodation. The result is that a considerable percentage of those assigned leave without permission. As there is no private practice in the Soviet it is difficult to understand what happens to these doctors. I can cordially recommend this book to anyone who wants to know what a really planned bureaucratic medical service is like.

ALFRED COX.

ENZYMES AND ANAPHYLAXIS

Enzymatic Concept of Anaphylaxis and Allergy. By Z. Z. Godlowski, M.D. (Cracow), Ph.D. (Edin.), M.R.C.P. (Edin.). Foreword by Professor A. Murray Drennan, M.D., F.R.C.P. (Ed.), F.R.S. (Ed.). (Pp. 120; 17 figures. 15s.) Edinburgh and London: E. and S. Livingstone. 1953.

Dr. Godlowski's theory is that, in the process of sensitization to an antigen, specific proteases are formed in certain cells. These enzymes will break down only the specific antigen, and break this down only to the stage of toxic proteoses.

The nature of the reagin, in the serum of allergic patients, that produces the Prausnitz-Küstner reaction is indeed a problem. Any theory should be considered, even when it postulates highly specific proteolytic enzymes which have not been shown to exist. But Dr. Godlowski also applies this theory to anaphylaxis, including passive anaphylaxis. The quantitative work of Kabat and his colleagues has shown that the sensitizing agent in passive anaphylaxis is almost certainly ordinary antibody.

In the second part of the book Dr. Godlowski maintains that certain eosinophilic cells are formed in the intestinal mucosa after absorption of foreign protein. The evidence for this is unconvincing and no explanation is given of the acquired affinity for eosin.

Some of the statements in the book are questionable: it is usually supposed that no breakdown of protein occurs in lysis, such as lysis of red blood cells by specific antiserum and complement (p. 5); there is no evidence to suggest that agglutination is due to the viscosity of newly formed protein molecules localized on the surface of bacteria or cells (p. 5); the definition of a haptene (p. 4) is wrong.

J. R. MARRACK.

ABERRANT BEHAVIOUR

Encyclopedia of Aberrations. Edited by E. Podolsky, M.D. Foreword by Alexandra Adler, M.D. (Pp. 550. Price \$10.) New York: Philosophical Publications. 1953.

The sketches of corsets and high-heeled shoes on the dust-cover and the title of the book suggest, and presumably are meant to suggest, that this is a comprehensive work on sexual deviations. This might be permissible on the hypothesis that the neuroses and all other mental disabilities are caused by disturbance in the development of the sexual function. But the validity of this hypothesis is not claimed, and sexual, social, religious, sensory, and other types of "aberrational behaviour" are described. The subjects chosen are dealt with by providing a simple definition or, when detailed consideration is called for, by reprinting an article previously published in a psychiatric journal. The selected articles are by representatives of the Freudian discipline of psycho-analysis.

The word "encyclopedia" is clearly inappropriate, as the terminology used by non-psycho-analysts is left out entirely. But even the psycho-analysts may complain about the omissions and so may "the intelligent laymen as well as the expert in interpersonal relations" whose requirements the editor has in mind. Transference, insomnia, sleep walking, trance states, impotence, vaginismus, and neurosis are forgotten. The number of neologisms is remarkable. Triakadekaphobia (irrational fear of the number 13), hade-phobia (the delusion that one has committed the unpardonable sin), and philonasm (obsessive interest in fads) are examples. The hotch-potch of good and bad, fact and theory, contained in this expensive volume has little value for the general physician or psychiatrist who possesses a reliable medical dictionary.

E. A. BENNET.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 17 1953

CHRONIC GASTRIC ULCER

In their important review of the treatment of chronic gastric ulcer published this week in our opening pages, Dr. B. F. Swynnerton and Mr. N. C. Tanner stress the importance of considering gastric and duodenal ulcer separately. There is much to suggest that different factors are concerned in the causation of gastric and duodenal ulcer, and certainly their surgical treatment presents different problems. To provide an authoritative opinion in this field needs a particularly wide personal experience, and there are few centres where one individual has been responsible for nearly 500 patients with chronic gastric ulcer over seven years. This was possible in Mr. Tanner's gastric unit at St. James's Hospital.

Swynnerton and Tanner report a series of 498 patients with chronic gastric ulcer treated between 1940 and 1946. Of these, 262 had medical management after an active chronic ulcer had been diagnosed gastroscopically, while in the surgical series there were 254 patients; 18 patients appeared in both series. The posterior aspect of the upper part of the lesser curve was found to be the position of predilection for gastric ulcer in women, and ulcers in the pyloric antrum and canal constituted only 0.8%, as compared with 13.5% among men. In both sexes ulcers were found much more commonly on the posterior, rather than on the anterior, aspect of the lesser curve.

In the surgical series partial gastrectomy was the operation of choice initially with an antecolic Polya-Hofmeister, but this has now been replaced by the Billroth-I type, an operation which is considered a simpler and perhaps more physiological procedure. The surgical mortality for the whole series was 6.3%, but most of these deaths occurred during the first five months of intensive night bombing on London, and in the last 350 cases on which Mr. Tanner has performed partial gastrectomy there have been only four operative deaths, an incidence of just over 1%. This is a particularly fine record, for they include thirty-eight emergency operations for haematemesis.

¹ Swynnerton, B. F., and Truelove, S. C., *British Medical Journal*, 1951, 2, 1243.

² Cain, J. C., et al., *J. Amer. med. Ass.*, 1952, 150, 781.

A careful follow-up was organized and information obtained from all but fourteen patients—a remarkable achievement. Sixty-one patients in the medical and sixty-six in the surgical series had died since their initial stay in hospital; seven deaths were due to cancer of the stomach, nine to tuberculosis, and the remainder to a wide selection of diseases. Among the survivors in the medical series, 32% had undergone gastrectomy for troublesome relapses and only one-quarter had remained free from symptoms. Among the surgical cases, out of every ten patients still alive the results had been satisfactory in eight, moderately successful in one, and poor in one. Among the unsatisfactory cases there were often severe associated medical conditions, such as chronic bronchitis and angina pectoris. Analysis shows that at St. James's Hospital partial gastrectomy is the most satisfactory treatment of chronic gastric ulcer available at present; it is indicated except in those patients with a short history or with troublesome concurrent diseases. It is interesting to note that Swynnerton and Tanner are not convinced that partial gastrectomy increases the risk of pulmonary tuberculosis. The evidence from the literature clearly points in this direction, and further studies are needed.

The experience of this series does not lend any support to the view that simple gastric ulcer is liable to malignant degeneration. The view is increasingly held, at least in Britain, that most so-called "ulcer-cancers" are, in fact, "cancer-ulcers," the initial lesion being a malignant degeneration with a secondary ulceration. In a previous paper¹ Swynnerton and Truelove showed that the sites of these ulcers conform with the distribution of carcinoma of the stomach and not with that of gastric ulcer, the majority of them being prepyloric in situation. But many workers in the U.S.A. still insist that a gastric ulcer carries a 10% chance of malignancy. While a safe distinction cannot be made by examining the peritoneal surface during operation for perforation, in ordinary clinical practice the combination of careful radiology, aided when necessary by gastroscopy, can safely distinguish between the two. Radiologically, an ulcer cleanly projecting from the lesser curve above the angulus is virtually never malignant; the differential diagnosis arises when the ulcer is situated within the line of the lesser curve. Size is of no real significance, small lesions often being among the most suspicious.

In reviewing the cases of gastric carcinoma which had developed during the follow-up, Swynnerton and Tanner did not consider that there was any evidence that they had begun as ulcer-cancers. They con-

cluded that, if there is an association between gastric ulcer and gastric carcinoma, it is because both lesions are apt to develop in the same type of degenerative mucosa. There is certainly some evidence that patients who have suffered from gastric ulcer are more liable subsequently to develop gastric carcinoma. Cain and his colleagues,² in a series of 414 patients followed up for five years after medical treatment of gastric ulcer, found that 4.9% had developed gastric carcinoma, an incidence which is many times greater than among the general population. From the histories it seemed highly probable that many of the carcinomas were unrelated to the original ulcer. Again, the removal of the ulcer by partial gastrectomy does not confer immunity from subsequent malignant disease. An interesting feature of the American series is that the proportion of completely successful cases treated medically, 20%, is almost identical with Swynnerton and Tanner's figure of 23.6%. The proportion of medically treated cases subsequently coming to surgery was also remarkably similar in the two series, being 32% and 33.8%, east and west of the Atlantic.

In spite of these impressive figures it is doubtful if it would yet be generally accepted that gastric ulcer is essentially a disease that must have surgical treatment, for there are many patients in whom gastric ulceration is an occasional episode. This is particularly true of cases of acute gastric ulcer, in which the prognosis, especially in women, is far better than with chronic ulcers. Although a high proportion of patients treated medically may have subsequent relapses, yet a high proportion of their follow-up years are entirely free from symptoms. For a persistently unhealed ulcer there can be no doubt at all that surgery is the correct treatment, but most clinicians would still prefer to give every patient with gastric ulcer an initial chance to respond to medical treatment, and indeed it is surprising how many may heal while on a hospital waiting-list. It is not uncommon for an ulcer to develop after physical or mental stress, particularly if associated with under-nutrition or some other disease, such as bronchitis. In these circumstances there is often much which can be done by the physician together with the almoner in improving the patient's circumstances and getting him readjusted to his individual problems.

There are many diseases in which the best results in any series of cases are achieved only by close co-operation between physician and surgeon. This is especially true of hypertension, thyrotoxicosis, ulcerative colitis, and peptic ulcer. In these condi-

tions the decision to operate should be agreed on by both the physician and the surgeon. The value of such co-operation is also to be seen when physician and surgeon collaborate in the analysis and publication of the results of treatment, as they have done in this series.

STATISTICS AND MEDICINE

The vital statistics of this country—and indeed of the world—owe much to the genius of Dr. William Farr, medical statistician at the General Register Office from 1839 to 1879, and it is fitting that in Somerset House has been held this week the first World Health Organization Conference of National Committees on Vital and Health Statistics, under the presidency of Sir Russell Brain. National committees on vital and health statistics are of recent origin. They were first suggested in 1948 at the Sixth Decennial Revision Conference of the International List of Diseases and Causes of Death, when it was recommended that governments establish such committees for the purpose of co-ordinating statistical activities within their own countries and to serve as links between national medical-statistical institutions and the World Health Organization. These national committees would have the function of studying broadly the problem of producing satisfactory national and international statistics in the field of health. National committees have now been established in some twenty-five countries, and a number of others, including Britain, though lacking a formal national committee, have co-ordinating bodies and arrangements that amount to much the same thing.

The conference, attended by delegates from some thirty countries and international organizations, and with the United Kingdom strongly represented, has been discussing the structure and functions of these national committees. In addition it has devoted time to questions such as the types of health statistics essential to countries at different stages of development, how those statistics are to be obtained, and what part W.H.O. ought to play in this connexion. Other topics discussed have been the extent to which health statistics might be obtained by sampling rather than by more traditional methods, and the national implementation of international regulations on vital and health statistics, particularly in relation to death certification and the classification of diseases.

The conference has been dealing with topics somewhat remote from clinical medicine. Indeed, it is a criticism sometimes made that vital statistics in general provide little of interest or of direct value to the majority of medical practitioners. There is

no doubt an element of truth in this, for the general practitioner and the hospital consultant, going about their daily affairs, find little need to delve deeply into national and local vital statistics. Statistics are unpopular but necessary: they are troublesome to collect and compile, some of them are difficult to understand without the requisite training, and they have a habit either of failing to provide a convincing answer to the question asked or, worst sin of all, of contradicting preconceived ideas and long-held beliefs. Moreover, not even the most enthusiastic advocate of vital statistics would claim that statistical tables of births, marriages, and deaths make exciting reading. Yet vital statistics are not a mere academic luxury. They have a very real practical value in almost every field of medicine. A knowledge of prevalent infectious diseases and causes of death, for instance, is useful to most doctors, and may be gained from a scrutiny of the vital statistics section in this *Journal* each week.

One of the topics discussed at this W.H.O. conference was how to secure a wide appreciation of the value of vital statistics and how to obtain the co-operation of those who could supply needed data. Perhaps the answer lies not only in giving medical students instruction in statistics, their sources, their value, and their limitations—as suggested by Professor Bradford Hill at the recent First World Conference on Medical Education¹—but also in trying to present vital statistics in a way that will appeal not only to statisticians but also to medical men, who are after all the people most concerned with the true import of those statistics. We are frequently reminded that, when undertaking a piece of research likely to require statistical analysis, the medical worker should consult a statistician at the beginning rather than at the end if effective collaboration is to be achieved. But the opposite also holds, and in the preparation and presentation of vital statistics, and indeed also in presenting the results of any investigation requiring statistical analysis, the statistician must likewise in turn seek medical advice, and ensure that what he is offering is of direct value to medical people and can be readily understood by them.

We have been fortunate in this country that our national vital statistics have all along been prepared under the supervision of men with a medical as well as a statistical training. The Statistics Division of W.H.O. also enjoys this advantage, but many national statistical offices are less fortunate, and have to rely on statisticians without medical qualifications. Unless these statisticians obtain the best possible medical advice, their contribution will not properly fulfil the

requirements of the medical profession whom they hope to serve. Vital statistics are essentially a medical rather than a statistical exercise; the medical profession supplies much of the basic data, and is the principal consumer of the resultant statistics: its tastes and needs must be consulted in deciding what statistics ought to be prepared and how they should be presented.

HEARTBURN IN PREGNANCY

The pregnant woman and her doctor do not always see things in the same perspective, and what the doctor considers a minor discomfort his patient may regard as a major affliction. This is particularly true of heartburn, which in some degree harasses two out of every three pregnant women. Formerly this symptom was blamed on hyperchlorhydria, but alkalis give inconstant relief, and in most pregnant women there is a notable reduction in the free and total gastric acidity, particularly during the second trimester.¹ Latterly, therefore, heartburn has been treated with small doses of dilute hydrochloric acid, but again with variable success. Williams² reported that in addition to a reduction in acidity there is a diminution of gastric motility in pregnancy, and it has been suggested that this, together with a neuromuscular disturbance at the cardio-oesophageal junction, allows regurgitation into the oesophagus. Williams therefore advocates the use of prostigmin to stimulate gastric motility and asserts that a single injection of 0.5 mg. may relieve heartburn for several days.

In a paper on page 864 of the *Journal* this week Dr. W. A. W. Dutton and Dr. H. J. Bland draw attention to herniation of part of the stomach through the oesophageal hiatus of the diaphragm as a cause of heartburn in pregnancy. A hiatus hernia may be asymptomatic, but they diagnosed nine cases in pregnant women within three years. The chief clinical features are heartburn, epigastric discomfort, and vomiting. The last may be persistent and severe, particularly during labour, and may culminate in a haematemesis, especially if peptic ulceration of the oesophagus supervenes, while the onset of dysphagia may betoken the formation of an oesophageal stricture. Diagnostic features are that all these symptoms are aggravated by lying down and by stooping forward, and become more severe in the last months of pregnancy. It might be thought possible that the bearing-down strain of the second stage of labour might precipitate a hiatus hernia, but four of the nine women in this series were primigravid. Moreover, all reports agree not only that the symptoms abate after delivery but also that the hernia may become much smaller or even be no longer demonstrable radiographically a few months after the end of the pregnancy. Nevertheless it should be borne in mind that hiatus hernia is commoner in later life, and it may be that a long-term follow-up of cases diagnosed during pregnancy might reveal that the condition recurs when the woman is older and fatter.

¹ Strauss, M. B., and Castle, W. B., *Amer. J. med. Sci.*, 1933, 185, 539.

² Williams, N. H., *Amer. J. Obstet. Gynec.*, 1941, 42, 814.

³ Osborne, W. W., and Foster, C. D., *ibid.*, 1953, 66, 682.

Heartburn in pregnancy may therefore be of some importance, and certainly the more severe and persistent cases, especially if associated with vomiting or dysphagia, deserve radiographic investigation. Not only will a certain number of cases of hiatus hernia be discovered thereby, but there will also be brought to light the uncommon case of more extensive diaphragmatic hernia, which carries a high mortality because it is rarely diagnosed before the onset of obstruction or strangulation.³

FEEDING CHILDREN WITHOUT MILK

In the western world mothers who are either unable or unwilling to feed their babies at the breast can rely on liberal supplies of efficient substitutes made from cows' milk. After the period normally occupied by lactation, it is considered sound policy for the child to be given large quantities of milk right up to adolescence. In many Oriental and tropical countries, however, cows' milk in any form is either scarce or absent. In order to bridge the gap between the end of breast-feeding and the development of digestive powers strong enough to cope with the normal local diet, vegetable substitutes for cows' milk are urgently needed. Countless lives are being lost because in many areas no suitable alternative is available.

The value of vegetable foodstuffs is generally considered to be limited by the quality of their proteins. Although human milk is not particularly rich in total protein, its contribution of some of the amino-acids—particularly tryptophan, cystine, and valine—is difficult to equal from vegetable sources. As a general principle mixtures of vegetable proteins are better than single proteins, because their strengths and weaknesses in the individual amino-acids tend to cancel each other out. In 1944 Italian workers in Rome found that foods made from mixtures of malted cereals were useful for infant feeding at a time of acute food shortage. Improved foods of this type, with their protein contents increased by the inclusion of soya flour, were brought to the notice of Dr. Harriette Chick, who confirmed their nutritional value in experiments with rats.¹

Further trials in which cereal mixtures were given to children in German orphanages and schools have now been reported by Dr. R. F. A. Dean.² Various combinations of barley, soya, and wheat or maize, sometimes fortified with milk, were given as part of the diet to about 25 newborn babies and to over 700 children of ages up to 11 years. The results seem hopeful, although it is clear that a perfect vegetable substitute for milk has still to be devised. For infants up to 1 year old about half of the milk in the diet could be replaced by some of the mixtures. For children from 1 to 2 years old at least two mixtures seemed nearly perfect substitutes for all the milk in the diet. For children aged between 2 and 11 years almost all the mixtures gave good results, but for optimum growth a small allowance of milk was necessary.

Difficulties in interpreting the results arose from illnesses unconnected with the diet and from variations in the methods of manufacturing the cereal mixtures. Thus

soya flour contains a trypsin inhibitor, which had to be removed or destroyed by heating before the foods could be efficiently digested. Some mixtures caused diarrhoea, or were regurgitated by the younger children. Apart from the trypsin inhibitor, suspicion falls on carbohydrate rather than on protein as the component affected by the mode of manufacture. For the present, therefore, it seems that theoretical considerations of protein requirements must take second place to the rule-of-thumb methods of food manufacturers in deciding whether human babies can subsist on cereal mixtures. More intensive investigation of the chemical changes occurring during the processing of milk substitutes is urgently needed.

LIVER BIOPSY

The practice of liver biopsy as a diagnostic procedure has increased in recent years, chiefly because of the introduction of new instruments most of which function on the principle of the trocar and cannula.¹⁻⁴ In assessing the value of the procedure two aspects of it have to be borne in mind. First is the question of its dangers and complications, which have figured largely in the literature produced by both its advocates and its antagonists, while secondly the adequacy of the biopsy material obtained and the accuracy of its interpretation deserve attention.

The dangers and complications may be grouped under the headings of haemorrhage, infection somewhere along the needle track, and, more rarely, bile peritonitis. Occasional deaths have been recorded.⁵ They are most commonly due to haemorrhage caused by tearing of the capsule or by bleeding into the liver parenchyma in patients suffering from diseases causing prolonged bleeding times. For this reason a prolonged bleeding or clotting time or a prothrombin time of less than 50% of normal should be contraindications to liver biopsy. Patients should be watched carefully for 24 hours after liver biopsy, and cross-matched fresh blood should be held ready for an emergency.

The technique chosen may increase or diminish the dangers from haemorrhage. In some methods the approach is intercostal and entails fixation of the needle, its rapid introduction and withdrawal, and cessation of respiration during the manipulation. When the liver is palpable below the costal margin an abdominal approach can be used, which is clearly safer in that the needle can more freely enter the liver.

The adequacy of the biopsy material obtained largely depends on the type of needle used, and with modern instruments cores of tissue some 2-3 mm. in diameter measuring 2-3 cm. in length can be obtained. The histological examination of a piece of tissue of this size is technically easy, and after suitable fixation affords opportunities for studying liver material in a fresh state, opening up a new field of observation which has obvious advantages over post-mortem examination. As a

research tool, therefore, in spite of its possible dangers, liver biopsy is useful. But the question of its value in practical diagnosis is a different one. Where a minute fragment of a large organ is being examined, the morbid changes must be diffuse and uniform in distribution if the appearances are to be representative. Again, if the pathological process is focal or if it varies considerably from one point to another, then interpretations may be inaccurate or even confusing. Thus in cases of toxic or virus hepatitis, or diffuse hepatic fatty degeneration or fibrosis, reasonably accurate results may be expected and interesting observations may be made. In cases of malignant infiltration, abscess formation, or any other focal abnormality the diseased area may be completely overlooked. It is therefore with the former group of conditions that most reports on the methods used are concerned.^{6,7}

At present it may be said that considerably more experience is required before a final judgment can be passed on liver biopsy. It is probably best confined to teams where both clinician and pathologist are experienced in its use and where proper precautions will be taken. In those circumstances it is an informative research procedure and, as a diagnostic test, useful chiefly in those diseases which produce diffuse changes in the liver.

BULBAR POLIOMYELITIS AND TONSILLECTOMY

The now well-known association between bulbar poliomyelitis and tonsillectomy, based chiefly on American experience, has been the subject of comment before in these columns, and there is general agreement that tonsillectomy should be postponed when possible until the risk of an autumn recrudescence in the outbreak is past. Although the evidence is conflicting on whether tonsillectomy predisposes to the contraction of poliomyelitis, there seems to be no doubt that, if the disease is contracted, it is more likely to be of the bulbar type. The risk of bulbar paralysis is considered to be up to sixteen times greater in patients who have had their tonsils removed. Some new work on this subject now comes from Australia.

Southcott¹ has made a detailed analysis of the data from the 1947-8 epidemic in South Australia; 103 paralytic cases were recorded, and of these 56 had had tonsillectomy. In this outbreak 40 cases of bulbar paralysis occurred, 35 in tonsillectomized patients, 4 in non-tonsillectomized, and 1 in a patient whose history of tonsillectomy was unknown. Only one patient had had recent tonsillectomy—a 15-day interval between operation and disease. Sixteen of the 35 patients had intervals of five or more years between operation and contraction of poliomyelitis. Although the number of patients with long intervals was small, it does seem that the effect of tonsillectomy lasts at least ten years. The age distribution of the bulbar and non-bulbar paralytic cases differed considerably. No child under 5 contracted bulbar paralysis, while 11 had non-bulbar paralysis; at ages 5-14 there were 28 cases of bulbar and 19 of non-bulbar paralysis. Sixteen of the 40 cases

of bulbar paralysis and 4 of the 63 cases of non-bulbar paralysis were fatal. No evidence could be obtained from the data to show that any relationship existed between tonsillectomy and non-bulbar paralysis or non-paralytic poliomyelitis.

OSTEOCHONDritis DISSECANS

Although osteochondritis dissecans is commonly regarded as a complaint of the young adult, it usually begins during adolescence. Most of the patients are males. In two series of cases of osteochondritis of the knee¹ and elbow,² reported by Green and Banks and by Roberts and Hughes respectively, 55 out of a total of 65 patients were boys, and all the patients were under 15.

The condition consists in an avascular necrosis of an area of bone lying beneath articular cartilage. Its cause is not known with certainty. The onset during adolescence, the many patients in whom several joints are involved, and the associated epiphyseal prematurity sometimes seen suggest that an endocrine disturbance may start up the condition. Of possible local causes trauma is thought the most likely, for there is a history of injury in many cases, most of the patients are males, and when the elbow-joint is affected it is usually the right.

An attack of locking during adult life may be the first indication of osteochondritis dissecans, particularly in the elbow-joint. In its early stages the condition must often escape recognition, for the physical signs and symptoms are easily overlooked. Indeed, in many cases there are no significant physical signs. Clear radiographs, sometimes giving special views, are essential.

Green and Banks have shown that the best treatment of osteochondritis dissecans of the knee in children is conservative. In their series this consisted in immobilization in a plaster-of-Paris cylinder or in a weight-relieving calliper for four to seven months. Full weight-bearing was permitted in plaster, but the joint was fixed in a position which prevented pressure on the osteochondritic area.

Healing occurs through revascularization by creeping substitution of avascular bone, even when there is evidence of sequestrum formation. The articular cartilage, which remains healthy during the early stages, must be protected from damage, for if it becomes fissured it may separate from the underlying bone and form a loose body. In the series reported by Green and Banks 25 out of 36 joints were treated conservatively; 18 patients were followed up for one year, and in 17 the results were excellent.

We record with great regret the death at Cardiff on October 13 of Sir Ewen Maclean, emeritus professor of obstetrics and gynaecology at the Welsh National School of Medicine. He was Chairman of the Representative Body from 1910 to 1912 and President of the B.M.A. in 1928.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

DISPATCH OF SPECIMENS

BY

MARTIN HYNES, M.D., M.R.C.P.

Clinical Pathologist, Royal Northern Group of Hospitals

The clinical pathologist is a bridge between the laboratory and the clinician, and can function only if he is as familiar with the patient's state as with his laboratory investigations. It is possible to churn out mechanical reports on swabs from unknown sources and blood from unknown diseases, but this is technicians' work, not pathologists'. Only when the pathologist is informed of the clinical aspects of the case can he select the most appropriate means of investigating the material sent to him, and interpret his findings to suggest a diagnosis or further investigations. The minimum information sent with every specimen should be:

The patient's name, age, and sex.

The source of the material, and when it was taken.

The investigations required.

The essentials of the clinical history, including details of any chemotherapy.

The probable diagnosis.

When the case is difficult the pathologist and clinician should at least consult by telephone, and should preferably meet at the bedside.

It is easy to forget to label a specimen, and thus to destroy all certainty that the pathological report truly belongs to the patient in question. The patient's name and the date and time of taking the specimen are essential, but it is wise to add to the label some other

details, such as the patient's age or the doctor's name, in case, as not infrequently happens in busy laboratories, two patients of the same or very similar names are being investigated at the same time.

Containers

Only four types of container, some throat swabs, and glass slides are needed for the great majority of specimens for pathological examination. All can usually be borrowed from the laboratory that will perform the investigations, for it is not reasonable to expect the general practitioner to clean and sterilize his own glassware. But, if he must,

glass containers are most conveniently sterilized at home by using the ordinary domestic pressure-cooker as an autoclave: 20 or 30 minutes' cooking at full pressure is adequate.

Liquid specimens should be placed in sterile wide-mouthed screw-capped bottles (Fig. 1); corks too readily come out in transit. Three types are required:

1. Plain sterile 1-oz. (28-ml.) bottles to contain blood for serum, urine, and other fluids for culture, etc. Wash the bottles well but do not use detergents, which grossly interfere with the Wassermann reaction and some other tests. Dry thoroughly and sterilize in the pressure-cooker with the caps lightly screwed on the bottles.

2. Oxalate bottles, for most biochemical estimations on blood. Add a knife-point of sodium or potassium oxalate to a plain bottle prepared as above.

3. Wintrobe bottles for blood counts and E.S.R. (sedimentation rate) determinations. In a sterile 4-oz. (7-ml.) screw-capped bottle, prepared as above, place 0.2 ml. of a solution containing 2 g. potassium oxalate and 3 g. ammonium oxalate in 100 ml.; evaporate to dryness in a warm but not hot place. A bottle thus prepared is for 5 ml. blood.

Faeces and sputum are best sent to the laboratory in waxed cardboard containers (Fig. 2) which can be burnt after use. These containers need not be sterilized.

Throat swabs can be purchased prepared ready for use, together with suitable containers for the post (Fig. 3). They should be sterilized before use (unless obtained from a laboratory) by pressure-cooking for 30 minutes.

Glass slides can be used straight from their box. If they are washed they should be dried with a freshly laundered grease-free linen cloth. There is no advantage in storing them in spirit.

Less frequently used containers, such as bottles of broth for blood culture, fluoride tubes for blood-sugar estimations, and jars of formalin solution for histological material, will certainly be supplied by the laboratory when they are required.

The Behring venule* (Fig. 4) conveniently replaces both syringe and container. It comprises a vacuum tube to which is attached a sterile needle protected by a sealed glass covering. When this covering is removed the vacuum is preserved by a simple valvular arrangement until, when the needle is

* Obtainable from Bayer Products Ltd., Africa House, Kingsway, London, W.C.2.

FIG. 3.—Throat swab tube, with wooden container.

FIG. 4.—Behring venule. The dotted line shows the position when the vacuum is released.

FIG. 1.—Bottle for liquid specimen, with wooden container.

FIG. 2.—Waxed cardboard container for faeces or sputum.

in the vein, the needle is flexed on the tube. When the valve is thus opened blood is drawn into the container. Venues are prepared to correspond to the plain bottles, oxalate bottles, and Wintrobe bottles described above, as well as one containing glucose broth for blood culture. Containers suitable for postal delivery can be obtained with the venues.

Specimens for Bacteriological Examination

The proper selection of material for bacteriological examination often demands a little thought. For example, pathogens are always present in the advancing edge of a lesion, whereas they may have died out in the necrotic centre.

TABLE I.—The Viability of Common Pathogenic Organisms on Swabs, etc.

VERY RESISTANT (Survive for days or weeks)	
Staphylococci	
Streptococci	
Bact. friedländeri	
Diphtheria bacillus	
Tubercle bacillus	
Actinomyces bovis	
Anthrax bacillus	
Clostridia (tetanus, gas-gangrene, etc.)	
Viruses	
Rickettsia (typhus, etc.)	
Fungi	
E. histolytica cysts	
VERY DELICATE (Survive at most a few hours when dry)	
Meningococcus	
Gonococcus	
T. pallidum (syphilis)	
E. histolytica, vegetative forms	
Trichomonas	
INTERMEDIATE (Survive two days or more)	
Pneumococci	
Bact. coli	
Salmonellae (typhoid and food-poisoning)	
Shigellae (dysentery)	
Haemophilus (whooping-cough, H. influenzae)	
Brucella (abortus and Malta fever)	

With a few exceptions (Table I) pathogenic bacteria readily survive the normal time of transit to the laboratory. Drying and exposure to sunlight are the most deleterious factors; chilling does little or no harm. Even gonococci and Trichomonas vaginalis survive for two days or more in Stuart's transport medium, which keeps them moist while suspending their animation by lack of oxygen. A further disadvantage of delay is that saprophytic bacteria may multiply in the specimen at room temperature and come to outnumber the pathogens. The pathologist can often counteract this process by the use of selective media, but it is better to avoid it. Finally, it is necessary to remember that sulphonamides and antibiotics may suppress causative bacteria without curing the patient. If specimens are not taken before starting treatment diagnosis may be greatly delayed or even made impossible. If specific therapy has already been started, this fact should be noted.

Blood Culture.—Many bacteria are rapidly killed by the patient's undiluted blood (the typhoid-paratyphoid group are an exception). Blood for culture should therefore be diluted immediately in bottles of the appropriate medium, using about 7 ml. blood to 50 ml. medium. Ordinary broth suffices for most bacteria, but *Str. viridans* prefers glucose broth. If rarer infections are suspected (for example, meningococcal septicaemia or brucellosis) the pathologist should be asked to supply the most appropriate medium. Special media, containing p-aminobenzoic acid, are also required if the patient is receiving sulphonamide therapy.

Blood culture demands a careful but not an elaborate technique. The patient's arm need be cleaned only as for any venepuncture, and sterile towels are not needed. The most common sources of contamination are imperfect sterilization or careless handling of the syringe and needle, re-

peated attempts to enter a vein, a leaky syringe, or careless exposure of the broth while the blood is added.

Faeces.—Faeces are best carried to the laboratory in a waxed cardboard container, which can be burned. A rectal swab is as efficient as faeces for the bacteriological diagnosis of bacillary dysentery, and may save valuable time in the diagnosis of enteric fever when faeces are not available. Helminth ova are generally found in faeces, but it must be remembered that threadworm ova are deposited outside the bowel on the perianal skin. They readily adhere to a piece of "cellophane" rubbed gently over the skin; the cellophane is sent to the laboratory in a screw-capped bottle.

Pus.—A throat swab of the pus, with a smear if more than an hour or two's delay is likely, is sufficient for the diagnosis of pyogenic infections. If tuberculosis or actinomycosis is suspected, 5 or 10 ml. of the pus should be sent to the laboratory in a sterile 1-oz. (28-ml.) screw-capped bottle.

Hairs.—The infected stubs of hair in ringworm infection need to be carefully chosen. Lengths of hair broken or snipped off are quite useless, for the infection is in the hair root. It is best to send the stubs to the laboratory in a piece of white paper folded in the manner of a chemist's powder packet.

Scales.—Scales of skin may be sent to the laboratory in a paper packet like hairs (above) or may be enclosed between glass slides held together by rubber bands. The scales must be chosen from the advancing edge of the lesion, not from the centre.

Pleural Fluid (and other serous fluids such as ovarian or ascitic fluid) should be sent to the laboratory in a sterile 1-oz. (28-ml.) screw-capped bottle. A part should also be sent in an oxalate bottle for cytological examination. If malignant cells are to be looked for the fluid should be diluted with at least an equal volume of 10% formalin solution (see next page).

Sputum is best carried to the laboratory in a waxed cardboard container, which can be burned. An early-morning specimen is best, but the patient should be reminded that saliva is useless. Sputum to be examined for carcinoma cells should be sent to the laboratory as promptly as possible. Formalin or other fixatives are deleterious.

Swabs.—The ordinary throat swab is a convenient means of sending a variety of materials to the laboratory for bacteriological examination. Most bacteria survive well on the swab (see Table I), but good smears cannot be made if it has dried. A smear should therefore be made on a slide (sterilized in the flame and cooled) if more than a few hours' delay is likely. Pernasal swabs, passed through the anterior nares along the floor of the nose to the nasopharynx, are at least as efficient as post-nasal swabs, as well as being less troublesome to take.

Urine.—A mid-stream specimen of urine from the male suffices for bacteriological examination, but a catheter specimen must be obtained from females if culture is required. In doubtful cases the women need not be subjected to the discomfort of catheterization until microscopy of an ordinary specimen of urine has revealed the presence of pus. Examination for tubercle bacilli should always be made on an early-morning specimen of urine. A 24-hour specimen is often desirable if it can be carried to the laboratory. An early-morning specimen is also required for pregnancy tests.

Haematology and Serology

Blood in ordinary oxalate bottles is of little use for any haematological examination except a simple haemoglobin estimation. Blood for counts and E.S.R. determinations should be placed in Wintrobe bottles. The amount of anticoagulant used is near the minimum, so the blood and oxalate must be thoroughly mixed by repeated inversion of the bottle at intervals for two or three minutes. Even the Wintrobe oxalate mixture soon distorts leucocytes; therefore two or three blood smears should be sent with the

specimen. It is important to remember that a too-thin blood smear always gives some information whereas one that is too thick may be completely useless. A smear is generally too thick if it does not peter out before the end of the slide. Blood in Wintrobe bottles can be used for haemoglobin determinations and red-cell counts for at least two days after taking the blood, but the leucocyte count begins to fall after a few hours and may be misleadingly low after 24 hours. The sedimentation rate is also spuriously low at periods greater than three hours after taking the blood.

Blood Grouping (including the Rh factor) is best done on blood allowed to clot in a plain bottle. The specimen must arrive at the laboratory within 24 hours of withdrawal if rhesus antibodies are to be sought for.

Blood for Serological Tests.—Blood for the Wassermann reaction, Widal reaction, and other serological tests should be allowed to clot in a sterile screw-capped bottle. Contamination of the blood should be avoided. Haemolysis, whether from water or spirit in the syringe or from bacterial contamination, vitiates the W.R. and many other tests. Blood from infants for the W.R., etc., is simply obtained by pricking the well-warmed heel and allowing the blood to flow into a Wright's capsule (Fig. 5).

FIG. 5.—Wright's capsule.

Biochemical Estimations

The majority of biochemical estimations on blood can be performed with either serum or plasma from oxalated blood. Serum is generally preferred to plasma, and is essential for a few estimations (Table II). Wintrobe bottles should not be used for blood for biochemical determinations; in particular, blood from them cannot be used for urea determinations. Most biochemical determinations are valid if done within a day or two of the withdrawal of the blood; the exceptions are indicated in Table II. The blood sugar can be satisfactorily estimated after 36 hours if fluoride is used instead of oxalate.

TABLE II.—Containers for Blood for Biochemical Estimations (Minimum quantity of blood 1 ml. except where indicated)

PLAIN OR OXALATE BOTTLES	
Bilirubin (minimum 2.5 ml. blood)	
*Chlorides	
Cholesterol	
*CO ₂ -combining power (minimum 5 ml. blood)	
Non-protein nitrogen	
Phosphatase (acid or alkaline)	
*Phosphates (minimum 2.5 ml. of blood)	
Proteins (minimum 2 ml. of blood)	
*Sugar	
Urea	
Uric acid	
PLAIN BOTTLES ONLY	
Serum calcium (minimum 5 ml. of blood)	
*Serum potassium	
*Serum sodium	
Thymol turbidity	

*Estimations marked thus must be made within two hours of withdrawing the blood.

Faeces for the occult blood test should be sent to the laboratory in the same way as bacteriological specimens. Other biochemical tests on faeces, urine, etc., are rarely needed in general practice. If any should be required, the advice of the laboratory should be sought before sending the specimen.

Histological Examinations

Material for histological examination must be sent to the laboratory in a fixative solution, otherwise autolysis may make interpretation of the sections impossible. The most

generally used fluid is a 10% aqueous solution of commercial formalin. Screw-capped jars of all appropriate sizes can be obtained. Larger pieces of material should be wrapped in gauze before being placed in their container.

Postal Regulations

Every effort should be made to send pathological specimens to the laboratory by hand, thus eliminating delay and minimizing the possibility of loss or breakage. The Post Office regulations permit pathological specimens to be sent by letter post to a recognized medical laboratory or a qualified medical practitioner. Sending such specimens by parcel post is absolutely prohibited. The material must be placed in a securely closed container, which must itself be enclosed in a strong wooden or metal box in such a way that it cannot shift about, and with sufficient sawdust, cotton-wool, or other absorbent packing to prevent any possible leakage from the parcel in the event of damage to the container. The packet must be conspicuously marked "Fragile with Care" and bear the words "Pathological Specimen." Figs. 1 and 3 illustrate examples of containers and outer boxes that comply with the regulations.

Next Article on Clinical Pathology.—"Venepuncture," by Dr. I. A. B. Cathie.

Refresher Course Book.—The first collection of articles in the Refresher Course for General Practitioners (fully revised) are available as a book containing 55 chapters, price 25s. Copies can be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

PREVENTION OF TRANSFUSION ACCIDENTS CONSULTING PATHOLOGISTS' GROUP CONFERENCE

The Consulting Pathologists' Group Conference was held at B.M.A. House on September 30. Professor D. F. CAPPELL was voted to the chair. Dr. J. G. GREENFIELD, Chairman of the Group Committee, presented its report, which was approved.

Dr. GEORGE DISCOMBE opened a discussion on blood transfusion, its dangers, and the precautions which should be taken. The form of the problem was determined to a large extent by one's clinical colleagues. It sometimes happened that blood had to be provided in a hurry, perhaps several times in a day. Since 1946 in his department they had transfused about 14,000 bottles. Some 6,000 patients had received blood, and among those 6,000 only about 6% had developed some sort of reaction. Ten recognizable haemolytic reactions were found. In two of these no cause was discovered; eight were ABO incompatibles. He had been brought up to believe that in many cases of incompatible transfusion death ensued, but in the cases of incompatible transfusion experienced in his department there had been no deaths.

For a long time they had used capillary blood for grouping and found it satisfactory. But their technicians had been instructed to look for the slightest deviation from the normal, and if this happened they immediately sought advice and help. Mistakes were analysed, and it was found that three mistakes were due to hurry, two were due to blunders made by an inadequately trained member of the laboratory staff who gave out blood to the wrong patient, and one was due to a nurse who had not read a label on the bottle. Laboratory administration had since been tightened up so that fewer people handled the blood, and recently a unit-recording system had been introduced. Thus mistakes were obviated whereby in one case two women with the same surname, one called Margaret and the other

Peggy, were confused. If a guiding statement was needed one required a serologist, regional transfusion officers, and at least two hospital transfusion officers to put their heads together and produce an agreed document. "I believe," he said, "that the main reason why I have not spent most of my time at the coroner's court is because I have kept a very close watch on my transfusion problems, even to taking over the cross-matching and doing it all myself, and also being available to my technicians for any help I can give them."

It was comforting to be given a set of rules by which to conduct one's practice, but he did not think one could ever frame rules in such a way as to make them perfect, and if they stuck to rules rigidly "sooner or later somebody will die in consequence." The choice had to be left to the individual consultant.

Too Much Blood Ordered

Dr. J. F. HEGGIE said that many of his views had been expressed in articles in the *British Medical Journal*. The pathologist had been given the responsibility of the blood banks as regards matching, supply, and delivery to the wards, as well as collaboration with his colleagues to make sure that the number of patients placed at risk was kept to the minimum. Often blood transfusion had been prescribed by quite junior persons when it was not necessary, and in view of some accidents they had been asked to look into the matter. It was found that the situation varied enormously in different regions. Generally, however, there was a tendency to order too much blood, and so a memorandum had been formulated instructing their colleagues on the risks which they were running and the greater serological care required in cross-matching blood in people who were having to be transfused for the second or third time. They had also asked that the element of urgency be so far as possible avoided.

The hospital officers concerned were told of the substitutes that could be used immediately; also that healthy young women suffering from abortion did not in general lose as much blood as might warrant transfusion. They were also reminded that the supply of blood was limited. The methods of grouping and matching in different laboratories had been reviewed, and the advisers to the Ministry were called in and a list of what were considered to be reasonable precautions and techniques was approved. If a hospital were large enough a resident pathologist should be employed. But there were many places in his region where the hospitals were small, and in those areas it had been ensured that a senior technician or a technician suitably experienced in blood grouping and matching should be available for emergencies. All this ensured that the standard of technique was good and that it was not a matter of having a house officer engaged who had merely been shown how to group and cross-match for a week or so.

In hospital administration the rules with regard to taking blood from the bank had been made more rigid. In his own hospital it had been arranged that no nurse should be allowed to handle a bottle of blood. The blood was grouped in the laboratory by an experienced technician who was supervising the work, and a check was carried out by the senior registrar or a registrar of experience. The bottle then passed, with the name of the patient and of the donor, to a central refrigerator, from which it was taken by a member of the medical staff. By this means the number of persons handling the blood had been reduced to the minimum—the one who checked and the one who gave.

Dangers of Domestic Refrigerators

In some general discussion Dr. T. V. COOPER pointed out the danger of using the ordinary domestic refrigerator for storing blood. In fact, unless there was a recording thermometer, any type of refrigerator might let one down very badly. Dr. J. C. BRUNDRET said that in Liverpool he had a fairly complex unit. He thought that to establish a rigid national procedure would be far more trouble than it was

worth. Generally speaking, a separate technician was responsible for the checking system. Not only was the blood carefully labelled but a register went with it and signatures were required. He thought that the handling of blood could not be restricted entirely to medical people, but it should not go beyond the qualified nursing staff.

Dr. R. A. SLADDEN complained of the unduly large amount of blood which was used in many cases. Often, where two or three bottles would be adequate, eight or ten were demanded. When they were asked in an emergency to match up a bottle of blood, this could be done reasonably quickly, but if six or eight bottles were required it obviously made a great difference. Many surgeons had built up a system of using very large amounts of blood, and, as most patients responded well to treatment, the success had been credited to the massive transfusion, but no control series had been taken. He also referred to the difficulty of attending to blood transfusion demands in small hospitals in the middle of the night. There were not at present enough really skilled technicians to cover the needs of all the hospitals.

Dr. S. C. DYKE said that there was one aspect of this matter which ought to have a wider publicity. His own principle was to make it as difficult for anybody to get blood out of his bank as out of a stone, unless they had very good reason indeed. The occasions when large quantities of blood were required were relatively rare, and that was an aspect of the matter which he would like to impress upon clinicians. The ultimate giving of the blood was the clinician's responsibility, and he thought the clinician should have much more cognizance of the dangers of giving too much blood, one of which was liver damage.

A Standard Procedure

The CHAIRMAN said that there was one recurring theme in this discussion—namely, the desirability or otherwise of having a standard method of doing the whole of the cross-matching and so forth. He felt that this was a rather important matter, and, while it would never, he imagined, be true that any standard method could be followed in every case, he thought it would be helpful to have resort to such a method when necessary. A procedure might be laid down which was considered to be the ideal procedure, and any deviation from it should be a matter for very careful consideration.

Dr. HEGGIE said that in the North-eastern Metropolitan Region they had had in use for the last eighteen months a memorandum of instructions on the lines which the Chairman had suggested. They had a scheme which they had regarded as ideal, and also they had suggestions for agreed limitations and minimal degrees. He thought that if this were carefully followed they would have a perfectly valid defence in any court proceedings which might follow in a particular case. One little-known complication in blood transfusion was caused by organisms which might be present in bottles of blood but gave no sign of their presence by change of colour or by haemolysis. He knew of three fatal cases as a result of these organisms, the patients dying from massive protein shock.

Dr. C. R. LANE, Dr. J. G. A. MCSORLEY, and Dr. C. J. C. BRITTON also contributed briefly to the discussion.

Journal Article

Dr. J. M. ALSTON referred to the article under the heading "Blood Transfusion Accidents," published in the *British Medical Journal* of August 15 (p. 390). The article was published under the name of the Consulting Pathologists Group Committee, and he wanted to know how far the Group was committed by what was stated in the article.

Dr. E. E. CLAXTON (Assistant Secretary) explained that the Group was in no way responsible. The article was written by Dr. Heggie at the request of the Group Committee, but it did not mean that the Committee was responsible for what was stated in the article.

Dr. ALSTON said that he regarded the article as a very good one. He was not expressing any criticism of the article, but he did not wish it to be taken as committing the Group.

Dr. DISCOMBE, in replying on the discussion, agreed that the domestic refrigerator was a source of great trouble. One point had not been mentioned. In cold weather the refrigerator went down well below freezing-point, and he had had on occasion to put an electric radiator in his refrigerator. With regard to hepatitis, there were so many subclinical cases that he doubted whether any proper assessment could be made on how far this condition was due to previous blood transfusion. He did not think they had many extravagant demands for blood.

ADVANCES IN PATHOLOGY

The 51st General Meeting of the Association of Clinical Pathologists was held in London from October 1 to 3. Twenty-six papers were read and there were 11 demonstrations. In this report prominence has been given only to those contributions likely to interest the general reader. Not unnaturally at a meeting of this kind, most of the papers were concerned with specialist and technical problems. On the second day Professor Dorothy S. Russell delivered her presidential address on "Further Advances in Pathology."

A Relapsing Diarrhoea

Dr. A. G. SHERA (Eastbourne) described what he claimed to be a hitherto unrecognized type of relapsing diarrhoea, characterized by an explosive early-morning diarrhoea with offensive yellow stools which are often streaked with blood. It was caused by Vincent's organisms from chronic infections in the mouth and tonsils which passed the acid barrier in the stomach and settled in the rectum or sigmoid, forming characteristic "strawberry lesions." The way was prepared for the inception of these lesions by an associated vitamin-C deficiency. Diagnosis was by examination of stained faecal films or films made from swabs taken from the strawberry lesions, and by a vitamin-C saturation test. Treatment was specific, with acetarsol and ascorbic acid orally.

Colonel H. R. GILMORE (U.S.A.M.C.) described the epidemiology and clinical and pathological features of epidemic haemorrhagic fever ("Korean disease"). There was no evidence of spread from person to person or through water and food. Russian and Japanese work suggested that the causative organism is a virus or rickettsia carried by a mite, *Laelaps jettmari*, which infests the common field-mouse. In contrast, American workers preferred to incriminate a trombiculid mite, since *L. jettmari* is most prevalent in Korea, where the incidence of haemorrhagic fever is low. But they had not succeeded in passing the disease to animals or chick embryos, and the causative agent and its means of transmission were still undetermined. There were no specific laboratory tests for the disease, though albuminuria was a constant finding and 90% of cases showed increased capillary fragility. Post-mortem findings were haemorrhages into the kidneys, right auricle, anterior pituitary, and occasionally the suprarenals. Apart from these more dramatic findings, there were also submucosal petechial haemorrhages throughout the gastro-intestinal and respiratory tracts.

Dr. G. J. CUNNINGHAM (London) described two cases of malignant hypertension in which aberrant renal vessels were found at necropsy. One of these aberrant vessels had become thrombosed, and the parts of the kidney supplied by it showed mild hypertensive arteriolosclerosis, while the rest of the organ, supplied by patent vessels, contained necrotic lesions of both arterioles and glomeruli.

Dr. A. A. G. LEWIS (London) described some studies he and Mr. L. P. LEQUESNE had made on the retention of salt and water in patients after surgical operations. The usual sequence of events in such patients might be divided into three main phases. During the first 24-48 hours after opera-

tion there was diminished water excretion, owing to release of pituitary antidiuretic hormone, probably as a result of emotional disturbances caused by the operation; this phase was accentuated by anaesthesia and the giving of morphine. Sodium retention occurred on the day of operation, and was due mainly to haemodynamic factors, although increased potassium excretion was associated with it. Thirdly, a second period of sodium retention usually began on the third day after operation, often separated from the earlier phase by a period of increased sodium excretion. The magnitude of the retention during this second period might be lessened by ensuring an adequate intake of potassium.

Limitations of the Test Meal

Dr. F. AVERY JONES (London) drew attention to the limitations of the fractional test meal in the diagnosis and treatment of gastric diseases, pointing out that the widely accepted normal range of acidity is based on findings in only 80% of Bennett and Ryle's series of healthy subjects. Achlorhydria was generally regarded as implying a gastric juice with a pH greater than 3.5, at which reaction, however, there was still about 0.3 mEq HCl per litre. There was little advantage to be gained from the routine use of test meals in cases of peptic ulcer, but they might help in the diagnosis of difficult cases with symptoms referable to the upper abdomen, in which radiological reports had been negative.

Dr. P. W. DARBY (London) described the results of a battery of liver function tests in 50 patients with rheumatoid arthritis and 45 hospital patients with non-hepatic disease; 23% of the rheumatoid and only 4.5% of the control group gave abnormal results to the bromsulphalein test, and 31% of the rheumatoid compared with 5% of the controls had an abnormal urinary coproporphyrin excretion. These differences were statistically significant, and suggested that there is a higher incidence of liver damage in patients with rheumatoid arthritis than in those with other forms of chronic ill-health. Drs. J. HARKNESS and C. DONOVAN (Portsmouth) confirmed previous reports that there is an increase in total ascorbic acid of the plasma with a greater proportion of reduced ascorbic acid during four hours after an injection of A.C.T.H. Injections of cortisone had no effect on the level of total ascorbic acid but did increase the proportion of reduced ascorbic acid. These changes could be used as a test of pituitary function, since by using an unvarying stimulus to the pituitary the ascorbic acid test indicated differences in individual responses. For example, the response in some psychotics was lower than in normal controls. Changes similar to those produced by A.C.T.H. were caused by electric convulsion therapy, emotional stress, and the administration of salicylates and phenylbutazone.

NEW ACADEMIC YEAR

FACULTY OF MEDICINE, SHEFFIELD

Professor L. J. WITTS, Nuffield Professor of Clinical Medicine at Oxford, delivered the opening sessional address to the Faculty of Medicine, Sheffield University, on October 8. He took as his subject "The Opportunities of Medicine."

Professor L. J. WITTS said that he approached the task of speaking at an inaugural meeting in the spirit of Lincoln's Gettysburg address, and, rather than exhort the student, he wished to express the responsibility of the teacher, to whom so much precious human material was entrusted. There was no lack of enthusiasm for teaching on the part of the staffs of our hospitals and medical schools; the question rather was what they were to teach, and this was intimately linked with the nature and purpose of the medical profession.

The medical curriculum had not changed except by accretion since the early 1890's, when Osler and his colleagues at the Johns Hopkins Hospital started the combination of a university education in anatomy, physiology, and other sciences with an apprentice type of teaching in general

medicine and surgery. Those who asked for more training in general practice, dermatology, or psychiatry did not usually wish to disturb this general framework. More radical reformers, however, would substitute statistics, semantics, logic, psychology, and anthropology for some of the present basic sciences, and an even more revolutionary change was to reorganize the curriculum entirely, so that the basic sciences, pathology, and clinical medicine were taught simultaneously instead of in succession. In fairness it should be said that, with all its faults, the present curriculum does work. It was no good planning curricula which could be run only by completely dedicated teachers. For most teachers in medical schools, practice, research, and administration were the major preoccupations. This was right if we believed in the great didactic of Comenius, that our objective should be to seek and find a method of instruction by which teachers may teach less and learners may learn more.

The Status of Doctors

Despite the delightful pictures of Luke Fildes and Robert Louis Stevenson and the querulous letters in the medical press, there was no doubt that the medical practitioner was better off now than ever he was. The future maintenance of this status depended on our own efforts. Medicine must remain a learned profession, and it would be unwise for the universities to spend too much time on technological studies. Doctors are the most important group of biologists in the population, and in the recent war the contribution by doctors to greater efficiency in the fighting Forces and in industry was very great. This influence should be maintained in peacetime, for the great mass of the nation, including many of its leaders, was scientifically uneducated.

Medicine as a profession had three functions to perform—utilitarian, academic, and humanitarian. The humanitarian function required something corresponding to the minister's training in pastoral theology. It was doubtful if this was entirely a question of more hours devoted to the teaching of psychology and psychiatry. Patients and their relatives looked to the doctor for moral support in their hour of need, and most doctors, like their patients, still stood between two worlds, in a place where the orthodox creeds were no longer accepted but the need for a coherent philosophy remained. It was essential for the doctor to know something about religion, even if he did not believe it, and he should study the lives of great and good men, if only to carry out the Hippocratic injunction, "In purity and holiness shalt thou pass thy life." Much was learned from working with patients, for their heroism was often remarkable. Just as the doctor learned to transmit scientific knowledge, so it might be possible for him to transmit courage and serenity from his studies and his experience.

CHARING CROSS HOSPITAL MEDICAL SCHOOL

The inaugural session of Charing Cross Hospital Medical School took place at the neighbouring Royal College of Physicians on October 9. The chair was taken by Lord Inman and the address delivered by Admiral of the Fleet Sir Philip Vian.

Domiciliary Medicine for the Student

The Dean of the School, Dr. E. C. WARNER, reported a year of consolidation and progress. The level of success at examinations was high, and there were many individual distinctions. But the aim of the School, said Dr. Warner, was not so much to prepare the students for examination as to give them a grounding in the principles and practice of medicine so that they went out properly equipped for the work they had to do. To be a successful doctor something more was needed than learning: the human touch must be acquired. Arrangements had been made for students to attend domiciliary midwifery cases and also to be attached to general practitioners so as to see the family doctor's work at close quarters. One difficulty in a hospital like Charing Cross was to obtain experience in paediatrics owing to the smallness of the child population in the neighbour-

hood, but this had been met, at least in part, by association with a hospital in the East End of London. In view of building delays the intention of the hospital to move to a site outside London has so far not been realized.

Sir PHILIP VIAN gave an address in which he breezily related some experiences in the Royal Navy, both in peace and war. He said that his association with the medical profession had been chiefly with officers in the Royal Naval Medical Service, whom he had found uniformly kind, conscientious, and able men. For a short period during the war he had his own personal surgeon—a man who threw up his practice in Essex in his eagerness to serve in the Navy, and after several refusals by the authorities succeeded in persuading them to allow him to accompany Sir Philip Vian on his staff, and in that capacity took part in the Normandy landings. He also spoke of his pleasant association with Charing Cross, where his sister had until lately been on the nursing staff.

The vote of thanks was proposed by Professor W. J. Hamilton and seconded by Mr. H. G. Everard Williams.

BRITISH POSTGRADUATE MEDICAL FEDERATION

The inaugural lecture of the new session under the title "The Scientific Basis of Medicine," arranged by the British Postgraduate Medical Federation of the University of London, was delivered on October 8, in the Senate House, by Sir Henry Dale, O.M.

Need for a Broad View

The chair was taken by LORD WAVERLEY, who reminded his audience that the Federation, of which he was Chairman, embraced a number of scientific specialist institutes each providing higher instruction in a limited but clearly defined part of the general field of medicine and surgery. Since the tendency must inevitably be towards greater specialization it was becoming increasingly difficult for any student to keep abreast of the continually changing and developing basic knowledge in subjects outside his own specialty. It had therefore been decided four years ago to provide under the aegis of the Federation a series of lectures on the scientific basis of medicine. The lectures were intended for young research workers, primarily for specialists in training, and were designed to give them a knowledge of the scientific foundations of their subjects and to show something of the advance that was taking place.

Introducing Sir Henry Dale the Chairman said he was a doyen of medical science, to whom they would be happy to listen as often as he could spare the time to speak to them.

Sir HENRY DALE said he was rather diffident about giving this lecture, since it was almost identical with that which he had delivered three years ago on a similar occasion, and which had been published in full in the *British Medical Journal* (1950, 2, p. 1186) under the title "Scientific Method in Medical Research." He had, however, been persuaded by Sir Francis Fraser, Director of the Federation, who had used the argument that the audience would be almost entirely different from the one of three years ago. Referring to the programme of lectures arranged for the new session, Sir Henry Dale said, "Knowledge is advancing at such a rate in so many parts of a widening field that the supply of special topics seem likely almost to outrun rather than to fall behind the number of lectures which a session like this could manage to accomplish." Little more than thirty years ago the position was that the only hormone treatment known was by thyroid gland, and no vitamins had been identified; less than twenty years ago there were no sulphonamide drugs and no antibiotics. It was almost impossible to think oneself back to the helpless position of medicine in the face of many infections at that time. On the other hand, he was inclined to think that the triumphs of therapeutics might have claimed so much attention that too little might have been said of other remarkable changes that had been taking place. "What impresses me more and more about

the present position is that at last the whole of medical research activity, whether in the ward or in the experimental laboratories, is moving forward on a common front."

Sir FRANCIS FRASER, in proposing a vote of thanks to the lecturer, gave it as his opinion that the new series of lectures could not have been better inaugurated than in the way they had heard that evening.

Nova et Vetera

THE ROYAL CHEST HOSPITAL

One by one the little lamps are being extinguished, and it will not be long now before the Royal Chest Hospital is snuffed out. Commonly regarded as the first chest hospital in the world, it owes its existence to the enterprise of one man.

Dr. Isaac Buxton (1775-1825), of New Broad Street, was struck by the fact that, although there were separate hospitals for many diseases, and although deaths from pulmonary complaints were extremely numerous, yet there was no establishment where the treatment of pulmonary disease might have a "fair and persevering trial." His own partiality was for a moderate summer temperature of 60-65° F. in the wards all the year round, combined with skilled nursing, and he founded the hospital principally for that purpose.

Its first full name was Infirmary for Asthma, Consumption and other Pulmonary Diseases. In the course of time there were several variations on this theme, and in 1848 Queen Victoria bestowed the Royal title. Later the "Heart and Great Vessels" was also incorporated in the name, and cardiovascular disease has had its place in the hospital work ever since. In 1919 all the activities were telescoped into the title of Royal Chest Hospital. Sir Astley Cooper was interested and helped to secure the Duke of Kent as President, and in 1814 the Duke opened the Infirmary at 36, Union (now Brushfield) Street, Bishopsgate. It was a twelve-roomed house on a site now occupied by a tavern at one corner of Spitalfields market.

In 1832-3 it went first to No. 13 and then to No. 10 Artillery Street (now Lane) for fifteen years, to premises previously used as a dispensary. The house was in such a condition of insanitary squalor that for three years Dr. Ramadge, physician in charge, refused to admit in-patients, but he could not persuade the committee to improve the drains or water supply. In 1847-8 there was another move to 4, Dean (now Sun) Street, Finsbury Square, for about a year. Then in 1849 the hospital finally settled in the City Road in a house belonging to St. Bartholomew's Hospital.

Shepherds at the Angel

At that time residential terraces were springing up in the City Road, and there were already three hospitals on its south side. To the north, behind the new hospital, there were green pastures, and shepherds still guided their flocks through the two turnpikes in the road and refreshed themselves at the Angel Inn. Islington Spa and the entertainment halls in the locality were popular, but not so fashionable as they had been.

In 1862 the house was pulled down and a building more suitable for hospital use was erected. In 1876 further building was done to provide for the increasing number of out-patients, and in 1880 St. Bartholomew's sold their freehold and further extensions were made, completing the frontal appearance familiar to us with the later addition of a nurses' home and a pathological department behind.

In 1912 the tuberculosis dispensary for the boroughs of Islington, Shoreditch, and Finsbury was housed in the hospital, an arrangement which earned special praise from William Osler. In 1919 the hospital amalgamated with the Great Northern Hospital, which paid its debts and acquired a title, leaving the medical staff to continue their work independently and unimpaired until the second world war, when the whole of the front portion was destroyed by a bomb in 1941.

Pampered by Royalty

For material support in the early days the infirmary had the interest of the City Corporation, the City companies, and the City magnates, and for patronage it had the Royal Family. It was positively pampered by Royalty. Three Royal dukes in succession were presidents; Queen Victoria subscribed liberally and became a patron at a low ebb in its fortunes; other members of the Royal Family visited, and Princess Louise laid a foundation stone in 1876. Three princes of the blood presided at different festival dinners for raising funds; these were usually held at the celebrated London Tavern, Bishopsgate, where the ladies were callously relegated to a watching gallery until one day a rebel in the shape of Dr. Horace Dobell flouted the angry conservatism of the stewards and a very jolly evening ensued, with a benefit of £1,000 for the hospital.

The Early Physicians

Some of the early physicians were interesting personalities. Dr. Buxton started life as a nonconformist minister, then graduated in medicine at Göttingen. He was physician at the London Hospital for fifteen years, but there seem to have been strained relations with the governors at the time of his resignation. He succeeded in persuading several members of his philanthropic family to help the infirmary in different ways.

Dr. F. H. Ramadge followed Dr. Buxton as sole physician in 1820, and he also was possessed of a pioneer spirit. He very soon instituted a regular course of postgraduate lectures at the infirmary and started assembling a pathological museum, both of which pursuits must have been unusual at a non-teaching hospital in those days. It has been said that Ramadge was one of the first advocates of artificial pneumothorax for consumption, but the truth is just the opposite. He invented an inhaling tube for keeping the lungs well inflated, and he published many papers on the curability of consumption on those lines. He may have exaggerated the value of his instrument, but his methodical necropsy work had rightly convinced him that consumption was not so invincible a disease as most of his colleagues believed. Dr. Ramadge had disapproved of the Artillery Street house from the first, and was on very bad terms with the committee in consequence. After an exchange of offensive letters from both sides he yielded to pressure and resigned in 1847, full of resentment.

Dr. Thomas Davies was elected additional physician in 1825, and he was perhaps the most successful of the early medical staff. Having worked under Laennec for two years, he was adept at auscultation, and he did a great deal to promote the rational use of the stethoscope among practitioners in the City between the years 1825 and 1839, when he died. He also designed the first thoracic exploring needle in order to spare patients from paracentesis for purely diagnostic purposes. His postgraduate lectures were so renowned that the London Hospital invited him to repeat them and made a place for him as physician. They make good reading even now.

Dr. B. G. Babington was an early member of the committee, though not on the medical staff. In spite of this close connexion with the man who invented the glottoscope in 1829, it was not until 1866 that the hospital bought a laryngoscope, as the finished instrument was eventually named.

Subsequent physicians and surgeons maintained the reputation of the hospital, which already in 1862 was noted to be drawing patients from the home counties, the north of England, and Scotland. Among the names (other than those still alive) we find A. Leared, Herbert Davies, W. Hale-White (the first pathologist), Jonathan Hutchinson, A. Pearce Gould, Bertrand Dawson, and Symes Thompson, to whom I am indebted for some of these notes.

Teaching and Experiment

The postgraduate teaching started by Dr. Ramadge in 1822 has continued, off and on, ever since. In 1883 a medical school was included in the plan of the new building,

and in 1889 there was a public row when the medical staff were accused of using the hospital more for teaching and experimental purposes than for relief of the sick poor. One of the incidents in dispute was Moore's wiring operation for an aneurysm by Mr. Pearce Gould; another was an emergency tracheotomy performed by a house-surgeon.

Mr. Austin, the secretary of that period, was very popular with the humbler citizens of the district, who were fond of their cosy little hospital round the corner, and with his encouragement they collected one-sixth of its income, mostly in pennies. It was probably on his initiative that the board was progressive enough to admit representative "working men" as governors on a collective subscription of £10 from a group.

The Royal Chest Hospital has never had many beds. It started with 8 and ended with 80. There have been intervals when there were no in-patients at all, and in the last thirteen-year period after the wards were damaged and never repaired it has been possible to attend only to out-patients. The hospital has enjoyed the advantages of a compact, enthusiastic unit and suffered the disadvantages of smallness, whatever they may be. Next year nothing will be left except the scorched earth, a crowd of ill people, a few frustrated consultants, and some faithful members of the staff.

NORAH H. SCHUSTER.

Preparations and Appliances

A VEIN STRIPPER

Dr. ELIAS N. TSARDAKAS, Whittington Hospital, N.19, writes: In the modern and popular operation of vein stripping I have found the following modification of the Babcock instrument of great use. It has the following advantages: (1) The varying sizes of head allow for the wide range in the diameter of veins encountered; (2) the

great flexibility of the spiral spring stem—24 in. (60 cm.) long and silver-coated—facilitates the removal of veins, no matter in what direction they run; (3) the whole apparatus is very easily sterilized and stored, and will fit into an ordinary cigarette packet of 20; (4) it is manufactured very cheaply. The vein stripper has been made for me by Messrs. Allen and Hanburys Ltd., Wigmore Street, W.1.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Cancer and the Public

SIR.—Dr. J. F. Brailsford writes (*Journal*, October 3, p. 779): "One might think from the propaganda enthusiasts that there was a cure for cancer. . . . Whereas the truth is that we have no cure." He must know that for years it has been customary to talk about the results of treatment in terms of five-year "cures" or ten-year "cures," the word implying that the patient is apparently free of the disease over the period stated. It seems to me rather mischievous to infer, as Dr. Brailsford does, that the propagandists are misleading the public by telling them that cancer can be cured. What they do keep on telling the public is that treatment of cancer is improving and they should know about it. It is rather difficult always to avoid using the word "cure"; one is entitled to speak of the chances of being cured rather than in terms of "the percentage survival with no evidence of the disease." Few people are really interested in percentages.

Dr. Brailsford hardly serves his case by quoting Shakespeare, for the patients who had knowingly had cancer 7-10 years but failed to consult a doctor had indeed let cancer "feed on the pith of life." The poet saw the danger centuries ago, but we are still boggling at the idea that the public should be told some of the most pertinent facts about cancer.—I am, etc.,

SIDNEY RUSS.

London, W.C.1.

SIR.—The counsel of despair implied in Dr. James F. Brailsford's letter (*Journal*, October 3, p. 779) cannot be allowed to pass unchallenged, and one wonders whether it really represents his considered opinion. He must know that the fear of cancer is already present in the minds of the public just as the fear of having an abnormal baby is in the thoughts of every pregnant woman. It is to allay such fears that education may be of service.

When the figures of the British Empire Cancer Campaign's inquiry are analysed it will be seen that three-quarters of the doctors consulted did not even reply. To say, therefore, that the majority of general practitioners are opposed to lay education when only about 1 in 8 gave such an opinion is surely a false use of statistics.

Those who see many cases of cancer, however, would welcome any method of encouraging patients to seek treatment early, and if lay education can do this we would welcome it, for without holding out hopes of absolute cure quite a proportion of patients are spared considerable suffering for many years. No exaggerated claim has, in fact, ever been made for lay education; it is evident, however, that the lay mind must be educated to realize that what happened in the treatment of cancer 100 years ago should not be accepted for to-day. Or is Dr. Brailsford prepared to discredit the statistics of so many reliable centres all over the world? He surely would not advocate that patients with cancer should retire to some secluded spot and allow it unmolested "to feed on the pith of life." The reference to the curability of syphilis is somewhat inapposite, for surely neurosyphilis may be completely incurable even with the most violent treatment. Quite obviously the search for a cure for both syphilis and cancer must go on, but until then we must use every available method of treatment and suitable propaganda to combat them. Dr. Brailsford would surely subscribe to Montaigne's dictum, "To cure sometimes, to relieve often, and to comfort always.—I am, etc.,

E. D. GRASBY.

Pembury, Kent.

SIR.—To suggest, as Dr. J. F. Brailsford does (*Journal*, October 3, p. 779), that the removal of a carcinoma, without recurrence and with a patient leading a normal active life,

is no cure seems to me to be a terminological hair-splitting quibble. Two years ago I had a partial colectomy for a carcinoma of the colon. I live a perfectly normal life, and practise as a busy consultant surgeon. I am free of all symptoms. To suggest that I might as well not have consulted a surgical colleague because no cure can be held to occur merely by the removal of the affected area is, to me, just nonsense. I hope that others may benefit as I have, and nothing should be said or written to discourage them from seeking advice as early as possible. For obvious reasons I prefer to sign myself

A GRATEFUL PATIENT.

Television in Health Education

SIR,—The report of the General Practice Review Committee (*Supplement*, September 26, p. 103) includes some strong adverse criticism on the use of television in health education. The fact is that television is an extremely potent but delicate weapon for health education, and must be handled with great skill or its effect on the public will be deplorable.

If, as the report stresses, the use of this medium has not always been happy, it seems ungrateful not to mention at the same time how valuable a contribution television can make when expertly used, as in the three brilliant documentaries written by Dr. Cormac Swan—"Dangerous Drugs," "Family Doctor," and "Under Her Skilled Hand"—each of which perfectly fused instruction and entertainment and did the job they were designed to do.

I should be sorry to see a medium potentially so powerful in this field condemned and cast aside through a failure to learn from these documentary models.—I am, etc.,

London, S.W.1.

GUY WIGLEY.

Orthopaedic Care in Poliomyelitis

SIR,—Like Sir Reginald Watson-Jones (*Journal*, October 10, p. 828), I am glad that physicians, laryngologists, and anaesthetists are making so determined an effort to save the lives of patients severely stricken with poliomyelitis. At the same time I share his disquiet at the apparent tendency to equate the early care of the patient in danger of his life with the whole treatment of the disease. I, too, have seen the Welsh Regional Hospital Board's circular, and it is a disturbing document. Undoubtedly we must be prepared for a catastrophe such as has stricken Copenhagen—and it happens that part of the work on the design of the British cuirass respirator is being undertaken here by my colleagues Dr. Kinnier-Wilson and Dr. J. C. Scales. But I am beginning to wonder whether, in anticipating an epidemic of a kind that has occurred only twice in the history of poliomyelitis, there is a danger of neglecting to strengthen our resources for dealing with the disease as we find it in Great Britain and as it has occurred this year. In Coventry, for example, there has been only one death and only four patients requiring respirators. Even in Copenhagen the ordinary manifestations of poliomyelitis, paralysis of the limbs and trunk, and the ever-present tendency to contracture and deformity, were and still are important.

May I try to illustrate what I mean by reference to but one aspect of the early treatment of poliomyelitis—namely, the prevention of deformity? This word does not appear in the Welsh Board's document, yet the title is "Poliomyelitis" without qualification. Nevertheless, the prevention of contractures and deformity is of immense interest to those primarily concerned with their prevention and treatment—namely, orthopaedic surgeons. It was W. J. Little, a physician on the staff of the London Hospital, who, in 1838, founded the first orthopaedic hospital in London. He was well informed about the mechanisms of deformity, and wrote a remarkable book on those affecting the foot. There was a good reason for this; he himself had a deformity of the foot that was almost certainly caused by poliomyelitis. But I have not yet met a twentieth-century W. J. Little. Those interested mainly in the acute disease see before them a

patient who has paralysis and who is perhaps gasping for breath and unable to swallow; at this stage his joints are not stiff and his body is not misshapen. They are but dimly aware of what lies ahead; they have not seen the grotesque deformities that can occur; they do not appreciate the significance of, say, a little stiffness in the joints of the fingers.

Twenty years ago I saw many operations performed on bones, joints, and tendons for correction of paralytic deformity. Most of these operations are now obsolete. It was increasingly recognized that deformity can easily be prevented if what for the sake of brevity may be called orthopaedic treatment is started before contractures can develop—that is to say, in the first weeks of the disease. Furthermore, if late deformity was to be avoided, supervision of the patient was necessary over a period of years. Gradually a vast apparatus for dealing with crippling conditions, of which poliomyelitis is now one of the most important, was built up: the orthopaedic establishment (there are no fewer than 43 special hospitals) with its physiotherapy department and pool, plaster room and splint shop, hospital school, rehabilitation scheme, and follow-up clinics. Are we to understand from our brethren in Wales that all this is now of no consequence, or perhaps something taken for granted like the supply of electricity or water? If the orthopaedic surgeon and what he represents are excluded—as was done in Cardiff—a most vital element is missing.

In the report of the meeting mention was made of additional facilities, and no doubt they are needed. But, whatever form an epidemic may take, the place where additional facilities are most urgently required is the orthopaedic hospital. At the present time most orthopaedic surgeons are handicapped by long waiting-lists and by inadequate assistance. Yet theirs is the ultimate responsibility. The patient will come to the orthopaedic department or hospital at last, however many sorts of people may have dealt with him on his way there. I once visited a capital city of northern Europe where the role of the orthopaedic surgeon was to take charge of the victims of poliomyelitis at a time dictated by the physician who treated them in the early stages. I found the surgeon I met there was far busier with his cases of poliomyelitis than we are accustomed to be. He was expert in the sort of corrective procedures that most of us here had hoped never to practise again. Are we in Great Britain to go the same way? Already there are a few signs of it. They are there to be seen in the wards of our country hospital at Stanmore. We estimate that inefficient treatment in the early stages lengthens the patient's stay in hospital by one-third to one-half.

This interest in bulbar paralysis is welcome, yet although there is the potential threat in every case, the plain fact is that most patients with poliomyelitis escape it. It is becoming difficult now to hear the still small voice of common sense above the whirring of pumps and the whistling of tracheotomy tubes. Would it not be better to make a concerted effort to provide better treatment for every aspect of poliomyelitis, each member of the team contributing his own special skill for the benefit of those who have fallen victims to this dreadful disease?—I am, etc.,

London, W.1.

H. J. SEDDON.

SIR,—It is regretted that the British Orthopaedic Association should have gained the impression, as suggested in Sir Reginald Watson-Jones's letter (*Journal*, October 10, p. 828), that orthopaedic surgeons are in any way excluded from their rightful place in the treatment of poliomyelitis in Wales. It is only fair to point out that the special committee of consultants which met some time ago were dealing essentially with one aspect of poliomyelitis, that of the respiratory complications.

The recommendations in the memorandum to which Sir Reginald refers are additional to the already existing arrangements, which are described and which make special mention of the necessity for orthopaedic supervision.—I am, etc.,

Cardiff.

A. TREVOR JONES,
Senior Administrative Medical Officer,
Welsh Regional Hospital Board.

Succinylcholine Chloride for Casualty Anaesthesia

SIR,—We should like to suggest the following technique as a simple and effective method of obtaining adequate relaxation during manipulations in the casualty department.

A syringe, containing 100 mg. of succinylcholine chloride ("scoline") and fitted with a small-bore needle, is introduced into a vein on the dorsum of the hand and strapped in position. The hand is then placed across the patient's chest, where it can easily be reached by the anaesthetist while he is still holding the face mask in position. Light anaesthesia is obtained with nitrous oxide and oxygen from a Boyle's apparatus. As soon as consciousness is lost, 25 mg. (for an average healthy adult) of succinylcholine chloride is injected, and approximately 15 seconds later the surgeon commences reduction. This dosage gives excellent relaxation without causing complete apnoea. By the time the plaster has been applied, completely normal respiration is re-established and the anaesthetic is discontinued. The patient is now able to walk out of the theatre and may safely go home. Should momentary apnoea occur, this is readily dealt with by gentle compression of the rebreathing bag. If a check x ray is required, the patient is maintained on gas and oxygen while films are taken and developed. Should further correction prove necessary, the dose of succinylcholine chloride may be repeated.

We have used this method with success in small children, reducing the dosage of succinylcholine chloride according to the patient's size.

This method is particularly valuable in a busy casualty department where the shortage of nurses and recovery rooms renders it necessary to send the patient home as soon as possible.—We are, etc.,

TERENCE VAZ.

J. M. BISHOP.

Slough.

Bornholm Disease and Poliomyelitis

SIR,—Dr. Gilbert Dalldorf (*Journal*, August 1, p. 287) asks whether poliomyelitis and Bornholm disease ever occur simultaneously. As Bornholm disease is not notifiable, evidence on this point is probably scanty, so the following may be of interest.

Since the beginning of 1952 a group of 10 general practitioners, strategically selected to cover the city of Auckland, have been reporting to me every week details of non-notifiable infectious diseases seen in their practices. Their figures represent about one-fifteenth of the cases attended by doctors in the population of 302,560 within 10 miles of the centre of the city. The table below shows the actual numbers of cases of Bornholm disease seen by this group, as compared with the number of poliomyelitis cases occurring in the same area.

Month	B'holm	Polio.	Month	B'holm	Polio.	Month	B'holm	Polio.
1952			1952			1953		
Jan. . .	9	0	Jan. . .	3	41	Jan. . .	8	9
Feb. . .	22	4	Feb. . .	1	49	Feb. . .	0	7
Mar. . .	18	5	Mar. . .	2	69	Mar. . .	2	4
Apr. . .	4	5	Apr. . .	0	45	Apr. . .	1	7
May. . .	4	0	May. . .	2	38	May. . .	6	0
June. . .	1	2	June. . .	0	17	June. . .	5	0
July . .	2	20	July . .	0	17	July . .	2	2

It will be noted that Bornholm disease waned as the poliomyelitis epidemic developed, and has shown a tendency to recrudescence as the epidemic subsided. The last case of poliomyelitis previous to February, 1952, occurred in April, 1951. The poliomyelitis incidence in the city on the present occasion reached 107 per 100,000.—I am, etc.,

Auckland, New Zealand.

A. W. S. THOMPSON,
Medical Officer of Health.

Poliomyelitis Vaccine

SIR,—The international committee on poliomyelitis, which recently met in Rome, has focused attention on the need for an effective vaccine against this disease. If it were ever to be shown that poliomyelitis and any other disease con-

sistently occurred in different areas, or were in any way mutually exclusive, such a discovery would intensify the hope that we might eventually find a virus which stands in relationship to poliomyelitis as does vaccinia to variola. This would indeed be one of Nature's kindest gifts.

Every summer and autumn, nowadays, we are called to see a higher proportion of the fevered in our practices than used to be the case. Behind each such call is the fearful hope that "it is nothing really serious." Dr. A. P. Grimby (*Journal*, September 12, p. 628) has recently stressed the importance of realizing that many of these cases may in fact be non-paralytic poliomyelitis, even in the absence of an epidemic of paralytic cases. Dr. Gilbert Dalldorf (*Journal*, August 1, p. 287) has asked for reports of any evidence that Bornholm disease and poliomyelitis do not commonly occur in the same district at the same time. Of equal importance would be reports from areas, consistently free from poliomyelitis, about the nature and epidemiology of any outbreaks of pyrexia of unknown origin and transient duration which occur about the same season as poliomyelitis. For from such information a clue might come to show that non-paralytic poliomyelitis and paralytic poliomyelitis, though antigenetically similar, were sometimes separable. This could happen if a viscerotropic variant of poliomyelitis virus exists and was ever distributed in epidemics under natural conditions.

Its existence could only be recognized in an area where it had succeeded, by prior immunization, in "blocking" the spread of the normal neurotropic virus. I believe that if an intensive survey could be carried out of the unknown pyrexias of summer and autumn, particularly in relation to those villages or groups of villages and small towns where paralytic poliomyelitis has not appeared since the war, we might find a natural viscerotropic virus which could better serve our purpose as a starting point for a vaccine than would normal neurotropic virus derived from paralytic cases.

Dr. R. Wigglesworth (*Journal*, August 29, p. 507) calls for an intensification of research into the ecology of a number of virus diseases, including poliomyelitis. In collecting information of this sort the College of General Practitioners might play a most valuable part.—I am, etc.,

Peaslake, Surrey.

G. I. WATSON.

Cortisone and A.C.T.H.

SIR,—A widely read report on cortisone and A.C.T.H., based on two articles published in the "Annual Advances in Treatment" number of your contemporary *The Practitioner*,^{1,2} appeared recently in *The Times* (October 2). We feel that these articles express inadequately the true status of these drugs in the modern treatment of rheumatoid arthritis. The authors state correctly that cortisone can have a profound and gratifying effect in suppressing the symptoms of rheumatoid arthritis. They go on to say, however, that after early hopes and optimism disappointment inevitably follows. After more than three years of experience, during which time we have returned many previously incapacitated patients to an active life on relatively small doses, we feel that this second statement is no longer true.

Both articles state that prolonged treatment may bring with it a host of difficult and even dangerous side-effects, mentioning addiction, fluid retention, cardiac embarrassment, and mental change—as well as others which we find more hypothetical than real, such as spontaneous fracture. The art of medicine would seem to us to be concerned with obtaining the effects desired while avoiding unwanted sequelae, and prolonged and unskilful treatment with many other drugs might also justify these statements. We agree that cortisone is a more difficult drug to use properly than was at first hoped, and this has discouraged many on both sides of the Atlantic who like fool-proof weapons. We have found it possible to achieve success, however, in a majority of cases if enough time and trouble are taken.

The authors also decry treatment with these substances on the grounds that quiescent infections, such as tuberculosis, may be masked, hypertension made worse, or a rebound of the disease occur on stopping treatment. All these possibilities should be well known to anyone using cortisone or A.C.T.H. Such infec-

tions must be excluded before cortisone or A.C.T.H. treatment is considered, and, if found, are absolute contraindications to their use. Treatment never should be stopped abruptly, but tailed off very gradually.

Readers are also advised against using these substances in rheumatoid arthritis, as "there is some evidence that in the long run the ultimate state of patients controlled by cortisone is no better than those controlled by adequate doses of aspirin." This amounts to saying that both drugs suppress but do not cure the disease. In those cases where such suppression can be adequately produced by aspirin we would agree that this should always be our drug of choice. It is only in cases where simpler drugs fail that cortisone is indicated. The authors conclude that "before using cortisone it is necessary to balance carefully the beneficial effects . . . against the risks which its use involves." Such advice is surely applicable when we consider the use of any powerful therapeutic substance. They also both suggest that "the early beneficial effects may need progressively larger doses for its maintenance." This statement is entirely contrary to our observed experience.

We believe that the modern status of cortisone and A.C.T.H. in the treatment of rheumatoid arthritis would be more accurately stated as follows. These drugs constitute the only short-term therapeutic weapons we possess with which we can, in many cases, completely suppress the signs and symptoms of this disease. They are not applicable to all cases—indeed, candidates for such treatment must be carefully selected, as there are many known contraindications. These substances are by no means fool-proof, and considerable experience in their use is required if good results are to be maintained. Patients on such treatment must be constantly reviewed, as their therapeutic needs and responses may vary rapidly. Such treatment should be used together with the other basic forms of treatment designed to prevent deformity, etc., and never as the sole therapeutic method.—We are, etc.,

W. S. C. COPEMAN,
O. SAVAGE.

Danger of Penicillin Injection

SIR,—The reports of severe anaphylaxis following injections of penicillin are extremely interesting, and this condition is undoubtedly becoming more common (*Journal*, October 3, p. 770 and 777). I have seen one severe reaction in a nurse, following an injection of 200,000 units procaine penicillin.

Sulphonamides could be used in very many cases where penicillin and other antibiotics are now given. There is no doubt whatever that if sulphonamides had been discovered after the antibiotics they would have been regarded as a tremendous advance. Surely we should use sulphonamides much more frequently than we do, for they cause less inconvenience to the patient and the nursing staff, and are likely to give rise to less severe toxic reactions.—I am, etc.,

London, N.W.10.

HORACE JOULES.

Spectacles

SIR,—The recent letters by Drs. R. U. Gillan and Christopher Heath (*Journal*, September 5, p. 568) concerning the probable or possible connexion between migraine and errors of refraction remind me of a wise saying by my late revered chief, Dr. Samuel Gee, which may be not without interest to your readers. Dr. Gee was a lifelong sufferer from severe and quite erratic attacks of migraine. He frequently consulted ophthalmological colleagues and they invariably prescribed spectacles. I have often heard him say that while he wore no glasses he never knew at what moment he might be prostrated by an attack. "When, however," he would add in that curious hesitant method of speech which it is quite impossible to reproduce in print, "I wore the spectacles which they ordered for me I was quite certain that I should be laid up by an attack within half an hour." It was Dr. Gee's invariable custom during a

great many years to commence his rounds at St. Bartholomew's at 1.30 p.m. every Tuesday, Thursday, and Saturday. It is a curious and perhaps not uninteresting fact that during this long period he was never once prevented by an attack of migraine from carrying out this invariable routine.—I am, etc.,

Esher.

C. F. HADFIELD.

Myxoedema Coma

SIR,—Dr. V. K. Summers in his interesting article (*Journal*, August 15, p. 366) states: "Once coma develops (in myxoedema) it seems to be irreversible." The following two cases show that this is not always so and that recovery may be spontaneous.

A 63-year-old housewife was admitted in December, 1951, having lost consciousness a few hours before. She was grossly myxoedematous and was in coma, though responsive to stimuli. There was nothing else to account for the coma. The patient spontaneously recovered full consciousness within 24 hours of admission without specific treatment. A typical history of myxoedema was then obtained extending over two years. For six months she had been increasingly lethargic, drowsy, and sensitive to cold. The radioiodine excretion pattern was hypothyroid in type and did not alter materially after a course of thyroid-stimulating hormone. Her ketosteroid excretion in 24 hours was 5.1 mg., kepler factor A was 143. The patient remained fully conscious while these investigations were being done. She steadily improved with L-thyroxine therapy and was euthyroid three months after starting treatment.

The second case was a woman of 69 who was seen at her home in 1949. She was immensely fat, obviously in an advanced stage of myxoedema, and stuporose. Her trunk felt almost as cold as the surrounding January air. She had been vomiting for a few days and the blood pressure was 90/70–85/60. In spite of immediate admission to the hospital and prompt oral treatment with thyroid extract, stupor deepened to coma and she died five days later without recovering consciousness. Necropsy revealed almost complete atrophy of the thyroid. The pituitary was normal. There were large medullary haemorrhages in both suprarrenals, but apart from recent compression the cortices were normal. The patient's history was obtained in detail from her daughter with whom she lived. She had clearly suffered from myxoedema for some years. The point of interest was that two years before her terminal illness the patient had been in coma at home for several days and had made a spontaneous recovery. It seems reasonable to suppose that on that occasion the coma was due to the myxoedema. In her last stages the vomiting and hypotension were probably due to the unusual occurrence of suprarenal haemorrhages which must have hastened the end.—We are, etc.,

Cardiff.
Isleworth.

L. BROTMACHER.
N. F. COGHILL.

Appendix in the Hernial Sac

SIR,—Mr. T. E. Winckworth's letter (*Journal*, September 5, p. 567) records a case of acute perforative appendicitis in a hernial sac in a man of 62, and inquires as to the frequency of this condition. It may be of interest, therefore, to report its occurrence at the earlier extreme of life. In March, 1951, there was admitted to hospital a baby of 7 weeks, with a tender irreducible swelling occupying the right inguinal canal. An occasional lump had been previously noted in this place by the nurse. The child had vomited once about 48 hours before, and after a normal motion had been constipated for this period. The temperature was 102° F. (38.9° C.), pulse 120, abdomen soft, both testicles normal in size and situation.

At operation on a diagnosis of 'strangulated inguinal hernia, a foetal type appendix perforated at its middle was found in a sac full of pus, the neck of the sac being shut off by the caecum. The appendix was removed, the stump being easily invaginated. The neck of the sac was closed,

OCT. 17, 1953

CORRESPONDENCE

nd the canal was drained. The child was discharged ealed on the tenth day, and has remained well since, having ashed through an attack of pertussis without any sign of eherniation.—I am, etc.,

H. B. WALKER.

Minehead.

SIR,—I was very interested in the case described by Dr. E. Winckworth (*Journal*, September 5, p. 567), because have on two occasions seen a similar condition associated with femoral hernia.

Two years ago, while I was working with the late Mr. N. E. Tanner, he operated on a woman for a femoral hernia which had recently become tender. At operation the sac was found to contain the tip of the appendix, which was considerably swollen and congested. There were early signs of inflammation, but the congestion was considered to be secondary to the impaction of the appendix in the neck of the sac. Curiously, exactly one week later, I personally operated on an identical case in a woman. I have not, however, heard of any similar cases.

With regard to the occurrence of the normal appendix in a hernial sac, I recently found one in the sac of an inguinal hernia in a small child.—I am, etc.,

Birmingham.

D. G. MAURICE.

Possible Sequel of Treating Infants in the Erect Posture

SIR,—I was interested to read Professor John Craig's reference (*Journal*, July 11, p. 98) to flattening of the head noticed in infants nursed in an upright posture. At this hospital a similar condition has been present in three cases of cardiochylasia or hiatus hernia nursed in a "chair." In one child the flattening was marked during the period of treatment, but at the age of 2½ years the shape and measurements of his head seem to have reverted to normal. He has not required any form of therapy since he was a year old.—I am, etc.,

Pontypridd.

W. DAVIES.

Pain of Transurethral Manipulations

SIR,—As a urologist, I heartily agree with your two correspondents, Dr. E. C. Atkinson (*Journal*, August 22, p. 440) and Mr. H. Calvert Dales (*Journal*, September 5, p. 567). May I put in a plea for the use of smaller instruments as well as lignocaine ("xylocaine") and/or general anaesthesia?

In my clinic I use a 16 French viewing cystoscope, which I had specially made. This is only three-quarters the size of the 21 French cystoscope generally used. For double catheterizing I use either an 18 or 21 French American Brown Bueger instead of the 23 French double catheterizing cystoscope in general use, some of which in practice tend to be even larger than the listed scale. For anyone who is accustomed to endoscopy these smaller instruments give an adequate view, and I am sure contribute considerably to the comfort of the patient, both during the procedure and afterwards.—I am, etc.,

Luton.

HENRY CLARKE.

SIR,—I am glad that Dr. E. C. Atkinson (*Journal*, August 22, p. 440) has raised the question of anaesthesia for transurethral instrumentation. It is a matter of astonishment to me that even now some surgeons pass instruments per urethram without any anaesthetic at all. I think that there is a tendency to decry local surface analgesics as useless because they are never given a chance. I have seen surgeons use a local analgesic, and immediately start to operate. Mr. Lang Stevenson waits for ten minutes, and Mr. Winsbury-White for five minutes (*Journal*, September 19, p. 674). I am sure it would surprise many readers to know how long five minutes' waiting means. If checked by a watch it is very much longer than one thinks.

For many years I have followed the advice of my colleague, the late Mr. Douglas Crow, who was in charge of the throat department at the Royal Sussex County Hospital. He used to teach that after anaesthetizing a patient with a

local analgesic one should treat another patient, and after that return to the patient one has anaesthetized—by then the analgesic will have taken effect. I am sure that, if adequate time were allowed, local analgesics would be more effective, and Mr. Crow's simple method ensures this.

No surface analgesic will anaesthetize the deep structures, and gentleness is still necessary. I have had patients attending my out-patient clinic for years for dilatation of a stricture under a local analgesic, who have occasionally had to submit to this treatment without an analgesic when I have been away, and they tell me the local analgesic makes a very great difference. I follow the technique of the late Canny Ryall, but, having had a few alarms with cocaine, for many years now I have used 1/1,000 cinchocaine ("nupercaine") with good effect and no untoward results.—I am, etc.,

Hove.

H. J. MCCURRICH.

Neonatal Asphyxia

SIR,—Your annotation (*Journal*, August 8, p. 328) and the correspondence on this subject have prompted me to quote an article describing a resuscitation trolley that was photographed and produced in the *Journal of Obstetrics and Gynaecology of the British Empire* (1949, 56, 1044).

This referred to a resuscitation trolley the purpose of which was to facilitate the passage of an endotracheal tube so that a newborn baby might be insufflated with oxygen and respirations established. Since this time in the last 3½ years this trolley has been present at every caesarean section (215) and forceps delivery, and a large percentage of the babies have required this method of resuscitation consisting purely of the rhythmic insufflation of the lungs through an endotracheal tube with oxygen controlled at the correct pressure with a water manometer. No other method of resuscitation has been used, and no drugs of any kind have been administered to a baby to stimulate respiration.

With the use of a resuscitation trolley as described it soon becomes practicable for an anaesthetist or obstetrician to pass an endotracheal tube in any sized baby, and with the use of a water manometer no injury to the baby will occur by too great a pressure of oxygen being applied to the baby's lungs.—I am, etc.,

Workington, Cumberland.

JAMES B. JOYCE.

SIR,—I am grateful to Mr. W. G. Mills (*Journal*, September 19, p. 675) for writing that my "arguments are sound" and that my "practice can be shown to give dramatic results" but I cannot claim by anyone who takes the trouble to try, but I cannot claim the special skill with which he credits me in giving intracardiac injections. They are, in fact, simplicity itself in infants.

All that is required is a hypodermic syringe with a 1-in. (2.5-cm.) needle of fairly fine bore—a No. 15 or 16 is suitable. This is inserted about 3–4 cm. internal to and superior to the position of the normal apex beat, and slight suction is applied from time to time as it is inserted the last half of its length. Immediately blood appears in the syringe the desired dose of "cardiazol" ephedrine is injected. If by any chance the ventricular cavity is not struck the first time it is only a matter of seconds to have another try. The fine needle cannot possibly do any damage, though it is possible that it and the injection of 0.5 ml. of fluid into the cavity might stimulate a contraction in a heart which had practically ceased to beat.

The great advantage of the method is that it is certain. The dosage does not depend on or get lost in the peripheral circulation before it reaches the heart, and, if by any chance the result is not, as Mr. Mills says, "dramatic" owing to the heart having ceased to beat, I have in one case found that firm alternating pressure on the thorax apparently initiated enough circulation to take the blood to the brain and make the baby breathe. In such cases milking the umbilical cord would have been useless, and of course all oxygenating methods—such as that mentioned by Dr. David Morris (p. 675)—depend on the existence of quite a reasonable peripheral circulation. I am glad to see that quite a few textbooks now suggest intracardiac injections. The great

difficulty is to get people to use a drug, cardiazol ephe-drine, which no textbook mentions but which is much more effective and logical than nikethamide ("coramine"), and still more so than lobeline, which is practically useless in these cases.

May I take this opportunity to correct and apologize for a slip in my previous letter (*Journal*, August 29, p. 510)? I there wrote that you noted (*Journal*, July 25, p. 199) that, while the maternal mortality has been quartered in the last 20 years, the stillbirth rate remains unchanged. What you actually wrote was: "While in the last 20 years the maternal mortality has been quartered, stillbirths and neonatal deaths have shown no comparable decline." The difference is significant, though not sufficiently so to affect the argument or need correction except in a scientific journal. I am sorry it happened.—I am, etc.,

Winsford, Cheshire.

W. N. LEAK.

Some Complications of Temporal Arteritis

SIR,—Dr. David Kendall's article entitled "Some Complications of Temporal Arteritis" (*Journal*, August 22, p. 418) comments on the occurrence of this disease in arthritic patients.

A woman of 78 years in good health, and who had not previously suffered from arthritis, experienced sudden acute pain in the right hip-joint. The onset of the pain could be timed to within a few minutes, occurring on rising from her chair after lunch. The pain was of such intensity as to suggest a fracture of the neck of the femur. The leg could not be raised from the bed for several weeks. This attack was shortly followed by a similar acute pain in the left hip-joint, and two months later by temporal arteritis affecting both temporal arteries and the occipital branch of the right occipital artery. As the arteritis resolved, the patient rapidly became blind in the right eye, and has only a little vision in the left eye.

I would like to suggest that the lesion in the region of the hip-joints was possibly of the same nature as the inflammatory condition of the other arteries with the same type of onset and resolution.—I am, etc.,

Newport, Mon.

The Age of the Menarche

SIR,—Referring to Drs. Dagmar C. Wilson and Ian Sutherland's memorandum (*Journal*, September 12, p. 607), Stefansson¹ mentions that the girls in the Arctic begin with their menstrual period at an early age, but he points out that they protect themselves against the cold so efficiently that their bodies are as warm as if they were in the Tropics. This is further evidence that climate is not the determining factor, and suggests that clothing must be taken into consideration.—I am, etc.,

Wilshire, Lancs.

Emergency Bed Service

SIR,—Dr. Stephen J. Hadfield reports, in his field survey of general practice (*Journal*, September 26, p. 683), that the Emergency Bed Service has attracted a certain amount of adverse criticism. This is perhaps inevitable, but he adds: "There seems a lot to be said for the principle that if a general practitioner has decided that admission to hospital is urgently necessary then the job of the Emergency Bed Service should be to find a bed and not first to decide whether or not a bed should be found."

The Service is only too well aware of the resentment felt by many practitioners at being asked clinical details by lay staff. It fully recognizes that its job is to find a bed and not to "decide whether or not a bed should be found"—a decision which, as a lay organization, it does not and cannot make. With nothing but a bare diagnosis, however, finding a bed is always a difficult and hopeless task. Deplorable though it may seem to general practitioners, the fact remains that the majority

of London hospitals are unwilling to accept a case from the E.B.S. without clinical details. The information requested from the practitioner, which varies with the diagnosis, is that which experience has shown is most often required by the hospitals, and which the doctor himself presumably gives if he applies direct to the hospital.

A further reason for requiring clinical details is that, on occasions when difficulty is experienced in finding a bed, the case is submitted to a doctor representing the regional boards. This doctor cannot assess the case and give instructions to the Service without adequate information.—I am, etc.,

G. F. ABERCROMBIE,
Chairman, Emergency Bed Service Committee,
King Edward's Hospital Fund for London.
London, E.C.2.

The Method of Execution

SIR,—I am amazed at the complacency of chaplains and others not about to be hanged regarding our present method of execution. It is defended because only 9 to 12 seconds are said to elapse between the procession from the condemned cell and the pulling of the scaffold lever, as against the minute which would elapse before unconsciousness supervened upon the first inhalation of carbon monoxide gas.

It is a well-known fact that the first effect of carbon monoxide poisoning is a blunting of the emotions, while in any case there would be no need for a staged execution, and the fatal gas, being odourless, could be introduced without pomp and circumstance, after the expiration of the customary period for grace.

In contrast, let any person of imagination picture himself taking the horrid drop with its awful culmination, after the expiration of those few seconds. Would anyone, Sir, not prefer for himself almost any other method?

As a doctor, I would not hesitate to administer euthanasia to any unfortunate so condemned to execution, and I would be infinitely grateful to anyone who would administer to me any hypodermic or intravenous injection to save me from the horror of our present barbarous method.—I am, etc.,

South Molton, N. Devon.

R. A. NASH.

SIR,—May I most emphatically dissociate myself from the activities of the B.M.A. representatives who have been discussing improved methods of killing persons convicted of murder?

May I point out that our activities should only be concerned with life and its preservation and that the B.M.A. has no place in discussions on taking life?

Finally, may I please be permitted to suggest that, if as an Association we are consulted, we should in all humility recognize that there are no circumstances which absolve us individually or collectively from the ancient Commandment "Thou shalt not kill"?—I am, etc.,

Gateshead, 8.

K. T. BROWN.

St. Luke's Day

SIR,—The small international society of which Luke, the physician, was a foundation member is now world-wide. On October 18 its many thousands of members recall with gratitude his life and work. How much poorer the world would be had Luke never lived and laboured. We of the medical profession may well take our part in commemorating with gratitude his life and work, and join in the hope and prayer that by the prescriptions he has left to us all the diseases of the world's mind and soul may be cured.

Shakespeare's Macbeth demands of his physician: "Canst thou not minister to a mind diseased?" It is in this branch of medicine that Luke excelled. Though it is rather as a writer than a physician that he has gained fame, his writings entitle him to a high place of honour among the world's psychiatrists. How many minds, sick with foolishness and selfishness, have found relief in studying his textbook.—I am, etc.,

Banstead, Surrey.

HERBERT CAIGER.

Obituary

J. F. CARTER BRAINE, M.D., F.R.C.S., F.F.R.

Dr. J. F. Carter Braine, director of the radiotherapeutic department of Guy's Hospital, died at his home at Speldhurst, Kent, on September 20 at the age of 60.

Born on January 21, 1893, John Francis Carter Braine received his medical education at Guy's Hospital, qualifying M.R.C.S., L.R.C.P. in 1916. After qualification he entered the R.A.M.C. and served in France and East Africa in the first world war. On demobilization he returned to Guy's as demonstrator of anatomy, and later was appointed Griffiths demonstrator in the department of pathology, a post he held for some years, during which time he took the Durham M.D. in 1925, winning a gold medal for his thesis. He had previously graduated M.B., B.S. at Durham in 1920; in 1921 he took the D.P.H. of the English Royal Colleges; and in 1922 he obtained the diploma of F.R.C.S. It is interesting to recall that both his father and grandfather were Fellows of the Royal College of Surgeons of England.

Always attracted to radiotherapy, Carter Braine was chief assistant in the old actinotherapy department at Guy's Hospital from the mid-twenties, with the late Colonel W. Langmuir Watt, who died two months ago, as an assistant surgeon. In 1925 Carter Braine was appointed surgeon to the radiotherapy department of the hospital, and in due time he acquired a wealth of experience in this field of treatment, working, as he did, unceasingly to improve techniques and results, so that his selection in 1939 as director of the department was an obvious choice. In the same year he was elected a Fellow of the Faculty of Radiologists.

During the last war he acted as adviser in radiotherapy to the group officer in the Guy's sector, and when, in 1941, the Guy's U.S.A. Hospital was opened at the Wildernesse, near Sevenoaks, he helped to create in hurried accommodation a radiotherapy department which was in use until the end of the war, when it was transferred to Pembury Hospital. From 1941 to the end of hostilities it is estimated that Carter Braine travelled by road each year in black-out conditions at least 20,000 miles between Tunbridge Wells, Pembury, the Wildernesse, and London in the performance of his duties. The strain such calls made on his frame, robust though it was, must have provided fertile ground on which the seeds of his fatal illness were sown. His ability as an organizer showed itself most clearly during the war years; an inspiration to his staff, Carter Braine's enthusiasm and encouragement produced a remarkable loyalty in those under him.

He was civil consultant in radiotherapy to the Royal Navy, and was formerly surgeon in charge of the radium department at King Edward VII Hospital, Windsor, and radiotherapist to the West London Hospital. He was a foundation member of the Society of Radiotherapists of Great Britain and Ireland (now part of the Faculty of Radiologists). A member of the official British delegation to the fifth International Congress of Radiology held at Chicago in 1936, he was also assistant treasurer and a member of the board of management of the sixth International Congress of Radiology, held in London in 1950. Carter Braine had wide interests outside

his profession. His love of the countryside was shown in the careful husbandry of his farm. Art and architecture, too, appealed to him; and he was a competent photographer, as the fine clinical photographs and slides used in his department could testify. His unpretentious manner, his modesty, and his sympathy and understanding inspired the affection of colleagues and patients, to whom he was the beloved physician. A keen sense of humour and an even temperament ensured him many friends, who, with his widow and daughter, have suffered a very severe loss by his death.

L. A. ROWDEN, M.B., D.Sc., F.F.R.

The death occurred at Harrogate on August 16 of Dr. L. A. Rowden, a former president of the British Institute of Radiology, at the age of 82.

Leonard Alfred Rowden was born at Newcastle-upon-Tyne on March 23, 1871, and was educated at Lenzie Academy and at Glasgow and London universities, graduating M.B., C.M., with a commendation, at Glasgow in 1892. After graduation he was in general practice at Thirsk and Morley before finally setting up his plate on his own account at Leeds. The discovery of x rays by Röntgen in 1895 saw the birth of radiology, and it was to this branch of medicine that Dr. Rowden devoted most of his working life. He became one of the pioneers in the use of x rays, starting before the turn of the century, when the first plant at the General Infirmary at Leeds was installed at a cost of £5 15s., and he later fitted up his own electrical laboratory, one of the earliest of its kind in this country. In 1908 he was appointed director of the x-ray department at the General Infirmary at Leeds, and in 1910 he became radiologist to the Hospital for Women and Children, holding both positions until 1917. From 1910 to 1919 he was radiologist to the Leeds Public Dispensary, and he was also honorary consulting radiologist to Dewsbury General Infirmary. In the first world war he served in the R.A.M.C. from 1915 to 1919 at home and in France. After the war he returned to Leeds, where he remained until his last illness. He retired from practice in 1948. The ambulance movement in Yorkshire also received his support. He was examiner and instructor in the ambulance department of the old London and North-Eastern Railway, examiner for the St. John Ambulance Association, and he gave the Rowden challenge shield for yearly competition by the ambulance teams in Leeds workshops and factories.

Dr. Rowden was a past president of the British Institute of Radiology, the Society of Radiographers, and the Leeds and West Riding Medico-Chirurgical Society. A member of the British Medical Association for some forty years, he acted as one of the secretaries of the Section of Radiology and Medical Electricity at the London Annual Meeting of the Association in 1910, and when the B.M.A. met at Glasgow in 1922 he was president of the Section of Radiology. He also represented his constituency at eight Annual Representative Meetings from 1918 to 1927. In 1939 the honorary degree of D.Sc. was conferred upon him by the University of Leeds, and when the British Association of Radiologists and the Society of Radiotherapists of Great Britain and Ireland amalgamated as the Faculty of Radiologists in 1940 he became a Fellow of the Faculty. Dr. Rowden was always ready to help any young man who showed interest in x-ray work. He had a fine collection of positive prints and films, and nothing pleased him

more than to be able to show them to visitors. He was not a prolific writer, but his contributions to *A Descriptive Atlas of Radiographs* outnumbered all others. Latterly he was particularly interested in pelvimetry. He was one of the few pioneers who escaped injury through radiation. A widower, he leaves six sons and two daughters. His eldest son, Dr. W. H. Rowden, is in practice at Leeds.

The *British Medical Journal* has lost an old and valued contributor by the death, which took place in Edinburgh on September 27, of PHILIP FRANCIS SULLEY, London editor of the *Sheffield Daily Telegraph* and Parliamentary Lobby correspondent. For many years—indeed, the beginning of the association does not seem to be discoverable from the office records, but it may well have been 30 years or more—right down to the Parliamentary recess last summer, Sulley contributed Medical Notes in Parliament and generally acted as watchdog for the *British Medical Journal* over the proceedings at Westminster. This was, of course, only one of his extra-activities; his main job was to interpret Parliamentary doings to Yorkshire in the form of a London Letter; but he did it, as he did everything else, with great care, good judgment, and a profound knowledge of Parliamentary procedure, personalities, and affairs. He had also, which was very important for such work, a capacity for compression, and could condense into a few lines a statement or fragment of discussion when an amateur would have straddled across a page.

Sulley, who was in his seventieth year, was a Scotsman who, having passed through St. Andrews University, came south to make his reputation. He began his Parliamentary journalistic work about 1906, when the Campbell-Bannerman Government came into power. He had been chairman of the Press Gallery, and twice chairman of the Lobby. He was indeed the "father" of the Lobby, and was much esteemed by his colleagues as well as by Parliamentarians and others as a political journalist, able to express himself with frankness and wit, and always keen on safeguarding the highest standards of journalism. A year or two ago he had a severe illness for which he underwent an operation, and, although he returned to his accustomed haunts at Westminster, he was, as one of his colleagues expressed it, "rather like a winged bird." Proceedings in Parliament cover all human interests, and to dissect from the daily question times and from the debates in the House and its committees matters of interest in health and medicine called for an alert mind and no uncommon labour. But Sulley did his job admirably and his practised pen will be greatly missed.

We record with regret the death on September 7 of Miss WINIFRED LINTON, honorary F.C.S.P., formerly head of the department for remedial exercises at the Brompton Hospital.

Sir GEOFFREY MARSHALL writes: The death of Winifred Linton brings to an end a life of unremitting work which formed one of the stepping-stones for the spectacular rise of chest surgery and medicine in our time. She was trained as a nurse at St. Bartholomew's Hospital, and served as such with the Army in the Dardanelles in the first world war. After her return home she took up physiotherapy, and began her association with the Brompton Chest Hospital, where she developed and was head of the department for remedial exercises. There she worked first with the late Mr. J. E. H. Roberts, and then with the late Mr. Tudor Edwards, whose brilliant team-work set new standards in surgery which have since become standardized in every civilized country. Miss Linton was the most modest and self-regardless of women; but she was a genius. If the disability of a patient was explained to her, she would devise exercises and postural procedures which would reduce the disability to a minimum, and she would gain the confi-

dence and eager co-operation of patients of all ages and of every rank of society. A patient about to undergo a major operation, such as the removal of the whole of one lung, would be taught beforehand how to breathe and cough using the other lung only. She was equally successful in dealing with patients suffering from chronic disease, showing them how to overcome the shortness of breath associated with such conditions as asthma and chronic bronchitis. She trained many other physiotherapists, and her pupils have become heads of departments in hospitals here and abroad. She was a woman of small stature and of no special distinction in appearance; but her zest and her complete devotion to the relief of her patient carried instant conviction and made her respected and beloved. She had a delicious sense of humour, and she was a dear. Her work lives on and expands.

Dr. HOMER FORDYCE SWIFT, a former member of the Rockefeller Institute for Medical Research, died in New York on September 24 aged 72. He graduated M.D. New York and Bellevue Medical College in 1906. He was assistant pathologist and dermatologist at Bellevue from 1908 to 1910, and then became associated with the staff of the Rockefeller Institute. In 1914 he was appointed associate professor of medicine at Columbia University, and three years later obtained a similar appointment at Cornell Medical College. In 1912, with A. W. M. Ellis, he introduced the autoserosalvarsan method of treatment of neurosyphilis (the "Swift-Ellis treatment"). During service with the Allied Armies in France in 1918 he collaborated in the production of an important report on trench fever for the American Red Cross Society's Commission. He returned to the Rockefeller Institute as an associate member in 1918, becoming a full member three years later. He was made a physician to the Rockefeller Institute for Medical Research in 1936; he was a member of the Council of New York University from 1942 to 1946, and consultant to the Secretary of War during the same period.

Medico-Legal

CLAIM AGAINST DOCTORS FAILS

After a five-day hearing, Mr. Justice Finmore dismissed on October 9 at Birmingham Assizes a claim for damages for personal injuries by a man who contended that the injuries resulted from a supposition that he had venereal disease when he was actually suffering from cancer. Later amputation of the penis had been performed.

Daniel Edwin Hulse, 36, of Oldbury, Worcs, alleged negligence by Dr. C. J. Wilson, resident surgical officer, and Mr. J. H. Kirkham, stipendiary surgeon, both of the West Bromwich and District General Hospital, and also against the Birmingham Regional Hospital Board, who administer the hospital.

The defence was a denial of negligence.

Mr. E. Ryder Richardson, Q.C. (for Hulse), opening the case, said that in 1948 Hulse underwent a number of tests for venereal disease at a Birmingham hospital. The tests proved negative. He was also seen at West Bromwich Hospital. The pain increased, and on January 1, 1949, Hulse entered the West Bromwich Hospital, where they still thought he was suffering from the disease. An operation was performed and he was sent home three days later. In March Hulse saw another surgeon, who began deep x-ray treatment for cancer, but on July 25 an amputation operation was performed. Mr. Ryder Richardson alleged that the doctors had wrongly diagnosed a disease as the source of the trouble, instead of cancer, and Hulse was claiming damages for personal injuries.

Giving evidence, Hulse said he had nineteen operations altogether, including several plastic surgery operations.

His last operation was on May 27 this year, and he still suffered from pains in the lower abdomen and had spells of giddiness.

Dr. H. Barrada, Hulse's doctor, said he thought Hulse was fit enough to do clerical work, but unable to carry out many forms of manual work, to which he had been accustomed.

Mr. M. Harmer, of London, said that if the diagnosis of Hulse's trouble had been made earlier he might eventually have had to have only a partial amputation instead of a total one. The subsequent extensive plastic operations would also probably have been found unnecessary, because a man with a partial amputation was to a large extent able to carry on a normal life. He thought that a man who had only a partial amputation could work better, and there was less risk of infection, than if he had a total amputation. In his opinion, if Hulse had been treated in January, 1949, three months would have been saved, and the man might have escaped with a partial amputation, but he agreed in cross-examination that in 1948 a time lag of about six months before admission to hospital was not unreasonable for a minor operation.

Dr. William Henry Bond, consultant radiotherapist to United Birmingham Hospitals, said that the cancer did not respond to radiotherapy, but it would probably have been resistant to radiotherapy even if it had been diagnosed earlier. Having regard to Hulse's age, cancer was the least probable cause of this condition, and he thought Dr. Wilson had acted correctly under the circumstances.

Professor B. W. Windeyer, director of radiotherapy at Middlesex Hospital, London, said there was no reason why Dr. Wilson should suspect cancer when he first examined Hulse. In a man of Hulse's age such a cancer was extremely rare.

Professor F. A. Stammers, professor of surgery at Birmingham University, said he considered that Mr. Kirkham's actions after the minor operation in January, 1949, were quite reasonable.

Mr. Kirkham, giving evidence, said that he did not see Hulse at all until he performed a minor operation on him in January, 1953. The operation disclosed an ulcer, which might have been due to one of three causes. He considered cancer to be the least likely one, particularly in view of Hulse's age.

Mr. Vaughan (for Dr. Wilson and the regional hospital board), in his closing speech said there was a waiting-list of six to nine months in 1948 for operations at the hospital. There was nothing to induce any reasonably minded doctor to think that there was anything in Mr. Hulse's case requiring a higher priority than for the first operation—a very minor one.

On behalf of Mr. Kirkham, Mr. A. P. Marshall, Q.C., said that Mr. Kirkham had acted reasonably and properly in delaying the serious surgical cancer test until after the possibilities of inflammation and syphilis had been disproved. There was no evidence of negligence on Mr. Kirkham's part.

The judge, dismissing the claim, said that he found no evidence of any negligence against any of the defendants. There was no reason for Dr. Wilson to suspect cancer in the early stages, and at that time there was no reason for the case to be treated as one of urgency. Mr. Hulse had not been told to go back to the hospital if the pain became worse, but there was nothing to stop him going to his doctor, or to the hospital, if this happened. "I don't think you can blame the doctor for not saying 'Please come back' to him," said the judge.

Referring to the question of whether Mr. Kirkham should have diagnosed cancer when he discovered an ulcer during an operation, the judge commented: "The dangers of making a diagnosis too quickly are just as great as making a diagnosis too slowly. I don't think anyone can complain that Mr. Kirkham did not diagnose cancer straight away."

"I think the real gravity of the case against Mr. Kirkham was that he delayed too long satisfying himself beyond doubt that venereal disease was not the cause, and that he should have turned to the only other alternative—cancer. Such a cancer is extremely rare: in a young man of about 30 it is rarer still. Until you get rid of the other more likely causes you would not expect it was cancer in a man of this age." In any event, if Mr. Kirkham had at once diagnosed cancer no one could say that Mr. Hulse could have avoided an amputation altogether.

Messrs. Hempsons acted on behalf of the Medical Defence Union for Mr. Kirkham.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending September 26 (No. 38) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenza pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in the week ending October 3 (39th week of the year) were as follows: paralytic, 79 (119); non-paralytic, 78 (99); total, 157 (218). This is a decrease of 61 compared with the previous week, the figures for which are in parentheses. The reduction is satisfactory, and there is no doubt that the drop to the winter levels of the disease is under way.

Cancer Statistics

The Royal Cancer Hospital, London, has issued the first of a series of reports giving detailed statistics on the type of cancer and results of treatment in patients admitted to it. It is entitled *Clinical Statistical Report* (Number 1), and covers the years 1945-9. The report includes figures showing the yearly survival and recurrence rates of all new patients with cancer, classified by site, age, sex, clinical stage, and histological type. In the words of its introduction, "It is intended for those who are seriously interested in studying the position as it is to-day rather than in advocating one particular treatment method or supporting some already entrenched belief." The authors are Mr. A. H. Hunt, Dr. J. B. Harman, Mr. M. H. Harmer, Mr. P. M. Payne, B.Sc., Professor D. W. Smithers, and Mr. K. M. Turner, B.Sc.

Infectious Diseases

The largest variations in the number of notifications of infectious diseases in England and Wales during the week ending September 26 were decreases of 784 for whooping-cough, from 3,555 to 2,711, and 116 for measles, from 608 to 492, and increases of 153 for scarlet fever, from 633 to 786, and 61 for dysentery, from 202 to 263.

The incidence of scarlet fever rose slightly in most regions of the country. The largest local variation was an increase of 38 in the number of notifications in Lancashire, from 117 to 155. The largest decreases in the number of notifications of whooping-cough were 103 in Yorkshire West Riding, from 317 to 214, 91 in London, from 281 to 190, 77 in Essex, from 223 to 146, and 73 in Glamorganshire, from 148 to 75. A small decline in the incidence of measles was recorded in most areas, but no large fluctuations were reported. 29 cases of diphtheria were notified; these were 4 more than in the preceding week and the largest total for 28 weeks. The largest local fluctuation in diphtheria was a decrease in Durham from 4 to 0. 6 of the 13 cases of paratyphoid fever and 2 of the 6 cases of typhoid fever were notified in London.

218 cases of acute poliomyelitis were notified during the week. These were 4 fewer for paralytic and 5 fewer for non-paralytic cases than in the preceding week. The largest returns were Warwickshire 29 (Coventry C.B. 11, Birmingham C.B. 7, Shipton-on-Stour R.D. 3), Lancashire 20 (Preston C.B. 5, Blackpool C.B. 4, Liverpool C.B. 4), London 15 (Lewisham 3, St. Pancras 3), Southampton County 12 (Bournemouth C.B. 3), Yorkshire West Riding 12 (Sheffield C.B. 3), and Northamptonshire 11 (Kettering M.B. 8).

The largest centres of dysentery during the week were London 45 (Southwark 12, Chelsea 9), Lancashire 30 (Liverpool C.B. 7), Yorkshire West Riding 22 (Bradford C.B. 8), Durham 18 (Stanley U.D. 9), Middlesex 17, Kent 14 (Maidstone M.B. 9), Worcestershire 12 (Bromsgrove U.D. 12), Surrey 10, and Yorkshire North Riding 10 (Middlesbrough C.B. 10).

Week Ending October 3

The notifications of infectious diseases in England and Wales during the week included scarlet fever 992, whooping-cough 2,292, diphtheria 24, measles 621, dysentery 212, paratyphoid fever 16, and typhoid fever 10.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 are shown thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Medical News

Postgraduate Travelling Fellowships.—The British Postgraduate Medical Federation (University of London) is prepared to offer a limited number of Postgraduate Travelling Fellowships, tenable for one year, to registered medical and dental practitioners who are in the course of training as specialists in one of the preclinical or clinical branches of medicine, surgery, or dentistry, at one of the medical or dental schools or teaching hospitals and Postgraduate Institutes of the University of London. Further information about these Fellowships will be found in the advertisement columns.

The Pathologist in Court.—Speaking from the chair of the Medical Protection Society, to which he was unanimously re-elected at its annual meeting on October 7, Sir Ernest Rock Carling referred to the tendency in some coroners' courts for pathologists to express opinions on clinical matters. The pathologist had the remarkable advantage of being wise after the event and of entire exemption from the responsibility of having decided what the treatment of the deceased person should have been. He considered that in expressing such opinions the pathologist or morbid anatomist was stepping outside his proper province, and in his view coroners should not in future attach the importance some of them seemed to do to the clinical opinions of pathologists. Sir Ernest Rock Carling went on to say that the Society had been anxious about the attitude taken by some hospital authorities to complaints against members of their staff. In repudiating liability on its own account one authority had gone so far as to present the plaintiff with a series of points on which it was alleged a member of the staff had been negligent. One regional board had told its staff that they would individually be held responsible for any accident connected with blood transfusion which might occur at the hands of registrars, house-surgeons, and others looking after their patients. On these matters representatives of the defence societies and the British Medical Association had been conducting negotiations with the Ministry of Health, and there were signs that a different attitude between the employers and the employed staff in this respect might obtain in the future. He also referred to the tendency to increase the amount of damages awarded against doctors.

Charing Cross Hospital Medical School Dinner.—A record number of past and present students attended the annual dinner at the Savoy Hotel, London, on October 10, under the chairmanship of Lord Inman. The occasion was marked by farewell presentations to Mr. Norman Lake, the senior surgeon, and Professor H. W. C. Vines, head of the pathology department and formerly Dean, who are retiring under the age limit. Responding to the toast of "The Medical School" proposed by Dr. C. M. Scott, the Dean, Dr. E. C. Warner, reviewed the School's progress. This done, he turned to the main business of the evening. A fund had been opened to commemorate the many years' service by Mr. Lake and Professor Vines, and £720 had been collected. The bulk of the money would go to establish a Norman Lake prize for clinical surgery and to augment the Vines prize in pathology. Both Mr. Lake and Professor Vines, he was glad to say, would continue to work for the hospital, the former as chairman of the hospital research committee and, for a time, as director of surgical studies, the latter on the board of governors and the school council. Mr. David Trevor, to whom it fell to propose their healths, nicely blended reminiscence with appreciation. Mr. Lake had been on the staff for 34 years and senior surgeon for 20 years—surely a record. He would be remembered as a general surgeon in the widest sense of the word. Professor Vines, who had come to the hospital in 1928, was distinguished as an educationalist and an organizer. Above all, he was the force behind the planning of the new hospital at Harrow. The chairman then pre-

sented a tape recorder to Mr. Lake, on which the proceedings of the evening were being registered, and a cocktail cabinet to Professor Vines. Mr. Lake, whose speech will long be remembered, spoke of his great gratitude to the hospital, which had afforded him a "lifetime of most absorbingly interesting work." Professor Vines asked his hearers to remember that the life of an institution depended, not on its buildings, but on the enthusiasm and good will of its alumni. He predicted a rosy future for the Charing Cross School. These speeches were greeted with enthusiasm, and the evening ended with a vote of thanks to Lord Inman by Mr. Arthur Gray.

King's College Hospital Medical School Dinner.—The annual dinner of past and present students was held at the Dorchester Hotel, London, on October 3, with Mr. V. E. Negus in the chair. The toast of the chairman was proposed by Mr. W. I. Daggett, and Mr. V. E. Negus replied on behalf of himself and the guests, and gave the toast of the medical school. The wit of the speakers fittingly matched the brevity of their speeches, to the evident delight of the diners. It was announced that next year would be the 125th anniversary of the medical school, when it is hoped that a specially large number of past students will be able to take part in the celebrations.

The London Hospital Old Students' Dinner was held at the Trocadero Hotel, London, on October 8. Mr. George Neligan, from the chair, proposed the toast of "The Hospital and Medical School," which was replied to by Dr. A. E. Clark-Kennedy, who is retiring as Dean of the Medical College. Dr. A. G. Maitland-Jones proposed the chairman's health. Among the guests were Professor A. D. Gardner, Sir Lionel Whitby, Lieutenant-General Sir Frederick Harris, Surgeon Vice-Admiral Sir A. Ingleby-Mackenzie, Air Vice-Marshal J. M. Kilpatrick, and Sir James Spence, who had earlier in the day delivered the Schorstein Lecture on "The Varieties of Clinical Experience."

Charles Best Institute.—The new Charles H. Best Institute, at the University of Toronto, was officially opened on September 15, when Sir Henry Dale, O.M., turned a golden key in the door of the new building. The Institute will be used by the Department of Physiology for teaching purposes, research, and by the associated Banting and Best Department of Medical Research. At a special convocation held before the opening, the University presented honorary degrees to Dr. Detlev W. Bronk, the new Director of the Rockefeller Institute for Medical Research; to Dr. B. A. Houssay, of Argentina; to Dr. E. P. Joslin, of Boston; to Dr. W. G. Penfield, of Montreal; and to Sir Lionel Whitby, the Vice-Chancellor of the University of Cambridge. Convocation addresses were given by Sir Henry Dale and by Sir Lionel Whitby.

Italian Visit by R.S.M. Delegation.—At the invitation of the president of the Lombardy Region of the Italian Red Cross a small delegation of Fellows of the Royal Society of Medicine have been lecturing in Northern Italy. The party was led by Sir Gordon Gordon-Taylor, and included Sir Clement Price Thomas, Mr. L. R. Broster, Professor L. J. Witts, Dr. H. M. Sinclair, and Mr. R. T. Hewitt, secretary of the Royal Society of Medicine. Lectures were given at the Universities of Milan, Pavia, and Padua.

Opinion on Crime.—The Nuffield Foundation has invited Lord Pakenham, a Fellow of Christ Church, Oxford, and formerly Minister of Civil Aviation and First Lord of the Admiralty, to undertake a critical appraisal of current views of the causes of crime. He will be assisted by a small group of assessors, some of whom are medical. They are Dr. Desmond Curran, psychiatrist at St. George's Hospital, and Dr. T. C. N. Gibbens, lecturer in forensic psychiatry at the Institute of Psychiatry. The non-medical assessors include Dr. M. Grünhut, reader in criminology at Oxford, Mr. Frank Milton, a Metropolitan magistrate, and Mr. Leslie Farrer-Brown, secretary of the Nuffield Foundation.

Grenfell Association Christmas Cards.—Once again the Grenfell Association is offering Christmas cards for sale, all proceeds of which will be devoted to the maintenance and furtherance of the Grenfell Mission's medical work in Labrador and Northern Newfoundland. An illustrated leaflet giving details of cards available (ranging in price from 3½d. to 1s. 2d.) may be obtained from the association office, 66, Victoria Street, London, S.W.1, on receipt of 1½d.

Electroencephalographic Society.—At the annual general meeting of the Electroencephalographic Society, held at the National Hospital, Queen Square, on October 3, Dr. Denis Hill (Institute of Psychiatry), and Dr. Geoffrey Walsh (Edinburgh) were elected to the council to fill vacancies caused by retirement. The general meeting was followed by a series of papers. Summaries may be obtained from the honorary secretary, Dr. D. A. Pond, Maudsley Hospital, London, S.E.5.

The Annual Report of the Board of Medical Auxiliaries for 1952-3 records that the Association of Operating Theatre Technicians has been recognized as a qualifying body. A register of operating theatre technicians is to be published in due course. The British Dietetic Association has withdrawn its membership.

The Births and Deaths Registration Act, 1953, came into force on September 30. It simply consolidates, with a few minor amendments, previous legislation on the registration of births and deaths in England and Wales.

Sir James Learmonth, regius professor of clinical surgery at Edinburgh, has been appointed Sir Arthur Sims Commonwealth Travelling Professor for 1954 by the Royal College of Surgeons of England.

Sir Harry Platt will leave on October 24 for Cyprus and Israel for a two weeks' lecture tour under the aegis of the British Council. He will spend the first week in Cyprus, giving a number of formal lectures and clinical demonstrations, and the second week in Israel, where he will lecture, hold clinics, and operate in Tel-Aviv, Haifa, and Jerusalem.

COMING EVENTS

Cambridge University Courses for General Practitioners.—A series of one-day symposia for general practitioners will be held on Saturdays at Addenbrooke's Hospital during the academic year. The following programme has been arranged: October 24, "Tuberculosis and Other Diseases of the Chest"; November 14, "Disorders of the Blood"; December 12, "Dermatology"; January 9, "Obstetrics and Gynaecology"; February 6, "Infectious Diseases"; March 6, "Cardiovascular Diseases"; April 3, "Orthopaedics, Treatment of Injuries and Physical Medicine"; May 1, "Cancer"; May 29, "Paediatrics"; June 26, "Nervous Diseases"; July 24, "Diseases of the Ear, Nose, and Throat; Diseases of the Eye." Further information may be obtained from the secretary, the Medical School, Tennis Court Road, Cambridge.

University College Hospital Medical School.—The annual dinner of past and present students will be held at the Savoy Hotel, London, W.C.2, on October 30 at 7.30 for 8 p.m. Dr. Kenneth H. Stokes will be in the chair. Tickets (price £1 7s. 6d.) may be obtained from the dinner secretary, University College Hospital Medical School, London, W.C.1. On October 29 and 30 there will be the usual postgraduate demonstrations at the Medical School. These include a symposium on the treatment of severe hypertension.

27th General Hospital Reunion.—The annual dinner will be held at the Eccleston Hotel (near Victoria) on October 31 at 6.15 for 7 p.m. Tickets £1, inclusive of wine; informal dress. Those wishing to attend should communicate with Dr. L. S. Potter at B.M.A. House, Tavistock Square, London, W.C.1.

The British Occupational Hygiene Society.—The first conference of the society will be held on November 2 at

11 a.m. at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1. The Minister of Labour, Sir Walter Monckton, will open the conference, and Dr. T. Bedford will deliver the presidential address. The main subjects for discussion will be the measurement of the worker's environment, chemical toxicity, and occupational hygiene and the industrial designer.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Friday, October 16

ROYAL EYE HOSPITAL.—5.30 p.m., Dr. A. A. Guild: Ocular Manifestations of Neurosyphilis.

Monday, October 19

● HUNTERIAN SOCIETY.—At Talbot Restaurant, 64, London Wall, E.C.4, 7 for 7.30 p.m., dinner meeting. Presidential Address by Sir Heneage Ogilvie: Life is Like That.

INSTITUTE OF NEUROLOGY.—5 p.m., Dr. Robert Aird (U.S.A.): Recent Work on Epilepsy.

INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: Lecture demonstration.

LONDON UNIVERSITY.—At Guy's Hospital Medical School, 5 p.m., Professor William Montagna (Brown University): The Architecture, Growth, and Differentiation of Skin.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. B. G. C. Ackner: Aches and Pains of Psychogenic Origin.

Tuesday, October 20

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor J. H. Burn, F.R.S.: Acetylcholine and Cholinesterase in Heart Muscle.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. I. Williams: Erythrodermia.

ROYAL EYE HOSPITAL.—5 p.m., Dr. R. D. Lawrence: Diabetes and the Eye.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Mr. A. M. Clave: Sexual Disorders.

SOCIETY FOR THE STUDY OF ADDICTION.—At Medical Society of London, 8 p.m., quarterly meeting. Presidential Address by Dr. H. K. V. Soltau: Scope and Effect of Institutional Treatment in Alcoholism. Discussion to be introduced by Professor A. D. Macdonald: Pharmacology of Addiction.

UNIVERSITY COLLEGE, LONDON.—At Anatomy Theatre, 1.15 p.m., Professor J. B. S. Haldane, F.R.S.: Physiology of Diving.

● Wednesday, October 21

LONDON UNIVERSITY.—At Guy's Hospital Medical School, 5 p.m., Professor William Montagna (Brown University): The Architecture, Growth, and Differentiation of Skin.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor N. H. Martin: Circulating Proteins in Health and Disease.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Urology Lecture by Mr. L. N. Pyrah: Uretero-colic Anastomosis: Technique, Management, and After-care.

Thursday, October 22

● ABERNETHIAN SOCIETY.—At St. Bartholomew's Hospital, London, E.C.4, 5.30 p.m., Opening Address by Sir Lionel Whitby: Devils, Drugs, and Doctors.

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor F. G. Young, F.R.S.: Growth Hormone of the Anterior Pituitary Gland.

DURHAM UNIVERSITY: DEPARTMENT OF SURGERY.—At Royal Victoria Infirmary, Newcastle-upon-Tyne, 4.30 p.m., Rutherford Morison Centenary Lecture by Sir Gordon Gordon-Taylor: The Rutherford Morison Tradition.

HARVEIAN SOCIETY OF LONDON.—8.15 p.m., Buckston Browne Prize Essay by Dr. Sheila P. V. Sherlock: Jaundice.

HONYMAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Professor David Whitteridge, F.R.S.: Cardiovascular Disturbances in Paraplegia.

● INSTITUTE OF CARDIOLOGY, National Heart Hospital.—9.30 a.m., Professor M. L. Rosenheim: Oedema.

● INSTITUTE OF CHILD HEALTH AND INSTITUTE OF NEUROLOGY.—At National Hospital, Queen Square, W.C.1, 5.30 p.m., Sir Russell Brain: Aetiological Factors of "Acquired" Group (Virus Infections, Lipodosis, Vascular, Degenerative Diseases).

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Structure and Classification of Pathogenic Fungi.

INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—5 p.m., Professor F. C. Ormerod: Tuberculous Disease of the Upper Air Passages.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Professor J. S. Young: Dissemination of Malignant Tumours.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Dr. K. G. Lowe: Acute Renal Failure.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. J. H. Paterson: neurology demonstration.

SOCIETY FOR CULTURAL RELATIONS WITH THE U.S.S.R.—7.30 p.m., Dr. B. Kirman: Impressions of the Soviet Health Services. Report of Visit to the Soviet Union.

Friday, October 23

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. H. J. Wallace.

● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Queen Charlotte's Hospital, 4.30 p.m., Mr. A. W. Bourne: Conservatism in Obstetrics.

LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.—Mr. F. P. Rapet: Recent Advances in the Treatment of Some Common Urological Diseases.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., Dr. Lindsey W. Batten: Scope and Limitations of Preventive Medicine.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor E. J. Wayne: Clinical Evaluation of New Drugs.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Erasmus Wilson: Demonstration by Dr. G. D. Lumb: Irradiation Changes in Malignant Disease.

ROYAL EYE HOSPITAL.—5.30 p.m., Dr. A. A. Guild: The Myopathies.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—F. Alberts, M.B., B.S., D.A., Consultant Anaesthetist in Wisbech and Doddington Area; C. C. Smith, M.B., B.S., D.M.R.D., Assistant Radiologist in Peterborough and Stamford Area; M. Barry, M.D., M.R.C.P.I., Assistant Chest Physician at Ipswich Area Chest Clinic; D. P. F. Embleton, M.R.C.S., L.R.C.P., Senior Registrar in Chest Medicine at Ipswich Area Chest Clinic; T. J. Sullivan, M.B., B.Chir., Medical Registrar at Peterborough Memorial Hospital; S. K. Chatterjee, M.B., B.S., F.R.C.S., Surgical Registrar, Peterborough Memorial Hospital; K. N. Kamdar, M.B., B.S., D.M.R.D., Registrar in Radiology, East Suffolk and Ipswich Hospital; A. J. Abraham, F.R.C.S., Registrar in Plastic Surgery, West Norwich Hospital; J. V. Fennell, M.B., B.Ch., D.P.M., Consultant Psychiatrist in Ipswich Mental Hospital Group; J. L. Dunscombe, M.B., Ch.B., Assistant Pathologist to Hospitals in West Suffolk Area; L. Capper, M.B., B.S., M.R.C.P., Senior Registrar in Chest Medicine at Cambridge Chest Clinic; M. A. Birnstingl, M.B., B.S., F.R.C.S., Surgical Registrar, J. M. Brownlie, L.R.C.P.&S Ed., Orthopaedic Registrar, and E. R. S. Hooper, M.B., B.S., D.A., Anaesthetic Registrar, all three at Norfolk and Norwich Hospital; D. D. Guha, M.B., Surgical Registrar at West Norfolk and King's Lynn Hospital.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—E. Fischer, Ph.D., L.R.C.P. & S.I., Senior Hospital Medical Officer, Royal Western Counties Institution, Starcross, Devon; R. C. Allison, M.B., B.Chir., D.A., Assistant Anaesthetist (S.H.M.O.) to West Cornwall Clinical Area; J. A. Smith, M.B., B.Chir., F.F.R., D.A., Consultant Anaesthetist to Plymouth Clinical Area; F. S. W. Brimblecombe, M.D., M.R.C.P., D.C.H., Consultant Paediatrician to Exeter Clinical Area; H. P. Guerrier, M.B., B.S., F.R.C.S., Consultant Surgeon to Exeter Clinical Area (Torquay and Newton Abbot Hospitals); Kathleen J. Harrison, M.B., Ch.B., D.Obst.R.C.O.G., D.C.H., Registrar in Pathology, Frenchay Hospital, Bristol; A. G. G. Toomey, M.R.C.S., L.R.C.P., D.M.R.D., Senior Registrar in Radiology to North Gloucestershire Clinical Area; S. R. Hewitt, M.B., B.S., D.Obst.R.C.O.G., M.R.C.O.G., Senior Registrar in Obstetrics and Gynaecology, Plymouth Clinical Area; P. W. Seargeant, M.B., Ch.B., F.R.C.S., Surgical Registrar to Cossham/Frenchay Group of Hospitals, Bristol; Patricia M. Gilbert, M.B., Ch.B., Registrar to South-west Regional Blood Transfusion Centre, Southmead, Bristol; R. L. Batten, F.R.C.S., Surgical Registrar, Westover super-Mare Hospital; R. M. Norman, M.D., M.R.C.P., D.P.M., Research Consultant in Neuropathology; A. G. Freeman, M.D., M.R.C.P., Senior Registrar in General Medicine, Exeter Clinical Area; S. Mallick, L.R.C.P. & S. Ed., D.Obst.R.C.O.G., Registrar in Obstetrics and Gynaecology, Gloucestershire Royal Hospital, Gloucester; P. A. Oye Anyegbum, M.B., B.Ch., D.L.O., Ear, Nose, and Throat Registrar, South Devon and East Cornwall Hospital, Plymouth.

SWANN, W. G., M.D., D.P.H., D.Obst.R.C.O.G., Medical Officer of Health and Port Medical Officer of Belfast.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Eedy.—On September 16, 1953, to Francoise, wife of Dr. B. N. Eedy, 39, King Edward Avenue, Mansfield, Notts, a brother for Bernardine and Patrick—Michel.

Graves.—On October 3, 1953, at Kitts Croft, Writtle, Essex, to Valerie (formerly Scotland), M.B., B.S., wife of Dr. J. C. Graves, a son.

Macaskill.—On September 28, 1953, at the Boston General Hospital, to Daphne, wife of Dr. John S. M. Macaskill, 2, Church View, Coningsby, Lincs, a daughter—Elizabeth Mary.

Mills.—On October 1, 1953, in Birmingham, to Dr. Margaret J. Mills, wife of Wilfrid Mills, F.R.C.S., a son.

Ogan.—On October 4, 1953, at Queen Charlotte's Hospital, Goldhawk Road, London, W.2, to Ovidia, wife of O. Kesandu Ogan, M.R.C.S., L.R.C.P., D.R.C.O.G., a daughter.

Roddie.—On September 24, 1953, at Johnstone House, Royal Maternity Hospital, Belfast, to Alix P. M. Roddie (formerly Hurst), M.B., B.S., wife of T. Wilson Roddie, M.B., B.Ch., M.R.C.O.G., a daughter.

Shaw.—On October 5, 1953, to Joyce (formerly Dadds), M.B., B.S., wife of Kenneth V. Shaw, A.R.I.B.A., of Quarry End, Waltham, Darlington, Co. Durham, a son.

Shepherd.—On October 1, 1953, at Enfield, Middlesex, to Demetra, wife of Henry Robert Shepherd, D.S.C., M.B., Ch.B., a second son—Michael Charles.

Slovick.—On September 28, 1953, at King's College Hospital, London, S.E., to Pamela, wife of David Slovic, M.R.C.S., L.R.C.P., a daughter.

DEATHS

Alden.—On September 14, 1953, John Wenham Alden, M.B., B.Ch., of 186, Woodstock Road, Oxford.

Barer.—On September 22, 1953, at 29, The Avenue, Hitchin, Herts, Max Barer, M.B., B.S.

Bartlett.—On September 15, 1953, at Kisumu, Kenya, James Henry Bartlett, B.M., B.Ch., aged 44.

Clark.—On September 15, 1953, at his home, Lanadon Lodge, Churston Ferrers, Devon, John Clark, M.B., C.M., formerly of Radcliffe, Lancs, aged 82.

Dow.—On September 20, 1953, in a nursing-home, Edinburgh, Robert Charles Scott Dow, L.R.C.P.&S. Ed., L.R.F.P.S., F.D.S.R.C.S. Ed., of 4, Peel Terrace, Edinburgh.

Gibson.—On September 13, 1953, at Cartref, Terrick, Aylesbury, Bucks, Michael Joseph Gibson, M.D., F.R.C.O.G., late of Dublin, aged 77.

James.—On September 18, 1953, Robert Blake James, M.R.C.S., L.R.C.P., of Riverside, Hungerford, Berks, aged 84.

Jaques.—On September 20, 1953, at Worthing Hospital, Robert Jaques, F.R.C.S., of Worthing, Sussex.

Kahan.—On September 16, 1953, Nest Kahan (formerly Thomas), M.B., B.S., D.P.M., D.C.H., formerly of Kingston, Surrey.

Keats.—On September 18, 1953, Bertram Abbott Keats, L.M.S.S.A., of 37, The Ridgeway, Finchley, London, N., aged 71.

Kennedy.—On September 15, 1953, at Boughton-under-Blean, Faversham, Kent, Arthur Kennedy, M.C., M.B., Ch.B., aged 61.

Scott.—On October 2, 1953, at his home, 22, Longton Avenue, Manchester, James Murray Scott, M.B., Ch.B., aged 44.

Scroggie.—On September 20, 1953, in a nursing-home, Strirling, William Keith John Scroggie, C.I.E., M.R.C.S., L.R.C.P., Colonel, I.M.S., retired, of Abbotford Lodge, Callander, Perthshire.

Wills.—On September 22, 1953, Ronald Leonard Wills, M.R.C.S., L.R.C.P., of Sheerness, Kent, formerly of The Lizard, Cornwall.

Wright.—On August 22, 1953, at his home, Takapuna, New Zealand, John Edward Wright, M.B.E., F.R.C.S. Ed., F.A.C.S., L.D.S.R.C.S.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Protection by A.T.S.

Q.—For how long does the usual prophylactic dose of A.T.S. (say 1,500 I.U.) confer protection against tetanus arising from (a) infected wounds, and (b) further infected wounds received several days later?

A.—(a) A single prophylactic dose of 1,500 I.U. (1950), which is equivalent to 3,000 I.U. (1928), is regarded by many surgeons as adequate insurance against the risk of tetanus. The protection is usually at its maximum two or three days after a subcutaneous or intramuscular injection of antitoxic serum, and then slowly diminishes as the A.T.S. is eliminated; it is probably very low after about three weeks. Occasionally, however, the duration of adequate immunity may be only a few days in some sensitive persons who have had previous injections of horse serum. If it is desired to prolong the period of protection, some surgeons double or treble the usual dose for cases considered to be tetanus-prone—for example, those with dead tissue or foreign bodies in wounds, particularly when there has been delay between wounding and efficient surgical treatment. But the more usual practice in such cases is to give two further doses, each of 1,500 I.U., at weekly intervals. There is no hard-and-fast rule. Children may be given the same doses as adults.

To-day emphasis is being laid increasingly on active immunization with tetanus toxoid. The first dose of toxoid may be injected, if desired, six weeks after the last dose of antitoxic serum.

(b) It is probably unwise to assume that the protection afforded by antitoxin, given more than a day or so previously, will be adequate in all persons. Another dose of serum is indicated.

Folic Acid and Diarrhoea

Q.—It has been my experience that folic acid checks the diarrhoea in both sprue and idiopathic steatorrhoea, often before there is any recognizable improvement in the blood picture. What is the explanation of this? On the contrary, I have failed to observe any improvement in the diarrhoea of coeliac disease in children when this is treated with folic acid. Why is this?

A.—During the war it was discovered that large doses of sulphaguanidine were effective in the diarrhoea of sprue, even though no pathogens were present. The same was true of crude liver extract. It is probable that the common action of these three agents—sulphonamides, liver, and folic acid—is a change of the intestinal flora to one which is less irritant to the mucosa. Cortisone may act in the same way or, more probably, by diminishing the irritability of the mucosa. At any rate, it is clear that, although diarrhoea, anaemia, and the defect in fat absorption are roughly parallel, they may diverge, particularly in the early stages of treatment. Diarrhoea usually improves first, next anaemia, and only after a long interval fat absorption.

It is probable that the pathology of coeliac disease is somewhat different from that of sprue, sensitivity to foods—for example, wheat gluten—being more important than disturbance in the intestinal flora. Moreover, the anaemia of coeliac disease is rarely megaloblastic. Deficiency of folic acid *per se* probably favours diarrhoea, as is suggested by the intestinal upsets of untreated pernicious anaemia. Finally, the consequential effects on the diarrhoea of improvement in the anaemia are not to be despised.

Homosexual Tendencies in Middle Age

Q.—What treatment is advised for a man in his fifties with homosexual tendencies which have been getting worse during the last year? This is causing him considerable worry. He is married, and has two children. He is physically fit, and has no signs of prostatic disease.

A.—Your questioner does not make it clear whether conscious homosexual tendencies were present before the patient reached his fifties, or whether they represent a new orientation. In the former case, no help could be anticipated from psychotherapy. In the latter case, it would be essential to establish the diagnosis (that is, the reason for hitherto repressed tendencies of this kind complicating the psychosexual picture) before thinking of treatment.

In either case, should moral and social considerations demand it, "biochemical castration"—that is, planned extinction of the sexual libido—should be considered. This can be effected by means of a daily dose of up to 15 mg. of stilboestrol. The possible side-effects must, however, be remembered.

Unilateral Premenstrual Mastalgia

Q.—I have a patient who for the past year has had mastitis in the left breast coming on fourteen days after a period. It lasts until the next period starts and has gradually been getting worse, the left arm being also affected by pain. On the last occasion, the pain started again on the second day of the period (which lasts only two to three days) instead of on the fourteenth day. Latterly, she has been having some pain in the right breast too. The pain is becoming very severe and, being more or less continuous, is making her ill and depressed. She had a similar occurrence some five years ago, but this lasted some six to seven months only. Is there any treatment?

A.—This condition is probably an exaggeration of the usual premenstrual mastalgia—an exaggeration which is part of a menstrual tension state. The breasts are often unequal in development and function, so it is common for this type of discomfort to be worse on one side. In this condition there is nearly always a background of overanxiety and frequently a fear of cancer. Indeed, the general illness and depression in this case are more likely to be the cause than the result of the pain.

The patient should be reassured and instructed to wear a well-fitting brassière. Her intake of fluid should be restricted to not more than 30 oz. (850 ml.) in 24 hours for two weeks premenstrually, and at the same time salt should be avoided as far as possible. Sodium retention is also discouraged by giving ammonium chloride 10 gr. (0.65 g.), in capsules, three times daily.

Hormone therapy is not very satisfactory for premenstrual mastalgia. Oestrogens may reduce the discomfort but at the expense of upsetting the menstrual cycle. Small doses of androgens are preferable but involve some risk of producing masculinizing effects. If the simple measures mentioned above are insufficient, then the first hormone to be tried should be ethisterone 5–10 mg. sublingually three times daily for ten days premenstrually. It is unlikely to have any undesirable side-effects and sometimes appears helpful.

Otitis Externa in the Tropics

Q.—Why is otitis externa so common in the Tropics? How is it acquired, and what measures of prevention are recommended?

A.—The external auditory meatus is lined with skin, and this is the only area of skin in the body which is not readily accessible for cleansing purposes. In consequence any excess of moisture either from perspiration or from water getting into the ear may cause maceration of the superficial epithelium, thus allowing organisms to gain entry and produce an acute inflammation. The common pathogens are the streptococcus, *Pseudomonas pyocyanea*, and certain fungi of the aspergillus group. Though the infecting agent

is different the mechanism of production of external otitis is similar to that responsible for athlete's foot. In both the infection is in an area of skin not always readily accessible and is most commonly found in visitors to hot countries. Unlike athlete's foot, however, otitis externa does not commonly spread from one person to another.

In the very acute stage great pain and considerable constitutional disturbance may be experienced, and rest in bed with sedatives and an antibiotic may be needed. Locally a wick of wool soaked in half-strength metacresyl acetate ("cresatin") and left in for a few hours will often give relief if combined with local heat. For a fungus infection 2% thymol in spirit may be needed.

The prevention of otitis externa in the Tropics is best achieved by preventing water from getting into the ear canal, and by using a mild oily mercurial solution as ear drops twice weekly (dilute mercuric nitrate ointment, 1 drachm (4 g.); expressed almond oil to 1 oz. (28.4 ml.)).

Resorcin Stains

Q.—Please can you tell me how to remove the brown stains of resorcin from a wash-basin?

A.—Fresh stains of resorcin may often be removed by sponging with alcohol, ether, or glycerin. Older stains should be treated with a warm 3% solution of citric acid. If the stain has seeped through cracks in the glazed surface of the porcelain, prolonged soaking may be necessary.

NOTES AND COMMENTS

Filatov's Tissue Therapy.—Dr. W. M. CORBET (of *Excerpta Medica*, Amsterdam) writes: Your expert dismisses the query about Filatov's tissue therapy ("Any Questions?" September 12, p. 634) somewhat lightly, and this misleads the questioner. Many enthusiastic reports have appeared, and continue to appear, more especially in the Italian and Spanish literature.

OUR EXPERT writes: I am quite certain that I have not misled the questioner as to the therapeutic value of Filatov's treatment, though I may have been slightly misleading in suggesting that nearly all the references were confined to French and Russian journals. I do not think it is a matter of any importance.

Car Sickness in Small Children.—Dr. FRANCIS LESLIE (London, S.W.1) writes: Some children are completely cured of car sickness and the feeling of nausea ("Any Questions?" August 29, p. 519) if the car is earthed by means of a metal chain attached to a bumper, provided that one or two links of that chain touch the ground at slow speeds or when the car is stationary. A car, just because it is insulated by rubber tyres, must presumably possess quite an appreciable electrical charge similar to the rubber-tyred operation theatre trolley, and the fact that some children are cured of sickness and nausea by the earthing of the vehicle suggests that an electrical charge is responsible for their symptoms. I know of one firm of car agents who did not like the appearance of a chain hanging from a car delivered to one of their clients, and so they installed a metal tube under the car through which passed the earthing chain, and reserve chain could be released as the end links were worn away by contact with the road surface. Surely these facts invite fuller investigation, and I would welcome the comments of those with children who suffer from car sickness or nausea.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

THE PLACE OF FORCEPS IN PRESENT-DAY OBSTETRICS*

BY

T. N. A. JEFFCOATE, M.D., F.R.C.Sed., F.R.C.O.G.

(From the Department of Obstetrics and Gynaecology, University of Liverpool)

The Former Place of Forceps

The invention of the forceps was probably the most important event in the history of obstetrics, for dissemination of knowledge of the instrument, coinciding as it did with the first serious incursions of the medical profession into the realms of midwifery, gave the supremacy to the man midwife and afforded him, for the first time, opportunities for the study of normal as well as abnormal labour—a study from which all modern knowledge has come. So great an advantage did this instrument give the obstetrician of two centuries ago that it became hated by the midwives, who did everything possible to discredit it in the eyes of parturient women. It was this attitude which prompted Smellie and others of his day to use wooden- or leather-covered forceps, which, being devoid of a tell-tale metallic rattle, could be applied surreptitiously without the knowledge of either patient or handymaid.

The early patterns of forceps were short and straight, so they can have been used only when the foetal head was low in the pelvis. This, together with the fact that anaesthesia was not available, must have given them a high degree of safety and freedom from certain, although not all, misuses. It might therefore now be argued that it was unfortunate that the early instruments were very soon lengthened, curved, and supplied with axis-traction mechanisms, because it was these modifications which not only allowed but encouraged the accoucheur to reach higher and higher for the foetal head. It should be noted, however, that Smellie lengthened and curved his forceps primarily for use on the aftercoming head, and he always preferred the short straight instrument when the head presented, insisting that the presenting part must be low before they could safely be applied (see Johnstone, 1952). Responsible obstetricians of the past always recognized and taught that forceps are useless for overcoming major degrees of disproportion, but inexperienced and less skilful practitioners repeatedly tried them when the pelvic brim or cavity was contracted—with disastrous results. The objection to forceps, based initially on prejudice and vested interests, thus quickly became justified by their abuse.

With more general observance of the rules governing the safe use of forceps, the instrument gradually became

more popular, but even to-day it has not completely lived down its evil reputation. It achieved a clearly defined place in obstetric practice during the latter half of the nineteenth century, and this place remained relatively static until about 25 years ago. At that time, when many of us were undergraduates, the high-forceps operation was banned even if it had not completely disappeared from the practice of the unscrupulous and less learned. Mid-forceps and low-forceps operations were regarded as proper in both domiciliary and hospital midwifery, but only as a last resort, conservatism in their use being justified by the risk of sepsis if by nothing more.

Recent Developments in Obstetric Practice and Results

The last 25 years has seen a revolution in obstetrical methods and outlook, a revolution which has, or should have, modified our views on the place of forceps as on other matters. The main factors in the revolution are well known: the introduction of the lower-segment type of caesarean section which made abdominal delivery safe even when carried out late in labour; the discovery of sulphonamides and later of antibiotics; the provision of facilities for immediate and adequate blood transfusion; developments in anaesthesia; the extension of antenatal supervision to cover practically all pregnant women; the increased facilities for hospital delivery; and the upgrading of maternity hospitals and of their staffs. These and other changes have brought about a dramatic fall in the mortality and morbidity rates not only of the mother but also of the child. Indeed, in some respects modern trends are better shown by foetal than by maternal results.

The fall in the stillbirth and neonatal death rates is here illustrated by the experience of the Liverpool Maternity Hospital for the 25 years 1926–50, an experience which covers the birth of 50,622 babies (Fig. 1). During this period the neonatal death rate was reduced by one-third, and the stillbirth rate by two-thirds. Moreover, there was an important change in the relative importance of the various causes of foetal death (Fig. 2). Birth injury, which has long been credited with approximately 33% of deaths, now accounts for less than 10% of stillbirths and neonatal deaths. Intranatal and neonatal asphyxia still take a heavy toll, mainly because of associated prematurity. Foetal malformation becomes relatively more important as preventable causes disappear.

*Read in opening a discussion in the Section of Obstetrics and Gynaecology at the Annual Meeting of the British Medical Association, Cardiff, 1953.

All manner of factors have played a part in this reduction in foetal mortality, and it is impossible to apportion the credit exactly, but study of the results suggests that it is mainly due to better intranatal care of the foetus. This in turn is the result of the appointment of *resident* obstetricians of greater skill and experience and, along with this, a change in obstetric management. In obstetrics, as in politics, the last quarter-century has seen a swing from the conservative to the radical outlook. There has been more and more interference with natural delivery, no matter whether the foetus presents by the head or by the breech. Thus the forceps delivery rate has risen from 6-7% to 16-17% of total births (Fig. 3), an increase which has occurred at the expense of spontaneous delivery and not of caesarean section. Indeed, during the 25 years the section rate also rose

FIG. 1.—Diagram showing the change in maternal and foetal results at the Liverpool Maternity Hospital during 25 years.

FIG. 2.—Relative importance of various causes of all foetal deaths for five-year periods during 25 years, shown in percentages. "Intranatal and neonatal asphyxia and atelectasis" includes deaths associated with prematurity except where there was definite evidence of intracranial injury. "Antenatal asphyxia" includes all deaths *in utero* before the onset of labour.

FIG. 3.—Rates for caesarean section and forceps delivery expressed as percentages of all births in the Liverpool Maternity Hospital during 25 years.

FIG. 4.—Diagram showing the falling foetal mortality associated with forceps delivery. Foetal mortality in this and other tables includes both stillbirths and neonatal deaths.

from 5 to 15% (Fig. 3). Altogether, in a hospital which deals with highly selected material and includes a high proportion of abnormal cases, approximately one-third of the babies are now delivered either by forceps or by caesarean section.

Decreased Risks of Forceps Extraction

Not only have the forceps operations increased in number, they have at the same time decreased in risk. Thus the foetal mortality attending the operation has fallen from 20 to 2% (Fig. 4). At the same time the danger to the mother has become very small. During the last 15 years of the period under review 3,522 women were delivered with forceps and 13 died. The fatal outcome was unrelated to the operation in at least seven of these; in the remaining six anaesthesia was the cause of death of three women and contributed to the death of a fourth. There was only one case, in 1941, in which the operation was the direct cause of death. In this, severe shock developed after a difficult mid-forceps delivery.

The risks of forceps have been reduced by changing their method of use and their indications.

Changes in Technique

Under this heading many matters might be mentioned: the discarding of all forms of axis-traction instrument; the substitution of skill for force in traction; the use of episiotomy; the correction of the position of the foetal head

before or after the application of the forceps, and, more recently, the use of local analgesia. The most important of all changes in technique, however, has been the ever-increasing emphasis placed on the accurate application of the blades to the sides of the foetal skull.

Changes in Indications

The decision on when forceps can safely be used is probably more important than knowing how to use them, and a modification in outlook regarding the time and place for forceps is a striking feature of the obstetrical revolution of the last 25 years, and the main reason for the improvement in results. This modification in outlook is not unrelated to other developments. The increased safety of caesarean section has, for example, done away with the need to use forceps in cases mechanically obstructed late in labour. Whereas formerly only the high-forceps operation was condemned, it has gradually but convincingly been demonstrated that many mid-forceps operations, even though technically possible, are prejudicial to the health

FIG. 5.—Duration of the second stage of labour in cases of forceps delivery, expressed in percentages. 1929 is the first year for which details are available. "Cervix barely fully dilated" refers to those cases in which the anterior lip was not fully taken up or in which cervicotomy was carried out.

and life of both mother and child. Difficult mid-forceps operations have therefore become fewer and fewer, the safer alternative of caesarean section being preferred. On the other hand, the number of forceps deliveries has become swollen at the expense of what would have been spontaneous deliveries had the second stage been allowed to continue longer. The situation might be summarized by saying that babies previously born dead with forceps are now being delivered alive by caesarean section, while those stillborn as a result of spontaneous delivery are now extracted alive with forceps.

Formerly, in accordance with conservative principles, the second stage of labour was allowed to continue almost indefinitely provided foetal distress did not develop. This usually meant that when it was finally decided to use instruments not only was the mother exhausted but the foetus was asphyxiated and already suffering from cerebral congestion if not more serious damage. A baby in poor condition was then subjected to anaesthesia and to the trauma involved in rotation and extraction, with considerable risk of a fatal outcome.

The ever-improving results are associated not only with more frequent use of forceps but with their more timely use. The trend towards a shorter duration of the second stage prior to forceps delivery is shown in Fig. 5.

Indications for Forceps Delivery in Modern Practice

Nearly every student taking the final examination, if asked the indications for forceps, gives priority to "maternal

distress" and "foetal distress." It is the traditional answer, but is it still acceptable? If by maternal distress is meant physical exhaustion manifested by a rising pulse rate, prostration, ketosis, and possibly pyrexia, then it should no longer be accepted as an indication for forceps. It is indefensible to allow any woman in the second stage of labour to reach such a state, and forceps extraction (if it is the appropriate treatment) should have been carried out much earlier. Similarly with foetal distress. This condition may come on suddenly and without much warning, in which case immediate forceps delivery is called for, provided the usual conditions are satisfied. In most cases, however, prolongation of labour and slow advance give ample warning that foetal asphyxia is likely to develop. In all such cases the distress should be anticipated and forceps applied while the foetus is in relatively good condition. Good obstetrics calls for intelligent anticipation, and if it is clear that the presenting part is held up on the perineum it is unjustifiable to withhold assistance because an arbitrary time limit has not expired or because the foetal heart is steady. Similarly, if the mother and baby have been exposed to a long and tiresome first stage of labour it can be assumed that neither is well fitted for the ordeal of the second stage, and that they will show evidence of stress sooner or later.

One condition which deserves special mention is uterine inertia in the second stage of labour. There are still some who, fearful of poor uterine action in the third stage, recommend deferring delivery. This outlook again is a relic of the past and takes no account of modern efficient methods for preventing and controlling post-partum haemorrhage. With care over anaesthesia and with ergometrine at hand, forceps extraction is nearly always the best treatment of inefficient uterine action once the cervix is fully dilated.

A low-forceps delivery before evidence of foetal distress or before an absolute indication is present is often called a "prophylactic forceps" operation—a term introduced by De Lee in 1920. It was some time before it was accepted in this country, and it has caused derision amongst older obstetricians, who regard it as an excuse for meddling some midwifery. I am not concerned to defend the term, although it is expressive in that it indicates that the operation is preventive—preventive of foetal asphyxia and death, preventive of maternal injury and nervous stress. I am concerned, however, to justify the use of forceps as a leisurely planned operation *before* the onset of a situation which results in their use becoming dangerous. Even if the prophylactic forceps operation is sometimes an unnecessary operation, no harm comes of it in skilful hands.

It is necessary to recognize, however, that the freedom with which forceps can safely be used must vary with the circumstances under which midwifery is carried out. The decision in each individual case must always rest on whether the application of forceps is safer for mother and child, bearing in mind the skill of the obstetrician, the availability of assistants, and the facilities and equipment of his environment. The indications are therefore different in domiciliary and hospital practice.

Domiciliary Practice

Outside hospital it is probably wisest and safest for no one, no matter how expert, to attempt any forceps delivery unless the vertex is below the level of the ischial spines and is visible at the vulva. Even then it is necessary to ensure that the head is really as low as it appears and that the signs are not deceptive because of shallowness of the pelvis and extreme moulding and caput formation. No part of the head should be palpable abdominally. If high standards of asepsis cannot be maintained, and if an anaesthetist is not available, it is usually best to leave it to Nature as long as is reasonably possible and until a clear indication for delivery is present. There is only a limited place for a "prophylactic" operation in domiciliary practice.

Hospital Practice

Granted a fully equipped and expertly staffed hospital, a low-forceps operation combined with episiotomy can usually be carried out with impunity, and therefore with freedom. It involves less risk for both mother and child than does a spontaneous delivery after a protracted second stage of labour. No matter whether the occiput be anterior or posterior, it does not require rotation at this level in the pelvis. Care has to be taken to exclude such possibilities as contraction of the bony outlet, but this is a bogey which has been grossly exaggerated. Outlet contraction sufficient to cause real difficulty is exceptionally rare in a pelvis where inlet and cavity are adequate.

Even in hospital, however, a mid-forceps delivery must be approached with caution, recognizing that it almost always involves dealing with an unrotated head. This does not mean that the head is malrotated; it is normal for the sagittal suture to remain transverse or oblique until the vertex reaches a low level. Other speakers are dealing with the problem of the unrotated head, and I would stress the second difficulty associated with the mid-forceps operation—namely, the presence of previously unrecognized disproportion at the level of the mid-plane of the pelvis. Although in most cases the experienced obstetrician can sift the cases accurately and decide beforehand which will deliver easily with forceps and which will not, there is always the possibility of meeting unexpected difficulty, and particularly so in a multigravida with an unusually large baby. The likelihood of an error in judgment is reduced by intranatal radiography, facilities for which should be available in all maternity units.

It is in the case in which forceps have been applied, and in which unexpected difficulty is encountered, that tragedy may occur. The tragedy results from a train of human reactions which have personal pride and prestige as their basis. We have all experienced them. The unexpected resistance to delivery is followed by a stronger pull and then removal of the blades to confirm the position of the foetal head. Further traction with little effect brings to mind the vision of a stillbirth. Now is the time to stop, but the patient and her relatives have been prepared for forceps delivery, not caesarean section. Moreover, it requires much courage to admit to assistants, midwives, and onlookers that a mistake has been made and that vaginal delivery is not safe. The remote possibility of successful delivery spurs the obstetrician to renewed and more frantic efforts. Now he is seized with dread, casts caution to the winds, and ultimately he may or may not succeed in extracting a mangled foetus, the mother also being injured in one way or another.

The situation is more dangerous if some progress is made than if the passage of the foetal head is completely obstructed. In the former case the foetal head is crowded more and more into an ever-decreasing pelvic diameter, with inevitable injury; in the latter it can come to no harm except from the pressure of the forceps themselves.

One of the fears which drive the obstetrician to make frantic efforts is that the case may become one of "failed forceps"—a label which by tradition involves everyone concerned with ignominy, and which itself can be responsible for bad obstetrics. How much better it would be if it were generally recognized that even the best exponents can make a mistake occasionally, and that failure to deliver with forceps is not so great a sin as a failure to recognize defeat at an early stage. If the forceps are applied skilfully no harm comes to the baby or to the mother, provided the attempts at extraction are discontinued immediately it becomes clear that there is greater difficulty than anticipated. All that is necessary is to have the courage to proceed to caesarean section before the life of the foetus is jeopardized.

Trial of Forceps

This raises the question of whether, under proper conditions, a "trial of forceps" is an acceptable procedure.

This means that when the head is arrested in the mid-pelvis forceps should be applied tentatively with the declared intent of abandoning the operation in favour of caesarean section if it does not proceed smoothly. The forceps need to be applied accurately to the foetal head, and traction has to be cautious. If all mid-forceps deliveries in hospital were viewed as trial operations the dread of failure would disappear from the mind of the operator and he would be happy not to proceed in the face of difficulty. The idea of a trial of forceps is not new. It was suggested and practised by Frank (1908) and again by Fraenkel (1925) and others in the 1920s. It has been recently advocated by Parry Jones (1952) and by Douglass and Kaltreider (1953).

When it was first introduced it was difficult to justify because of the maternal risk of caesarean section after interference *per vaginam*. Now, however, that this risk has largely gone, it should be re-examined and not discarded merely on the grounds of prejudice. It could, of course, be abused, and it has no place save in the hands of the expert working in hospital—the same qualifications which apply to the accepted practice of trial of labour. The only difference is that trial of labour is concerned with disproportion at the brim; trial of forceps is concerned with disproportion in the cavity. The trial of forceps may have only a small place, but if it has a recognized place it may well help to do away with the tragic condition of "failed forceps" and it may revolutionize the outlook of everyone concerned in any forceps delivery. As Douglass and Kaltreider (1953) point out, "It is a most comforting thought, when sitting down to do a mid-forceps operation, that one is not irrevocably committed to vaginal delivery."

Do Forceps Protect the Baby?

It has often been argued in recent years that the blades of the forceps, if properly and accurately applied, protect the foetal head from injury. The argument is not illogical, and its truth is already established in the special case of the after-coming head. The frequent and almost regular use of forceps for lifting the after-coming head from the cavity of the pelvis is one of the most important factors in the Liverpool Maternity Hospital (Cox, 1950).

Forceps are also said to protect the fore-coming head, especially the small and soft head of the premature baby (Studdiford and Salter, 1938; Scott, 1940; Assali and Zacharias, 1947). This matter still awaits proof, but in our experience forceps certainly do no harm and may do good so far as the delivery of small babies of toxæmic mothers is concerned (Hamilton, Jeffcoate, and Lister, 1949).

Advantages to the Mother

So far, the use of forceps has been considered almost entirely from the standpoint of the foetus. If under modern conditions this instrument must be regarded more and more as being primarily used in the interests of the child, it should also be recognized that Smellie, too, viewed it in this light and adopted it with the idea of reducing his stillbirth rate. It offers a means for speeding delivery to give the baby opportunity to establish its own respiratory function before the respiratory function of the placenta fails. Nevertheless, the question arises whether forceps bring any advantage to the mother. If properly used after full dilatation of the cervix, and in conjunction with episiotomy, and assuming asepsis, they should have no ill-effect. They are sometimes blamed for fistulae and other injuries, but these are mostly due to the condition calling for the use of forceps. They are clearly of advantage in that they shorten labour and spare the woman much mental and physical stress.

Do they prevent prolapse? There is some evidence to show that a prolonged second stage with overstretching and devitalization of the paravaginal tissues is more important

in causing prolapse than a quicker delivery with a tear or episiotomy. The matter is still *sub judice*, but meanwhile there is nothing to suggest that forceps in the hands of the expert do any harm to the mother, and they may be instruments of good as well as of mercy.

Dangers of Forceps in Modern Practice

The greatest danger of forceps delivery at the present time is anaesthesia, and this danger has, if anything, increased with the introduction of modern anaesthetic agents whose safety depends on increasing skill on the part of the anaesthetist. As mentioned previously, there have been six maternal deaths associated with forceps delivery in the Liverpool Maternity Hospital during the 15 years preceding 1950. Three of these were the result of the inhalation of vomit during induction of general anaesthesia, and the fourth was due to the effect of an anaesthetic on a diseased heart. Since 1950 there have been more cases of inhalation asphyxia and pneumonia as a result of vomiting during induction or recovery from anaesthesia given for the purpose of the application of forceps. This risk is very great when labour has been prolonged, as it has in many cases in which forceps delivery is indicated. The other risk is third-stage and post-partum haemorrhage associated with depression of myometrial activity by the anaesthetic.

To recognize these risks, and to have them ever present in mind, is to reduce them to a minimum. They constitute the chief reasons for advocating the use of local analgesia for all easy low-forceps extractions.

Conclusion

There is danger in praising forceps too highly and in claiming too large a place for them; it might encourage their abuse. There is also danger in adopting an ostrich-like attitude and failing to recognize that times have changed, and are changing. It will not do to condemn forceps merely on the grounds that they represent interference with Nature, if it can be shown that their results improve on those achieved by Nature.

The fact that childbirth is a physiological process does not necessarily mean that it is a benign one. The reproductive function in all species is both dangerous and wasteful. Nature is not concerned with making reproduction safe for individual mothers or offspring; she expects losses, and for this reason provides a supply of potential offspring which is so bounteous as to offset them and ensure the continuance of the race.

The natural maternal and foetal mortality rates are unknown, but it is quite certain that they are much higher than those which obtain when the medical and nursing professions stand by ready to interfere judiciously with Nature. Obstetricians do well to leave childbirth to Nature only so long as she is efficient, but when she fails—as she often does—lives can be saved only by carefully planned and skilful intervention. Moreover, as the means and methods for intervention become safer, they can offer more and more to the individual than can Nature.

"FAILED FORCEPS": A REVIEW OF 37 CASES

BY

R. G. LAW, M.D., M.R.C.O.G.

Assistant to the Obstetric Unit, University College Hospital, London; Late Senior Registrar, Norfolk and Norwich Hospital, Norwich

During the period January 1, 1948, to May 31, 1952, 37 cases of "failed forceps deliveries" were admitted to the Norfolk and Norwich Hospital. Of these patients 21 were primigravidae and 16 multiparae. This paper is based upon an analysis of these cases.

Maternal and Foetal Hazards

A study of the recent annual reports of nine hospitals shows the maternal mortality rate in "failed forceps" cases to be 2.0%, while the foetal loss is 36.2%. So far as the risk to the foetus is concerned these findings are in reasonable conformity with those in the present series as shown in Table I. It will be seen that seven infants were

TABLE I.—General Analysis of the Present Series

	No. of Cases	Maternal Morbidity	Foetus Dead on Admission	Stillbirths	Neonatal Deaths	Total Foetal Loss
Primiparae	21	6 (28.6%)	2	3	1	4 (19.1%)
Multiparae	16	4 (25.0%)	4	4	1	5 (31.2%)
Total	37	10 (27.0%)	6	7	2	9 (24.3%)

stillborn, while a further two died during the neonatal period, the total foetal loss being 24.3%, or 22.2% if correction is made for one case of hydrocephalus.

Although no mother died as a result of this intervention, the maternal morbidity rate stood at the high figure of 27.0%. The remote prognosis for these patients may thus be less favourable than the immediate results suggest, since, as emphasized by Miller (1928), Clave (1931), Stacey (1931), and Feeney (1947), the sequelae of puerperal infection often persist for many years.

Duration of Labour

Table II shows that labour tended to be prolonged in these cases compared with normal vertex deliveries, this being most marked in primigravidae. In these patients the

TABLE II.—Duration of Labour in Failed Forceps Deliveries

	Total Cases	First Stage Over 24 Hours	Second Stage Over 2 Hours
Primiparae { Failed forceps* ..	19	12 (63.2%)	14 (73.7%)
{ Normal ..	185	36 (19.5%)	19 (10.3%)
Multiparae { Failed forceps* ..	11	2 (18.2%)	7 (63.6%)

first stage lasted over 24 hours in 63.2% of cases, a finding that suggests that, in some cases at least, delivery may have been attempted for this reason alone. The second stage lasted more than two hours in 73.7% of primigravidae, and 63.6% of multiparae. This, however, was mainly due to the time expended in transferring the patient to hospital.

Past Obstetric History in Multiparae

The past obstetric history in the 16 multiparae is summarized in Table III. It will be seen that a history of previous dystocia was given by eight patients (50%), while of eleven cases in which details regarding the size of

former infants were available, in no fewer than seven the present infant was larger than its forerunners and was thus capable of causing difficulties not previously experienced.

Causes of Failure

As pointed out by previous writers on this subject (Phillips, 1926; Murray, 1927; Miller, 1928; Claye, 1931; Stacey, 1931; Feeney, 1947; Browne, 1949; Freeth, 1950), the three fundamental factors responsible for failure to deliver the patient are disproportion, incomplete cervical dilatation, and some malposition of the foetal head. That two or more of these factors may be present in one and the same case is shown in Table IV, where, for the sake of clarity, the main cause is emphasized.

TABLE IV.—Causes of Failure to Deliver the Patient

	No. of Cases	Cause Present			Type of Cause		
		Single	Multiple	None	Disproportion	Undilated Cervix	Malposition of Head
Primiparae	21	14	3	4	3	3 (2)	11 (2)
Multiparae	16	7	7	2	4	3 (5)	7 (4)
Total	37	21	10	6	7	6 (7)	18 (6)

The numbers in parentheses indicate subsidiary conditions.

In 18 cases some malposition of the foetal head—usually an occipito-transverse or occipito-posterior position—was the main reason for failure. In addition this feature was observed in a further six patients, although here it was not the main cause. Thus, in 64.9% of cases the foetal head was not in a suitable position for a straightforward forceps delivery. By contrast, disproportion was present in only seven cases—three primiparae and four multiparae—an incidence of 18.9%. Incomplete cervical dilatation occupied a position mid-way between the two conditions already mentioned, being encountered as a main factor in six cases and as a subsidiary in a further seven, the total incidence being 35.1%.

It is interesting to note that these results compare closely with those observed in the much larger series reported by Freeth (1950), with the difference that malposition of the head was often observed in multiparae. This finding is also contrary to the views of Claye (1931), who was of the opinion that anterior rotation of the occiput almost invariably took place in these patients.

Method of Delivery in Hospital

This aspect of failed forceps deliveries, which was fully described by Freeth (1950), is summarized in Table V. Craniotomy was necessary in two cases only (5.4%). In one the foetus was hydrocephalic, while in the other, in which disproportion was present, the foetal heart sounds disappeared shortly after admission. This low incidence of destructive operations—Stacey (1931) gave the proportion

of cases thus delivered as 25%—together with the fact that caesarean section was carried out in six cases (16.2%), supports the prevailing view that the indications for section in cases of this nature could well be broadened.

Of the remaining 29 cases, 6 (16.2%) delivered themselves spontaneously after time had been allowed for full cervical dilatation to occur. A forceps delivery was necessary in 23 patients (62.2%). In this latter group seven of the deliveries were classed as "easy low forceps," the presenting part being on the pelvic floor and the occiput anterior. Thus in a total of 13 cases (35.1%) delivery ultimately presented no special problem, the original difficulty encountered in the attempted extraction having disappeared.

TABLE V.—Methods of Delivery in Hospital

	Spontaneous	Forceps				Caes. Section	Caes. Hyst.	Craniotomy
		Low	And Rotation	As O.P.	Total			
Primiparae	3	5	8	2	15	2	—	1
Multiparae	3	2	6	—	8	3	1	1
Total	6	7	14	2	23	5	1	2

Discussion

Taking into account the three main causes of failed forceps deliveries, it is evident that the incidence of these cases could best be reduced by timely recognition of disproportion, incomplete cervical dilatation, and malpositions of the foetal head.

Disproportion.—In most cases this abnormality can be recognized during the antenatal period. Although even in a primigravida the fact that the foetal head fails to engage at or near term is not necessarily indicative of disproportion, this must always be excluded. In every such case, therefore, clinical pelvimetry, supported if necessary by radiological assessment of the pelvis, should be carried out. This policy is the one generally followed in primigravidae. In multiparae the possibility of disproportion is often overlooked. To a large extent this is due to the belief that in these patients engagement of the foetal head before the onset of labour is the exception rather than the rule. Whatever the truth of this view, the fact remains that in some of these patients disproportion is present. This is shown in Tables III and IV, which suggest that stricter antenatal assessment is necessary in multiparae, especially with regard to the relationship between the size of the present infant and that of its predecessor. Recognition of disproportion after the onset of labour, although even more vital, is often more difficult. It is usually agreed that once the lowest bony part of the head has descended to the level of the ischial spines engagement has taken place. Although this is true in most cases, such a finding may be misleading either if excessive moulding has occurred or if the pelvis is abnormally shallow. At other times the presence of a large caput obscures the actual bony level of the foetal head. For these reasons it is safer to determine whether or not any portion of the head can be palpated above the symphysis pubis, it being taken that should any be felt delivery will be dangerous (Browne, 1949).

Incomplete Cervical Dilatation.—Although in theory full cervical dilatation can be present when a rim of cervix is still palpable, in practice this is rarely the case. It is therefore safest to assume that so long as any portion of the cervix can be felt on vaginal examination full cervical dilatation has not yet been reached. To attempt a forceps delivery under such conditions would be unwise. This rule should apply as rigidly to multiparae as to primigravidae. Although in the former patients the cervix is often reputed to be soft and easily dilatable this is not always so, the residual rim of cervix on occasion proving an effective bar to delivery. At other times delivery may only succeed at the expense of a dangerous cervical laceration. If indications to terminate labour arise before full dilatation,

Colonial Medical Service

incision or manual stretching of the cervix has been recommended (Browne, 1949). These procedures, however, have a limited application and are fraught with hazard. In such cases, therefore, it is probably wiser to transfer the patient to hospital.

Malpositions of the Foetal Head.—Since, as has been pointed out by Freeth (1950), it is unwise to assume that the occiput is necessarily anterior, it is essential to determine the position of the foetal head before applying the forceps. For this it is usually recommended that an ear be sought or, failing this, that the nape of the neck be identified (Browne, 1949). These measures, although possessing a high degree of accuracy, have the disadvantage that full anaesthesia is necessary for their proper application. This objection no longer obtains if use is made of the suture lines to determine the position of the occiput. These landmarks can easily be reached in most patients, and with practice a high degree of accuracy in their identification may be obtained. Late in labour caput formation may obscure these features to some extent, though in all but exceptional cases they can usually be made out with time and patience. If doubt still exists a good case can be made for examination under anaesthesia, the whole hand being passed into the vagina. Such a measure should, however, in no way commit the obstetrician to immediate delivery if the position of the head or the state of the cervix implies that this course would be unsafe.

Conclusions and Summary

An attempt has been made to determine the causes and assess the dangers, both to the mother and to the foetus, of "failed forceps deliveries."

The importance of these emergencies lies mainly in the fact that they represent a small subgroup of that category of deliveries loosely termed "difficult forceps" in which essentially the same conditions and the same dangers exist. Thus, as Fletcher Shaw (1928) pointed out, for every case in which failure occurs there must be many in which delivery is accomplished only after prolonged and dangerous traction, often through an incompletely dilated cervix.

The amount of maternal disability and foetal loss in these cases must be considerable. In consequence, every effort should be made to reduce the extent of this hazardous intervention.

Thirty-seven cases of "failed forceps deliveries" admitted to the Norfolk and Norwich Hospital are reviewed.

In over half of the multiparae consideration of the past obstetric history might have provided grounds for suspecting dystocia.

The causes of failure at the initial attempt at delivery were malpositions of the foetal head, incomplete cervical dilatation, and disproportion. This last factor, however, was not a common finding in the present series.

In a considerable proportion of cases (35.1%) delivery ultimately presented no particular problems.

Suggestions for the earlier recognition of the causes of failure have been discussed.

It has been found impossible, in reviewing the literature, to assess the incidence of sickle-cell anaemia either in America or in Africa. The incidence of sickle-cell anaemia to the sickle-cell trait has been reported in America to vary from 1:2 (approximately) (Winsor and Burch, 1945) to 1:71 (Switzer and Fouché, 1948), with many intervening estimates. These figures show great disparity, but they do prove that sickle-cell anaemia is relatively common in America when it is remembered that approximately 900,000 negroes in the United States exhibit the trait (Beacham *et al.*, 1950).

On the other hand, the majority of writers in Africa regard sickle-cell anaemia as rare, in spite of the fact that the incidence of the trait in the African native may be more than double that of the American negro (Gelfand, 1944; Murray-Lyon, 1944; Beet, 1947; Robertson and Findlay, 1947; Mackey, 1949; Raper, 1950; Lehmann, 1951; Jelliffe and Humphreys, 1952; *British Medical Journal*, 1952). Smith (1943), however, estimated the incidence of the anaemia to the trait to be 1:5 in Nigeria, and Lambotte-Légrand (1951) stated that 6% of trait-positive Africans in Leopoldville suffered from sickle-cell anaemia. Foy *et al.* (1951), in Kenya, did not describe any cases, but stated that there were four cases of sickle-cell anaemia in the 13 trait-positive Africans examined, and concluded that the anaemia was commonest among infants and newborn babies. This statement, however, requires confirmation, as it has been shown that the neonate may be protected against sickle-cell anaemia (Watson, 1948; Edington, 1952), and there are only three reports in the literature of sickle-cell anaemia occurring under the age of 4 months (Cohen *et al.*, 1947; Frazier and Rice, 1950; Heldrich, 1951). Thus the part that the sickling phenomenon plays in the morbidity and mortality rates of the African native has still to be assessed.

I have diagnosed sickle-cell anaemia in 33 instances. Only one examination was possible in 13 patients, however, and these are consequently not considered in this review.

The following investigations were employed to discover those who were suffering from sickle-cell anaemia. (1) One patient was discovered on routine surveys of the population in which 2,255 Africans were examined and questioned. The findings are shown in Table I. It is not intended to discuss these surveys in detail. (2) Patients in the Gold Coast Hospital in whom a sickling test had been requested and found positive were examined. Of 60 sickling-positive patients investigated four were considered to be suffering from sickle-cell anaemia. (3) Patients in the Gold Coast Hospital showing many target cells in the peripheral blood smear on which routine differential counts were being performed

*This paper is based on part of a thesis submitted for the degree of M.D. of the University of Glasgow.

were examined. Of 50 patients investigated two were considered to be suffering from sickle-cell anaemia.

The remaining 13 cases were discovered among patients referred to me by medical colleagues as suspected cases for investigation.

Diagnosis of Sickle-cell Anaemia

The diagnosis of sickle-cell anaemia in Gold Coast Africans is not an easy task, as their "normal" values in clinical medicine are unknown. Colbourne *et al.* (1950), in an attempt to discover the "normal" clinical findings, thoroughly investigated a village of 255 inhabitants in the Southern Gold Coast. The diseases from which these villagers suffered are shown in Table II.

TABLE II.—Incidence of Diseases in a Village of 255 Inhabitants

Condition	%	Condition	%
Ancylostomiasis	52	Malarial parasitaemia	32
Ascariasis	76	Signs of malnutrition	26
Enlargement of liver	33	Schistosomiasis	9
" spleen	46	Streptococci	21
Guinea-worm infection	52	Yaws	75
Herniae	10	Sickle-cell trait	22

The blood counts and the haemoglobin and haematocrit values fell much below the standards regarded as normal in Britain. Malaria, liver disease, malnutrition, ancylostomiasis, and bilharzial infection are all capable of causing anaemia, and may all be found in one individual. The haematological findings in Africans suffering from anaemia may thus not be clear-cut. In one individual there may be present both a haemolytic factor (malaria) and a macrocytic factor (liver disease and malnutrition) in addition to an iron deficiency (ancylostomiasis and schistosomiasis). I thus had difficulty in deciding the criteria necessary for the diagnosis of sickle-cell anaemia. In the surveys it was decided primarily to rely mainly on the history given by the individual and to investigate thoroughly all cases in which a history of recurrent attacks of joint pain, vague ill-health, or jaundice was given. In addition, individuals showing more than 4% of target cells in peripheral blood smears were investigated, as Diggs and Bibb (1939) found these cells in all the 47 cases of sickle-cell anaemia they discussed. The method of discovering patients suffering from sickle-cell anaemia employed in the survey is open to criticism, but in the one girl in whom sickle-cell anaemia was diagnosed the history was dramatic and was not simulated by any of the other individuals examined and questioned. It should be noted that acute rheumatism is extremely rare in the Gold Coast.

Sickle-cell anaemia was not finally diagnosed unless the following criteria were fulfilled: (a) sickling of the erythrocytes; (b) signs of increased haemolysis in the peripheral blood with a persistently raised reticulocyte count; (c) lack of response of the haemolytic anaemia to antimalarial therapy; (d) a low erythrocyte sedimentation rate and lack of response of the joint pains to salicylate therapy; and (e) absence of any other condition which might be responsible for the haemolytic anaemia.

Methods Employed in the Investigation

The rapid bacterial method (Robinson, 1945) was used throughout to detect the presence of sickling. Haemoglobin was estimated by Sahli's method, using two haemoglobinometers which were afterwards kindly calibrated by Dr. J. V. Dacie at the Postgraduate Medical School, Hammersmith, and Dr. J. N. Marshall Chalmers at St. George's Hospital. The packed cell volume was estimated by centrifuging oxalated venous blood (Wintrobe's method) in a haematocrit tube at 3,000 r.p.m. for 30 minutes. Red- and white-cell counts were performed in three sets of pipettes which were checked against each other and against normal individuals (European). They consistently gave similar results, and it is not felt that grave inaccuracies have resulted. Reticulocytes were counted by the coverslip method, using an alcoholic solution of brilliant cresyl blue. Five hundred cells were counted. Target cells were enumerated on a thin blood smear stained by Leishman's method.

The 500 cells were counted by moving transversely across the centre of the smear and the percentage of target cells to the nearest whole number was calculated. Serum bilirubin was estimated by the use of a Lovibond's comparator. Coombs's test was performed, using dried anti-human-globulin serum supplied by the Ministry of Health Blood Group Reference Laboratory. The erythrocyte sedimentation rate was estimated in the manner described by Wintrobe (1947). No correction for anaemia was made. The bromsulphthalein excretion test was performed with a dosage of 2 mg. per kg. and blood was withdrawn at the end of 30 minutes. An alkalized portion of the serum was compared with prepared known percentage standards and acidified serum. The standard three-tube Kahn test was employed. Routine blood culture, Widal, and Weil-Felix tests were performed when considered necessary. It was not possible to perform investigations requiring the use of a colorimeter. The faecal urobilinogen output or haemolytic index was not calculated. Schlesinger's test was employed to detect urinary urobilin and the resultant colour was compared with a normal standard.

Review of the Cases

Three females and 17 males, representing six Gold Coast tribes, were considered to be suffering from sickle-cell anaemia (see Table III).

TABLE III.—Age and Sex Groups of 20 Cases of Sickle-cell Anaemia

Sex	No.	Age in Years					
		0-5	6-10	11-20	21-30	31-40	Over 40
Male	17	—	3	8	4	1	1
Female	3	—	2	—	—	1	—

In only five cases was it possible to examine both parents, and they all showed the sickling phenomenon. In another case one parent was available for examination and the erythrocytes also sickled. None of the parents were found to be suffering from sickle-cell anaemia. Twenty-three siblings were examined and five were considered to be suffering from sickle-cell anaemia; three of these five were in one family. The results of the examination of the families agreed with the homozygous theory of the inheritance of sickle-cell anaemia (Neel and Valentine, 1947).

Previous Histories

The previous histories in all cases were strikingly similar. A history of severe recurrent attacks of pain in the larger joints of the limbs was given. The first attacks had occurred in "infancy" in 12 instances, and the latest onset of the attacks occurred at the age of 7½ years. The present number of attacks a year varied from "continuous" to nil, the latter in an African male nurse, aged 44, who stated that the attacks had ceased at the age of 35. In nine

instances it was stated that the attacks became less severe as the patient became older, and in ten the attacks of joint pain were associated with cold weather. Wintrobe (1947) does not mention that sickle-cell anaemia may become less severe with age, but cold weather was regarded as a possible factor in precipitating the acute episodes of sickle-cell anaemia by Graham (1924) and Berk and Bull (1943).

In the Gold Coast, however, cold weather is associated with the rainy season and with an increase in the mosquito population and a corresponding increase in malarial infection. Knisely and Bloch (1942) described massive intravascular agglutination in vivax and falciparum malaria with local haemoconcentration and tissue anoxaemia resulting from the clumping of the erythrocytes. Similar findings were reported in the one case of sickle-cell anaemia they examined. Malaria may thus act as the "trigger" mechanism in precipitating a crisis in sickle-cell anaemia. Intravascular sickling could be produced by the local anoxaemia caused by the malaria parasite, with resultant increased stasis, increased sickling, and a further increase in the local tissue anoxaemia. A vicious circle would thereby be established. The history of a decrease in the number of attacks as the patient becomes older is also compatible with the theory that malaria may be a precipitating factor in the crises—the attacks lessening in frequency as the patient's premunity to malaria develops. It is suggested that in the Gold Coast the association between cold weather and the acute episodes of sickle-cell anaemia are in all probability associated with the greater incidence of malarial infection found during the rainy season.

Symptomatology

Seven of the 20 patients did not complain at the time of examination. The symptoms, in order of frequency, were: joint pains (11), fever (9), nausea (9), headache (5), abdominal pain (4), pains in the limbs (4), pain in the chest and lumbar pain (2), weakness (2), yellow eyes (2), eye complaints (2), dizziness (1), leg ulcer (1), and palpitation (1). In general the symptoms are those usually described in the literature. The eye complaints were, however, unusual, and micro-aneurysms of the retinal vessels were found in these two patients (Edington and Sarkies, 1952).

Clinical Signs

Eleven of the patients were asthenic and resembled the type of habitus described by Winsor and Burch (1944a, 1944b) with a short trunk and long slender limbs and fingers. "Tower" skull was noted in two patients and mongoloid features in a further two. Jaundice was noticeable in nine and scars of leg ulcers in seven. Active leg ulcers were present in one patient only. The elbow-joint was swollen in one patient and the small joints of the fingers in another.

The heart was considered to be enlarged clinically in five patients. Systolic bruits were present at the mitral area in four and at the pulmonic area in one. The blood pressure was consistently low. The incidence of cardiac complications in this series (25%) is lower than that usually reported, and figures as high as 95% have been recorded (Winsor and Burch, 1945).

Enlargement of lymph nodes was not a striking feature, but small rubbery cervical nodes were palpable in eight patients.

The liver and spleen were palpable in eight and 11 patients respectively. In only one patient was hepatic insufficiency marked, and the bromsulphthalein retention was 35% at the end of 30 minutes. The hepatic insufficiency gradually improved without improvement in the anaemia or in the signs of increased haemolysis. The aetiology of hepatic insufficiency in sickle-cell anaemia is obscure, but has already been described in five patients by Henderson (1950). The diagnostic importance of a palpable liver or spleen in the Gold Coast African is difficult to assess. "Normally" in children the liver may be palpable in 58%, and the spleen in 86%. In adults the figures are lower, and are in the region of 21 and

24% respectively (Colbourne *et al.*, 1950). The spleen in sickle-cell anaemia is enlarged in the younger age groups and diminishes in size with the progress of the disease until only a fibrosed remnant with a characteristic histopathological picture may be found. The spleen in races living in a hyperendemic malarial area follows a similar course, but the histological appearances are different and the small size of the fibrosed spleen in sickle-cell anaemia is not seen. In my opinion no reliance can be placed on enlargement of the spleen or liver as diagnostic points in sickle-cell anaemia in the Gold Coast African.

As already noted two patients revealed aneurysms of the retinal vessels, and dilated and tortuous retinal vessels were observed in a further two.

Blood Findings

The types of anaemia found in the 20 cases were normocytic orthochromic in 7, normocytic hypochromic in 4, macrocytic orthochromic in 1, macrocytic hypochromic in 4, microcytic orthochromic in 3, microcytic hypochromic in 1. These findings are discussed below. The haemoglobin varied from 4 to 14.2 g. per 100 ml. of blood, with a mean of 10.1 g.; the packed cell volume from 14% to 41%, with a mean of 31%; and the white blood cells from 5,400 to 25,300 per c.mm., with a mean of 11,000.

The most striking and constant feature, however, was the presence of numerous target cells in the thin blood smears of each patient. They varied from 32 to 87%. Sickle- or oat-shaped cells were seen in 10 instances and nucleated red cells in 14. The thin smear of one patient contained more nucleated red cells than white. Anisocytosis and poikilocytosis were features of the severe cases only. The reticulocytes varied from 3.4 to 25% and the serum bilirubin from 0.8 to 14 mg. per 100 ml. of blood. The Coombs test was negative in the nine instances in which it was performed. Howell-Jolly bodies were seen in three instances and Cabot's rings in one. The erythrocytes in all instances were more resistant to hypotonic saline than normal controls. The E.S.R. varied from 3 to 40 mm. in the hour, with a mean of 14.

The haematological findings in these cases agree closely with the reported findings of Diggs and Bibb (1939), who reviewed 44 cases. The procedure with the least number of variables in routine haematology is the packed cell volume. Unfortunately this does not hold in sickle-cell anaemia. The rapidity and degree of sickling vary from patient to patient, and the replacement, in varying proportions, of the flexible biconcave disk by a rigid oat- or sickle-shaped cell cannot but influence the packed cell volume. This change also influences the sedimentation rate of the erythrocytes, which is low in sickle-cell anaemia (Bunting, 1939; Diggs and Bibb, 1939; Altmann, 1945). The variation in the types of haemolytic anaemia diagnosed can be explained by this variability of the packed cell volume, from which the absolute values, used in the classification of the anaemia, are calculated. It should also be noted that Diggs (1932), discussing the blood picture in 74 cases of sickle-cell anaemia, stated that sickled cells in a blood smear were the exception rather than the rule. In this series sickled cells were seen in 10 instances only.

Examination of the Bone Marrow

Table IV illustrates the findings in nine patients in whom sternal marrow puncture was performed. The marrow in all cases was of thin consistency, and marrow fragments could not be satisfactorily separated from blood. The recorded results are therefore those of the "haemomyelogram." The nomenclature adopted is that of Israëls (1948). At least 500 cells were counted, and the results are shown in percentages. The cells enumerated under the heading "macronormoblast" resembled superficially the megaloblast, but the nuclear chromatin was clumped in blocks and could not be mistaken for the fine network arrangement of the true megaloblast.

Sickled cells were rarely seen in smears, and target cells were much more common, although in no case did they

approach the numbers seen in peripheral blood smears. Nucleated red cells were never seen in sickled form in direct smears, although it is known that they are capable of sickling (Herrick, 1910; Sydenstricker, 1924a, 1924b; Diggs and Bibbs, 1939; Watson, 1948).

Malaria parasites were not detected in any of the marrow smears. In all cases a normoblastic hyperplasia was present; the myeloid-erythroid ratio varied from 1.6:1 to 1:3.3.

Radiology

Radiological changes which were considered to be due to sickle-cell anaemia were found in 9 out of the 17 patients who were x-rayed. Two mechanisms are thought to be involved in the production of the radiological changes described in sickle-cell anaemia: (a) hyperplasia of the bone marrow producing non-specific lesions which have been described in other haemolytic anaemias, the most important being Cooley's; and (b) lesions produced in bone by the blockage of blood vessels by sickled erythrocytes, with consequent infarction.

Lesions due to hyperplasia of the bone marrow were seen in nine patients and infarctive lesions were present in three. Absence of a well-defined outer table of the skull with perpendicular trabecular striations radiating outwards from the inner table, giving the "hair-on-end" appearance, was the most common lesion, and was seen in eight patients. A generalized mottling of the ribs with trabeculation in

Antero-posterior and lateral views of left femur, illustrating an infarctive lesion. Accentuated growth lines can also be distinguished. Case 2.

the direction of the long axis and enlargement of the heart were seen in two instances. Infarctive lesions in the femora (see Fig.) were noted in four patients, and changes in the tibia and fibula in one.

Treatment

Antimalarial treatment with mepacrine hydrochloride, 0.1 g. thrice daily for five days, followed by proguanil, 0.1 g. thrice daily for five days, was given to the 20 patients without relief, and crises occurred in two patients who were on suppressive proguanil therapy. Salicylates and aspirin did not relieve the joint pains or arrest the condition. Liver and iron therapy had apparently no effect on the anaemia.

In two cases splenectomy was considered for the mechanical relief that was thought might follow removal of the grossly enlarged spleen. It was felt, however, that, in view of the poor results of splenectomy in sickle-cell anaemia recorded in the literature and the absence of readily available blood for transfusion, the risks involved were not justified. One of these patients died some months after discharge from hospital. The cause of death could not be ascertained.

It was considered that the various treatments described above had no effect on the course of the disease in any patient.

Many drugs have been prescribed in sickle-cell anaemia, but few, if any, have proved of value. Diggs (1934) reviewed the literature and personally treated seven cases. Iron, copper, liver, and hog's stomach were therapeutically useless. Murphy and Shapiro (1945) confirmed these findings and added anticoagulants, blood transfusion, and salicylates to the list. Oxygen therapy has also been reported to have little effect on the crises (Hughes *et al.*, 1940). Leivy and Schnabel (1932) and Torrance and Schnabel (1932) believed that the administration of alkali and potassium sulphocyanate relieved the crises, and Grek and Findlay (1951) thought that oxygen inhalation combined with nicotinic acid given intravenously was of help if administered early in the acute crisis. Josephs (1938) reported that the injection of normal plasma or of a protein-free plasma concentrate reduced the rate of blood destruction in patients suffering from sickle-cell anaemia. Kaplan and Lewis (1949) confirmed these findings, but the effect was transitory and tended to reversal with repeated injections.

Course of the Disease

These patients have been followed up for periods varying from two months to four years. Only one patient has died. The remainder have been observed in and between crises. All grades of severity of the anaemia were seen, but even

when the haemoglobin was as high as 14.2 g. per 100 ml. signs of increased haemolysis were constantly present in the peripheral blood and urobilin was present in excess in the urine. One boy aged 16 lost 95 days from school in five acute attacks in the 1948-50 period, and only 18 days in two acute attacks in the 1950-2 period. It would seem that the condition tends to improve with advancing years.

Differential Diagnosis

In the 20 patients investigated a clinical "triad" of a history of recurrent joint pains, many target cells in the peripheral blood smear, and sickling of the erythrocytes has invariably been associated with signs of increased haemolysis in the peripheral blood. In my opinion three important conditions have to be considered in the differential diagnosis. These are acute rheumatic fever, a chronic haemolytic anaemia due to malaria, and so-called "Mediterranean anaemia."

The absence of sore throat, palpable nodules, or joint swellings, or evidence of valvular disease of the heart, with, in many instances, a normal sedimentation rate, eliminates the possibility that this condition is a rheumatic manifestation. In addition there was no response to salicylate therapy.

Malaria parasites were detected in the blood of only four patients and there was no haematological or symptomatic response to malaria therapy in any of the 20 patients. In addition, in five instances the spleen was not palpable and the history of recurrent attacks of joint pain given by these patients was striking, and was not simulated by any of the many hundreds of Africans examined and questioned—all of whom were developing or had developed premunition to malaria. From these facts it is felt that malaria can be excluded from the list of possible diagnoses.

It is difficult to exclude Cooley's anaemia, as, apart from the sickling of the erythrocytes, sickle-cell anaemia and Cooley's anaemia may present an almost identical blood picture in fixed films. Many patients showing target cells in peripheral blood smears were investigated, however, and in no instance was the syndrome described in these 20 patients found in the absence of the sickling phenomenon.

Discussion

If the homozygous theory of the inheritance of sickle-cell anaemia is correct, and if the incidence of the trait in the population of the Accra District of the Gold Coast is taken to be approximately in the region of 19%, by calculation the incidence of the anaemia should be 1%.

I examined 2,255 Africans and diagnosed sickle-cell anaemia in only one instance, giving an incidence of approximately 0.05%. This figure is, however, completely fallacious, as multiparous women, mothers at term, and newborn infants were included in the survey. It is most probable that the incidence of sickle-cell anaemia in mothers at term and in multiparous women is extremely low, as, excluding the mortality from the anaemia in the younger age groups, the primigravida may die suddenly before term in an acute sickle-cell crisis (Edington, 1951). It is also unlikely that the newborn child suffers from sickle-cell anaemia.

In addition, in the surveys the age groups most likely to exhibit the active disease (infancy and early childhood) were, unavoidably, not examined. It is perhaps significant that, in the group of 200 young schoolchildren examined, whose ages ranged from 8 to 12 years, one girl was found to be suffering from sickle-cell anaemia—an incidence of 0.5%. Although I have reviewed only 20 cases in this article, sickle-cell anaemia has now been diagnosed in 33 instances and the sickling phenomenon has been considered to be the cause of death at 13 necropsies (to be published). It can thus be stated that sickle-cell anaemia is not rare in the Accra District of the Gold Coast. It has not been possible to assess the incidence of sickle-cell anaemia, but

I consider that the calculated incidence of 1% may well be correct, which would agree with the homozygous theory of the inheritance of sickle-cell anaemia.

Summary

In the Accra District of the Gold Coast 2,255 Africans were examined for the presence of the sickle-cell trait and the anaemia. Sickling of the erythrocytes was present in 407 instances—an incidence of 18.1%. No ill effects were attributed to the presence of the trait in 406 Africans. The remaining African girl was suffering from sickle-cell anaemia.

The case reports of 20 patients suffering from sickle-cell anaemia are discussed. It was found that, in the Gold Coast, a history of recurrent attacks of pain in the larger joints and the presence of many target cells in the peripheral blood smear was invariably associated with sickling of the erythrocytes and signs of increased haemolysis in the peripheral blood. The importance of malaria as a "trigger" mechanism in initiating the crises of the anaemia is considered.

It is concluded that sickle-cell anaemia is not rare in the Accra District of the Gold Coast.

I am grateful to Dr. L. G. Eddey, Director of Medical Services, Gold Coast, for permission to publish this article and to Drs. A. J. Hawe, J. W. R. Sarkies, M. H. Hughes, and M. J. Colbourne for their unfailing interest in this investigation. Lastly, I must thank Dr. A. B. Brereton for the many radiographs taken.

THE HEALTH VISITOR AND THE FAMILY DOCTOR*

BY

LLYWELYN ROBERTS, M.D., M.R.C.P., D.P.H.
Medical Officer of Health, Sheffield

When I started collecting my thoughts for this paper I rather naturally began by considering the health visitor, but I was inevitably led to the realization that health-visiting work was only an aspect of the increasing service that is now expected from the general practitioner. No doctor who has been in practice over the last twenty-five years can have failed to realize that the conception of general practice has been, and is, changing; it will depend to a large extent upon the attitude of mind of the general practitioner himself if it is to be for the better. The medical profession, with the service it provides, is becoming increasingly important as a prop to the general weal of the nation; it must also be remembered that over the years we, as doctors, have been largely allowed to keep our own house in order. The number of Acts of Parliament regulating the profession of medicine has been very small. The first Acts I know of occurred in the time of Henry VIII† and simply said who could be allowed to practise medicine under certain conditions. The next Act was in 1858‡ and tightened up the controls, made more formal arrangements for entry into the profession, and provided, through the General Medical Council, for doctors who misbehaved to be taken off the list. Then we had the National Health Insurance Act of 1911, and the scope of this Act was much widened by the National Health Service Act of 1946. This last Act not only laid certain duties upon the doctor but by the comprehensive nature of the Act, and the associated obligations laid on the local authorities, increased the scope of the doctor's responsibilities.

There are, of course, other Acts which have affected doctors, and Parliament, through the Midwives Acts and the Nurses Acts, has provided assistants for him and arranged that they are adequately trained.

Although up to a century ago nurses were often disreputable, there has been little difficulty in their relationship with doctors: Florence Nightingale was more than a match for any man, even a doctor, and her influence remains.

It took a long time for the midwives and the doctors to settle down together; in the eighteenth century there were some very acrimonious discussions with midwives proper and the so-called "men midwives," who were beginning to make their presence felt. I cannot refrain from quoting William Smellie, about 1750, regarding the conduct proper to a midwife, for it is surely applicable,

*Read in opening a discussion in the Section of Preventive Medicine at the Annual Meeting of the British Medical Association, Cardiff, 1953.

†(a) The Physicians Act, 1540 (32, Hen. 8, C. 40).—The Act exempted members of the Fellowship of Physicians from having to undertake the duty of constable, and allowed physicians to practise medicine in all its branches. (b) The Herbalists Act, 1542.—In order to avoid "Sorceryes, witchecraftes and other inconveniencies, it was enacted that no p'son within the Citie of London, nor within seven myles of the same, shoulde take upon himself to exercyse and occupie as physician or surgeon, except he be first examyned approved and admitted by the Bisshopp of London," etc.

‡The Medical Act, 1858 (21 and 22 Vict. Cap. 90).

with obvious modifications, to the relationships between doctors and their other handmaidens:

"She ought to be a decent, sensible woman of a middle age, able to bear fatigue and well instructed in the elements of practical midwifery.

"She ought to live in friendship with other women of the same profession, contending with them in nothing but in knowledge, sobriety, diligence and patience; she ought to avoid all reflections upon men practitioners; and when she finds herself at a loss, candidly have recourse to their assistance—this confidence should be encouraged by the man who ought to rectify what is amiss without exposing her mistakes.

"These gentle methods will prevent that mutual calumny and abuse which too often prevails among the male and female practitioners, and will redound to the advantage of both, for no accoucheur is so perfect but that he may err sometimes."

One is now led to wonder why the health visitors—the other assistants—have been introduced into the medical scheme of things. As I have pointed out, the scope of medical practice has widened—almost entirely owing to the work of the profession. The family doctor now appreciates that the full therapeutics of a sick person includes the welfare of the patient's family. The cure of the actual ailment and the full economic and medical recovery of the patient are often associated with such matters as the patient's occupation, his housing, his financial position, his relationship with other members of his family, and other medico-social aspects of the case. If the general practitioner loses sight of these facts he is in danger of ceasing to be the family doctor.

General practice as I knew it thirty years ago was largely a matter of medicine and personality. A country practitioner for whom I worked was an outstanding man, and combined a good knowledge of medicine with the means of meeting many of the social responsibilities of ill-health in his patients. I am quite certain he would not be able to do it now. Personality and integrity are still as important, but medicine is not merely a matter of medical therapeutics—it must include social therapeutics.

The widening outlook has been obvious in the field of hospital practice, where the hospital practitioner is buttressed by an increasing army of auxiliaries—almoners, physiotherapists, dietitians, occupational therapists, and others. The same has been happening in general practice—for have we not there the children's officer, the probation officer, the N.S.P.C.C. officers, and others?—but in the subject of our talk we also have a key worker, one who can assist the practitioner to deal rationally with these other useful auxiliaries, and one who can also help the practitioner himself.

How the Health Visitor can Help the Doctor

I would therefore like to introduce to you the health visitor and let you know how I feel she can help you in your work. First of all, it is not always realized what a well-qualified and well-trained person she is. She must (1) be a fully trained registered nurse; and (2) have taken at least the first part of the midwifery certificate (as a matter of fact most health visitors are fully trained midwives and have worked as such); and (3) have passed an examination following a nine-months course in social medicine, including a knowledge of infant and child care, welfare work in relation to the disabled and the aged, maternal care; personal, domestic, and community hygiene, including household management; together with knowledge of social, industrial, and economic conditions and of the means of teaching.

I have analysed the qualifications of about 370 health visitors in some of our largest cities. Apart from the qualifications mentioned above, which they all possess, a number of them have also been trained and had experience in fever nursing, orthopaedics, housekeeping, tropical diseases, nursery nursing, the care of the tuberculous and mental cases—a few hold a higher qualification such as a tutor in public health training, the diploma in nursing, or are Queen's nurses. Taking gross populations, there appears to be about one health visitor per 9,000 of the population in these big cities. There will therefore be in this 9,000 about 130 births per annum, and about 500 children under school age; there will also be about 900 persons over the age of 65, a number of whom require some constant supervision. Apart from these there will be disabled persons, both young and old, problem families, and tuberculous patients. It is no light task helping to keep this mixed family under observation and to provide for them, but the health visitor's training equips her to do much for them, although I know only too well the magnitude of the task and the severe shortage of health visitors that exists.

The general practitioner will obviously want to know what assistance he can get from the health visitor. In a talk such as this I can only indicate the various fields where she can assist the doctor through her intimate knowledge of the family, or by invoking the assistance of other voluntary or statutory organizations. In many towns the health visitor is already carrying out the work I shall mention. I would like her to do this in a closer association with the family doctor. Before proceeding, I may remind you that the health visitor trained as a nurse is fully aware of her ethical obligations towards any patient she visits.

1. Care of the Mother and Child

This has been the primary function of the health visitor for over a hundred years when society in general was little concerned regarding the health and happiness of women and children. Although uninvited, and with no statutory right of admission to a home, the health visitor has been instrumental by her knowledge and perseverance in promoting the welfare of mother and child, and surely the husband also. The health visitor can assist the doctor in seeing that his advice on infant feeding and the care of premature children is followed, and in dealing with minor ailments and maladjustments. The continuing oversight of problem families, who cause such expense to the nation and such trouble to society, has been safely entrusted to her, although she would welcome some guidance and encouragement from the doctor.

The anxious mother welcomes the opportunity of discussing her difficulties with a knowledgeable person. These mothers ask questions and seek advice. How much better it would be if the health visitor knew that she was reinforcing the opinion of the family doctor. When emergencies occur—a mother is ill at home or has to leave a family to go to hospital—the health visitor can be left to do all she can to provide assistance. Then there is the preparation of the family for the return of a patient from hospital, sometimes imperfectly cured, needing special attention, diet, or care. Health visitors are encouraged to make direct contact with the hospital almoners so that there is a continuity of care.

Sometimes the aid of specialist agencies must be invoked—the children's officer, the probation officer, the N.S.P.C.C., and the doctor's time can often be saved by requesting the health visitor to make the necessary arrangements with these persons.

2. The Aged

Every general practitioner has a quota of persons who are old and, as a consequence, more frail and subject to disabilities, and more in need of friendly assistance, care, succour, and comfort. We are encouraging our health

visitors to keep these elderly people under supervision, report to the general practitioner when a special need arises, and ask for his assistance when a question of the disposal of these old people, either to an old persons' home or to a hospital, arises. The health visitor will, with his permission, call in a district nurse or suggest the need of a domestic help. Very often, in cases of inattention, arrangements can be made for the old person to be bathed, for the home to be cleansed, and for laundering the linen. The health visitor also frequently arranges for relatives to be informed of the condition of one of the elderly members of their families.

During the period of shortage of beds, either for the chronic sick or for the old people's home, the health visitors are asked for an assessment of the patient's "social" needs in assessing priorities for accommodation. I would much prefer that this was done with the assistance, or at the request, of the general practitioner, and, in fact, in my city it is an invariable practice for the general practitioner to be informed of the opinion of the health visitor regarding the disposal of such a case. Very often the health visitor is able to provide assistance to the elderly people by making their needs known to the Assistance Board or the Ministry of National Insurance, to invoke the assistance of voluntary agencies such as the "meals on wheels" service, or to arrange for assistance in shopping.

3. The Disabled and Handicapped

I very much doubt if a large number of general practitioners are aware of all the agencies that are willing and anxious to help disabled persons. Knowledge of these agencies can often lead to the provision of necessary help and comfort; not only that, but the local authority itself has an obligation to promote the welfare of the disabled, who include many aged persons. Special arrangements are also in force for caring for the mentally handicapped, both psychiatric cases and mental defectives. There are special visitors to provide for the particular needs of blind persons. As time goes on it will be possible to provide training in new work, occupational therapy, arrangements for the sale of goods made, for recreational facilities, for clubs, and so on. One of our big difficulties at the moment is to know the number and needs of persons in the different categories, for special facilities are often necessary to deal with special disabilities. The local authority would welcome information from the general practitioner, and much of the investigation of the case can, to begin with, be undertaken by the health visitor, especially if she has the co-operation of the doctor. The family health visitor is the general social worker; she will call for the specialist social worker—the psychiatric social worker, the probation officer, the home teacher for the blind, etc.—when necessary. With one key worker the number of visitors can be reduced.

In some cities, particularly in Cardiff, there are specialist health visitors dealing with certain types of aftercare. Specially trained health visitors visit diabetic cases, cases of gastric ulcer, and so on, in order to ensure that the regime prescribed at the hospital or by the doctor is being followed; but practice varies in different areas.

4. Tuberculosis

As our therapeutic advances begin to show a result it is likely that we shall have more cases of chronic tuberculosis on our hands, and not all of them can be contained in hospitals. The health visitor, working either as a specialist tuberculosis visitor or as the family-care worker, can see that the instructions of the general practitioner, the chest physician, or the medical officer of health, in relation to prevention are followed. She will see to it that the child is segregated where necessary, that contacts are shepherded to the chest clinic for investigation, and that extras, whether from statutory or voluntary agencies, and any special allowances which are necessary for the tuberculous patient himself, are

obtained and properly used. Tuberculosis is a chronic disease presenting a great variety of problems taxing the resources of the doctor and the local authority. Non-medical problems of finance, housing, and employment are frequent, and opportunities for discussion of a case with a social worker such as a health visitor must be very useful.

5. Accidents

As infection and other disease of childhood are becoming less prevalent it is surprising how accidents have emerged as a major cause of death and injury. Accidents in the home are very numerous. We are arranging for our health visitors to obtain as full information as possible about these, and to advise the mother how best to prevent recurrences.

Obligations of the Local Authority

I have pointed out the social and economic repercussions of sickness and the many agencies that are available to assist. The obligations of the local authority are very important: it must provide midwives, district nurses, home helps, and an ambulance service, and is encouraged to provide "care and aftercare"—a territory insufficiently explored but full of possibilities, both for the patient and for the doctor. A social worker like the health visitor can, with the doctor's assistance, make the needs known to the local authority.

A frequently heard complaint is that there are too many persons, representing well-intentioned and often necessary organizations, knocking at the door of the harassed housewife requiring information or offering assistance. I have counted over twenty such organizations in my own city. It is surely a waste of time for them to call indiscriminately. I would like to use the health visitor as a funnel, which, with the doctor's assistance, could be concerned with the economic deployment of these agencies. She could do this if she knew she was the accepted assistant of the doctor.

I have spoken of the health visitor in a city, but I know very well that in a country area, where the health visitor is also the district nurse and also the midwife, a close association has already evolved, and there is a good understanding between the doctor and her. It is not so easy in a town. The doctor may not know where to get hold of the health visitor, and hesitates to bother with officialdom in the town hall. We, as medical officers of health, are always ready to help, and would respond to any request from the doctor or the patient—and it often happens in this way—but I would much prefer that the contact was direct between general practitioner and health visitor. No general practitioner in Sheffield thinks of getting in touch with me when he wants the services of a district nurse or a midwife, and I am not particularly interested in supervising the day-to-day work of the health visitor.

It would save much trouble if the health visitor and doctor dealt direct with one another, either by telephone or in person, or that there was an arrangement for a regular transmission of information as required. No doctor thinks it necessary to provide his own midwife or district nurse; and, indeed, the State, appreciative of the value of these women, arranges to provide them and for the local authority to pay for them. The health visitor is in exactly the same position, and although the local authority engages her, supervises her, and deals with her terms of service, she is there for the good of the public, and in particular for the help that she can give to the general practitioner, who is primarily concerned with the care of the sick person and the welfare of his family.

Finally, although I have stressed the importance of the personal association between the doctor and the health visitor, I would like to say that this co-operation could be much better brought about if there was a closer association between the general practitioner and the medical officer of health and his medical staff. Both of us have our responsibilities to the patient, and we all have, I hope, the same desire to serve.

THE GENERAL PRACTITIONER AND THE HEALTH VISITOR*

BY

J. STANLEY THOMAS, M.R.C.S., L.R.C.P., J.P.
General Practitioner

During my 30 years in general practice I have had the advantage of a happy family partnership and the privilege of having practised medicine in an era which exemplified Mr. Churchill's dictum, given to a Royal College of Surgeons gathering, that the "longer we look back the further we can look forward," for we have seen more striking advances than could have been thought possible, among which must be counted the present liaison that is developing between those engaged in preventive medicine and general practitioners.

All my days the medical officer of health, owing allegiance to the local authority, has been respected as an administrator and regarded as an able colleague having specialized knowledge of infectious diseases, but whose duties in the main were no concern of ours. During my early years of practice, apart from social contacts, relationships between the work of the general practitioner and the medical officer of health were poor, and my then seniors in practice regarded welfare clinics as a form of subsidized competition which they disliked and mistrusted. In fact, in populous areas the work of the whole-time medical officer and that of the general practitioner were poles apart.

Let it be remembered, however, in arriving at a true conception of the picture, that the general practitioner was, in the main, a single-handed individualist, and obviously the time was not then ripe for the liaison we envisage to-day.

Nursing, the Keynote

The value of nursing has, to my mind, been paramount in the conduct of a practice, and I believe that nursing is the keynote to its success. I have had the advantage of having the same nursing sister with me for over a quarter of a century. At an early date I realized that her value was not just that of a nurse whose duties I understood and who officially carried out my treatment. The knowledge of the lives and habits of our patients which she gleaned and passed to me, and of the effect of their social problems on their illnesses, gave me an understanding which was invaluable in appreciating and treating their real difficulties—a knowledge which I had never encountered, or even considered, in my impersonal hospital life. It was she who revealed that a large proportion of patients who consulted us without physical signs, or who did not make progress, had financial, marital, or other family problems. It was she who comforted the pregnant single girl, and advised all patients, from the young mother to the aged sick, in those problems which were outside my clinical approach. She assisted in running our own infant clinic and became the confidant and friend of the parents, and, of course, of the children, who are now our second generation of patients. I suppose that, in the confines of one practice, this was the forerunner of social medicine and the liaison between doctor and health visitor as we are beginning to understand it to-day.

I am sure that all interested parties agree that the closest possible co-operation exists between the general practitioner and the nursing profession so far as the district nurse and the midwife are concerned. In my own area, with a popula-

*Read in opening a discussion in the Section of Preventive Medicine at the Annual Meeting of the British Medical Association, Cardiff, 1953.

tion of 120,000, the district nurses made over 60,000 visits last year. Without their co-operation and invaluable help a reasonable standard of efficiency in general practice could not be maintained in these busy days. In my first ten years in practice the "Gamp" still survived, and one had to fight hard to convince patients, even the intelligent ones, that trained nursing was essential to their safety. It is unthinkable that midwifery would be possible to-day without the closest co-operation between doctor and trained midwife.

Necessity for Liaison

It is with the public nurse—the health visitor—that lack of liaison is still so apparent, and some of the reasons become obvious when the problem is studied. Health visitors have always been the employees of the local authority, acting under the jurisdiction of the medical officer. They have worked in clinics, which, as we have said, were not looked upon with favour in the days of competitive practice, and they are a comparatively recent innovation, for it is only since 1919 that the health visitor has been recognized by the Government as an integral part of the social welfare structure. Study of their training syllabus and examination papers shows that primary qualification as a hospital-trained nurse and midwife is a requirement, followed by an intensive course of specialized nursing and social welfare; and this skill and competency has been kept, as it were, in the watertight compartment of the public health department. (In fact, many are actually unaware that a health visitor is primarily a trained nurse.)

The busy general practitioner, concerned with the treatment of minor ills and the diagnosis of major ones, cannot be pardoned for giving little time or thought to preventive medicine. This, he felt, was the sphere of others, and thus he never reaped the benefit of contact with that branch of the nursing—except, unfortunately, when advice given in the local authority clinic conflicted with his own and often created antagonism. If I may again speak from personal experience, it was in the field of tuberculosis that my colleagues and I first saw the real light of day in preventive medicine. In 1921 a physician was appointed by our local authority to take charge of this sphere who, if I may say so, was many years ahead of his time. He eliminated the concept of the tuberculosis dispensary and inaugurated a "chest clinic"—a title which to-day is finding favour everywhere. He pioneered extensive x-ray investigation, but he had, too, the foresight of social medicine, and encouraged all general practitioners to attend his clinics, and, to complete the liaison, brought them into contact with his enthusiastic sister in charge.

It was she who saw to it that she and her nurses were in touch with the patients, not just in the clinic but in their homes. She took a quite revolutionary step in making every possible contact—by telephone and personal visits—with the general practitioner, and it was she who gave us a vivid picture of how the social conditions of the home intensified the problems of the afflicted. The same sister still reigns, and with the recent enormous advances in the treatment of tuberculosis the liaison with the general practitioner, who now comes more than ever into the picture in this antibiotic era, has been firmly cemented. It is the welfare nurse who so impresses upon the patient that it is the family doctor who is to the forefront in this field. If I may digress, the value of that liaison has been exemplified in placing in suitable employment an ever-increasing number of tuberculous people who are fit to return to work; for there is contact via the chest clinic, the general practitioner, and the health visitor, so that details of the social environment, as well as the medical problems, are placed in the hands of the Ministry of Labour.

The 1946 Act, by opening the watertight compartments into which the care of the patient had gravitated, will ultimately revolutionize the practice of medicine and thus alter the whole conception of the broad issue of medical care. It was not until 1948 that the preventive sections of medi-

cine and the general practitioner began to work together in harmony, to the great benefit of the public.

The obvious key to this liaison is the health visitor, and the section of the Act which enlarged the duties of health visitors was in this respect visionary. I think we can prophesy that in the near future she will be regarded as invaluable as the district nurse in the conduct of modern practice.

What must be done, therefore, to accomplish this liaison? First, the general practitioner has to be satisfied—and many are not—that the work of the public health nurse is indispensable to him. When the doctor examines his records he will surely find, at a modest estimate, the great majority of his patients have been discovered, after hospital investigation, to be without physical signs of organic disease—perhaps a real justification for the general practitioner, for it is this majority who need his services and not that of specialism. When we come to analyse the matter, what do we find? The problems of the young mother, whose difficulties in infant feeding and whose natural anxieties due to inexperience cause her to need a good deal of comfort and advice, for which, although qualified to do so, the practitioner rarely has the time to give. We find, too, home problems which, undisclosed and unravelled, tend towards disharmony and discord, delinquency and mental ill-health, only too often reaching the psychiatrist, when they might have been dealt with much more effectively at an earlier stage.

Excursions into juvenile court magistracy gave food for thought when I recognized delinquent children and truants as cases which had been seen in the surgery and to whose problems I had neither a clue nor time to elucidate them. How often do those requests for a "tonic"—bromide and phenobarbitone sedatives—mask a state of affairs which the patient is unwilling to disclose to a busy doctor? Where active disease is concerned, only too often extensive measles and whooping-cough epidemics, a high incidence of tuberculosis, etc., are due to overcrowding and unsuitable home conditions. In such cases the health visitor would be invaluable in assisting in diagnosis and treatment—for example, she might find that immunization and vaccination had been postponed or neglected; might help the tired mother, often the subject of chronic ill-health and anxiety states, but responding quite satisfactorily to common-sense help and advice; might advise in the problem of the parent returning too soon to household duties or full employment following parturition or hospital treatment, by arranging necessary convalescence or home help. How many practitioners are aware, while recognizing that overcrowding is responsible for much mental and physical ill-health, that the rehousing of families by the local authority is often contingent on reports given by health visitors?

The Aged and Chronic Sick

It is my belief that much can be done for the aged and chronic sick by health-visitor liaison. The ventilation of this problem in Parliament and elsewhere has brought us face to face with the fact that the aged population is living longer and increasing numerically to an extent that may affect our whole social system. I found some excellent advice on this subject in a brochure issued by the Bristol Local Medical Committee. The 1946 Act, with its obliteration of the Poor Law hospital, however progressive it may have been, virtually cost, in my area, the use of 1,000 chronic-sick beds, and the general practitioner who prior to 1948 could easily lodge his chronic sick is now faced with a grave problem; for in spite of the excellent treatment afforded to a few in a geriatric unit, they cannot be accommodated in hospital. Also, the public has not yet been educated to this abrupt alteration, which has come to stay, and I feel sure that here the health visitor can do much by giving advice regarding hostels and by discussing with the family the problem that arises when the rest of the household are at work and unable to cope with the inevitable series of illnesses of old age, so rarely well

managed at home. The influence of a nurse, and her manner of approach, will do much to assist the aged who decide to maintain their sturdy independence by continuing to live at home; and by her contact with home helps, and often by tracing relatives, will be able to give invaluable service in this direction.

A Changing Phase

The changing phase of general practice, in which the practitioner will work in and with local authority services, will make the health visitor an essential factor, but the practitioner cannot assess the value of this ancillary service unless he has the means to study it; in effect he must have access in one way or another to local authority services. The Birmingham plan, published in the *Lancet* of April 5, 1952, is based on the assumption that general practitioners will work in local authority clinics. My visit to Birmingham was amply repaid by the courtesy and help afforded by the medical officer of health. (All good general-practitioner members of the B.M.A. should make pilgrimage to Birmingham, for it provides the vast majority of their leaders.) Birmingham regards the present services of local authorities as outmoded because they were inaugurated at a time when it was their duty to provide such services for those who could not afford them, and because the passing of the 1946 Act, which gives full facilities to the whole population, alters the entire position. The time is approaching when the general practitioner will, in the first instance, be the person responsible for the treatment of the family unit, and when the employment of junior staff by the medical officer of health's department for clinical duties will cease. The success of the scheme in Birmingham is obvious; Croydon, too, has an excellent liaison which enables the general practitioner to work in clinics if he so desires.

In my own area all clinics are open to practitioners, so that they may use the clinic or staff for ante-natal and post-natal care of patients, utilize the special services of the local authority such as physiotherapy for the pregnant mother, seek the help of the child guidance clinic, invoke the aid of the dental x-ray department, and have access to special departments for speech therapy, etc.; and this, combined with access to the chest clinic, gives great opportunities for further services to their patients. Thus practitioners will appreciate the value of the health visitor. Liaison of even the senior generation of doctors with the health visitors can be rapidly inaugurated by social contact, which will soon establish the happy relationship which always exists when doctor and nurse work together. But I feel it should be stressed that the practitioners must learn to regard the health visitor as an ancillary who has a highly specialized knowledge collateral with his own, not merely as a nurse acting under his official directions. So far as the younger generation of practitioners are concerned, they will come to regard health visitors as indispensable.

The student now sees them in the wards of hospitals, doing the rounds with him so as to assess the social after-care; but unless he meets them subsequently, the inestimable value of their knowledge is lost to him. Surely he will now enter practice, work when he so desires at adequately staffed clinics, and in the sphere of social medicine will have the advantage of calling upon the health visitor for the elucidation of his problem and of keeping contact, because he will meet her in the course of his work. His obstetric work will be immeasurably helped by meeting, through the offices of the health visitor, the midwife, either at the clinic or in his own surgery; and the present position will be improved, for only too often the general-practitioner obstetrician does perhaps two of the "antenatals" and the nurse the others—the two never meeting except in a possible emergency at a confinement.

Conclusion

Although enthusiastic about this subject, none of us would be so foolish as to suggest that health visitors are the complete solution to the many problems of practice, for history

teaches that enthusiasm is invariably followed by a stage of caution; but the most conservative would agree that in a large proportion of the cases which constitute our life's work and in which we need and would welcome assistance, this is waiting for us on our doorstep. May I say, too, that the use which is made, in certain areas, of open access to pathological services is so much less than was forecast that those in charge of administration in local authority need have no fear, in the first instance, that they would be overwhelmed by demands on their health-visitor services.

However, as the Minister said at Scarborough, it is the general practitioner who must captain the ship. It is not for him to evade his responsibilities but to increase them—because he has the necessary help. It is my belief that closer contact with the nursing profession must raise one's own standard; and I understand that, already, general practitioners who are working in clinics are becoming keen on postgraduate instruction that will keep them abreast of their subject when working side by side with health visitors.

So the doctor of the future, if he decides on general practice as a career, must realize that one of the most important factors in helping him to maintain personal contact with his patients, to understand their difficulties, and to guide those whose problems are not purely of disease but of social background, will be a firm liaison with the health visitor.

Finally, may I express my gratitude to the medical officer of health for East Ham, and his health visitors, past and present; for, without their invaluable help and co-operation and his advice to his authority to make liaison with general practitioners by offering the use of local authority services, this paper, however imperfect it may be, could never have been presented.

HYDROCORTONE AND SOFT-TISSUE LESIONS

BY

JAMES CYRIAX, M.D.

Physician, Department of Physical Medicine,
St. Thomas's Hospital

AND

OLIVIER TROISIER, M.D.

Attaché de Rééducation, Service du Professeur Merle
d'Aubigné, Hôpital Cochin, et du Dr. Grossiord,
Hôpital Raymond Poincaré

The formation of painful scars in the moving parts of the body is a common cause of disablement. Non-specific inflammation of fibrous tissue follows injury or overuse and characterizes also the rheumatoid disorders.

Though there had been no satisfactory way of dealing with rheumatoid trouble, the problem of the painful scar due to trauma had been largely solved by the elaboration of manual methods. By means of deep massage in some cases, in others manipulation, it has proved possible to restore painless mobility, but it is usually a laborious business. For example, we have hitherto been quite satisfied with cure of tendinitis at the shoulder in say six or eight sessions, or tennis elbow in four to six sessions, since the breaking down of fibrous tissue in strong deep-seated tissue demand time and considerable ability and experience on the part of qualified personnel.

The fact of painful treatment, obtainable only from a minority of physiotherapists who have had special training in these techniques, naturally calls for constant exploration of alternative measures for dealing with

lesions of muscle, tendon, ligament, and joint-capsule. Fifteen years ago therapeutic local analgesia was extensively tried, but in the end we found it suited to only a few muscle lesions, to ligamentous injuries during the first day only of their occurrence, and, introduced epidurally, to some cases of low lumbar disk lesion. More recently we have experimented with short-wave diathermy and ultrasonic waves, and found they afforded no benefit in these disorders. When cortisone became available this was tried for its systemic anti-inflammatory effect, but it proved useless in non-rheumatoid conditions. However, hydrocortone, applied locally, has given excellent results.

Hydrocortone Acetate

This is supplied by Merck in 5-ml. phials containing in sterile suspension 125 mg. of the hormone. Hydrocortone has the same anti-inflammatory effect as cortisone, but exerts a local action. Hence it can be injected in small amount at infrequent intervals. It seems that no more need be injected than is required adequately to reach the whole affected tissue.

We were anxious to find out if hydrocortone could be used as effectively in traumatic as in rheumatoid inflammation. Since the reaction to aseptic injury is always excessive, we sought to control it by topical application of the hormone. We have found 25 mg. injected into the joint adequate for the shoulder, hip, and knee; 10 to 15 mg. for a tennis-elbow. After injury the cause of the inflammation is not, as in rheumatoid conditions, a continuing state; once the inflammation has been abolished there is nothing to reactivate it. Hence one or two injections suffice for those traumatic disorders in which hydrocortone is effective.

Since scarcity, expense, and possible toxicity with large doses all dictate that only small amounts of hydrocortone should be used, the importance of deciding on the exact site of the lesion is obvious. Hence the same system of diagnosis that originally enabled us to prescribe deep massage to one small point becomes more important than ever; for the 0.5 to 1 ml. of hydrocortone has to be injected into one precisely defined spot.

Diagnosis by Selective Tension

Tension brings on or aggravates pain in lesions of the moving parts. The approach is indirect and depends on assessment of function. Hence the diagnosis is arrived at by applying selective tension on each of the moving tissues in turn. From these responses a pattern emerges that identifies the precise tissue at fault. Search for tenderness is avoided so far as is possible, and, if it proves necessary, is confined to the structure already identified by this study of function as containing the lesion. When a number of movements are tested, some are found to be painful, weak, or limited, others normal. The negative side of the examination is as important as the positive, since, if one movement indicates that a lesion lies in a certain position, it follows that all movements that do not affect that part of that tissue must be of full range, painless, and strong. Hence interpretation is based on the pattern—that is, positive findings at one point balanced by negative findings elsewhere.

The main distinction when the moving parts are examined is between the contractile structures (muscle and tendon) and inert structures (capsule, ligament, bursa, dura mater, nerve-root, or nerve-trunk). Resisted contraction applies strong tension on muscle and tendon; stretching in the opposite direction may hurt too. Pain arising from inert structures appears on stretching only.

Examination of Function

Five different sets of data are correlated, as follows:

1. *Active Movements*.—These give a combined indication of the range of movement, muscle power, and state of volun-

tary control. Since range and power are assessed separately later, their chief virtue is to indicate willingness. Marked discrepancy between the range of active movement on the one hand and, on the other, the range of movement and muscular strength indicates psychogenic disorder.

2. *Passive Movements*.—These indicate the state of the inert structures without introducing complications due to muscle power and willingness. *Capsular pattern*.—If the entire fibrous cuff about any joint is found contracted, arthritis is present. The limitation of movement found corresponds to the capsular pattern. This is different for different joints, but maintains constant proportions at any one joint. For example, in arthritis at the shoulder, if abduction is, say, 45 degrees limited, lateral rotation will be 60 degrees limited but medial rotation only 15 degrees limited. *Non-capsular pattern*.—If the known proportions are not found, ligamentous sprain, internal derangement, bursitis, neoplasm, contracture of an extra-articular structure, or hysteria is present.

3. *Resisted Movements*.—One movement is tested for each group of muscles, and such a degree of resistance is applied that the joint itself does not move. The state of the muscles is thus assessed in isolation. If a full range of movement exists and only one resisted movement hurts, a muscle lesion is present. If several contradictory restricted resisted movements hurt, the muscles are unaffected. Painless muscle weakness without increase of pain characterizes complete rupture or a neurological condition.

4. *Painful Arc*.—If a tender structure lies between two bony surfaces it can be painfully squeezed when they are approximated. A painful arc results—that is, pain at mid-range of a movement disappears as the extremes are approached. For example, in supraspinatus and infraspinatus tendinitis, and in subdeltoid bursitis, the lesion lies between the acromion and the greater tuberosity of the humerus. Therefore, tenderness of any of these three structures may give rise to a painful arc. In the case of the tendons, the arc is associated with pain on resisted abduction and lateral rotation respectively. If the bursa is at fault neither resisted movement hurts. Since the simplest anatomical considerations indicate clearly where the tissue, since it is pinchable, must lie, an arc is a valuable localizing sign.

5. *Palpation*.—This may reveal warmth; if so, the finding indicates an active lesion. It occurs with recent injury or operation, fracture, internal derangement, neoplasm eroding bone, blood in the joint, rheumatoid or gouty arthritis, and bacterial infection. Fluctuation indicates fluid. Synovial thickening, crepitus, loose bodies, cysts, osteophytes, and bony enlargement are detectable. Tenderness serves to indicate the exact site of a lesion only if palpation is confined to the tissue already singled out by study of the diagnostic movements as that affected.

6. *Confirmation*.—Radiography seldom clarifies a diagnosis in lesions of the soft tissues and may prove most misleading; hence the paramount importance of the clinical assessment of function. Local analgesia provides the only means of disproving or confirming a localization arrived at clinically, and in all cases of doubt should be induced at once. After the injection whatever movement had been found painful is tested again. If the right spot has been reached this movement remains painless for one to two hours. Once the right spot has been found—if necessary by repeated small infiltrations—the hydrocortone can be injected the next day.

Choice of Cases

Most soft-tissue lesions of the moving parts respond rapidly to the standard methods used in orthopaedic medicine—deep massage, manipulation, traction, and therapeutic local analgesia (Cyriax, 1950). Thus we have selected for treatment by hydrocortone patients who either had failed to respond to our normal procedures or lived too far away to attend for such treatment.

Technique

Intra-articular injection presents little difficulty except at the shoulder. At the smaller joints, traction is useful to form a gap into which the needle can pass.

Shoulder.—The patient lies prone, the forearm on the affected side under his abdomen. However arthritic a shoulder-joint, this position is not painful; and it secures fixation of the humerus in slight medial rotation. The operator identifies the posterior bony projection lying at the point where the acromion and the spine of the scapula meet at right angles. He selects a spot 1 cm. below this point and thrusts in a thin needle 5 cm. long. He identifies the coracoid process anteriorly and aims the needle directly at it. He feels nothing as the needle traverses the fleshy infraspinatus, but the capsule of the joint offers clear resistance. Once the capsule of the joint is pierced the needle becomes embedded in articular cartilage—another characteristic sensation, quite unlike the impenetrable surface offered by bone. If the operator wishes to be doubly sure that the needle lies intra-articularly, he can pierce the capsule in several adjacent spots until resistance to the needle suddenly ceases and it passes easily to its full length between humerus and glenoid. 25 mg. of hydrocortone (1 ml.) is now injected.

Results

Shoulder.—Between us we have treated 21 cases, as follows: freezing arthritis, 9; infective arthritis, 6; post-traumatic capsulitis, 3; post-operative adhesions, 1; immobilizational capsulitis, 3; subscapular tendinitis, 1. The hope that an effective treatment had at last been found for freezing arthritis was again disappointed. The results were largely negative, and in several patients seen when the arthritis was in the early part of the first stage the disorder was uninfluenced, and progressed in the usual way towards increasing pain and limitation of movement. In one case no less than 125 mg. of hydrocortone was injected in the course of a month without effect. By contrast, the six patients with infective arthritis reported immediate relief. The constant pain ceased by the same evening, and the patients were able to lie on that side at night for the first time for months. The range increased, and so far (maximum seven months later) there has been no return of symptoms.

In the cases following trauma and immobilization the results were generally good and patients with lesions in the active stage (that is, unsuited to the physiotherapist's repeated gradual stretching) were brought within a fortnight to the point where this could be undertaken with success. Months of disablement were thus avoided. In the post-operative case (stiffness following operation for recurrent dislocation) no benefit resulted. The patient with subscapular tendinitis responded well. He had had two months' pain, and six days after injection of 1 ml. of hydrocortone had lost his symptoms; these have not returned.

Tennis and Golfer's Elbow.—These cases number 14: teno-periosteal tennis elbow, 9; tendinous tennis elbow, 3; golfer's elbow, 2. These disorders provided our most consistently spectacular results. We confined our treatment by hydrocortone to cases in which the lesion lay at the teno-periosteal junction or in the body of the common extensor tendon itself. Only 0.5 ml. of the suspension was used. Ten days after the injection 10 patients were playing tennis again painlessly. In the two remaining cases relief was incomplete, but cure followed a second injection. Two cases of golfer's elbow (strain of the common flexor tendon at the medial condyle) were fully relieved by one and two injections respectively. As a precaution (possibly unnecessary) patients were asked not to exert the wrist during the first few days after the injection, so as to give the anti-inflammatory action of the hormone a favourable environment for its action.

Knee.—Infective arthritis, 2 cases; sprained coronary ligament, 1 case. Infective arthritis of the knee had been present for two months in a woman of 26 years. After the

injection the heat, fluid, and synovial swelling almost disappeared for a week, and then returned rather more so than originally. By contrast, three fortnightly injections of 1 ml. suspension into a hot, swollen, painful knee of two years' standing had an excellent result, which has now lasted two months. The coronary sprain was of two months' standing. The ligament was infiltrated with 0.5 ml. of the suspension. Within a few days the symptoms ceased, but a small effusion remained. This was abolished by 1 ml. injected intra-articularly.

Miscellaneous.—One case of sprain of the deep aspect of the acromio-clavicular joint responded very well to two infiltrations; in another case it had no effect. A dancer who had been unable to dance for two months because of a sprained toe-joint was symptom-free after two injections. A tenosynovitis of the flexor carpi radialis which had responded indifferently to deep massage was cured by two infiltrations.

Other Uses.—Quite possibly, hydrocortone will have an important part to play in orthopaedic surgery. Introduced into the knee-joint after—for example, meniscectomy—it should serve to abort the traumatic arthritis and thus shorten convalescence materially. It may prove the treatment of choice in traumatic arthritis at the elbow-joint. Medical uses may include injection into the pleura and pericardium, and perhaps spraying the nasal mucosa in allergic conditions.

Conclusions

Hydrocortone exerts a strong anti-inflammatory action when in contact with fibrous tissue. Lesions of tendon, ligament, and joint-capsule caused by injury or overuse can apparently be cured outright within a week or two. Naturally, the smaller the area of tissue affected the more thoroughly it can be infiltrated. Precise diagnosis by means of the method of selective tension described is therefore an essential preliminary.

Tennis elbow and other tendinous disorders respond particularly well. However, another failure must be recorded in the apparently endless search for the effective treatment for freezing arthritis at the shoulder.

The indications for deep massage by the physiotherapist are narrowed, but those for manipulation remain unaltered.

REFERENCE

Cyriax, J. H. (1950). *Textbook of Orthopaedic Medicine*, 5th ed. Cassell, London.

Since the Scientific Film Association's *Catalogue of Medical Films* was published in 1952, many more films on medical and allied subjects have been brought to the association's notice, and details of these have been compiled and published as a supplement (Harvey and Blythe, London, price 6s.). Information about some 260 films is given in the supplement, and with the main catalogue short descriptive notes on over 1,200 medical films are now provided. The supplement is intended for use with the 1952 catalogue, in which abbreviations are interpreted and distributors listed. The films cover many aspects of medicine. Most of them have been made in Britain, but some films from the United States of America, Canada, New Zealand, and Russia are also listed. The new films include three on accident prevention, fifteen on health education and health services, several of which are especially suitable for showing to children, and eight on rehabilitation. There are more than twenty on general and specialist surgical subjects, ten on anatomy, several on diseases of the ear, nose, and throat; a large selection on gynaecology and obstetrics, paediatrics, industrial medicine, personal hygiene, and nursing. There are also films on neurology, orthopaedics, pharmacology, psychology and psychiatry, and anaesthetics, and a number on veterinary science.

TECHNIQUE AND VALUE OF
AORTOGRAPHYREPORT OF A CASE OF EXTERNAL ILIAC
ARTERIAL GRAFT

BY

R. E. HORTON, M.B.E., M.S., F.R.C.S.

AND

E. M. NANSON, F.R.C.S.

(From the Department of Surgery, Bristol University)

Although aortography was introduced by Dos Santos *et al.* in 1929, it has never been a popular form of investigation in this country, and it is still considered by many to be a difficult and hazardous procedure of no clinical value. Recent developments in vascular surgery, however, have made aortography an absolutely essential investigation in certain cases. It is, in fact, neither difficult nor hazardous, and can be performed under sedation alone. The use of general or high spinal anaesthesia is unnecessary.

Technique

The patient is brought to the x-ray room having had, one hour before, "omnupon," $\frac{1}{2}$ gr. (22 mg.), and scopolamine, 1/150 gr. (0.43 mg.). In the x-ray room he is given a test dose of 1 ml. of 70% diodone. This is an important precaution, as, although toxic manifestations are rare, an occasional severe reaction will be encountered. The patient is placed on the x-ray table in the prone position and a marker is fixed opposite the spinous process which is judged to be correct. If aortography is being performed to show the iliac vessels the injection is made opposite the third lumbar vertebra. If it is desired to display the renal vessels the injection must be made opposite the first lumbar vertebra or opposite the twelfth dorsal vertebra, to show the coeliac axis and its branches.

A preliminary film is taken. This is viewed and the position of the marker checked before the injection is given. Before proceeding with the injection a dose of intravenous pethidine is administered. This is a most important part in the technique, as it obviates the use of spinal or general anaesthesia. In an average case 100 mg. gives good sedation, but sometimes less is sufficient. A small intradermal weal is raised with 2% lignocaine hydrochloride opposite

the selected vertebral spine and 4 to 4½ in. (10 to 11.4 cm.) from the midline. The needle is of s.w.g. 16 and 7 in. (18 cm.) in length. It is inserted through the weal and directed towards the vertebral body. If the latter is struck the needle is redirected to pass in front of it. The aorta is easily punctured and at once a strong pulsating flow of blood comes from the needle. It is important to advance the needle a few more millimetres before giving the injection. The needle is connected to the syringe filled with 30 ml. of 70% diodone by an intervening length of about 12 in. (30 cm.) of pressure tubing. In this way the surgeon making the injection stands well clear of the beam of x rays. The needle itself is firmly held in 5 in. (12.5 cm.) of soft tissue, and it is unnecessary for the surgeon to steady it with a hand, thereby exposing himself to x rays. The injection is given as rapidly as possible and the film exposed as the last few millilitres are going in. If the injection is to be

FIG. 2.—Case 3. Extensive atheroma and thrombosis.

made at the level of D 12 or L 1 it is necessary to direct the needle obliquely upwards, as the twelfth rib prevents its insertion opposite the first lumbar vertebra.

We have not encountered any serious ill effect using this technique. On two occasions the needle has been satisfactorily placed at the beginning of the injection but has come out before the injection was completed and a periaortic deposit of dye has been made. This occasions some pain in the back, which passes off readily as the dye is absorbed. Two patients with acute embolic occlusion of the aorta have died within 48 hours of aortography. In each case the site of the needle puncture was difficult to find at necropsy, and no extravasation of blood was seen.

Indications and Results

There are many occasions in which aortography may give extra help in the elucidation of a pathological process, and because it is simple to perform we have used it on a variety of clinical problems. Its greatest value is that it can be used to define exactly the site and extent of a block in the aorta or iliac arteries, the result of embolus or thrombosis.

We have not had a patient with aortic embolus admitted early enough to get a recovery, but the following two examples will illustrate the value of aortography in these cases.

Case 1.—A man aged 56 had complained of anigral pain for five years, but there was no clear history of a recent coronary occlusion. Four weeks before admission he had a sudden loss of power in both legs which lasted only 10 minutes. Two weeks later he went to bed after a sudden attack

FIG. 1.—Case 2. Aortic embolus.

FIG. 3.—Case 4. Arrows indicate extent of block in external iliac artery.

of pain in the left calf and a cold foot. He was treated with tolazoline hydrochloride and improved somewhat. Thirty-six hours before admission he developed severe pain in both legs and within six to eight hours sensation was gone. A clinical diagnosis of embolus at the aortic bifurcation was made, but operation was considered inadvisable as the condition had been present for so long. Aortography confirmed the diagnosis and indicated the exact sites of obstruction. These were at the origin of the left common iliac and in the right external iliac. Necropsy confirmed the clinical diagnosis.

Case 2.—A woman aged 42 was known to have had auricular fibrillation and mitral stenosis for some years. She was admitted with a 30-hours history of loss of power and sensation in both legs. The lower limbs were mottled and cold and pulsations were absent. A clinical diagnosis of aortic embolus was made and an aortogram taken (Fig. 1). It was evident that the aorta was blocked at the level of the second lumbar vertebra. In view of the lateness of the condition no treatment was attempted and she died 24 hours later. Necropsy confirmed the site of the block.

It is in the locating of arterial thrombosis above the femoral artery that we have found aortography of greatest practical value. Such an obstruction may give rise to gangrene of the toes or to claudication in the calf, thigh, or buttock. The possibility that these symptoms may be relieved by endarterectomy or by arterial graft makes accurate visualization of the great vessels imperative. In many cases the disease will be shown to be diffuse and probably unsuitable for surgery, as in Case 3.

Case 3.—A man aged 59 was admitted with incipient gangrene of the toes of the right foot. The left leg had been amputated in 1948 for gangrene. Aortography (Fig. 2) showed that the left common iliac artery was obstructed at its origin, and that there was considerable narrowing of the proximal half of the right external iliac artery. The femoral artery is also obstructed just below the profunda femoris branch. The circulation to the legs is largely being maintained by anastomotic branches from the inferior mesenteric.

In Case 4, however, it was possible to excise and graft a thrombosed external iliac artery.

Case 4.—A man aged 64 had severe calf and thigh claudication of one year's duration. He had pain as soon as he took a first step and had to stop after 50 yards. There were no pulses in the left leg. Aortography (Fig. 3) showed this to be due to an obstruction of the whole of the external iliac

FIG. 4.—Case 4. Aortogram taken three months after graft to external iliac artery.

artery. The artery was exposed extraperitoneally on August 19, 1952, by one of us (R. E. H.). The great vessels were very atheromatous and the external iliac had no pulsation. The affected artery was dissected free, and after application of clamps to the common and internal iliac arteries trial section of the external iliac was begun. It was found to be blocked at its origin and had to be cut from the common iliac, leaving a window in the latter. In sectioning the lower end of the block a small arterial flow was found in the recanalized mural thrombus, but a clear artery was not found until about 1 cm. above the profunda branch of the femoral. A graft consisting of the aorta of a 4-year-old child was inserted by a continuous evert suture. The posterior tibial pulse did not become palpable until some six hours later, when it soon became strong. The patient was seen on November 1, nearly three months after the operation, and had no claudication, and said he could walk anywhere. The pulses are all present in the leg and are of

FIG. 5.—Enlarged spleen demonstrated by aortography. Arrow indicates artery to lower pole of spleen.

good volume. The post-operative aortogram (Fig. 4) shows the graft in position and of normal calibre. There was an excellent flow of blood in the femoral arteries. In October, 1953, 14 months after his operation, he was still getting an excellent functional result and all the peripheral pulses were present.

In addition to its outstanding value in the two types of case which have been described, aortography has occasional value in other circumstances.

In one patient a lump in the left hypochondrium was particularly difficult to feel because of the build of the patient. Serious doubt existed whether the lump was an enlarged kidney or spleen. Aortography clearly demonstrated that it was an enlarged spleen (Fig. 5), for the renal outline was clearly seen and the splenic arteries spread far beyond the confines of a normal spleen. Thus, in general terms, aortography may be of value in diagnosing a doubtful abdominal tumour. It may be of value in locating the site of a suprarenal tumour in a case of Cushing's disease, but we have not yet had the opportunity of testing this. Goodwin *et al.* (1950) record its use in such a case.

Aortography has been added to the more orthodox methods of pyelography in the investigation of kidney disease, as has been fully described by Griffiths (1950). It is claimed that the pooling of dye which occurs in a hypernephroma will distinguish it from a solitary cyst, but we feel that in the absence of such an appearance it would be dangerous to make a definite diagnosis of renal cyst and not submit the patient to an exploratory operation.

Summary

The technique of aortography under sedation without anaesthesia is described and its value is illustrated.

A case in which an external iliac arterial obstruction was accurately located by aortography is reported. The artery was excised and replaced by an arterial graft, with a satisfactory result three months after the operation.

It is estimated that at the present time out of every 100 average men and women in Great Britain only 2 have naturally perfect teeth; 16 need teeth extracted, 42 require other dental attention, and 40 have complete or partial dentures. These statistics appear in an article contributed to *Progress* by Sir William Kelsey Fry. "Dental disease is one of the consequences of civilization," he says. From examining large numbers of skulls, research workers now know that in the Middle Ages quite half the population had no carious teeth. But by fifty years ago it was unusual to see a patient with a healthy mouth; and during the 1914-18 war large numbers of men were rejected as unfit for active service on account of the state of their teeth. During the last war it was estimated that at 18 years of age 98% of the men and 90% of the women were in need of dental treatment. However, Britain has by no means the worst teeth in the world: some parts of the United States and Norway, Australia, and New Zealand have a much higher caries rate. The incidence of caries in Europe declined in both world wars, and the conclusion is drawn that this was closely linked with the reduction in sugar consumption and changes in bread texture. Nowadays dentists find themselves unable to keep pace with the alarming increase in dental disease. In England and Wales there are 10,000 practising dentists, the majority of whom are over 50 years of age. That means that one dentist is expected to keep between 3,000 and 4,000 people dentally fit.

VALUE OF SINGLE-SAMPLE TEST IN DIFFERENTIAL DIAGNOSIS OF JAUNDICE

BY

IAN WANG, M.B., M.R.C.P.Ed.

Medical Registrar, Victoria Infirmary, Glasgow

In the differential diagnosis of jaundice, although biochemical tests cannot take precedence over clinical findings, cases occur in which the clinical features are puzzling. For example, chronic hepatitis may in some cases present as painless jaundice simulating obstruction arising from a carcinoma of the head of the pancreas; while in other cases the main complaint may be of pain similar to that of biliary colic. In cases where the clinical picture is problematical, biochemical tests, by suggesting an earlier solution, can be of value, the importance of an early diagnosis being the necessity to decide whether surgical intervention is indicated. On the one hand, the dangers of an unnecessary exploratory operation in a case of hepatogenous jaundice must be avoided, and, on the other, the patient must be guarded from the harmful effects of prolonged extrahepatic obstruction.

The "single-sample tests" have the advantages of simplicity in obtaining the specimen with minimal discomfort to the patient, along with economy in time to the patient and the physician. Coleman (1950) has shown that such tests are reliable, irrespective of the stage of the illness. However, many such single-sample tests recommended (for example, by Schwimmer *et al.*, 1945; Shay and Siple, 1948; Mawson, 1948; Popper and Steigmann, 1948; and Hoffbauer *et al.*, 1949) involve an imposing number of biochemical determinations, employing a wide range of tests. Bearing in mind that this is a clinical problem as distinct from interesting research, the simpler tests, which can be carried out in any hospital laboratory, must be given prior consideration.

The object of the present investigation was to find out the minimal number of determinations that should be included in a single-sample test to make this of value in differentiating obstructive from hepatogenous jaundice. It is generally agreed that none of the tests employed will estimate the degree of liver damage, and this aspect of the problem is therefore not touched upon. Likewise, no attempt has been made to assess the prognostic significance, if any, of these tests.

Material and Methods

Material.—The present series consisted of 104 patients who showed signs of jaundice and whose records contained sufficient data to establish an undoubted diagnosis. This series was composed of the following:

Obstructive jaundice (67 cases)	
1. Carcinoma obstructing extrahepatic bile ducts ..	27
2. Calculus in the common bile duct ..	17
3. Chronic pancreatitis ..	4
4. Stricture of common bile duct ..	2
5. Carcinomatosis involving liver ..	17
Hepatogenous jaundice (37 cases)	
6. Cirrhosis of liver ..	20
7. Acute hepatitis ..	11
8. Miscellaneous cases of hepatogenous jaundice ..	6

Those grouped in "carcinomatosis involving liver" were patients in whom neoplastic metastases invading the liver

were demonstrated either clinically, at operation, or at necropsy, but where no definite extrahepatic biliary obstruction was found. The justification for including such cases among the obstructive groups was that Himsworth (1950) considered that the jaundice in such cases was due to pressure by deposits of growth upon the biliary passages. In the other obstructive groups the diagnosis of obstruction was based on operation or necropsy findings in all but two cases.

As might be expected, in the hepatogenous groups most of the diagnoses were based on clinical findings and progress. Cases in which there was doubt about the diagnosis were excluded from the series. Cases of haemolytic jaundice were also excluded, as this condition rarely presents a problem in the differential diagnosis of jaundice.

Methods.—The tests employed were serum alkaline phosphatase activity (King and Armstrong, 1934); serum total cholesterol (Bloor method as modified by Kenny, 1952); plasma protein; and thymol turbidity (Maclagan, 1944b). These determinations were carried out on a single sample of 20 ml. of venous blood divided into 10 ml. each of clotted and oxalated blood. At the same time a sample of urine was examined for urobilinogen and urobilin.

Results

The individual findings in the 104 patients are not detailed here, but the result of each determination in the patient's initial single-sample test has been classified as indicating obstructive or hepatogenous jaundice according to the criteria in Table I.

TABLE I.—Critical Levels

Test	Obstructive Jaundice	Hepatogenous Jaundice	Reference
Serum alkaline phosphatase	Over 35 units	Under 35 units	Maclagan (1944a)
Serum total cholesterol	Over 300 mg./100 ml.	Under 300 mg./100 ml.	Epstein and Greenspan (1936)
Plasma albumin	Over 3.4 g./100 ml.	Under 3.4 g./100 ml.	Gray (1950)
Plasma globulin	Under 2.9 g./100 ml.	Over 2.9 g./100 ml.	Gray (1950)
Thymol turbidity	Under 4 units	Over 4 units	Maclagan (1944b)
Urobilinogen and urobilin	Not increased	Increased	Watson (1937)

Analysis of the separate tests yielded the results summarized in Table II. The left column under each test contains the number of determinations in each group of patients suggesting an obstructive cause for the jaundice, the numbers in the right column being the determinations suggesting a hepatogenous lesion.

Serum Alkaline Phosphatase.—This was most often raised above the critical level in cases of obstruction due to carcinoma or to metastatic deposits (groups 1 and 5); but even where obstruction rose from other sources it was raised in 16 out of 23 cases (70%). In the present series, however, it was also raised in 10 out of 37 cases (27%) of hepatogenous jaundice. Using 35 units as the differential level, this test by itself would have suggested the cause of the

jaundice in 80 out of 104 cases, but would have been misleading in 24 cases. In no case of obstructive jaundice, no matter how mild, was the serum alkaline phosphatase below 20 units.

Serum Total Cholesterol.—In contrast to the above, hypercholesterolaemia was present most frequently where obstruction was due to causes other than malignant neoplasm. It failed to appear in more than half of the cases of obstruction where neoplasm was present, but in many of these cases cachexia, which tends to lower the blood cholesterol, was evident. Although positive in obstructive jaundice less often than the serum alkaline phosphatase, it was misleadingly raised in only three cases of hepatogenous jaundice. The results in Table II show that absence of hypercholesterolaemia need not indicate the absence of obstruction, but where hypercholesterolaemia is present obstruction is probable. Using hypercholesterolaemia as an indication of obstruction, and disregarding a serum total cholesterol of under 300 mg. per 100 ml. as of no differentiating value, this test would have diagnosed correctly only 35 out of 66 cases (53%) of obstructive jaundice, but would have been misleading in only 3 out of 35 cases (9%) of hepatogenous jaundice.

Plasma Albumin.—Hypo-albuminaemia was present in 40% of the cases of hepatogenous jaundice, but was also present in 41% of the obstructive cases. This test was obviously of no differentiating value in the present series.

Plasma Globulin.—Hyperglobulinaemia was present in 81% of the cases of hepatogenous jaundice, but was present also in 81% of the obstructive cases. This test also was obviously of no differentiating value.

Thymol Turbidity Test.—In hepatogenous jaundice this test was more often within normal limits than raised. A normal thymol turbidity is therefore no indication of the absence of liver-cell damage. When abnormally raised, however, it indicated correctly the nature of the jaundice in 16 out of 37 cases (43%) of hepatogenous jaundice, and was misleading in only 7 out of 67 cases (9%) of obstructive jaundice. In obstructive jaundice the level of 9 units was never exceeded in the present series.

Urinary Urobilinogen and Urobilin.—The anticipated absence of urobilinogen and/or urobilin from the urine in cases of obstructive jaundice was shown in 42 out of 62 cases (66%), while in hepatogenous jaundice only 8 out of 36 cases (22%) failed to show either in increased amounts.

Discussion

Serum Alkaline Phosphatase

Although its mechanism is still not clearly understood, this test has repeatedly proved its value since its use in the differential diagnosis of jaundice was described by Roberts (1930, 1933). In the present series there was a similar degree of overlap at the usual differentiating point at 35 units to that reported by Giordano *et al.* (1939), Gutman *et al.* (1940), Higgins *et al.* (1944), and Maclagan (1944a).

The present observation that the rise in serum alkaline phosphatase is most pronounced in the presence of malignant neoplasm has also been noted by Higgins *et al.* (1944),

TABLE II.—Analysis of Results

Group	No. Cases	Serum Alkaline Phosphatase		Serum Total Cholesterol		Plasma Albumin		Plasma Globulin		Thymol Turbidity		Urobilin and/or Urobilinogen	
		35+	35-	300+	300-	3.4+	3.4-	2.9-	2.9+	4-	4+	-	+
1. Carcinoma obstructing ducts	27	22	5	14	13	14	13	5	22	26	1	20	6
2. Calculus in common bile duct	17	11	6	12	5	11	5	1	15	16	1	10	7
3. Chronic pancreatitis	4	3	1	3	1	3	1	1	3	4	—	3	—
4. Stricture of common bile duct	2	2	—	—	2	2	—	1	1	1	1	—	—
5. Carcinomatosis involving liver	17	15	2	6	10	8	8	4	12	13	4	9	5

6. Cirrhosis of liver	20	8	12	2	17	10	10	2	18	11	9	4	16
7. Acute hepatitis	11	2	9	1	10	9	2	4	7	5	6	4	7
8. Miscellaneous hepatogenous	6	—	6	—	5	3	3	1	5	5	1	—	5
Total hepatogenous	37	10	27	3	32	22	15	7	30	21	16	8	28

Schwimmer *et al.* (1945), and Hoffbauer *et al.* (1949). This observation cannot be explained. Cleveland *et al.* (1950) found no detectable phosphatase activity in neoplastic cells in the liver.

In the present series none of the 67 cases of obstructive jaundice showed a serum alkaline phosphatase below 20 units, irrespective of the duration or degree of jaundice. Maclagan (1944a) reported only 3 out of 43 cases of obstructive jaundice as falling below 24 units. It would therefore appear that a serum alkaline phosphatase of under 20 units, in the presence of jaundice, strongly indicates a non-obstructive cause.

Concurrent serum bilirubin determinations with the serum alkaline phosphatase results reported in this paper showed that there was no tendency towards inverse relation with the height of the serum bilirubin in the two groups of jaundice. This is in keeping with the findings of Flood *et al.* (1937), Sherlock (1946), and Mawson (1948). Therefore interpretation of the serum alkaline phosphatase determination should not be influenced by the serum bilirubin level.

Serum Total Cholesterol

The value of this test has been doubted in the past. Sherlock (1946) regarded it as of no value, but her limits for hypercholesterolaemia were low. Hoffbauer *et al.* (1949), using 225 mg. per 100 ml. as the differentiating level, were also not impressed by this test. When, however, their figures are reviewed using 300 mg. per 100 ml. as the point of hypercholesterolaemia it can be seen that only 6 out of their 57 cases (10.5%) of hepatogenous jaundice showed hypercholesterolaemia. This value of 300 mg. per 100 ml. was the level above which Epstein and Greenspan (1936) considered significant hypercholesterolaemia to be present. They found that this level was exceeded by 78% of their cases of obstructive jaundice, while only 10% of their cases of hepatogenous jaundice showed hypercholesterolaemia. The comparable figures in the present series were 53% and 9% respectively. Cantarow and Nelson (1937) recorded that 11 of 28 cases (40%) of obstructive jaundice exceeded 300 mg. per 100 ml., while none of their 22 cases of hepatogenous jaundice showed hypercholesterolaemia. From these figures it would appear that a hypercholesterolaemia of over 300 mg. per 100 ml. is suggestive of obstruction, but that figures below this level are of no diagnostic value.

Determination of the serum total cholesterol is of value not only in confirming the more frequently positive serum alkaline phosphatase test, but also in picking up the case of obstructive jaundice missed, especially in the non-malignant groups, by the phosphatase test. In the present series the cholesterol test indicated the presence of obstruction correctly in six cases in which the phosphatase test had failed.

Estimation of cholesterol esters has been advocated, but, as this estimation is time-consuming and has been shown by Hoffbauer *et al.* (1949) to be of little value, it was not carried out in the present investigation.

Plasma Protein

The present results showed that determination of plasma albumin and globulin is of no differentiating value. This is in accordance with the results and opinion of Schwimmer *et al.* (1945) and Sherlock (1946). There is therefore a clear indication for the omission of these determinations from a single-sample test intended only for the differential diagnosis of jaundice.

Thymol Turbidity

This empirical test, first described by Maclagan (1944a, 1944b), has the advantages of being easy to perform, rapid in giving a result, and clear in its numerical assessment of the reaction. Maizels (1946) considered it to be the most useful of a number of empirical tests compared by him. Watson and Rappaport (1945) believed it to be more uniformly negative in obstructive jaundice than the cephalin-

cholesterol test. Franklin *et al.* (1948) found that this test showed statistically the most significant correlation with liver-cell damage.

The test has been criticized for being insufficiently sensitive (Mateer *et al.*, 1947), and this is confirmed by the present results, there being only 16 positive tests in 37 patients (43%) suffering from hepatogenous jaundice. The present results, however, also showed that it was reliable, only 7 misleading results being obtained out of 67 cases (9%) of obstructive jaundice.

None of the 67 cases of obstructive jaundice exceeded 9 units. Maclagan (1947) found none of 56 cases of obstructive jaundice to exceed 8 units; and Hoffbauer *et al.* (1949) found none of 77 cases of obstructive jaundice to exceed 9 units. It would therefore appear that a thymol turbidity of 10 units or over indicates hepatogenous jaundice, irrespective of other findings.

Urinary Urobilinogen and Urobilin

The present findings are similar to those of Cantarow and Nelson (1937). Snell (1947) and Coleman (1950) believed these tests to be of much value. However, as an increase of urinary urobilinogen and urobilin can occur in incomplete obstruction with secondary liver damage, as well as in hepatogenous jaundice, and as absence of both these substances can be found in hepatogenous jaundice at the height of the disease, less reliance can be placed on these urinary tests than on the blood tests. Nevertheless, where the latter are equivocal, the urinary tests may give a hint regarding the cause of the jaundice.

Serial Tests

Repetition of tests has been advocated by many authorities. Although not detailed in the present investigation, 82 tests were carried out on 28 patients. In 22 of these patients the initial biochemical interpretations were subsequently proved to be correct. In five cases with equivocal initial results, subsequent tests altered sufficiently to give a final interpretation later proved correct. In one case, the tests remained equivocal on all three occasions.

Combination of Tests

The present series once again confirms that no single test is absolutely reliable in the differential diagnosis of jaundice. Maclagan (1947), however, combining serum alkaline phosphatase with thymol turbidity results, obtained 68% accuracy. Using the same tests, Hoffbauer *et al.* (1949) had no erroneous results, but their interpretations were equivocal in 30% of cases; and Coleman (1950) found four misleading interpretations in 70 cases. Gutman and Hanger (1941), using serum alkaline phosphatase and cephalin-cholesterol tests in combination, obtained 72% accuracy.

In the present investigation, serum alkaline phosphatase, serum total cholesterol, and thymol turbidity tests have been found to be of most value. The present results have shown the following:

- Serum alkaline phosphatase
Under 20 units indicated hepatogenous jaundice
Under 35 units suggested hepatogenous jaundice
Over 35 units suggested obstructive jaundice
- Serum total cholesterol
Over 300 mg. per 100 ml. suggested obstructive jaundice
Under 300 mg. per 100 ml.—no value
- Thymol turbidity test
Over 10 units indicated hepatogenous jaundice
Over 4 units suggested hepatogenous jaundice
Under 4 units—no value

Obstructive jaundice was therefore suggested by either serum alkaline phosphatase over 35 units or serum total cholesterol over 300 mg. per 100 ml., or by both, when thymol turbidity was not more than 4 units.

Hepatogenous jaundice was suggested by: (1) serum alkaline phosphatase under 20 units, irrespective of other results; (2) thymol turbidity of over 10 units, irrespective of other

results; (3) thymol turbidity over 4 units when serum alkaline phosphatase was under 35 units, and serum total cholesterol under 300 mg. per 100 ml.

The results were interpreted as equivocal when: (1) either serum alkaline phosphatase was over 35 units or the serum total cholesterol over 300 mg. per 100 ml., or by both, with thymol turbidity between 4 and 10 units; (2) both serum alkaline phosphatase was between 20 and 35 units and serum total cholesterol was under 300 mg. per 100 ml., with thymol turbidity under 4 units.

Applying these rules to the individual results, this combination of tests can be correlated with the final diagnosis as in Table III.

TABLE III.—Interpretation of Combined Tests Correlated with Final Clinical Diagnosis

Group	In Agreement with Diagnosis	Equivocal Interpretations	Erroneous Interpretations
1. Carcinoma—obstructing ducts	22	5	0
2. Calculus in common bile duct	14	3	0
3. Chronic pancreatitis	4	0	0
4. Stricture of bile duct	1	1	0
5. Carcinoma—metastases in liver	11	6	0
6. Cirrhosis of liver	9	6	5
7. Acute hepatitis	8	2	1
8. Miscellaneous cases of hepatogenous jaundice	5	1	0
	74	24	6

Although the present accuracy of 71% shows no significant improvement over the figures obtained by Gutman and Hanger (1941), MacLagan (1947), and Hoffbauer *et al.* (1949), despite the addition of the serum total cholesterol determination to the tests, it is felt that this test is justified, as it correctly indicated obstruction in six cases where the serum alkaline phosphatase had failed, and yet on only one occasion was it misleading by itself. Furthermore, as has been shown in Table II, hypercholesterolaemia is more often present in non-malignant causes of obstruction, the type in which the serum alkaline phosphatase is less often helpful.

When the urinary tests were taken into account in those cases with equivocal blood results, in the obstructive groups 10 out of 15 cases showed absence of both urobilinogen and urobilin, three cases showed a misleading increase of these substances, and in the remaining two cases these tests were not carried out. In the hepatogenous groups, seven cases out of nine showed increase of urobilinogen and urobilin; in two cases neither was increased.

After applying the less accurate urinary tests, the final interpretation of the biochemical tests showed:

In agreement with diagnosis	
Blood tests	74
Suggestive urinary tests	17
Disagreement with diagnosis	
Suggestive urinary tests	5
Blood tests	6
Equivocal (urinary tests not done)	2

The erroneous blood tests were limited to cirrhosis and acute hepatitis, and the proportion to the total number in the series was similar to that reported by Coleman (1950).

Summary

A series of blood tests was investigated regarding the value of these determinations for inclusion in a single sample test for the differential diagnosis of jaundice.

Of the tests employed, the serum alkaline phosphatase activity, serum total cholesterol, and thymol turbidity were found to be of most significance. Deter-

mination of the plasma protein fractions was of no value and should be omitted from any single-sample test.

Tests for urobilinogen and urobilin in the urine were found to be of value as supplementary information where the results of the blood tests were equivocal.

Critical levels in the blood tests for the differentiation of hepatogenous from obstructive jaundice are suggested. Applying these criteria in a series of 104 cases of jaundice, the correct diagnosis of the type of jaundice was made in 91 cases. Of the remaining 13 cases, two gave equivocal results, while in 11 the biochemical findings were frankly misleading.

This paper was made possible only through the generosity of Dr. Ian A. Anderson, who gave me free access to the biochemical records of these tests. I cannot adequately express my thanks for his unstinted help and advice. I am also indebted to the physicians and surgeons of the Victoria Infirmary for allowing me the use of their clinical records.

In his annual report for 1952 the medical officer of health for the County Borough of Smethwick, Dr. Hugh Paul, comments on the rapid decline in infectious diseases, in particular tuberculosis, since the war. He attributes the decline mainly to the use of antibiotics, but he continues: "On the other hand, one cannot withhold a meed of praise to the conscientious chest physicians throughout this country who have achieved remarkable success during the past two generations. Many of us feared when the regional board took over our schemes in 1948 that the glamour of cure would swamp the infinitely more useful but infinitely less attractive aspects of prevention, and that the tuberculosis service would sink to the level of other branches of hospital cure. We have built better than we knew, however, and it would appear that the tuberculosis officers trained by us in the olden days, soaked in the gospel of prevention from their early days and imbued with the desire to look upon their task in the broadest possible light, are continuing in the olden ways, and have evaded the blandishments of the sirens of curative medicine. One can only hope that the new generation of chest physicians will be trained in the same way, but one cannot help but feel uneasy when one reads advertisements for chest physicians stating that the M.R.C.P. is necessary and that previous experience in tuberculosis is desirable. We must not sink to cure."

FLUID CONTENT OF THE NUCLEUS PULPOSUS AS A FACTOR IN THE DISK SYNDROME*

PRELIMINARY REPORT

BY

A. NAYLOR, Ch.M., M.Sc., F.R.C.S.

Consultant Orthopaedic Surgeon, Bradford Hospitals

AND

D. L. SMARE, M.Sc.Tech., F.Inst.P.

Head of Physics Department, Bradford Technical College

The erroneous term "slipped disk," which is often applied to the disk syndrome by the laity, and unfortunately by a large number of their medical advisers, is derived from an impression that trauma is an invariable concomitant of such lesions, yet in a high proportion of cases the onset is insidious. Armstrong (1952) states that approximately 60% of patients with lumbar disk protrusions give a history of injury initiating their symptoms, whilst Eyre-Brooke (1952), in reviewing a series of cases treated by operation, found a similar history in 13.7%. In a series of 121 cases of cervical disk prolapse I have found injury to be a relevant feature in only 9%. As the alleged injury is often trivial in nature, and previous symptoms are often recounted, we must assume that the injury or strain is a precipitating factor only, and therefore that other factors must play a part in the development of the syndrome. It is suggested that one of the many factors is an increase in the water content of the nucleus pulposus.

Göcke (1932) examined the effect of soaking portions of nucleus pulposus in acid, alkaline, and saline solutions, and noted that swelling resulted from the absorption of fluid. Nuclei removed from young subjects took up fluid equal to 95% of their weight when soaked in saline, while those from adult subjects absorbed 50–60% of their weight of fluid, and less than 25% was absorbed by nuclei removed from aged subjects. The increase in weight was greater when nuclei were immersed in alkaline fluid and less when placed in acetic acid. Such a degree of swelling suggests that a similar change within an intact disk would produce a high internal pressure. This prompted the suggestion (Naylor, 1951) that an initial factor in the development of the disk syndrome was a rise of internal pressure due to increase in the fluid content of the nucleus pulposus. The annulus fibrosus would be stretched, producing cervical or low back pain, depending upon the level affected. Should the annulus be thinned, bulging or actual herniation of the nucleus would occur. Once the herniation has appeared mechanical stress would maintain its extrusion. It is possible that the fluid change in the nucleus may be instigated by some endocrine or metabolic factor, and it is probable that the initial change is a depolymerization of the polysaccharide element of the polysaccharide-collagen complex.

Our measurements of the water absorption by the isolated nucleus confirm Göcke's findings, but there seems to be no linear relationship between the amount of fluid absorbed and the ages of the subject. Vary-

ing degrees of absorptive power were found in disks from subjects of similar ages. The annulus fibrosus will also absorb fluid, but to a less degree than the nucleus. The addition of hyaluronidase to the immersion fluid increases the weight of fluid absorbed by 20%. This is probably due to the depolymerization of the polysaccharides, causing reduction of size of the particles and increase in the osmotic power of the nucleus.

Measurement of Pressure Within the Disk

As an initial step a series of experiments was designed to measure the pressure generated within the disk, and an apparatus (see Diagram) was developed for this purpose. The manometer of the apparatus consisted of a glass capillary tube (A) fixed to a 20-gauge serum needle (B) by a brass connector; the joints were sealed with a high-vacuum wax. The needle had a series of slots cut in the distal half-inch to allow an even distribution of pressure to the mercury within the needle and to minimize any blockage. It was bent to 90 degrees at its centre so that it could be inserted horizontally into the disk. A mercury reservoir (C) was connected to another capillary tube (D) fixed parallel to the manometer, the latter being joined to the capillary tube by an inverted U-tube containing alcohol. Alcohol was

Diagram of apparatus.

used in preference to water as it has a smaller surface tension, giving ease of flow and facilitating elimination of air bubbles. Initially the apparatus was filled with mercury, the manometer clipped off, and alcohol then drawn into the inverted U-tube. The clip (E) was then opened, the manometer needle being immersed in mercury. By alternately raising and lowering the reservoir a column of mercury is drawn into the manometer. The clip (E) was then closed and the apparatus was ready for use.

Fresh lumbar disks from necropsy subjects were obtained with a thin sliver of bone on each side, this being important to prevent any force being expended on producing bulging of the nucleus. The disk under test was pierced by a hollow needle of the same gauge as that in the apparatus, and the manometer needle was then inserted along the track made. This minimized the risk of blockage by tissue. The specimen was then placed in a glass crystallizing dish and the screw clip (E) opened. The mercury in the reservoir and side tube was levelled and a travelling microscope focused upon the meniscus of the manometer and its scale read, the pressure then being equal to that of the atmosphere. The disk was then immersed in fluid, using water or normal saline. To note the pressure developed, the mercury reservoir was adjusted to bring the meniscus in the manometer to its initial level. The height of the reservoir above the level of the disk is then the pressure required to neutralize that developed within the disk. Initially 20 disks have been investigated in this manner.

*Based on a paper read to the British Orthopaedic Association in October, 1952.

Results

Three experiments were valueless, as blockage of the needle occurred and no readings could be obtained. Of the remaining 17, 11 developed a high, measurable internal pressure, whilst one developed enough pressure to rupture the bone end-plate, and no internal pressure was therefore measured. This disk had been cut with a very thin end-plate, and a complete transverse fracture of this developed, with protrusion of the swollen nuclear material. Simultaneously a disk from the same subject developed a pressure of over 80.2 cm. Hg. It was impossible to raise the mercury reservoir high enough to depress the mercury in the manometer to its normal level, and if the movements of reservoir and manometer meniscus are proportional then a pressure of approximately three atmospheres had developed.

The most significant result obtained was the spontaneous rupture of the annulus fibrosus in one specimen, which developed after 17 hours' immersion in water to which hyaluronidase had been added. At the time of rupture a pressure of 20 cm. Hg was measured, but, despite the production of the rupture, the internal pressure had increased to 80 cm. after eight hours' immersion. The disk bulged extensively, and, on section, the rupture of the annulus and herniation of the nucleus were easily demonstrated.

Two disks from very old subjects registered no rise of pressure, the nuclei being small, brown, and dry on section. Evidently no fluid had been absorbed, and this can be explained by the operation of two factors: (a) decreased permeation as a result of sclerosis of the end-plate; and (b) loss of polysaccharide, which occurs with advancing years.

There is little doubt that a large contribution is made by the latter factor. The absence of water absorption and change of internal pressure in disks of aged subjects is consistent with the known decreased incidence of disk prolapse in that age group. If the polysaccharide content of the nucleus is very much reduced, then fluid absorption, and therefore increase of internal pressure, will be minimal or absent and the potentiality of disk herniation reduced. Sylven (1951), using metachromatic staining methods, showed that the mucoid element in the nucleus was reduced with advancing degeneration. During the course of x-ray diffraction studies of intervertebral disks we have obtained confirmatory evidence of this (Happey, McRae, and Naylor, 1953). *In vivo*, where there is a compression force due to the superimposed body weight, a smaller absorption of fluid would lead to the development of considerable internal pressure.

A compression force was applied to disks, placed in the apparatus previously described, by means of a flat steel bar, weights being added to its ends. With the dry disk a gradual addition of weight was accompanied by a rise of internal pressure, except in those which showed advanced degeneration. The latter had lost their elasticity, and compression caused no rise of internal pressure, while subsequent immersion during maintenance of pressure was without effect. In contrast, a disk from a subject aged 35, compressed by a load of 24 kg., showed a rise of internal pressure from 47 to 119 cm. after immersion in water. Preliminary experiments in which absorption from one or both end-plates is blocked suggested that the fluid reached the nuclei by permeation through the end-plate.

Discussion

The preliminary experiments show that a high pressure can be developed within an intervertebral disk by absorption of fluid, this most probably entering through the bony end-plate. It is postulated that the possible sequence of changes leading to the development of the disk syndrome consists of: (1) depolymerization of the polysaccharides of the collagen-polysaccharide complex in the nucleus pulposus, leading to (2) increased power of water absorption, causing (3) absorption of fluid by the nucleus, the fluid

entering via the end-plate; (4) increase of pressure within the disk. The forces developed by leverage and muscular action would augment this.

It is possible that a return to the *status quo* by a process of polymerization does not occur, but that the internal pressure falls to normal as the depolymerized molecules are absorbed. This process can be repeated with each episode of symptoms, and would explain the gradual development of degenerative change in such disks. A stage is ultimately reached when the disk has degenerated to such an extent—and thereby lost its water absorption power—that prolapse cannot occur. It is possible that a similar process in multiple disks produces attacks of "fibrositis."

Further and more extensive experiments are being conducted to investigate this hypothesis, using modified apparatus to measure the high pressure generated within the disk.

Medical Memorandum

Thyrototoxicosis Complicated by Thrombocytopenic Purpura

The association of thrombocytopenic purpura with a toxic goitre is rare. The literature reveals approximately twelve such cases (six female and six male). In several the clinical picture may have been complicated by the administration of myelotoxic drugs (Jackson, 1931; Corson, 1942; Fewell *et al.*, 1950; Hart, 1951). In the remainder no such complicating factor is evident (Finochietto *et al.*, 1936; Lavastine and Cachin, 1940; Woodruff, 1940; Bomford and Rhoads, 1941; Bicknel and Dicker, 1942; Conklin and Shank, 1944; Roberts, 1948). In the following case associated drugs, such as bismuth, "sedormid," or thiouracil, were not given before the occurrence of the purpura. The purpuric manifestations were associated with the thyrotoxicosis before treatment. Propylthiouracil was administered pre-operatively after the combination of the two diseases had been noted.

CASE REPORT

A woman aged 62 was admitted to hospital on September 5, 1951. She had been breathless on exertion for years, but this had been aggravated after a three-weeks period in bed for generalized joint pains in January, 1951. Ten days before admission a slight cough and a mild tonsillitis developed. A small haemoptysis occurred with the onset of the cough. Blood had been passed per rectum, and a widespread purpuric rash had developed over the body and limbs and in the mouth. She had bruised very easily and had lost weight over the past year. A mild degree of ankle oedema had been present for years. She had had a right-sided pneumonia with pleurisy forty years before, and several attacks of tonsillitis since. There was no history of rheumatic fever and no relevant family history.

Physical examination revealed a cachectic-looking patient who was dyspnoeic. The mucous membranes were pale, the teeth were decayed, and a mild bilateral tonsillitis was evident. Tremor was marked. The hands were warm and moist. The thyroid gland showed a generalized enlargement of both lobes. Multiple purpuric spots were apparent all over the body and on the gums and tongue. Pulse rate 90. Rhythm regular. The apex beat was displaced laterally. On auscultation the grade II apical systolic murmur was heard and crepitations were present at the bases of both lungs. There was a mild degree of ankle oedema. The liver

was enlarged and the spleen was easily felt. The blood pressure was 160/75. The haemoglobin was 29%, red cells 2,000,000 per c.mm.; the white-cell and differential counts were normal. No platelets could be seen. The bleeding-time was 14 minutes, clotting time 5 minutes, and prothrombin time 94% of normal.

On the day after admission more blood was passed per rectum, and her condition was deteriorating; she was therefore transfused with 4 pints (2.3 litres) of blood, with much improvement. The haemoglobin rose to 50%, and a platelet count six days after admission was 180,000 per c.mm. A marrow biopsy was normal; the leucocyte:erythrocyte ratio was 6:1; megakaryocytes, normal in number, showed no obvious morphological abnormality.

A week later her condition deteriorated. New petechiae appeared over the trunk. The bleeding-time had risen to 20 minutes, and the platelets had fallen to 70,000 per c.mm. and the haemoglobin was 54%. During the next week her condition fluctuated, with a tendency to improve. From the twenty-fifth day until discharge, 36 days after admission, progress was maintained, the haemoglobin rising to 76%, and the platelet count to 186,000 per c.mm.

A culture from the throat revealed no pathogenic organisms. Thyroid metabolism, estimated by radio-active iodine tests, showed results which were consistent with a moderate thyrotoxicosis. Blood cholesterol was 121 mg. per 100 ml. An electrocardiogram showed the pattern of left ventricular strain. A skiagram of the chest revealed signs of old tuberculous infiltration at the right apex. Liver-function tests were all normal. Propylthiouracil therapy was started twelve days after admission, in doses of 50 mg. three times a day. In addition penicillin was given for the tonsillitis, with iron and vitamins for the anaemia.

When seen in the out-patient department on November 1 she was still showing signs of early heart failure, and there had been a recurrence of the purpura. She was still taking propylthiouracil.

She was readmitted to hospital on November 5, showing very much the same clinical picture as before, but to a less degree. She was dyspnoeic and pale. The thyroid gland was more enlarged than previously. The hands were moist and tremor was marked. There was widespread purpura, especially on the legs. The haemoglobin was 62%, with 4,000,000 red cells per c.mm. The white-cell and differential counts were normal. The platelet count was 165,000 per c.mm. The blood cholesterol had risen to 160 mg. per 100 ml. Partial thyroidectomy was decided upon to control the thyrotoxicosis. The petechiae gradually cleared, and, apart from an epistaxis and a small subconjunctival haemorrhage into the left eye, the patient was relatively well. Propylthiouracil therapy was continued up to the time of operation, the dose having been doubled.

A partial thyroidectomy carried out one month after the second admission was uneventful. She had a mild pyrexia for four days after this. A little extra bruising of the neck occurred around the wound, but there was no fresh attack of purpura. Auricular fibrillation supervened for four days after the operation, normal rhythm then being resumed without treatment. The thyroid gland, which was large and fleshy, showed, on section, changes characteristic of toxic adenoma, modified by thiouracil.

The patient was discharged from hospital forty days after her second admission. The haemoglobin was then 86%, and the platelet count 170,000 per c.mm. She had gained 9 lb. (4.1 kg.) during the second admission period and looked fit and well.

COMMENT

The association of thrombocytopenic purpura with certain endocrine disturbances is not uncommon. Numerous authors have reported this association with pregnancy. Minot (1936) and Pohle (1939) showed that thrombocytopenic purpura may occur in certain phases of the menstrual cycle. In the above case thrombocytopenic

purpura complicated thyrotoxicosis, and there is no suggestion in the history of any other intoxication, such as from myelotoxic drugs. So far as can be ascertained, the thyrotoxicosis preceded the purpura. The incidence of the combined diseases seems to be about equal between male and female. No case has occurred below the age of 28. Probably the total number of cases reported of the combined diseases, without any complicating factor, is less than ten. Wintrobe (1946) believes that there is no adequate reason to assume that the combination represents more than the coincidence of two unrelated diseases. The paucity of cases lends some support to this opinion. On the other hand, Woodruff (1940) takes the opposite point of view, and believes that the leucocytes and platelets are specifically affected by the thyrotoxic state. He believes that the degree of toxæmia produced may either stimulate or depress the number of platelets, according to the mildness or severity of the degree of toxæmia.

In a discussion on the cause of idiopathic thrombocytopenic purpura, Robson (1949) suggests that the spleen and other reticulo-endothelial tissues produce some factor which alters the state of the capillaries and reduces platelet formation from megakaryocytes. Such might be the case here. It does seem possible that the state of capillaries was a more important factor than the thrombocytopenia, on re-admission, when purpura was still evident with a platelet count of 165,000 per c.mm. It seems reasonable to suppose that the activity of the spleen might be reduced with the reduction of lymphatic hyperplasia which occurs after thyroidectomy. It was felt after readmission that partial thyroidectomy was necessary in this instance. Propylthiouracil, while having some effect on the thyrotoxic state, did not seem to benefit the purpuric manifestations. In view of the case reported by Fewell *et al.* (1950), in which purpura followed propylthiouracil therapy, it seems wiser not to use this drug when the two diseases are combined. It is suggested that operation is preferable to drug therapy when thrombocytopenic purpura and thyrotoxicosis co-exist.

Our thanks are due to Dr. Kenneth Robertson for permission to publish this case, and to Mr. L. A. Richardson, who carried out the partial thyroidectomy. We would also like to thank the laboratory for the haematological investigations, and the radio-therapeutic department for the radioactive iodine tests.

The new radiological department of the Clatterbridge Hospital, Bebington, Cheshire, was officially opened on October 2 by Dr. Peter Kerley. The department is entirely self-contained and has been planned to give direct access to the operating theatre and easy communication with the wards. It is divided into three main sections for general and fluoroscopic work, pulmonary, cardiac, and gastro-intestinal examinations, and for genito-urinary investigations.

Reviews

GASTRO-INTESTINAL RADIOLOGY

Gastrointestinal X-ray Diagnosis. By Max Ritvo, M.D., and I. A. Shaffer, M.D. (Pp. 838; 470 illustrations, with two in colour. £7 10s.) London: Henry Kimpton, 1952.

Drs. Max Ritvo and I. A. Shaffer have written an important book intended mainly for the radiologist and gastro-enterologist. After an introductory section of twenty-six pages the whole of the alimentary tract is considered serially from pharynx to rectum. Sections follow on the gall-bladder and liver, the pancreas, spleen and abdomen, and abdominal herniae. The scope of the book is wide. The authors have omitted very few lesions of the alimentary tract that are susceptible to x-ray demonstration. The pattern of the work is admirable from the radiologist's point of view, since in the description of each lesion of any importance the authors include an account of the aetiology, pathology, and clinical signs and symptoms in addition to the x-ray manifestations.

It is inevitable that the reviewer will find in any work like this some matters with which he is at variance, and in this one there are a few. The technique of examination of duodenal ulcer is not described in sufficient detail to be informative and some of the complications following gastric operations are not mentioned. The modern views on the causation of hiatus hernia do not appear: it seems that the authors regard most of these hernias as congenital. The views expressed on chronic appendicitis lack clarity. Various x-ray signs of chronic appendicitis are described, but whether or not there is such a pathological entity is left in the air.

These criticisms of detail are small in the perspective of the work as a whole, which is outstandingly good. It is a compendium of information, readable, beautifully produced, and abounding in well-chosen illustrations. In spite of the price, which, as of most American books nowadays, is high, it is a book warmly to be commended to all who are engaged or interested in gastro-intestinal radiology. It is a credit to the great school in Boston from which it comes, and the authors are to be congratulated on an outstanding work.

S. COCHRANE SHANKS.

EAR DISEASE

Lehrbuch der Ohrenheilkunde. By Dr. E. Lüscher. (Pp. 414; 246 figures. £3 6s. 6d.) Vienna: Springer-Verlag, 1952.

In his preface the author refers to the important advances in treatment by the systematic use of sulphonamides and antibiotics, in the new approach to the physiology of hearing by the extended use of electro-acoustic apparatus, fresh methods of vestibular investigation, and the important operation on non-inflammatory diseases of the ear—all developed during the last decade—and he considers that these facts call for this up-to-date book. Professor Lüscher has certainly justified his opinion, and it is striking that he has carried through this exacting task without calling on colleagues except to write on audiometry; here he has the assistance of the head of the acoustic laboratory, Dr. Zwislocki.

The book is arranged on conventional lines. Chapters on the anatomy and physiology of the ear are followed by a detailed description of the methods of examining the ear and tympanic membrane and of the testing of hearing and vestibular function—all fully illustrated. The student will find the early tests simple to follow, but the modern audiometric tests and their application are more suited to the expert. Audiometry is discussed very fully. The audiometer used and illustrated is that designed by Zwislocki and made at Basle. Tuning-fork tests and their results are compared with audiograms, intelligibility versus intensity being illustrated by good diagrams. The author's "ear-

microscope" allows a ten-fold enlargement of the view of the tympanic membrane to be obtained and coloured photographs to be taken. It is of great interest, and the reproductions of normal and abnormal conditions are lavishly scattered through the text. Such magnified views are so unusual that their interpretation requires practice. The use, too, of Dishoeck's "pneumophon" to investigate the function of the Eustachian tube is explained.

For the treatment of acute otitis media the author advises sulphonamides in the first place, and then penicillin unless an alternative is indicated by the organism found in the ear discharge; when paracentesis is required the incision is to be made from above downwards instead of from below upwards as recommended in English books. The simple mastoid operation is described but not illustrated. Chronic suppurative otitis media is divided into two classes—with and without cholesteatoma—and the author describes the radical operation and discusses the endaural and postaural approaches. Complications are treated in the usual way, and their pathology is admirably explained with excellent microscopical slides. For treating cerebral abscess the author advises an approach through a radical mastoid operation, though the neurosurgical approach is subsequently mentioned. It is interesting to find positional vertigo and nystagmus with their possible causes discussed. Ménière's disease and treatment are fully described. Vitamin B₁ has been found of considerable value.

This book is of such a high scientific standard that it would appear to be more suited to experts than students. Separate chapters on important subjects would make for easier reading and reference. The author gives evidence of world-wide reading, and quotes from Continental, American, and British authors, but it is unfortunate that he gives no references for readers who might wish to study the original papers. The specialist will find lucid descriptions of the science of audiology and modern work with the speech audiometer, together with the means of determining the site of the lesion causing deafness. The author fully discusses otosclerosis in relation to the fenestration operation, the choice of cases, prospective improvement, and complications. He describes the operation in detail but shows only two pictures, both Lempert's. There is one excellent photomicrograph depicting the results of a successful operation three and a half years previously. A special feature is the number and quality of the illustrations, many of them coloured, illustrating clinical conditions. These are in addition to the numerous coloured pictures of the tympanic membrane, of which all are good; perhaps those of exudative otitis media and rupture of the membrane stand out. The work will surely have a wide circulation among readers of German.

W. M. MOLLISON.

SURGICAL EXPOSURES

An Atlas of Surgical Exposures of the Extremities. By Sam W. Banks, M.D., and Harold Laufman, M.D., Ph.D. (Pp. 391; 552 illustrations, on 179 plates. £3 15s.) Philadelphia and London: W. B. Saunders Company, 1953.

A sound knowledge of anatomy is a necessity for a good surgeon. That is why the aspirant to the higher surgical diplomas must demonstrate to the examiners that he possesses such knowledge. A surgeon in active practice should have constantly in mind the normal anatomy of the part on which he is operating and ought seldom to need a series of pictures to show him how to approach the various aspects of the limbs. But memory is often fallacious, and surgeons sometimes find it difficult to keep up their anatomy, and some doctors whose anatomy is very rusty may, in a case of emergency, have to operate. For such this sumptuous book will be helpful.

The atlas consists of 179 pictorial plates on each of which are three or four illustrations of the structures met with in exposing various parts of one or other extremity. It is designed "to serve the student and resident in surgery . . . and to be a timely refresher to the experienced surgeon who operates on the extremities only occasionally."

The illustrations were all specially prepared and were based on photographs of actual dissections of the cadaver, so that the "final drawing is in every case a faithful representation of the anatomical findings encountered at surgery." This must have entailed an enormous amount of work, and the authors are to be congratulated on the successful result.

But a word of caution must be sounded. Every senior surgeon knows, and the junior surgeon will soon learn, that in many if not in most instances the parts seen at operation are seriously altered by disease or trauma, and the normal appearances depicted in this book will appear distorted and sometimes almost unrecognizable. Moreover, in dealing with malignant tumours one may have to discard all set incisions in order to cut clear of the growth. The pictures here will no doubt help many a novice and may give many a useful suggestion to the experienced surgeon. It would be a good plan if at least some of the main exposures could have been printed in colour, though no doubt that would have added greatly to the expense.

ZACHARY COPE.

STAMMERING

Understanding Stuttering. By A. B. Gottlob, A.B., Ph.D. (Pp. 274. \$5.50.) New York: Grune and Stratton, 1953.

This book is intended primarily for stammerers—or stutterers, the designation preferred in the United States—and their parents, relatives, and friends, in the hope of assisting the patient who would otherwise receive no understanding or help. Nevertheless, all who are concerned with speech therapy will derive much benefit from perusing it, although one can scarcely agree with the author that the term "block-ing" is preferable to "stammering" or "stuttering"; in fact, to find a stammerer continually referred to as a "blocker" becomes somewhat irksome.

After a simple outline of the physiological mechanism of speech, Dr. Gottlob gives a very good description of the various problems of personality associated with stammering. This is probably the most valuable part of the book, especially the observations on the upbringing of children of so-called nervous temperament. He gives some sound advice on preventive measures in psychoneurotic reactions, not only in relation to speech disorders but also in general circumstances.

As regards treatment, the author postulates four main therapeutic procedures: (1) the education of the patient to the understanding of his disorders; (2) reconditioning, by which he means the production of new speech patterns to replace the former and undesirable patterns, with the object of enabling the muscles concerned with speech to function more smoothly; (3) relaxation, both physical and mental, to reduce emotional tension; and (4) psychotherapy, both individual and group. This aims at uncovering the original and underlying causes of the speech disorder and any possible factors aggravating or sustaining the abnormal condition. While most of the methods described are advantageous for application to adult and adolescent patients, some are scarcely suitable for young children.

Certain of the author's views on the aetiology of stammering might not meet with general acceptance. But on the whole the debatable matters in the work are few, and Dr. Gottlob has made a valuable contribution to that difficult problem—the treatment of stammering.

C. WORSTER-DROUGHT.

CARDIAC ARRHYTHMIAS

Extrasystoles and Allied Arrhythmias. By David Scherf, M.D., F.A.C.P., and Adolf Schott, M.D. (Heidelberg), M.R.C.S. (Pp. 531; 212 figures. £5 5s.) London: William Heinemann, 1953.

This book is a most comprehensive treatise on a subject that has slipped quietly into the background nowadays. Thirty years ago the riddles of these disorders of rhythm were still the main object of interest for doctors using the electrocardiograph. But although their importance has hardly much share of the limelight in these times, and has rather

diminished in consequence, there is still a great deal that we do not know about them. Not infrequently one may wonder whether they do not require more attention. This book supplies everything that can be asked for at present. The opening historical chapter is very well done; the older accounts and conclusions are interesting to read. How that genius Morgagni, as usual, has often the first (and last) word to say on the subject!

In a long chapter the authors discuss the various types of extrasystole. They classify them by their site of origin as shown by the electrocardiogram and also by other signs. The authors conclude that extrasystoles which show varying forms in the electrocardiogram, and so are presumably from different foci, indicate myocardial disease.

There is a full description of the theory of parasystole; digitalis and infection are held to be the causes. A chapter is devoted to alternation of the pulse; flutter, fibrillation, and paroxysmal tachycardia are included, for the authors consider that the mechanism underlying these arrhythmias is akin to ectopic beats, particularly the auricular. It is satisfactory to see these discussed again in relation to modern knowledge. The physiological aspects of extrasystoles are fully considered.

The authors' style is clear and concise and free from jargon. The illustrations for the most part are very good, but some are dim and blurred. Usually the standard leads and one or two chest leads are shown. There is a summary at the end of each chapter, but sometimes it is disappointing and merely indicates what has been mentioned. There are full references. This is an admirable work; the clinical aspects are fully discussed; the opinions and judgments are sound. All cardiologists will want to have this book on their shelves and will often refer to it. It is much more than an academic study.

TERENCE EAST.

A PATIENT'S DRAWINGS

Schöpferische Gestaltung aus dem Unbewussten: Ein analytisches Bilderbuch. By Dr. M. Schultze-Niemann. (Pp. 45; 26 figures. M. 12.) Munich: J. F. Lehmanns Verlag, 1953.

Psychotherapeutic schools have searched hopefully, though with little success, to find standard procedures of treatment which could be applied with benefit by any trained and intelligent technician. But success in psychotherapy seems to require a personality endowed with intuitive and aesthetic gifts, so that the subtle play of unconscious motivations can be readily divined and appreciated. Psychotherapeutic practice has remained an art which has had a special appeal for artistically sensitive persons. It is no wonder therefore that there has been a recurrent tendency for therapeutic art to change into art therapy, affording pleasure to both patient and doctor.

In this book the author has attempted to share with a wider public the pleasure she derived from a course of psychotherapy which relied largely on the interpretation of drawings and paintings a patient had been encouraged to produce. There is no doubt that the author has been successful in her endeavour, for the book provides excellent reproduction of thirty-two pictures and an imaginative analysis of them in the text. The author wisely makes no claim about the particular therapeutic virtue or superiority of this form of treatment. The patient, a 29-year-old single woman, suffered from depressive symptoms following upon the death of her father. She recovered after nine months of treatment, having painted fifty-two pictures. Psychotherapy continued for another fifteen months and a total production of 300 paintings.

In her theoretical introduction the author refers mainly to the work of J. H. Schultz (the author of "autogenous training" as a psychotherapeutic method), who writes a foreword, and to K. Schultze-Jahde, who provides a theoretical framework couched in unattractive German neologisms. But the book can be enjoyed without this theoretical encumbrance, which is not an essential part of it.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY OCTOBER 31 1953

FAMILY DOCTORS AND PUBLIC HEALTH

The general practitioner of forty years ago was as well equipped as anyone else to deal with the social consequences of ill-health. But times have changed, and, though personality and integrity are as important as ever, medicine is no longer confined to bedside therapeutics and such amelioration as wise counsel brings. The public in a Welfare State expect, and indeed have a right to, what is now often called social therapeutics, and the wise family doctor will accept all the aid which his colleagues in the health departments of local authorities can give him. The growth of the hospital service has shown the need for many auxiliaries—physiotherapists, occupational therapists, almoners, and others—to assist the consultant. Similarly, in general practice the local health authority through its medical officer of health is required to provide the general practitioner with his helpers—midwives, home nurses, health visitors, domestic helps, and so on. The General Practice Review Committee in its recently published report¹ concluded that there was no need for an atmosphere of competition to persist between general practitioners and public health departments. And on another page in this issue Dr. J. S. Thomas, himself a general practitioner, in making a forceful plea for bringing the health visitor into the family-doctor team, emphasizes the fundamental change which the N.H.S. Act, by providing a full medical service for the whole population, has made in the orientation of the local authority services. Dr. Stephen Hadfield, in his field survey of general practice,² noted good relations with the public health service when the general practitioner was doing part-time work in a clinic—a finding only to be expected, for in this way the general practitioner can obtain a much better insight into the purposes behind the work of the health department.

In the past the medical officer of health was always requesting information from general practitioners—who often did not see the point of the inquiries because their training in the principles of preventive medicine had been inadequate—but now he is in the happier position of providing some assistance. The

¹ *British Medical Journal Supplement*, 1953, 2, 131.
² *British Medical Journal*, 1953, 2, 683.

district nurse, or home nurse, now employed by the local health authority, is an accepted and welcome helper to the general practitioner. The relationship with the midwife is not always so happy, but in very few areas is there a co-ordinated scheme of midwifery where the responsibilities of the hospital, the general practitioner, the midwife, and the local authority clinics are integrated into a well-knit scheme. There is need for a frank discussion among all concerned to achieve this desirable end. The domestic help service, although not free of charge, is accepted as an important contribution to the stability of a household in sickness, disability, or during childbirth. This is a new service for the local health authority to administer, and not all doctors are yet conversant with its working, though the medical officer of health is always willing to explain.

The newest recruit to the growing army of those who can help the general practitioner in his work is that sometimes controversial figure the health visitor. Even to-day it comes as a surprise to some doctors to learn that she is a State-registered nurse, a midwife, and also trained in social medicine. She came into the scheme of things primarily as a health educator with special responsibility towards the mother and child. Her success in this field has, despite the difficulties, been great. Under the National Health Service Act the scope of her work has been widened, and this is not always appreciated even by the health visitor herself. Elsewhere in this issue we reprint the paper read at this year's Annual Meeting by Dr. Llywelyn Roberts on the subject of the health visitor and the family doctor, and in this he not only makes plain the scope of the routine work of the health visitor but he also enumerates the ways in which she can help the G.P. Essentially a field worker, she can assist the family doctor in the care of the mother and child in seeing that his instructions on infant feeding and care are carried out, and she can also help him to supervise the welfare of the aged, the disabled, and the tuberculous in their homes.

Dr. Hadfield found that 28% of the general practitioners he questioned complained bitterly about the activities of health visitors. Some medical officers of health, convinced in their own minds that health visitors are the backbone of the public health service, take the view that those who remain hostile to the work of health visitors can be ignored as reactionaries. But such a view overlooks what has been, and often still is, a serious fault in the organization of a public health department. The ignorance of some general practitioners may be lamentable, but how often is it due to the failure of the M.O.H. to enlighten his colleagues in general

practice about the purpose of the work of health visitors? The Hadfield report should stimulate medical officers of health to make much greater efforts to explain the work of health visitors to the general practitioners in their areas and to impress on health visitors the fact that their work loses much of its point if they have not succeeded in obtaining the good will of general practitioners.

The success or otherwise of the health visitor will depend more and more on a satisfactory working arrangement being established between her and the general practitioner, so that she is working with him and for him in essentially the same way as the district nurse now does. She is employed by the local health authority, but should be able to work directly for the family doctor. During the discussion which followed the reading of the papers by Drs. Roberts and Thomas at Cardiff last July, Dr. Mary Esslemont made a plea for direct contact between general practitioners and health visitors, preferably by telephone, and it is good to learn that in some parts of the country medical officers of health are doing all they can to encourage general practitioners to ring up the health visitor when they feel her experience can be helpful. Many successful schemes of co-operation are in being, not only between health visitors and general practitioners, but also between health visitors and hospitals. In Cambridge, for example, the consultant and almoner in the hospital, the family doctor, the home nurse, the health visitor, and the home help all work together in arranging for the patient's early return home from hospital. Undoubtedly, much more could be done on these lines to increase the availability of hospital beds.

There are many outstanding problems affecting the general practitioner and the health department yet to be solved. Little has been done in the home care of the mentally ill patient, whose illness is often conditioned by environment, which can sometimes be influenced. Housing is one of these environmental factors, and the medical officer of health is often asked to assist. Rehousing is difficult during the present shortage of houses, but is made easier if undertaken in co-operation with the medical officer of health and the general practitioner. There are a number of other important aspects of general practice where team-work is essential. The field of health education has not been fully explored. It offers great possibilities, and is essentially one for co-operative effort. Similarly prevention, at one time restricted to the sphere of infectious diseases and the prerogative of the medical officer of health, is now a much wider matter embracing many fields of medicine; moreover, it holds out some possibility of reducing the

high cost of the medical services, apart from the alleviation of suffering. Associated with the study of prevention is the wider subject of research and local investigations into ill-health—and here again co-operation between the medical officer and the practitioner could be fruitful and interesting.

But co-operation is not something that can be made to order. The cleavage between various branches of the services has unfortunately been too deep and lasted too long. Co-operation springs from mutual understanding and confidence. It must grow gradually, and should not be forced on unwilling participants. Greater co-operation is inevitable, for the advantages are too great for it to fail. Both branches would do well to forget their past disagreements and with an open mind find out the best in each other for their mutual benefit and for the sake of the patient.

FORCEPS DELIVERY

The evolution of obstetrics is largely governed by two sets of factors—those which derive from progress in medicine in general, and those which follow advances in knowledge, refinements in technique, and extensions in facilities specific to midwifery. In his paper delivered at the Annual Meeting of the B.M.A. in Cardiff in July this year and printed in this issue of the *Journal*, Professor T. N. A. Jeffcoate describes how over the last 25 years these two groups of factors have effected a striking fall in maternal and foetal mortality and morbidity, and how in particular they have caused us to review the place of forceps in present-day obstetrics. He points out that in hospital practice the forceps delivery rate has almost trebled during the last quarter-century, an increase obtained at the expense of spontaneous deliveries, not of caesarean sections; indeed, section has largely replaced the difficult mid-forceps operation. This increasing use of forceps cannot be condemned as meddlesome midwifery, for it has been attended by a considerable reduction in risk to mother and baby. It is not surprising, therefore, that the discussion at Cardiff revealed that the forceps rate was as high or even higher in private practice. As Professor Jeffcoate puts it pithily, "Babies previously born dead with forceps are now being delivered alive by caesarean section, while those stillborn as a result of spontaneous delivery are now extracted alive with forceps."

The improved results of forceps delivery are due partly to improvements in technique and partly to a change in our ideas on the indications for forceps. Technically, for example, the accurate cephalic application of the blades reduces the risks to the foetus, while the use of local analgesia increases the margin

of safety for the mother. As to the indications for forceps, the keynote has become intelligent anticipation of the traditional indications, reinforced by the belief that the duration of the second stage of labour can be allowed to exceed two hours only to the detriment of the mother and baby. This freer conception of the indications applies in large measure only to hospital practice, where there are adequate facilities for treating any unexpected complication. In domiciliary practice, where the careful antenatal selection of patients for confinement in hospital will largely obviate the necessity for operative delivery at home, conservatism probably remains the better course: forceps should be reserved for cases where there is a clear indication and where all the conditions for a low-forceps delivery are fulfilled.

If these precautions are disregarded the result may be a "failed forceps." This disappointing and disconcerting sequel is discussed in some detail by Dr. R. G. Law in a paper on page 955 of this issue of the *Journal*. It is a complication which is not restricted to domiciliary practice, but in hospital the consequent problem of the method of choice for delivery is more easily resolved. Dr. Law points out, as others have done, that the three common causes of failure are unrecognized malposition of the head, incomplete dilatation of the cervix, and disproportion. More than one of these may be operative in any one case, and the first is more commonly the cause than both the others together. Disproportion is more likely to be overlooked in the multiparous woman, in whom the history of a normal delivery of an averaged-sized baby is no guarantee that there will be no difficulty with a larger foetus. It is surprising and indeed discouraging to note that there was a history of previous dystocia in 8 of the 16 multiparae in Law's series. He remarks on the difficulty there may be in diagnosing disproportion in the multigravid after the onset of labour, but in hospital more frequent recourse to intranatal radiography is very rewarding.

Failure due to incomplete cervical dilatation or to an unrecognized malposition points the moral that no one should embark on a forceps extraction unless experienced in vaginal palpation and in recognition of the "touch-picture" of the presenting part. The cervix should not be palpable either during contractions or in the intervals between them, and none of the head should be palpable abdominally. Dr. Law points out that for accurate diagnosis examination under anaesthesia may be necessary, but he wisely adds that the induction of anaesthesia does not and must not commit the obstetrician to undertake immediate delivery if the findings are adverse. The importance of this is amplified by Professor Jeffcoate, who graphically describes the tragic train of events, based on pride and prestige, which may ensue when

unexpected difficulty is encountered in a forceps delivery because of an unrecognized malposition or contraction of the pelvic cavity, culminating in the substitution of force for skill and in the infliction of severe injury on mother and baby. He draws attention to the advisability of recognizing that there is a place for a "trial of forceps," a procedure first advocated nearly fifty years ago. He contends that if all mid-forceps deliveries in hospital were viewed as trial operations, the dread of failure would disappear from the mind of the operator and he would be happy not to proceed in the face of difficulty. This attitude might well be extended to cover all cases of forceps delivery, at home as well as in hospital, although if the precautions mentioned above for forceps delivery at home are observed a failure to deliver will be rare. Nevertheless errors of judgment can occur, and if each case were regarded as a trial of forceps, to be abandoned courageously if it did not proceed smoothly, then the current ignominy would be detached from the "failed forceps" to the benefit of all three individuals concerned, the mother, the baby, and, not least, the obstetrician.

PHENYLBUTAZONE ON TRIAL

There is a lot to be said for trial by jury compared with the ordeal by fire or water, and not least in the field of medicine. Clinical trial in the past, especially just after the introduction of a new drug, was apt to be an ordeal. If the patient survived and the drug seemed to aid the healing power of nature, the advertising began. But nicer distinctions are possible now, when the evidence is usually marshalled in such a way that it can be added up and assessed impartially by the jury of readers and by posterity. In the June issue of *Annals of the Rheumatic Diseases* there are three papers on the effects of treatment with phenylbutazone ("butazolidin"). They contrast notably with each other, each showing a different approach to what is eventually the same problem—namely, is this drug useful in the treatment of a particular disease? Each approach is appropriate to a certain stage of development of our knowledge: first, the trial tentative, giving grounds for belief that the substance might be useful; then the trial statistical, showing that, with a certain dosage for a certain time, one method of treatment shows results significantly or not significantly different from those of another; finally, the trial magisterial, when a substance already found to be useful is administered, and the results are stated, but without detailed comparisons with any other treatment. In this category falls the paper by J. P. Currie and his colleagues.¹

Currie first brought phenylbutazone into current medical practice, and has therefore a longer experi-

ence of it than most. After reviewing the pharmacology of this and related drugs, he and his colleagues write in general of their experience with 424 patients with rheumatoid arthritis. These include 81 patients given injections whose cases were reported previously,² and we infer that most of the other patients received the drug by mouth. These authors claim that a blood level of 8–11 mg. per 100 ml. is needed for the suppression of symptoms in rheumatoid arthritis, and that this can usually be achieved by a dosage schedule of 800 mg. (in four doses) on the first day, followed either by 200 mg. per day thereafter (the earlier dosage schedule) or followed by 600 mg. for two days, 400 mg. for two days, and 200 mg. thereafter, as in the later dosage schedule. Complications were few (4.7%), and in only three cases was the treatment stopped because of them. (A rash appeared in one and oedema in two.) This contrasts markedly with the average of 23% listed from other series (range 0–100%), because of careful dosage and careful selection, "avoiding the aged and all suspected of having a poor cardiac reserve." Another factor was the introduction of keratin-coated tablets, administered to an unspecified number of patients, since which no digestive disturbances occurred. The results are given in the statement that 95% were subjectively improved ("pain, tenderness, and well-being"), 93% showed improved performance, and 30% showed objective improvement judged by joint measurements and appearance and sedimentation rate. The evidence for this statement has been assessed by the authors but is not available to the reader.

J. Fleming and G. Will, the authors of another paper³ in the same issue, cite five cases of acute rheumatism whose recovery coincided (within a few days) with the giving of phenylbutazone. The patients had previously shown little or no response to salicylates. The evidence as presented is insufficient to convince the reader, for in a self-limited disease the chances of recovery occurring at a certain time in only five cases are obviously not entirely remote. The authors conclude in their summing up that these results are sufficient to "raise the hope that further experience will establish butazolidin as a useful drug in the treatment of acute rheumatic diseases."

By contrast in the same issue R. L. Mason⁴ sets forth clearly and with all the evidence a comparison between the relative efficiency of phenylbutazone and corticotrophin in rheumatoid arthritis based on six patients. Despite this small number the conclusions

can be seen to be soundly based, because all the evidence is available and analysed. Justice is not only done but is seen to be done. Mason found that phenylbutazone, in contrast to corticotrophin, produced no significant change in erythrocyte sedimentation rate or in joint size. A decrease was seen in 17-ketosteroid excretion compared with the usual increase during treatment with A.C.T.H. On the other hand the two types of treatment caused much the same decrease of pain and tenderness and much the same increase in function. Other controlled trials on rather larger series of cases⁵⁻⁸ have shown with varying degrees of conclusiveness some superiority of phenylbutazone as an antirheumatic drug to such substances as "inert" tablets, saline, gentisate, amidopyrine, salicylate, and tab. codein. co., used in the various control series. In short, the evidence presented to date indicates that phenylbutazone is in many but not all cases of rheumatoid arthritis a more effective drug than aspirin in relieving pain and disability, but that it is also more dangerous; and it is similar in potency to corticotrophin in its effect on pain and function in that disease.

PARATYPHOID FEVER AND CREAM CAKES

Some unusual features were found in the large outbreak of paratyphoid fever in South Wales during the summer of 1952.¹ The outbreak, which was confined to South Wales, lasted for five months and spread into four counties. About two-thirds of the 575 cases could be associated with some bakers' confectionery, and most of them with cakes containing synthetic cream. But immediate special inquiries into the synthetic cream showed that it could not be incriminated. It was made in England and distributed all over the country, and no other outbreaks were associated with it. Moreover, it was virtually sterile on arrival in Wales. When inoculated with paratyphoid bacilli the cream did not support the growth of the bacilli, though it was not actively bactericidal. Paratyphoid excretors were found on the staffs of four different bakeries, but the evidence suggests that they were the victims and not the originators of the outbreak. An examination of the sources of supplies of the bakeries which had sold infected cakes showed that flour was the only substance common to all the bakeries. This seemed a most unlikely substance to contain infection. On inquiry it was found that an ex-employee of the flour mills concerned, whose job was to fill the flour into sacks—one of the few persons in the mill who came into contact with flour—was a symptomless excretor, but he had left his employment before the outbreak started. Experiments then showed that paratyphoid bacilli remain viable for nearly a year in flour and multiply freely in slightly damp flour sacks. Flour

had hitherto been an unsuspected source of infection, and, although conclusive proof was lacking that it did carry the paratyphoid bacilli into the bakeries, the experiments showed that this was possible. Bread or cake soaked in water are excellent culture media for paratyphoid bacilli, and cake containing cream is also an excellent medium.

A brief summary is also given of former outbreaks of paratyphoid fever caused by bakers' confectionery. In nine of these no excretor was found, in thirteen there was one excretor, and in five there were several excretors. Dr. Scott Thomson, the author of the report, suggests that in many of the outbreaks of paratyphoid fever the evidence incriminating the excretor in the bakehouse as the source of the infection is not very convincing.

MEDICAL NEEDS IN THE GOLD COAST

It has been an aim of medical administration in the British Colonies that the quality of medical care should not fall below the standards applied in Britain. In some Colonies there are too few doctors to cover the population adequately, and in those where there is a grave shortage some of the inhabitants cannot have their illnesses treated by qualified men. A demand therefore comes for official recognition of unqualified practitioners, on the false analogy that half a loaf is better than no bread. Elsewhere in this issue Mr. Ian Fraser, who visited the Gold Coast earlier this year at the request of the Council of the B.M.A., describes the precarious position of the medical services in that Colony, which now has a wide measure of self-government and is being quickly developed in other ways. Junior medical officers are required everywhere, and, as will be seen from Mr. Fraser's article, the shortage of specialists in a country which is already building a 510-bedded hospital is disastrous.

In the long run the Gold Coast's medical needs will be met by African doctors, and Mr. Fraser stresses the necessity for helping the African student and doctor to become well qualified. British medical schools can and do play an important part in training African doctors, but when the new hospitals are opened in the Gold Coast there is going to be a greater need than ever of specialists to undertake treatment and to train junior members of the staff. Where are these specialists to come from? Uncertainty about the period of time which will elapse before the Gold Coast government may feel it can dispense with British doctors causes concern to the medical officers already in the Colony, and is bound to affect recruitment adversely. But, as Mr. Fraser makes quite plain, the Gold Coast offers wonderful opportunities to medical men and women who are prepared to put up with the familiar disadvantages of life in the Tropics and the less well known problems of working for the government of a country subject to rapid economic and political change. Even so, most doctors contemplating service in the Gold Coast will want some assurance that they will not suddenly find themselves discarded. The B.M.A. is con-

sulting the Colonial Office on this matter, which bristles with administrative difficulties. It may be that an eventual solution will be found in the establishment of a Commonwealth Civil Service.¹

NOBEL LAUREATES IN MEDICINE

The Nobel Prize for Medicine and Physiology has been awarded jointly to Professor H. A. Krebs, F.R.S., of Sheffield University, and Professor F. A. Lipmann, of Harvard University, U.S.A. Both are distinguished biochemists who have carried out important studies on intermediary metabolism, and both are refugees from the tyranny that brought their native Germany to ruins.

In 1933 a Rockefeller grant enabled Dr. Krebs to come to Britain as a research student at Cambridge University. Two years later he moved to Sheffield under Sir Edward Mellanby, and in 1945 was promoted professor there and director of a Medical Research Council unit for research in cell metabolism. In 1947 he was elected F.R.S.

According to the official citation Professor Krebs receives his award in recognition of his discovery of the citric acid cycle in the metabolism of carbohydrates—now commonly called the Krebs cycle. In his crucial experiments pyruvic acid, which is formed in the earlier stages of carbohydrate metabolism, was mixed with oxaloacetic acid and was incubated with minced muscle in the absence of air. Citric acid was formed, with the elimination of carbon dioxide. Further losses of carbon dioxide produced α -ketoglutaric acid and succinic acid, and the cycle was then completed through fumaric and malic acids back to oxaloacetic acid, which was ready to combine with more pyruvic acid. In tracing the course of this cycle Krebs was not breaking entirely new ground, but he has solved problems which had long puzzled many workers in a crowded field of research, and he has illuminated what had previously been a maze of obscurities. During the war Krebs showed his abilities in other directions. On the resignation of Dr. Kenneth Mellanby from the Sorby Research Institute he took over the care of a group of conscientious objectors who helped in experiments on vitamin deficiencies for the M.R.C. His enthusiasm helped to sustain the volunteers through the boredom of subsisting through long periods on monotonous diets.

Professor Lipmann receives his part of the prize for his work on co-enzyme A. This factor, which is concerned with the metabolism of two-carbon fragments, plays a part in metabolic processes which are related to the Krebs cycle. The two discoveries for which the award has been shared, however, may be considered as independent in their origin. It was in 1939 that Lipmann was obliged to leave Germany because of Nazi persecution, and he arrived without funds in the U.S.A. A place was found for him at the Massachusetts General Hospital, and in 1941 he became head of the biochemical research laboratory. In 1951 he was appointed professor of biological chemistry at Harvard Medical School.

CLINICAL PATHOLOGY IN GENERAL PRACTICE PLEURAL, PERICARDIAL, AND PERITONEAL TAP

BY

THOMAS PARKINSON, M.D., M.R.C.P.

Consulting Physician to the Luton and Dunstable Hospital and St. Mary's Hospital, Luton;
Chief Clinical Assistant to the Brompton Hospital, London

Laboratory examination of serous effusions is a valuable adjunct to clinical diagnosis. The interpretation of the pathological changes in these fluids will be described later in this series. The present article is concerned only with the methods of obtaining specimens for examination. The technique of diagnostic pleural tap is described in detail, since this procedure is the one most often called for in practice. Pericardial tap, which is seldom indicated, and peritoneal tap, which is less informative, are described more broadly, some of the detail previously described being assumed.

Pleural Tap

Aspiration of pleural fluid for diagnostic purposes is an easy and safe procedure. It should, however, be carried out only when the diagnosis of pleural effusion has been

made with confidence, the diagnosis preferably having been confirmed radiologically. It should not be used blindly to discover whether fluid is present or not. Serious complications often follow the insertion of a needle into hydatid cysts, lung abscesses, and other intrathoracic lesions which might simulate pleural effusion on clinical examination. Whenever doubt exists recourse should be made to accurate radiological diagnosis by postero-anterior and lateral films before aspiration is done.

Apparatus.—Only the simplest instruments are required, and the following should suffice: a 2-ml. syringe; a hypodermic needle, size 17 (B.W.G. 25); a hypodermic needle, size 1 (B.W.G. 21); a 20-ml. syringe; a wide-bore chest-aspiration needle (B.W.G. 16) to fit the 20-ml. syringe; sterile containers; sterile 2% procaine; swabs; gallipots; sterile towel; cetrimide and surgical spirit or iodine; and surgical tape or collodion. The needles should fit the syringe nozzles exactly. The connexions must be airtight. The wide-bore aspiration needle should be thick enough to allow withdrawal of pus should this be encountered.

Preparation of Patient.—Diagnostic tap is an almost painless operation and usually no premedication is required, but a patient who is unduly anxious or who has a persistent cough should have $\frac{1}{4}$ gr. (16 mg.) of morphine half an hour beforehand. He should be placed in a posture which is comfortable to himself and convenient to the physician. A patient who is well enough may sit forward in bed with the knees flexed, the arms folded in front with the elbows resting on the knees and the head resting on the forearms (Fig. 1). The legs should be freed from the weight of the bedclothes to allow the knees to bend, since it is uncomfortable to lean forward with the knees straight. A patient who is not so well should be propped forward on a bed-rest or supported at the shoulders by an assistant.

Site of Aspiration.—In large effusions the best site for aspiration is in the ninth intercostal space in the posterior axillary line. The tip of the scapula, which lies over the seventh rib, is the most useful landmark in finding the right intercostal space. In smaller or localized effusions the needle should be inserted over the area of maximal dullness to percussion, but in such cases radiological location of the effusion should be carried out whenever possible. Lateral radiographs often show that an effusion is localized in the posterior part of the thorax in the paravertebral gutter, and in such cases aspiration should be carried out near the vertebral border. The radiographs of a patient with a posterior pleural effusion are shown in Fig. 2. It is clear that exploration in the posterior axillary line in such a patient would be fruitless, since the needle would pass in front of the effusion.

Technique of Pleural Tap

A wide area of skin around the site of operation is cleaned with cetrimide and iodine or surgical spirit. The 2-ml. syringe is then filled with 2% procaine and, using the size 17 hypodermic needle, a small bleb is made under the skin at the elected site of aspiration. The needle is then withdrawn, removed from the syringe, and replaced by the size 1 needle. After waiting about two minutes for the local analgesic to take effect

FIG. 1.—Position for pleural tap.

FIG. 2.—Radiographs of patient with posterior pleural effusion.

¹ The Times, September 7 and 8, 1953.

the deeper tissues are anaesthetized by injecting 2% procaine through the size 1 needle, which is advanced slowly until it is felt to pierce the parietal pleura. Not more than 2 ml. of procaine is required for this. The needle is then withdrawn and a further few minutes allowed for full analgesia to develop. The wide-bore needle is then attached firmly to the 20-ml. syringe, and the syringe tested by making sure the plunger moves freely up and down the barrel. With the syringe held firmly, the aspiration needle is pushed slowly but steadily through the intercostal space. During this procedure it is often helpful to rest the forefinger of the operating hand against the chest wall and to rest the flexed middle finger half-way down the needle (Fig. 3). This guards against the needle being thrust too deeply into the thorax when the skin resistance is suddenly overcome. A distinct "give" is felt when the needle pierces the pleura. The plunger of the syringe is then pulled back and the syringe filled with 20 ml. of pleural fluid. The aspiration needle is then withdrawn from the chest wall, and a small piece of gauze or wool is placed over the needle-hole with the other hand.

The pleural fluid is immediately transferred to the sterile specimen bottle before the fluid has time to clot. A small dressing is applied to the chest over the site of aspiration by means of adhesive tape or collodion. The specimen is labelled and dispatched without delay. Difficulty is seldom encountered except when there is a grossly thickened pleura or sometimes when the pleural space contains blood clot or thick pus. If fluid is not obtained easily the needle should be withdrawn and not be pushed forward aimlessly into the chest, since this entails risk of complications. The usual causes of difficulty are faulty choice of site or mistaken diagnosis. Failure to withdraw fluid should lead to

FIG. 3.—Introduction of the aspiration needle.

FIG. 4.—Pericardial tap.

careful reconsideration of these simple matters and not to adventurous blind exploits into the thorax. Performed in this way pleural tap carries little or no risk. Pleural shock is never encountered. Care should always be taken to avoid introducing air into the pleura.

Pericardial Tap

Although large pericardial effusions may be easy to diagnose and safe to aspirate, small effusions are extremely difficult to recognize with certainty and their aspiration is fraught with difficulty. Even with full radiological and cardiographical facilities small pericardial effusions may be difficult to differentiate from cardiac enlargement. Diagnostic pericardial tap is therefore of very limited application in general practice.

Pericardial effusions may be aspirated from in front by inserting a needle through the chest wall, or from below by approaching the pericardium from the costal angle. The second method is preferable because it gives access to the most dependent part of the pericardial sac, where small effusions first gravitate, and also because it is free from the risks of injuring and infecting the pleura, to which the anterior approach is particularly prone. The subcostal approach, which is both easier and safer, should be the method of choice.

With the patient sitting upright and propped comfortably on pillows the gap between the xiphoid process and the left costal margin is palpated, and the skin in this area infiltrated with 2% procaine. The deeper structures are then anaesthetized. A wide-bore needle with a sharp edge but a blunt bevel is securely attached to the 20-ml. syringe, and the pericardium is explored by pushing the needle steadily and firmly from the left subcostal angle. The needle is directed upwards and backwards and slightly towards the midline (Fig. 4). As the pericardium is entered a sudden fall of resistance is felt. Then 20 ml. of pericardial fluid is withdrawn and transferred to a sterile container. The risk of injuring the heart muscle in pericardial tap has often been exaggerated. If the needle is pushed too far a distinct grating can be felt as soon as the needle-point touches the contracting heart muscle. If the needle is withdrawn slightly when this is felt, no damage will be done. Even with greatly dilated hearts, where confusion with pericardial effusions is most likely to arise, it is easy to feel when the heart wall is touched, and the danger of rupturing or penetrating the heart wall is extremely remote.

Peritoneal Tap

Aspiration of ascitic fluid for diagnostic purposes is not commonly practised, since the information gained thereby is seldom of much help in clinical diagnosis. Physical examination is of paramount value in diagnosing the cause of ascites. If, however, peritoneal fluid is required for examination it can readily be obtained by inserting a needle through the abdominal wall. Before aspiration is attempted, two fundamental precautions must be observed. First, it is essential that the patient's bladder should be empty, and to avoid any risk of injuring the bladder-wall it is safer to catheterize the patient. Secondly, in the female a pelvic examination should be done to exclude as fully as possible the alternative diagnosis of ovarian cyst, which so often resembles ascites.

The best site for aspiration is a point midway between the umbilicus and the anterior superior spine of the ileum. When this point is found, the skin and deep structures are anaesthetized with 2% procaine. A wide-bore needle attached to the 20-ml. syringe is then plunged firmly through the abdominal wall and 20 ml. of fluid withdrawn and transferred to a sterile container.

SHORTAGE OF MEDICAL OFFICERS IN THE GOLD COAST

BY

IAN FRASER, D.S.O., O.B.E., M.D., M.Ch., F.R.C.S.

Earlier this year Mr. Fraser visited the Gold Coast at the request of the Council of the B.M.A., which had been considering the desirability of forming a Gold Coast Branch. In this article he describes the medical problems of the colony.

The present shortage of medical officers in the Gold Coast is causing anxiety, both in the colony itself and at home. There is a shortage of men in all branches of medical practice—shortage of medical officers for out-stations and for the medical field units, and shortage of specialists. These posts have in the past been filled partly by Africans trained in the medical schools in the United Kingdom, and the cost of this has been borne mostly by the Gold Coast Government, with the understanding that when qualified they would return either as junior medical officers, or, possessing higher qualifications, to fill some of the many specialist posts available. The result has been a little disappointing. Some of the men who have qualified in the United Kingdom have decided to stay here. Others have returned to the Gold Coast, but have soon left the service to take up the more lucrative private practice; and so the colony as a whole has not benefited to the extent that was hoped for. Very few have become specialists, because few of the senior specialists have the time or the facilities to introduce the young men returning to the colony to more advanced surgery or medicine, and so give them the basic training in a specialty that would later require only a short postgraduate course in the United Kingdom to enable them to obtain a higher degree.

Help in Qualification

Since 1948, with an increase in trainee specialists in the United Kingdom, as many as 400 candidates at a time may have attempted to pass higher examinations like the F.R.C.S. and M.R.C.P., with the possibility of 40 to 50 of them getting through. Obviously the chances of passing for young medical officers trained in the colony were diminished in the face of such stiff competition, though this state of affairs may be passing off now. I feel that something must be done to help the African student and doctor to become well qualified. There should be no question of lowering standards, but facilities should be improved. In England the facilities remain constant and are always available; but they are expensive and demand time. Therefore teaching in the colony itself must improve, and this means more teachers and more specialists, and hospitals which cater for a wider range of specialties.

The average hospital in the colony to-day consists of surgical wards, medical wards, a maternity ward, and a children's ward. The medical staff varies in quantity and quality. In some instances there may be only one medical officer capable of doing routine surgery, and he may be also responsible for dealing with gynaecology and complicated midwifery. The average list includes such cases as hernia, hydrocele, trauma, sepsis, ectopic pregnancy, hysterectomy, etc., and one surgeon has just completed a series of 150 operations for vesico-vaginal fistula. Another, a young African, had performed 97 caesarean sections within a few months. In one area two extrauterine pregnancies have to be dealt with every week. It will thus be seen that there is ample opportunity for practical experience.

The European or expatriate doctor starts at an advantage. He has found the examination in the United Kingdom easier and begins at a younger age. It is also easier for him to return on study leave and work for higher

qualifications. Therefore up to now the majority of the specialist posts have been filled by expatriates. Even so, there have always been too few of them; they have been so busy with routine work that teaching and organization of a department have been impossible, and, with the shortage of junior staff, no young doctor is left long enough in a potential teaching centre to get trained. After a brief stay he is hurried off to a district station where the need for his services is great; once there, his chances of specialization are increasingly difficult.

The expatriate specialist becomes more valuable to the colony the longer he stays there. He may in time have to maintain a home in the United Kingdom so that his children may be educated there; and this is costly. With the increased cost of living in the Gold Coast, these senior medical officers and specialists are finding their salaries insufficient, and many are tending to leave the service. It is most important something should be done to halt this tendency, and immediate replacement must be found when they do go.

In the next ten years the Gold Coast will experience one of the most interesting and dramatic expansions in its history. Money is being spent lavishly in many necessary projects—a new town, a new harbour, the Volta scheme, a new university, and a new hospital costing £5,000,000 for its 510 beds. These and other schemes will cost in the region of £144,000,000. This gives some idea of the expansion. Yet at the moment there are three surgeons for 4,500,000 people, one gynaecologist, no eye specialist, no ear, nose, and throat specialist, no dermatologist, no tuberculosis specialist (tuberculosis is very prevalent), no anaesthetist, no paediatrician, no orthopaedic specialist (yet injury is becoming increasingly more frequent, and will become still more so with the new mechanization). Yet at home here in Britain there are some 60 to 70 candidates for every hospital appointment; at a recent appointment there were two applicants—specialists—actually drawing unemployment benefit. What a contrast! And what wasted opportunity!

In a letter to the *Lancet* of April 11 this year a registrar wrote this: "There must be many hundreds of us throughout the country, growing yearly more hopeless, a stagnant pool of cheap specialists, deliberately created by the National Health Service. A great many of us have been qualified for ten to fourteen years, but we are paid less than a newly settled general practitioner. We are liable to dismissal at short notice and at regular intervals. We can settle nowhere and we can plan nothing. It is obvious that we cannot all become consultants overnight." But there are parts of the world where opportunities and vacancies are waiting, and the Gold Coast offers these to-day. Though one may sympathize with these young men it is difficult to understand the attitude of those who would rather do nothing and starve at home than go abroad and practise real medicine, with unrivalled opportunities for experience.

The man willing to do this must be of the right type; his integrity must be beyond question; he must be able to improvise, to turn his hand to anything. As a surgeon he may in the course of an afternoon have to remove a ruptured spleen, deal with an ectopic pregnancy, sew up or amputate a leg bitten by a crocodile, and perhaps repair a deep stab wound. An elephantiasis of the scrotum touching the ground may be thrown in for good measure. If he has a wife with the pioneering spirit—one who is a good companion as well as a wife—he will be doubly fortunate.

Reasons for the Shortage

Why are not enough British doctors going to places like the Gold Coast? One reason is that Africanization is going to exclude them from some of the higher positions. Certainly this will happen in time, but at the moment the question does not arise. It will be long before there are enough senior Africans of experience to take all the jobs in the various specialties and also fill the higher adminis-

trative posts. The obvious need in the Gold Coast is to increase the number of specialist posts and fill them with people of integrity and ability, with the skill to teach the younger generation and so build up a lasting service—the specialist at the top, the medical officers below, in training to become specialists, and dispensers, sisters, nurses, etc., all trained to a higher level. The standard of work in hospitals will rise, and the hospitals become recognized as suitable for the training of medical students. Only when all this happens should the Gold Coast consider forming a medical faculty. Certain back-benchers, with little knowledge of facts, may press for the early formation of such a faculty. It would be just as valuable as a Rolls-Royce car with no one able to drive it properly.

In the Gold Coast, therefore, the specialist service is priority No. 1. In the United Kingdom the men are available, but the colony must make the conditions attractive. In every country there is always the difficulty of paying for one service more than for another. Why should the doctor get more than the engineer? It is clear, I think, that he should. He spends himself more, his daily responsibilities are greater, he gives a 24-hour service, and he is doing more than curing an individual life—he is making a permanent service.

As I have pointed out, when the specialist is at an age to give his best to the colony his home commitments are unfortunately at their heaviest, and often that is the stage when he retires, as many are threatening to do at the moment. Some attraction must be offered these men, especially during the next ten years. If the present service deteriorates further it will be difficult to build it up again with new people. Better pay and some security of tenure, or compensation, would attract better men and women.

Appointments Available

The appointments in the Gold Coast are very varied: a medical officer of health to a port authority; a doctor to a bauxite mine, a diamond mine, or a gold mine; a specialist in every branch of medicine; a practitioner in a town; a practitioner in a country station; or, best of all, a bush doctor, with a shot-gun and the midwifery forceps both kept at the "ready" in the back seat of the car. At the moment there are many attractive short-time contracts whereby one can see the country. Having recently revisited the colony after an absence of ten years, I found that in the interval progress has been equivalent to that of 50 years at home.

But the shortage of doctors is being made good in a makeshift manner. Many areas are without a qualified doctor, and dispensers and dressers are doing the work, with perhaps a call every few weeks from the medical officer at the nearest station. This is a sad state of affairs. It is bad medicine and is dangerous: it is putting power into the hands of untrained and sometimes unscrupulous, greedy people. It is hard to be critical, as the gaps have to be filled. Some are allowed to practise with degrees of doubtful validity, and, finally, there is a tendency for the foreign doctor to infiltrate—Poles, Swiss, Germans, some stateless. One is not in a position in all cases to criticize their medical ability, but most of them have not the same interest in the Gold Coast as has the British doctor, with his long connexion with the colony: the interest of the former in the colony is that it affords a good living, but they give little in return in the way of teaching or in building up a service.

Conclusion

The next few years will be critical. The future of the medical service of the colony will depend upon whom we send out. The present service, its link with teaching, and its improvement in hospital work, will make up the foundation of the medical school. With the eventual formation of a medical school real Africanization of the service can be envisaged. Till then, promotion, if it is to be fair and if the appointments are to carry respect, must be made through merit and experience, and by no other way.

NOBEL PRIZE

(Walter Stoneman, London)

Professor H. A. Krebs, director of the Medical Research Council's Cell Metabolism Unit at Sheffield, who has been awarded the Nobel Prize for Medicine jointly with Professor F. A. Lipmann, of Harvard (see p. 984).

SEVENTH INTERNATIONAL PAEDIATRIC CONGRESS

[FROM A SPECIAL CORRESPONDENT]

The Seventh International Paediatric Congress was held in Havana from October 12 to 17 under the presidency of Professor Felix Hurtado. The opening ceremony was performed in the House of Representatives in the beautiful National Capitol Building on Columbus Day by President Batista, who gave a moving address on the need for child care. The British delegation of twelve was led by Dr. Bernard Schlesinger, President of the British Paediatric Association; Professor Alan Moncrieff represented H.M. Government. Nearly 50 countries were represented, and altogether nearly 2,000 registrations were made.

Epilepsy in Childhood

The first plenary session was devoted to epilepsy in infancy and childhood. Professor C. H. ALSTRÖM (Sweden) dealt with genetic problems, stressing the fact that acquired causes were more important than heredity factors. He emphasized that the risks in marriage as regards transmitting epilepsy were of the same order as for the majority of the population, provided that the affected parent was of normal mentality. Professor I. McQUARRIE (U.S.A.) traced the story of water balance in relation to epilepsy from the discovery that dehydration reduced the number of fits, to the modern use of deoxycortone acetate as an adjuvant to drug therapy. Professor M. A. PERLSTEIN (U.S.A.), in a review of drug treatment, gave much wise advice. There was "more to it" than drugs in treating epilepsy. It was better

to have convulsions and be normal in between than to walk about in a state of coma. It was clinical cure that was sought, not a completely normal E.E.G. tracing. Any new drug given with enthusiasm would help for a time, and caution was advised in accepting claims for new drugs. Nevertheless, it was important to try everything and use the drug that worked best. Professor W. LENNOX (U.S.A.) looked back over a long experience and pleaded for a better attitude to epilepsy as a public health problem. The first step was to remove all fear of the disease. Professor F. ESCARDO (Argentina) discussed certain unusual forms of epilepsy, and Dr. J. PICAZA (Cuba) surgical treatment.

A special evening session on social problems in paediatrics concluded the first day. Professor R. DEBRÉ (France) discussed international aspects in an account of the origin and present-day work of Unicef, which had recently had its mandate renewed by U.N.O. for an indefinite period. He was followed by Dr. E. MOURE (Cuba), who gave a wide review of the social work done for children in her country, with many challenging conceptions of the rights of the child, which the chairman—Dr. M. WEGMAN (U.S.A.—Regional Office of W.H.O. in Washington)—thought might not altogether gain acceptance "in a country a little further north." Dr. R. VALDÉS DIAZ (Cuba) described the work of the National Organization of Children's Dispensaries. Dr. S. FARRER (U.S.A.) spoke about the ideals of paediatrics which might be achieved in a children's hospital. Dr. R. DEL CASTILLO (Cuba) on rehabilitation of the paralysed child, and Dr. P. DANIEL MARTINEZ (Mexico) on maternity and child welfare in relation to health.

Congenital Heart Disease

The second plenary session, on congenital heart disease, was presided over by Professor A. CASTELLANOS (Cuba), who has done so much original work in this field. Dr. J. LIND (Sweden) dealt with technical advances in diagnosis, particularly with modern angiocardiology with simultaneous E.C.G. markings on the film. He gave a stern warning about the dangers of too much radiation in the investigation of small infants. Professor I. CHAVEZ (Mexico) then dealt with acyanotic heart disease—especially coarctation of the aorta and patent ductus arteriosus, followed by Professor R. KREUTZER (Argentina) on unusual types of pulmonary stenosis, a subject also dealt with more briefly in a subsequent contribution by Professor B. GASSUL (U.S.A.). Professor S. GIBSON (U.S.A.) brought the audience back to the bedside with an excellent account of the use of "eyes, ears, and hands" in the diagnosis of congenital heart disease, and Dr. HELEN TAUSSIG (U.S.A.), from her wide experience, discussed the results of operative treatment.

Prematurity

The third plenary session tackled some of the problems of premature infants. Professor A. YLPPÖ (Finland) surveyed the subject with special reference to his own country. There, as a contribution to the preventive side, every expectant mother must attend for antenatal care not later than the fourth month or she forfeits maternity benefit. Among measures for the care of the prematurely born he favoured gastric oxygen, early administration of fluid, and breast milk from the second day. He was pessimistic about reducing mortality below 20%. Professor H. HUNGERLAND (Germany), after remarking that modern methods of feeding premature babies did not differ much from those recommended by the older German authorities, went on to review in some detail problems of nutrition and metabolism. Professor M. LAMY (France) presented a paper for Professor M. LELONG on an interesting group of cases of retrolental fibroplasia in which partial regression had occurred. Professor C. SMITH (U.S.A.) surveyed the question of the importance of the respiratory system after premature birth, pointing out that many premature infants ventilate their lungs better soon after birth than a few hours later. Boston Lying-in Hospital had obtained a mortality rate among the premature infants of only 14.5% in 1950. Professor J.

OBES-POLLERI (Uruguay) suggested that, whereas post-natal care had very greatly improved, pre-natal problems and what he termed the "crisis of birth" still merited more attention. Professor A. MONCRIEFF (Great Britain) spoke of his twenty years' experience since getting on the staff of Queen Charlotte's Hospital. He pointed out that the percentage survival rate (to 28 days) of premature babies born at home in England and Wales in 1950 had been 86%, which made the results 0.5% better than the ideal conditions in hospital in Boston. He also showed how the deaths under 4 weeks for 1,000 live births ascribed to prematurity had fallen from 16 in 1931 to 5.6 in 1951. Professor B. VAHLQUIST (Sweden) discussed work on the causation of anaemia in premature infants, stressing that infection was no longer an important factor, and that inherent differences existed between the red cells in prematurity and in mature babies and later infancy. Dr. L. TORRES BARBOSA (Brazil) concluded with an account of official measures used for the care of premature babies in his country.

Complications of Primary Tuberculosis

The fourth plenary session dealt with the complications of primary tuberculosis. Professor A. WALLGREN (Sweden) first reviewed the ordinary course of primary infection, taking the skin as the simplest site to study this. He classified complications under local disease and systemic disease. Under the former heading came extension of the tuberculous lesion and the part played by secondary bacterial infection of a non-specific type. The systemic spread mainly meant meningitis, about which several subsequent speakers gave their experiences. Dr. EDITH LINCOLN (U.S.A.) discussed a group of nearly 1,000 cases of primary infection seen at the Bellevue Hospital, New York City. A mortality of 21.5% in the period 1930-46 was reduced to 4.5% when streptomycin and adjuvant drugs came in, and to 1.4% with the advent of isonicotinic hydrazide. With this last drug the use of intrathecal streptomycin had been practically eliminated. Professor R. DEBRÉ (France) was, on the contrary, not at all happy about the present tendency to omit intrathecal therapy. He stressed the prognostic importance of the state of consciousness on admission together with electroencephalographic examinations. He also stressed the great improvement with isonicotinic hydrazide. A paper from Professor C. COCCHI (Italy) (read on his behalf) also stressed the need for intrathecal treatment, although with modern adjuvants smaller doses would probably be used. Dr. B. SCHLESINGER (Great Britain) presented a study of over 400 children with primary tuberculosis followed at Great Ormond Street from 1945 to 1953 with a total mortality of 14%. He stressed that with good home conditions a large group could be treated and supervised as out-patients. Bronchoscopy had proved of limited value. Lobectomy in a small number (7) of patients indicated that more use might be made of this form of radical treatment in selected cases. Dr. A. SCROGGIE (Chile) described chronic massive lung collapse as one of the troublesome complications.

Metabolism and Nutrition

The last plenary session was a mixture of communications on various aspects of metabolic and nutritional disorders. Professor P. GYORGY (U.S.A.) described the discovery of a new "growth factor" in human milk. The first step had been the finding of a specific variant of *Lactobacillus bifidus* (from the stools of a breast-fed infant) which required this specific factor for growth. On studying the factor it was found to be present in forty times the concentration in human milk as compared with cow's milk. This new factor was different from all the known vitamins and growth factors. In concentrated form it had been shown to stimulate the growth of young rats and to have an inhibitory effect on the growth of certain viruses. Professor G. FANCONI (Switzerland) discussed the part played by the kidney in regulating chemical metabolism and gave a fascinating account of the clinical significance of the functions of the proximal and distal tubules. Professor D. DARROW

(U.S.A.) talked on the treatment of infantile diarrhoea, stressing that this was still a major cause of death in many parts of the world, and children who died did so because of chemical disturbances. He outlined the fundamental changes in water and electrolytes, and from this deduced a logical plan for treatment. Professor E. HOLT (U.S.A.) thought that great caution should be exercised before accepting the implications suggested by Gyorgy's paper. He thought its clinical importance had still to be proved, and he put up a spirited defence of the cow. His communication dealt with the findings that both in healthy and in diseased states the absorption of foodstuffs could be increased by an increased intake. Professor R. RAMOS (Spain) added electroencephalographic changes to the list of disturbances suffered by infants with diarrhoea. He stressed especially the need to restore the blood volume to normal. Professor G. FRONTALI (Italy) spoke of nutritional oedema and protein deficiency as studied in his country, and Professor F. GÓMEZ (Mexico) gave data on the cure of so-called deficiency complications of diarrhoea and severe malnutrition without the use of commercial vitamin preparations.

In addition to the main sessions there were nearly 30 "round tables" for discussions on selected subjects, several "free sessions" for communications not on the main chosen themes, and a "grand forum," where questions were answered by an impressive panel. The scientific exhibition was of a high quality. The congress concluded with a banquet, and, as with most of the social events, it was colourful and lively. The next international paediatric congress is planned for 1956 in Copenhagen.

INSTITUTE OF CLINICAL RESEARCH NEW FACILITIES AT THE MIDDLESEX

An Institute of Clinical Research and Experimental Medicine in association with Middlesex Hospital Medical School was opened at an informal gathering on October 22, when the staff of the hospital and school and a number of distinguished visitors attended a reception given by the chairman of the hospital, Colonel J. J. Astor. The Institute is housed in a large building of four stories in Hanson Street, a few minutes' walk from the hospital, and is furnished and equipped on the most generous modern scale.

The new Institute takes its place alongside the existing institutes and departments associated with the Middlesex—the Bland-Sutton Institute of Pathology, the Courtauld Institute of Biochemistry, and the Barnato Joel Laboratories of Physics. Its purpose is to provide the consultants of the hospital with research facilities for their exclusive use, and it is said to be the first such provision made by a British hospital for its clinicians. A clinical research committee is responsible for its control and also for reviewing applications for grants. Any member of the consulting staff of the Middlesex is entitled to put forward or sponsor a project for research, and the committee, if it accepts the application, may allocate—for a limited time in the first instance—either money or space, equipment, and facilities in the building. To maintain the high technical standards for a comprehensive institute of this description, liaison is maintained with the existing medical school departments, and, in addition to the technicians in charge of the pathological laboratory, the biochemistry laboratories, and the workshop, there are attached as advisory technicians those who are at the head of the technical staff of the Bland-Sutton Institute, the Courtauld Institute, and the Barnato Joel Laboratories respectively.

Endowment Funds Freed

This handsome provision has been made possible by the freeing of the endowment funds which the Middlesex, like many other hospitals, had in its possession when the National Health Service Act came in. The suggestion was made that part of the income from such funds should be spent on medical research, and on a proposal from the medical

committee the board of governors decided to allocate approximately two-thirds of the available money to projects falling under the head of clinical research. It became evident at once, however, that if the money was to be wisely and economically used space and facilities must be provided for clinicians desiring to carry out such work. In 1949 accordingly the present building, originally a boys' club, which had been erected ten years before, was purchased and structurally adapted to this new purpose. Altogether well over £100,000 has been spent on the purchase and conversion of the building and its equipment. The director of the Institute is Professor A. Kekwick.

A Tour of the Building

The main laboratory provision is on the second floor, where there is a large pathological laboratory, two biochemical laboratories, a workshop, and a small isotope room. Measuring and testing instruments, some of them familiar and some less so, were laid out on the benches for the inspection of the visitors—a photoelectric absorptiometer, a flame photometer, oscillographs, an electronic testmeter, freezing and base-sledge micrometers, microscopes, and the like, and in the workshop precision lathes and many other devices. On the first floor are five small individual laboratories, also library, reading, and record rooms, and administrative offices, as well as a large conference hall.

The ground floor provides six consulting-rooms of different types and sizes. The largest of these has six examination couches, with screens, trolleys, and all facilities. They are furnished rather more comfortably than the usual hospital consulting-room, because the patients for whom they will be used, whether from the hospital or privately, will be those who have volunteered for the research, and it is felt that they are entitled to a certain extra degree of comfort. There are also on this floor a nurses' room and a waiting-room.

The top floor has been assigned for work on animals. Here there are two air-conditioned animal houses, a preparation room and operation theatre with a recovery cubicle, and an isolation house. Above the animal houses is a large extent of flat roof wired in to allow open-air runs for the animals. In the basement is an x-ray set with a generator, to which other equipment can be added if necessary.

Among the projects already in view or started is an investigation of cancer of the lung and its causes; another is the tracing of the growth of bone by means of radioactive isotopes; and a third the development of a synthetic bone for grafting when the natural bone has been destroyed by disease. New drugs for use in breast cancer will be tested, and another investigation concerns the movement of bacteria in the nose in colds and other catarrhal conditions.

THE CARE OF MENTAL DEFECTIVES

MINISTER OF HEALTH AT FOUNTAIN HOSPITAL

The Fountain Hospital at Tooting Grove, London, which accommodates nearly 600 mentally defective children mainly of the idiot and imbecile grades, was visited by the Minister of Health, Mr. Iain Macleod, on October 23 on the occasion of its sixtieth anniversary. The institution began as a temporary fever hospital, and not until 191 was it devoted to its present purpose by the Metropolitan Asylums Board. It was taken over by the London County Council in 1929, and transferred to the South-west Metropolitan Regional Hospital Board in 1948. The children at work and play, were inspected by the visitors attending the celebration, and the results of their handicrafts were shown.

Mr. Macleod said that when it became possible a month or two ago to allocate an extra two million pounds to capital expenditure in the National Health Service he arranged that one million of that sum should be devoted to the mental health side of the Service. This had been

done with the full sympathy and consent of Mr. Butler, the Chancellor of the Exchequer, who was himself President of the National Association for Mental Health. It was important that the mental health services should be brought more closely into line with the rest of the Health Service so that people would not think that mental disease was something to be shunned and forgotten.

The Royal Commission

The newly announced appointment of a Royal Commission on mental illness and mental deficiency was a matter of great moment (see p. 998). Much of the law in these fields was out of date and out of tune with modern thought. One of the problems needing examination before any new legislation was whether the voluntary method of entering mental homes and hospitals should be extended, and whether there should be a much less formal entry into mental deficiency institutions. It was interesting to note that 70% of those who entered mental hospitals to-day did so as voluntary patients and that 40% even of those who entered as certified patients recovered within the first year of their certification. "Although many of our buildings are out of date," the Minister added, "I have no doubt at all that our treatment in the mental health field leads the world." Another matter which would doubtless be considered by the Royal Commission was the definition of mental deficiency.

Referring to the building of new hospitals, the Minister said that next spring he was to lay the foundation stone of the first new hospital to be built since 1939, and this was to be a large mental deficiency colony in the Liverpool region, where there was at the present moment desperate overcrowding and shortage of accommodation. He ended overcongratulating the Fountain Group Hospital particularly on the success it had achieved in nurse recruitment and on its research work. "There may be tragically little that can be done for many of the children here, but through research we may in time be able to prevent children suffering from mental deficiency."

Reports of Societies

POLIOMYELITIS IN COPENHAGEN

The Danish experiences during the 1952 epidemic of poliomyelitis were described at a joint meeting of the Epidemiology Section of the Royal Society of Medicine and the Fever Group of the Society of Medical Officers of Health which was held at the Royal Society of Medicine on October 16. Professor A. BRADFORD HILL was in the chair.

Epidemiology

Professor H. C. A. LASSEN explained that Copenhagen was a city with about 1,200,000 inhabitants with one large fever hospital, the Blegdams, which had 500 beds. During the period of the epidemic over 3,000 patients were treated. The experience was peculiar for a European epidemic in that about one-third of the paralysed cases showed respiratory involvement. At the height of the epidemic an average of 10 patients a day were admitted with severe impairment of ventilation, requiring as a rule urgent treatment. There were still to-day over 25 patients remaining from the epidemic who were receiving artificial respiration.

At the beginning of the outbreak it had been intended to carry out a full epidemiological investigation, but the numbers were so great that it became necessary to restrict the study to 300 cases, representing every seventh case in chronological order. A group of 300 controls of similar age, sex, and town district was used for comparison. Many points had been chosen for special examination, but attention was drawn to two interesting findings. In the poliomyelitis group 28.2% had been in contact with another

case of poliomyelitis and 33.5% gave a history of contact with minor illness, usually of a respiratory character. In the control group the equivalent figures were 4.1 and 5.7% respectively. Although the possibility of an association with head trauma, vaccination, intramuscular injections, and pregnancy had been examined the differences between the "sick" and the control groups were not significant.

The Cases With Respiratory Paralysis

At the outset of the epidemic the number of tank respirators was insufficient, and even when these were supplemented by loan it soon became clear that the use of the tank respirator in cases with pooling of secretions in the pharynx was fraught with great danger. The assessment of such cases was usually extremely difficult, and it was often impossible to decide which signs were due to virus damage and which were due to secondary changes. After the elaboration of the positive-pressure ventilation method* the results had steadily improved, and in succeeding groups of 50 patients the following percentage fatality rates were obtained: 87, 54, 50, 40, 26, 36, and 22. For the 345 cases the over-all fatality rate was 41%.

Attention was drawn to the prognostic value of certain signs, and the most important of these are shown in the following table:

	Frequency %	Fatality Rate %
Shock	39	67
Ileus	33	43
Hyperpyrexia	19	91
Hypertension	19	42
Azotaemia	22	78
Pulmonary oedema	8	93

It was apparent that sex was of some significance, for the fatality rate in men was 49% as against 29% in women.

Dr. J. R. IBSEN described vividly his introduction to the first patient treated, who was a girl of 12 years with paralysis of all four limbs, a developed atelectasis, extremely distressed, cyanosed, and sweating. Despite the immediate problems associated with the introduction of a new method, the establishment of a clear airway with adequate ventilation resulted in almost immediate relief, disappearance of cyanosis, and fall in blood pressure. An x-ray picture showed that the atelectasis had re-expanded. Thereafter a "standard" technique was gradually evolved in which a preliminary period of observation with adequate postural drainage was followed, when necessary, by positive-pressure ventilation through a laryngeal tube. The tracheotomy—which was usually through the second and third rings of the trachea—was usually performed under general anaesthesia. The cuffed tube was then inserted through the tracheotomy opening and positive-pressure ventilation initiated. Obviously, although there was what might be termed a standard treatment, it was often necessary to suit the special circumstances of the particular patient. They had, however, favoured an early tracheotomy, for it was found that late emergency operations were often unsuccessful.

In order to concentrate the patients for ease of treatment and post-operative care a special unit was opened to which were admitted all those with evidence of respiratory embarrassment. At each bedside there were all the essentials for suction, and on each corridor all equipment for tracheotomy, etc. On many occasions it became necessary to go out from the hospital to treat emergency cases at home; in this way the specialized help was brought to the patient so that he was made safely transportable before being transported.

In a rough way patients could be divided into two groups, the "wet" and the "dry." The latter, provided ventilation was kept satisfactory, often remained dry and in general did well in the tank type of respirator. The "wet" type could be divided into two broad groups. In the first, ventilation often improved once pharyngeal secretions had been dealt with. Some of these did well on postural drainage alone, but where there was some involvement of respiratory

*See *British Medical Journal*, May 30, 1953, pp. 1208 and 1216.

muscles tracheotomy was generally necessary. The second group showed ventilatory failure even after pharyngeal toilet and postural drainage, and for these tracheotomy with bag ventilation was essential. These cases always did badly in the tank respirator. Not the least advantage of the method was that treatment was available to every patient whether a tank respirator was available or not.

A large number of questions were raised in the subsequent discussion, to which the speakers replied. Dr. THOMAS ANDERSON and Dr. W. RITCHIE RUSSELL moved votes of thanks.

Nova et Vetera

WILLIAM HYDE WOLLASTON

It is just 150 years since the discovery of palladium by a medical man, William Hyde Wollaston. He was born in 1766 and graduated M.B., Cambridge, in 1787. He was

The obverse of the Geological Society's medal which is struck in palladium and awarded annually for outstanding researches concerning the mineral structure of the earth.

He was elected a Fellow of Caius College and spent two years working in pure sciences. After a period of clinical study in London he went into private practice in Huntingdon and Bury St. Edmunds. In 1794 he was elected a Fellow of the Royal Society, one of his sponsors being his uncle, William Heberden, and in 1797 he published a classification of renal calculi based on chemical analysis. He abandoned medicine for applied science in 1800, his decision being influenced by the fact that the sufferings of his patients caused him extreme mental distress. In 1803 he announced the discovery of palladium, and in the following year he discovered rhodium. He was secretary of the Royal Society from 1804 to 1816, and was elected president in 1820. Wollaston is regarded as the greatest pioneer in the platinum metal industry, since he was the first to bring a trained analytical mind to the problem of obtaining malleable platinum.¹ He died in 1828. In honour of the triple jubilee of Wollaston's discovery, the Institution of Metallurgists organized a Platinum Metals Exhibition in London during the week commencing October 19.

¹Nature (Lond.), 1953, 172, 700.

Over 300 representatives of Scandinavian and other countries attended ceremonies in Florence on October 24-25 in honour of Niels Stensen, the Danish anatomist. Stensen wrote an important treatise on muscular mechanics, and his *Observationes Anatomicae*, 1662, included the first description of the excretory duct of the parotid ("Steno's duct") and of the ceruminous glands. He travelled widely in Europe, especially in Italy, and much of his work was done in Florence. He became a convert to Roman Catholicism and was nominated as Bishop of Titopolis. Stensen lived for some years at the court of Tuscany, where he enjoyed the friendship of Duke Cosimo III. He died in 1686, aged 48, and was interred among the Medici tombs in the Basilica of San Lorenzo, Florence. During the recent celebrations his remains were borne in procession through the streets and back to the Basilica, where they were placed in a Roman sarcophagus given by the Italian government.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

The Returned Prisoner of War

SIR,—Your leading article on this problem (*Journal*, October 10, p. 820) merits careful attention.

The emotional background of life in a prisoner-of-war camp, although perhaps more intense, is not essentially different from that of the uncaptured Serviceman in overseas theatres of war. Both in fancy picture the future in rosy colours and both may experience disillusionment and become unsettled on return to civilian life. According to a recent report from the Ministry of Labour and National Service on the resettlement of registered disabled persons¹ the number of ex-Servicemen disabled by psychoneurotic illness is 22,960 out of a national total of 32,484 for this particular condition. Timely recognition by doctors that employment difficulties may precipitate enduring neurotic illness in the emotionally strained demobilization phase could in many instances avert a later catastrophe.

Ample facilities for rehabilitation, vocational assessment, and full industrial training in many trades are provided at the industrial rehabilitation units and training centres of the Ministry of Labour. Early referral to one of these units of any occupationally unsettled ex-Serviceman, whether he has been a prisoner of war or not, is a simple prophylaxis against the most malignant form of disablement.—I am, etc.,

Bromsgrove, Worcs.

A. A. WHITE.

Succinylcholine Chloride for Casualty Anaesthesia

SIR,—Have Drs. Terence Vaz and J. M. Bishop (*Journal*, October 17, p. 885) stopped to consider that the light anaesthetic in casualty departments is often administered by doctors inexperienced in the use of relaxants? Although this method can be ideal when carried out by a skilled and experienced anaesthetist, in inexperienced hands it affords frightening possibilities for the conscious yet relaxed patient, whom the anaesthetist thinks is asleep, but who really is pink, paralysed, and perceptive.—I am, etc.,

Cambridge.

G. A. HART.

SIR,—Like Drs. Terence Vaz and J. M. Bishop (*Journal*, October 17, p. 885) I was struck with the possibilities of nitrous oxide and oxygen, with succinylcholine chloride as a relaxant, as an anaesthetic technique for out-patient orthopaedic manipulations. After induction with nitrous oxide and oxygen the dose of succinylcholine chloride ("scoline"), in the majority of cases 50 mg., was injected by the surgeon, and after relaxation had been obtained the manipulation was carried out. From the surgical point of view such a technique is excellent, but from the patient's point of view there are distinct disadvantages.

The majority of patients do not like being rendered unconscious by nitrous oxide if they have once been anaesthetized with thiopentone. If the patient is apnoeic as a result of the succinylcholine chloride it is difficult to keep a balance between cyanosis and consciousness, for the conscious patient cannot respond when completely relaxed. Excessive salivation, even after atropine, may cause stridor, and coughing is weaker on recovery, so that it is difficult to clear the respiratory passages. Many patients complain of a temporary loss of voice, and find this most unpleasant.

Although this technique may be satisfactory in the hands of the expert it is not suitable for use in the casualty depart-

ment, where anaesthetics may be given by the inexperienced. My orthopaedic colleagues and I abandoned this technique some eighteen months ago.—I am, etc.,

London, W.1.

JOHN GORDON.

SIR,—I agree with the opinion expressed by Drs. Terence Vaz and J. M. Bishop (*Journal*, October 17, p. 885) concerning the use of succinylcholine chloride for manipulations on casualties. This technique provides ideal conditions for the setting of fractures or other manipulations.

However, I have repeatedly noted that, during oesophagoscopy, the cardiac sphincter of the stomach relaxes when succinylcholine chloride is given. The average patient attending hospital as a casualty is quite unprepared for anaesthesia, and may well have a full stomach. For this reason, it seems to me that it is unjustifiable to add the further risk of regurgitation of stomach contents with a wide-open larynx to the already existing risk of vomiting. I have given up the use of succinylcholine chloride for manipulations on out-patients, except when I can be reasonably certain that the patient on whom it is proposed to use this drug has had nothing to eat or drink for at least four hours previously.—I am, etc.,

Luton.

D. C. ADAMSON.

Succinylcholine Chloride for External Version

SIR,—You may be interested in the following technique that I have been using for the past 18 months in various obstetrical departments.

Premedication consists of atropine 1/100 gr. (0.65 mg.), given as a rule by subcutaneous injection 45 minutes before the intended procedure. A syringe containing 100 mg. of succinylcholine chloride is introduced into a suitable vein and fixed in position (by strapping, "third hand," or similar device). Anaesthesia of a light plane is obtained by nitrous oxide and oxygen using a Boyle's apparatus. When consciousness is lost, 25 to 50 mg. succinylcholine chloride (according to the size of the patient) is injected, and 15 to 20 seconds later the surgeon may commence his manipulations. Relaxation of abdominal muscles leaves nothing to be desired. There is no marked effect on the uterine tone and usually a successful version is completed by the time the effect of this first dose of succinylcholine has worn off. Should temporary apnoea occur, this can easily be dealt with by rhythmic compression of the rebreathing bag filled with oxygen. Should the relaxation wear off before the completion of the version, further small doses of succinylcholine can be administered from the syringe still *in situ*. The patient wakes up from her N₂O anaesthesia in the usual manner and is fit to proceed home (if an out-patient) within a short time.

We have found this method very useful. It substitutes a light plane of anaesthesia where, before, deep ether or chloroform was found to be necessary. Unpleasant post-anaesthetic sequelae are conspicuous by their absence.—I am, etc.,

Sutton-in-Ashfield.

Z. LETT.

Orthopaedic Care in Poliomyelitis

SIR,—Orthopaedic surgeons have never claimed that they were capable of treating "all aspects of the acute stage of the disease (poliomyelitis)," and throughout the many years that they held responsibility for such treatment, long before Dr. Ritchie Russell's recent and sudden enthusiasm (*Journal*, October 24, p. 935), they never failed to collaborate with physicians.

But now that Dr. Ritchie Russell claims this right for himself—fortunately in isolation from most other physicians—and, in so doing, dismisses the prevention of contracture and deformity as "a simple matter which can be dealt with by properly trained nurses" it is time to point out that this dangerous observation shows how little he really knows about it.

He wants to go back 20 years in asking orthopaedic surgeons to "concentrate their efforts on the later stages when

the need for their special skill is most apparent." The fact is that orthopaedic surgeons do not want to display their special skill. They want to prevent the need for it long before it is apparent—and they can do so if they share treatment with physicians from the beginning.—I am, etc.,

London, W.C.2.

REGINALD WATSON-JONES,
President, British Orthopaedic Association.

SIR,—I have learned a great deal from my friend, Dr. Ritchie Russell, during the last few years, especially about the treatment of bulbar paralysis. I don't much mind his saying (*Journal*, October 24, p. 935) that I belittle the whirring pumps and all that (*Journal*, October 17, p. 884); I know that he knows that I do not really. But I am beginning to think that I have not been very competent in coaching him about the things that orthopaedic surgeons do in the treatment of poliomyelitis, and now I feel very sad about this. I ought to have saved him from making two howlers: (1) that all we think about is the prevention of deformity; he ought to travel round a bit and look at what is being done for the treatment of the paralysis itself—some of the physiotherapy departments and their staffs are rather impressive; and (2) that we fiddle about with splints for patients in respirators and so interfere with the good work being done by our medical colleagues. The answer to this one is simple: We don't.—I am, etc.,

London, W.1.

H. J. SEDDON.

Cancer of the Breast

SIR,—In their statistical paper on breast cancer, based on operative results at St. Bartholomew's Hospital, 1930-9 (*Journal*, October 10, p. 787), Messrs. I. G. Williams, R. S. Murley, and M. P. Curwen, with great courage and perseverance, have endeavoured by statistical methods without the aid of lymphatic anatomy or systematic pathological investigation to arrive at the best treatment for breast cancer. I believe they have set themselves an impossible task, and the indecisive character of their conclusions confirms that impression.

The authors dismiss in two lines, without references, my work on lymphatic permeation. They say: "Anatomical investigation has shown no evidence for the centrifugal permeation of lymphatics by cancer cells." It seems evident that they have not happened to see the second edition of my book *Cancer of the Breast*,¹ which contains conclusive evidence on the subject. This edition is exhausted and the French and American editions may be unobtainable, but I shall be pleased, if it is acceptable, to present a copy still in my possession to the library of St. Bartholomew's Hospital.—I am, etc.,

St. Olaves, Norfolk.

W. SAMPSON HANDLEY.

Lead in Lollies

SIR,—In your annotation (*Journal*, September 12, p. 613) referring to lead in lollies you mention that a safe limit for domestic water is considered to be 0.3 p.p.m. of lead. In relation to public water supplies it may be pointed out that this figure would be unusually high, even for most soft waters after standing overnight in lead service pipes. In the U.S. Public Health Service *Drinking Water Standards*, 1946, for example, the presence of lead in excess of 0.1 p.p.m. was given as a ground for rejection of a supply.

With regard to your suggestion that "it would seem reasonable to make it illegal to sell lollies containing lead in a higher concentration than that found in the local drinking-water," this would appear to be indefinite and impracticable; a large proportion of drinking-waters, even when drawn from lead service pipes, contain no lead (less than 0.02 p.p.m.) detectable by a reasonably sensitive analytical procedure. The main feature of your annotation is that there should be a sufficiently strict limit, and for this purpose we tentatively suggest 0.2 p.p.m., bearing in mind the cumulative effect of this metal. This is the figure

suggested by the Food Standards Committee for beverages "ready-to-drink" other than beer, cider, or apple juice.

In instances which we have met recently, the lead in lollies has been due to the moulds used in their manufacture being tinned in a tin bath contaminated with a substantial percentage of lead. Lead-free tin can be used for moulds with satisfactory results. Your suggestion of aluminium would be likely to give rise to difficulties owing to this metal being susceptible to corrosion.

The above detailed comments are, however, of less importance than the general conclusion in your annotation that the limit for lead in lollies should be very low. I feel that this needs to be emphasized, because otherwise a much larger amount of lead might be permitted, as for solid foodstuffs. The fact that lead in excess of 0.2 p.p.m. can usually be avoided is proved by its absence from a large proportion of lollies now sold. In some high-grade products with a high content of total solid matter, however, a larger amount may be derived from the traces in the syrup, fruit pulp, citric acid, etc., without any contribution from the moulds, and this must be taken into consideration in fixing a standard for such products.—I am, etc.,

London, S.W.1.

ROY C. HOATHER.

Hop Dermatitis in Herefordshire

SIR,—We were most interested in the letters of Mr. C. L. Shaw (*Journal*, August 29, p. 511), Dr. F. Ray Bettley (p. 512), and Mr. John L. Struthers (*Journal*, September 26, p. 726). In reply to Dr. Bettley, it seems to us that an incidence of dermatitis of 1 in 30 does not necessarily suggest that hop-cones contain a primary irritant. Sensitizing agents vary in activity: with some, such as T.N.T., the incidence of dermatitis may be as high as 50%. Ten normal subjects were patch-tested with hop-cone; all tests after 48 hours were negative. This is in contrast with dermatitis patients, some of whom developed an eczematous reaction at the test site within 12 hours. Ten negative tests in normal subjects can, of course, prove nothing, but suggest that if hop-cones contain a primary irritant it is not a very active one. Tests may be done with dilutions of fresh hop-oil this year. The small quantity available last year was used to establish a difference between fresh and old oil.

We had supposed that hardening was the result of hypersensitization after repeated contact. Schwartz states¹ that if a worker does not learn to protect himself from a primary irritant he will be continually affected by industrial dermatitis. On the other hand, if the skin hazard consists of a sensitizer, and the dermatitis is not sufficiently severe to prevent the patient from working, he will in most instances develop a tolerance or hyposensitivity in from 3–6 weeks. The workers call this hardening. Schwartz also suggests that some workers who develop dermatitis so severe as to prevent them from working may develop tolerance on return to work. This is not supported by patients with severe hop dermatitis. For example, one patient who developed severe dermatitis after 10 days' contact last year succumbed after only half a day in the hop-yard this year.

In reply to Mr. Struthers, the damage to the skin by hop-spines was considered when cases were seen. Superficial scratches insufficient to draw blood are particularly common on the forearms and hands, but did not seem related specially to areas of dermatitis. Scratches are not common on the face, where dermatitis developed first in seven of our patients. One of these had an attack of dermatitis after visiting a hop-yard to deliver meat; he did not touch a single hop on that occasion. He also stated he developed dermatitis round his mouth after ingesting 10 pints of beer. In spite of this, in some cases abrasion may be an additional factor, due both to hop-spines and to efforts to clean hop juices from the skin after the day's work.—We are, etc.,

Potassium Permanganate Ulceration

SIR,—We were interested to read the article by Mr. E. A. J. Alment and Dr. C. S. Nicol on potassium permanganate ulceration of the vagina (*Journal*, October 3, p. 759). We feel that the authors should be commended for bringing to wider notice a method of attempted abortion which certainly appears to be on the increase.

One of us has seen three or four cases of such vaginal ulceration in the last few years, and the lesion is not unknown on the North American continent. We agree that there is no doubt about the severity of the haemorrhage which follows insertion of potassium permanganate tablets. The authors quite rightly describe the lesion as being similar to a Hunterian chancre, but it is our experience that the ulcers are usually larger than a typical chancre. This, of course, depends on the size of the tablet and length of time during which it has remained in apposition to a certain area of the vaginal wall. We have found that one of the characteristic features of these ulcers is the very sharp, clear-cut edge between the ulcer and the normal vaginal skin. The intense blackness of the ulcer, too, is almost diagnostic in itself, but this we have found to be only a transitory finding, since—in our experience—the ulcers heal with remarkable rapidity. There is in hospital at the moment a case of permanganate ulceration, and already, after six days, the lesions are well on the way to complete resolution.

Finally, we do agree with the authors that this is a most unsatisfactory way to procure abortion, since in no case in our experience has it been effective.—We are, etc.,

Manchester.

JEFFERY SPRY LEVERTON.
IAIN H. KIDD.

SIR,—I note from the article by Drs. E. A. J. Alment and C. S. Nicol (*Journal*, October 3, p. 759) that the first account was written by Lacassagne and Friess in 1932.¹

In February, 1931, I was called to a nulliparous married woman who was vomiting seemingly blood-stained fluid. The sight of the "blood-stained" vomitus was sufficient to alarm the woman, her husband, and personal confidants, and she was advised by them to desist from further abortifacient attempts. "You will only kill yourself," she was told. I discovered that she had obtained potassium permanganate tablets from a local chemist. It has taken me 22 years to discover that the wrong orifice was used by the pregnant woman for the deposition of the tablets. I have no idea how many tablets were swallowed by her, but they certainly had a powerful emetic and deterrent effect.—I am, etc.,

Slough.

Exposure Treatment of Burns

SIR,—With reference to your leading article (*Journal*, September 19, p. 665), I think the first, and main, indication in the treatment of burns is not so much the prevention of sepsis as the prevention of pain. The second main indication is the prevention of fluid loss via the burnt or scalded surface, and it is only after these two main requirements have been met that one should think of sepsis.

I think egg-white meets all three requirements, and ought to be given a trial in a burns unit. I was once allowed to try egg-white on a child with a burn, and immediately the egg-white was applied the child stopped crying; therefore the pain must have been relieved. And the burn did well. An old lady told me she burnt her hand through upsetting a frying-pan of hot fat. The pain was intense but stopped as soon as egg-white was applied, and "a skin formed over my hand." No bandages, nothing else apparently, and the hand healed perfectly.

I suggest egg-white could be applied by being smeared over the burnt or scalded surface by hands enclosed in sterile rubber gloves. The eggs must be fresh and could be kept in a refrigerator in the casualty department ready for immediate use. As eggs are now fairly plentiful and not too dear, may I suggest this method be given a trial in the Birmingham—or other—burns unit? It seems to me to be worth it.—I am, etc.,

North Shields

F. M. E. DAVIES.

Breast-feeding in Oxford

SIR,—The findings of the above survey by Dr. Alice Stewart and Dr. Celia Westropp (*Journal*, August 8, p. 305) confirm the views I have held with increasing conviction over the years that breast milk, while of value to the baby during the first few weeks of its life, should rightly be regarded as a "running-in" fluid for the new digestive apparatus and not necessarily as the ideal nourishment for any length of time. It is too weak and lacks some of the necessary elements for optimum development. Twenty years ago we urged mothers to keep their babies on the breast and on nothing else except cod-liver oil and orange juice. This we now know to have been bad advice—we were raising flabby, anaemic, rickety children such as, with modern scientific feeding, we rarely now see in this country.

For many women breast-feeding is an exhausting process, and their health picks up rapidly when they stop it. Babies fed at an inadequate breast show irritability amounting to anger—and become contented and eager for their feeds when put on to the bottle. Whenever this happens I ask the mother if her love for her baby has diminished in any way. The answer is a scornful, "No, Doctor." Maternal love is an instinct based upon something deeper either than breast-feeding or, as used to be maintained, painful labour. Nor does the baby give any sign of psychological upset such as the psychiatrists feel it should.

At the age of 1 year I would defy anyone to pick out the breast-fed baby from the bottle-fed one—and the same at 5 years of age. I have taken feeding histories of 400 children aged 5 and have failed to find any one aspect of physical development better in the breast-fed than the bottle-fed. In short, science in this department of life, as in so many others, has improved on nature. I see no reason to regret it.—I am, etc.,

Topsham, Devon.

GRACE H. WALKER.

Tuberculosis Classification

SIR,—Since Dr. Milosh Sekulich suggests (*Journal*, October 24, p. 938) that the review of his book which I contributed to your columns (*Journal*, September 26, p. 715) was unfair and misleading, I may perhaps be permitted a brief reply to his letter.

His book sets out to expound a classification of tuberculosis. A classification should conform to two criteria. It should be logical and self-consistent, its headings so far as possible mutually exclusive, and its basis a corpus of generally agreed and established knowledge; and it should prove convenient and neat when the facts are fitted into it. Of these the first is by far the more important, for any given body of facts can be fitted with more or less convenience into many different classifications, and whether or no any one of these serves its purpose in conducting to clarity of thought will depend principally upon its intrinsic qualities as a logical system. For this reason it seemed to me the duty of the reviewer to concentrate attention upon the logical aspects of the classification.

I have no doubt that Dr. Sekulich can fit any variety of pulmonary tuberculosis into his classification, since he accepts all the theoretical interpretations of observational data which, as I pointed out, are inextricably interwoven with it. But when I attempt the same task I find myself face to face with difficulties and doubts, since I (and, therefore, I imagine, many others) do not accept as established many of the theoretical assumptions which are implicit in

the classification, and of which I enumerated a few in the course of my review. Hence I am quite unrepentant in reiterating that simpler and less ambitious systems are less likely to give rise to confusion.—I am, etc.,

J. G. SCADDING.

London, S.W.3.

The Diploma in Public Health

SIR,—In criticizing the course of instruction for the Diploma in Public Health, Dr. Max Park (*Journal*, October 3, p. 778) has surely missed the point. This diploma is not designed merely to give the necessary technical instruction to a prospective assistant M.O.H. in England. A person with the letters D.P.H. after his name should be an expert in public health in the widest sense of the word. Primarily he should be trained to be an administrator—since public health is largely administration—and able to administer organizations that embrace fields far wider than that within the scope of the average English assistant medical officer of health.

The essentials of this course should include a thorough understanding of at least the following items: the law relating to health—the public, the school, and the factory; the functions of local and central government administration; epidemiology, not only of infectious diseases, but of all sickness, including accidents and occupational diseases; statistical methodology; health educational techniques; all this in addition to the fundamentals of classical public health and sanitary science, the immunology, environmental hygiene, and the like. Far from wishing to reduce his scope, the prospective public health expert should take every opportunity to widen it. Anyone with a real interest in his subject, and who is not interested in the diploma merely as a means of getting himself a job, will be glad to learn all he can about such related subjects as bacteriology, entomology, and parasitology. These are still essential to a real understanding of a large part of preventive medicine. Similarly the course should include a study of nutrition, carcinogenesis, mental health, etc. And one who will have to administer the work of sanitary inspectors, and perhaps factory inspectors, will not begrudge time spent in obtaining at least an understanding, if not a mastery, of these two subjects in addition to his own.

The science of preventive medicine, as developed in England, is honoured and respected throughout the world. It would be a sad day indeed if we followed the suggestion of Dr. Max Park and limited the course of instruction to the small world of the infant welfare centre and the school medical service.—I am, etc.,

Geneva.

W. NORMAN TAYLOR.

Prevention of Transfusion Accidents

SIR,—Several speakers at the Consulting Pathologists' Group Conference are reported (*Journal*, October 17, p. 878) to have stated that too much blood is ordered by clinicians for surgical and other cases. May not this attitude among the clinicians be a reflection of the advice given by Grant and Reeve in a recent Medical Research Council Special Report,¹ where it is pointed out that clinicians have habitually given too little blood, according to blood volume estimations in many surgical cases? The lessons of this report have been applied very widely, and with benefit, I feel sure. Some simple and rapid method of assessing blood volume in any patient is required. The report rather frowns on haemoglobin estimations as a guide to blood volume, but, with the limitations of the method in mind, a haemoglobin estimation gives useful information.

The greatest enemy of safe blood transfusion is haste: emergencies have to be dealt with adequately, but the technique of preparation must not suffer, and the person actually doing the preparations should be protected from alarmist procedures while at work.—I am, etc.,

Epping.

Obituary

ROBERT TENNENT, M.B., F.R.C.S.Ed.

The death of Mr. Robert Tennent in a nursing-home at Stirling on October 9 at the age of 62 has deeply affected a very wide circle of friends.

Robert Tennent was born at Strathaven, Lanarkshire, on November 13, 1890, and received his early education at Hamilton Academy, of which he was a distinguished pupil. From the University of Glasgow he graduated M.B., Ch.B., with honours, in 1914, a few months before the outbreak of the first world war, in which he served throughout in the Royal Navy. He was granted leave to take the Fellowship of the Royal College of Surgeons of Edinburgh, and this he did in 1917.

After the war he was appointed to the staff of the Royal Hospital for Sick Children, Glasgow, where he was junior to the late Mr. Alexander MacLennan, whom he also assisted in private practice. His appointment to the Victoria Infirmary soon followed, and there, after some years as first assistant to Mr. R. B. Carslaw, he was given charge of wards in 1927 at an unusually early age. Making this work his chief interest and regretfully discontinuing his appointment at the Sick Children's Hospital, he entered into a period of very active hospital and private practice, which terminated by his resignation in 1949, the end of his long and happy association with the Victoria being forced upon him by failing health.

In 1924 he accepted the invitation to become visiting surgeon to Falkirk Infirmary, and his connexion with this hospital was also a very happy one; he shared the responsibility and credit for the planning of the Royal Infirmary, which was opened there in 1932. It was therefore understandable that he should continue to do some work there even after his retirement from practice in Glasgow.

Tennent's work in the Victoria Infirmary earned for him in Glasgow and throughout the West of Scotland a very high reputation, particularly in the fields of abdominal and thyroid surgery; in the latter he achieved especial eminence, and it is to be regretted that he did not live to carry out his intention of publishing his results. Although he latterly tended to be more circumscribed, he was so much the general surgeon that any new method received consideration and underwent trial at his hands. He had been, for example, one of the first in this country to use the Harris technique for prostatectomy. Above all, Tennent was characterized by a dexterity and gentle-handedness which gave him results surpassed by few. He was a surgeon who could make surgery look easy, and his celerity, combined with a natural aptitude for work, made his life an exceptionally full and busy one.

Mr. Tennent taught well and was for many years a clinical lecturer in surgery in the university, and in his later years he examined for the final M.B., Ch.B. Probably the unofficial teaching which he did as an assistant surgeon gave him the greatest pleasure. For many years he gathered round him on Saturday mornings a large number of final-year men, and his ward rounds then were a delight. Many a student learned as much surgery from his informal, anecdotal talks as from a series of more sedate clinics, and these tutorials will live long in the memories of those who attended them. He was

regarded as a most kindly final examiner, and it is difficult to imagine any candidate being other than at ease with him.

In spite of all his activities Tennent found time for many interests apart from his profession. Angling was his first love, and he knew intimately most of the rivers of his native country. His friends were legion among countrymen in all walks of life, and his love of country things and country folk was exemplified by his wide knowledge of Scots ballads, which his retentive memory enabled him to recite freely. It was another of his Scots attributes that he could quote the Old Testament at length and with accuracy.

Robert Tennent was a fine surgeon, and he was also a fine man. He was generous to a fault, and his help was always available to patient and colleague alike at no matter what sacrifice of his time and energy. Many young men owe their start in general practice and in surgery to the unselfish help given by him. The second world war made increasing demands on him at a time when normally he might have been expected to begin to enjoy more leisure. These demands were met in full, but only at a cost, and in 1947 came the first signs of the vascular disorder which made it necessary for him to modify his activities. Shortly after this he went to live at Dunblane and gradually made his severance from the city of Glasgow wellnigh complete.

No greater tribute could have been paid to Robert Tennent than the presence of so many friends from so many walks of life at his funeral service in Dunblane Cathedral. He leaves a widow, three daughters, and two grandchildren, of whom he was exceedingly proud. He will be remembered by many with gratitude and affection.—J. P. G. and R. G. H.

I. WALKER HALL, M.D.

Professor I. Walker Hall died at his home at Godalming on October 9 at the age of 85, twenty years after retiring from the chair of pathology in the University of Bristol.

Isaac Walker Hall was born on September 16, 1868, and was educated at Owens College, Manchester, graduating M.B., Ch.B. with honours at the Victoria University of Manchester in 1899 and proceeding to the M.D. three years later. After graduation he continued his studies at Leipzig, Stockholm, and Wiesbaden, and met and worked under the leading bacteriologists and pathologists of those pioneer days. On his return to Manchester in 1900 he was appointed senior demonstrator of physiology, and in the following year he became lecturer in pathology in the university. In 1905 he published, with G. Herxheimer, a book entitled *Methods of Morbid Histology and Clinical Pathology*, which they dedicated to the memory of Carl Weigert. It was a remarkably useful practical handbook.

In 1906 Walker Hall was appointed the first honorary pathologist and bacteriologist to the Bristol Royal Infirmary and the first professor of pathology in the Bristol University College, as it then was. He rapidly gained a reputation throughout the West Country, and within a few years his laboratory at the infirmary was receiving specimens from as far away as Cornwall, there being then no other pathologist in the area. A small department was provided for him in the university buildings in 1910. All the public health bacteriology for Bristol and the adjacent counties and all the clinical

pathology were conducted in these small university laboratories with a staff which, by modern standards, was totally inadequate. Walker Hall's own enthusiasm, energy, and skill made this and much more possible. The first of a series of important papers on the role of carriers in typhoid fever came from his pen in 1908, and he made numerous contributions to the literature on the bacteriology of public health, including work on the pasteurization of milk, the contamination of ice-cream, *Brucella abortus* infection, and bubonic plague.

As a teacher Walker Hall will be remembered for his graphic illustration of immunological procedures. He had a collection of toy animals: a sheep would be "bled" and the "blood" injected into a toy rabbit to illustrate the production of haemolysin for the Wassermann reaction. His students suspected that these toys really belonged to his daughter. He was a delightful lecturer and a stimulating person. When he retired from the chair of pathology in 1933 and was made emeritus professor he became the first director of the university's new department of preventive medicine in laboratories provided by the university in what was previously a student hostel at Canynge Hall. The development of this department was due to his vision and was of immeasurable importance to the university and to the city of Bristol, providing a link between the two authorities which has remained happily without interruption, so that to-day the public health laboratories, the city analyst, and the food inspectors are all housed in the same building with the departments of pathology and bacteriology. He made a place for himself in the history of Bristol and in the history of public health bacteriology in this country.

A member of the British Medical Association for fifty-five years, Walker Hall served as a vice-president of the Section of Pathology when the Association held its Annual Meeting at Belfast in 1909, and at Liverpool in 1912 he was president of the same Section. He was a member of the consulting pathologists group committee of the B.M.A. from 1928 to 1934, and an honorary member of the Association of Clinical Pathologists.

In 1936 he finally retired from Bristol and went to live at Godalming, where his wife, long an invalid, predeceased him. He leaves a daughter.—T. F. H.

J. F. R. GAIRDNER, M.B., M.R.C.S.

Dr. Frank Gairdner, who died at his home at Bungay, Suffolk, on October 8 at the age of 82 after a long and varied life, came of an illustrious Scottish medical family, for his father, Sir William Tennant Gairdner (1824-1907), was professor of medicine in the University of Glasgow from 1862 to 1899 and a Fellow of the Royal Society, and his grandfather, John Gairdner (1790-1876), was President of the Royal College of Surgeons of Edinburgh from 1830 to 1832 and treasurer of the College for many years.

John Francis Robert Gairdner was born at Glasgow on February 6, 1871, and was educated at Uppingham School and Glasgow University, where he graduated M.B., C.M., with honours, in 1894. Although his natural bent was medical rather than surgical, his father's fame, at its height when his son graduated, made it not easy (he conceived) for the young Dr. Gairdner to adopt the career of a physician in Glasgow. He therefore took a series of surgical appointments which ended with his becoming assistant to Mayo Robson at Leeds. Eventual elevation to the full surgical staff at Leeds seemed certain, but the beginning of the South

African war in 1899 caused him immediately to join the Expeditionary Force. Extraordinary were the tales he would tell of the medical side of that campaign, for the ravages of enteric fever overwhelmed the Army medical services and led to appalling scenes, much like those described by Florence Nightingale in the Crimean war. When the South African war ended he found he had become much enamoured of that country and decided to stay abroad for a time. He practised first at Germiston, Transvaal, and later at Pretoria, where he became a member of the town council. At the outbreak of the first world war he joined the South African Medical Corps and served against the Germans in South-west Africa. He then joined the R.A.M.C., saw service in France, and later commanded the surgical division of a hospital in Macedonia, with the rank of major.

After the war Dr. Gairdner became surgeon and superintendent to a hospital which had been opened by the owners of a group of collieries in the mining town of Ashington, Northumberland, and there he worked for nineteen years. The work involved a good deal of assessment of compensation in cases of injury, and in this difficult field his patent integrity was of great account. Some years after he went to Ashington he was stricken with severe rheumatoid arthritis and seemed unlikely ever to be able to resume surgery. However, after many months he was able to return to work, albeit with sadly stiffened hands, with which, nevertheless, he was delighted to find himself able to operate as before.

Like many quiet and humble men, his influence upon all classes and kinds of men was great, as the many who served as his house-surgeons at Ashington can testify. "He was one of the most outstanding men whom I have been privileged to meet and to know," wrote one. He had a wonderful old-world courtesy and an endearing conviction of the all-round superiority of the opposite sex.

When the second world war began he had just retired, but was soon working again as medical superintendent of an E.M.S. hospital. In 1941, when he was 70, he learnt that there was a shortage of doctors in the Merchant Service and managed to sign on as a ship surgeon, serving for the next two years at sea, mainly on transatlantic runs. He is therefore one of the few men to have gained both the Queen's medal for service in the South African war and the Atlantic Star for service in the last war.

In retirement, Dr. Gairdner was able to cultivate his talents for archaeology, literature, and botany, but the loss of his wife in 1950 dealt him a blow from which he never fully recovered.

FLORENCE R. SABIN, M.D.

Dr. Florence Rena Sabin, the distinguished American anatomist, died at Denver, Colorado, on October 3. She was born on November 9, 1871, in the mining district of Colorado. After obtaining a B.Sc. degree in 1893 she became a schoolteacher in order to earn sufficient money for a medical education. In 1896 she entered Johns Hopkins Medical School and graduated M.D. in 1900. She then joined the research staff in the anatomy department of the school, a post made possible by an endowed fellowship provided for her by the Baltimore Association for the Promotion of University Education of Women. Under F. B. Mall (of whom she wrote an excellent biography in 1934) she embarked on her classical studies on the lymphatics and haemopoietic system. Her important monograph on *The Origin and Development of the Lymphatic System* was

published in 1913. She contributed more than a hundred papers to the literature on the lymphatics, blood vessels, origin of blood cells, bone marrow, and tuberculosis. She was associate professor of anatomy at Johns Hopkins from 1905 to 1917 and was then appointed to the chair of histology. She held this position until 1925, when she left to join the Rockefeller Institute for Medical Research, where she remained until 1938. From 1924 to 1926 she was president of the American Association of Anatomists. Dr. Sabin was the first woman to graduate from Johns Hopkins University, the first woman to teach there, and the first woman member of the Rockefeller Institute and the National Academy of Sciences. The late Simon Flexner once referred to her as "the greatest living woman scientist and one of the foremost scientists of all time."

We record with regret the untimely death of Dr. ANTHONY NOY SCOTT on October 14, at the age of 29. He was a most congenial and happy person and will be greatly missed by his many friends. The son of Dr. and Mrs. Steuart Noy Scott, of Plympton, Devon, he went to Clifton College in 1937, and from there to Jesus College, Cambridge. At Cambridge he was, as throughout his whole life, a most popular person. He attained great heights on the hockey field, playing for the university for three years, for one of which he was captain. In 1947 he went on from Cambridge to the London Hospital. He quickly made many friends there and became more than an asset to the hospital hockey team. He also played regularly for Essex county, having previously played for Devon. Soon after coming to "The London" he married Jean Duncan, and the following year their daughter was born. He had many interests besides medicine. He was very skilled with his hands, and ingenious in the uses he put them to; and his knowledge of motor-cars never ceased to amaze. After qualifying in 1952 he decided to take one or two house appointments, but these were cut short by the onset of his fatal illness. This he bore with extreme courage and outward cheerfulness. Our deepest sympathies go to his young widow and their daughter, and to his parents.—D. N. S.

The death occurred on September 25 at Lenox Hill Hospital, New York, of Dr. MAX EINHORN, the gastroenterologist. He was aged 91. Max Einhorn was born near Grodno (then in Russia) on January 10, 1862. He qualified M.D. Berlin in 1884. In the following year he emigrated to New York. After a house appointment at the German Hospital he became associated in 1889 with the Post-Graduate Medical School and Hospital, where, seven years later, he was appointed to the chair of internal medicine, becoming professor emeritus in 1922. He contributed several important textbooks to the literature of gastroenterology and originated the concept of achylia gastrica to indicate a primary nervous functional disorder of secretion.

Dr. THOMAS MCCLURE, who died recently, was a native of Northern Ireland and was educated at Queen's College, Belfast, and at Edinburgh University, taking the Scottish triple qualification in 1907. He then went to South Wales as chief assistant in an extensive colliery practice in Pontypridd, and afterwards joined his brother, Dr. Samuel McClure, in general practice at Cwmgwrach and Glyn Neath, where he practised for forty years. He retired in 1948. His long association with the district engendered a keen affection for all its inhabitants, and he was proud of the fact that he was not merely regarded as the doctor, but better still as a friend. He evinced a deep interest in the social life and welfare of his patients and proved a generous sponsor of every movement inaugurated for the benefit of the community. In his younger days Dr. McClure was a good angler, a good shot, and an accomplished photo-

grapher, but the rapid increase in the local industrial population curtailed his leisure for these pursuits, and his chief hobby then was gardening, on which he became an authority. His gardens were the admiration of all in the district, and in them he found the ideal recreation, for he was always on call, especially for the colliery accidents which were then so frequent in the district (the injured being usually treated at home). For the same reason he developed another hobby, carpentry in native Welsh oak, and in this, as in everything else, he showed considerable skill. Many fine examples of his work are to be found in his home and in the homes of some of his friends. His outstanding characteristic was that whatever he undertook to do he did well. He leaves a widow, who was his help-mate throughout a happy married life.

Medical Notes in Parliament

MENTAL LAW REVISION

Inquiry by Royal Commission

The announcement that there is to be a Royal Commission to inquire into the law and administration relating to the certification and detention of persons suffering from mental illness and mental defect was made by Sir WINSTON CHURCHILL in the House of Commons on October 22. The names of members of the commission will be announced later. The terms of reference are:

"To inquire as regards England and Wales into the existing law and administrative machinery governing the certification, detention, care (other than hospital care or treatment under the National Health Service Acts, 1946-52), absence on trial or licence, discharge, and supervision of persons who are or are alleged to be suffering from mental illness or mental defect, other than Broadmoor patients; to consider as regards England and Wales the extent to which it is now, or should be made, statutorily possible for such persons to be treated, as voluntary patients, without certification; and to make recommendations."

Sir Winston Churchill said that the Government had had this matter under consideration for some time, and realized that legislation was desirable to bring the law into line with modern thought and development. They considered, however, that there should first be a comprehensive review of the subject by an independent body.

Mr. ANEURIN BEVAN welcomed the announcement, but commented that the last part of it might give the impression that there were no voluntary patients. The Prime Minister knew that a large proportion of patients treated in mental institutions were voluntary, and it was because the treatment was so satisfactory that it was desired to extend it. Sir WINSTON CHURCHILL agreed, and said it was intended to extend voluntary treatment as far as possible, subject always to making sure that people were properly protected by certification in cases where treatment involved a considerable measure of restraint.

Mr. A. WOODBURN asked whether the terms of reference would include the difficulty of old people who were certified to give them room in mental institutions—people who were suffering from the decay of their mental faculties without necessarily being insane. Sir WINSTON CHURCHILL said he thought the matter would be considered by the Commission.

There were several questions about the restriction of the inquiry to England and Wales, and the exclusion of Scotland, where the law is different. Sir WINSTON CHURCHILL said that he was not ruling out a Scottish inquiry, but it would be a pity to mix them together. It seemed to him fairly certain that one would lead to the other—to which he added subsequently that he would like to convey an announcement about Scotland as soon as possible. He also stated that he would bear in mind, when considering the type of person to serve on the Commission, a point made by Mrs. Brad-dock, that it should include some of the younger school of medical practitioners who were fully qualified in psychiatry.

GIRL'S DETENTION IN MENTAL HOSPITAL

The Home Secretary made a long statement, in reply to questions by four Members on October 22, on the circumstances of the removal by the Home Office from Hollymoor Mental Hospital of a 14-year-old Shropshire girl. Two of the questions asked for an inquiry.

Sir DAVID MAXWELL FYFE stated that the girl, born on July 13, 1939, appeared before the Church Stretton (Shropshire) juvenile court on September 25, 1952, as being in need of care or protection, and was ordered to be sent to an approved school. The order authorized her detention in an approved school until September 24, 1955. The court had information that the girl had been before the court three times for stealing and had been put on probation, that her ability and educational attainment were below average, that seven men had been committed for trial at Assizes in September, 1952, on charges in connexion with her, and that the parents had been warned from time to time by probation officers about the family's association with one of these men, who had been a frequent visitor to their house since 1947 or 1948.

On October 24, 1952, after two outbursts of violent and hysterical behaviour in the remand home where she was awaiting a vacancy in an approved school, she was removed to Hollymoor Mental Hospital on an Urgency Order. Before the expiry of the Urgency Order at the end of seven days, the hospital authorities obtained the father's written consent as required by law to the girl's residence in the hospital as a voluntary patient. On January 14, 1953, the consultant psychiatrist of the regional hospital board wrote to the Home Office reporting that the girl appeared to have found an environment which suited her, but that she showed an impaired reasoning power and a distortion of reality, and that there was a strong schizoid element. He thought she was unfit to be sent to an ordinary approved school or to be sent home, and that she could very well remain at Hollymoor Hospital, where she was receiving no schooling, provided that she was given regular psychiatric treatment as an out-patient in the children's department of another Birmingham hospital. The Home Office accepted this view, and accordingly suggested to the Shropshire County Council that the approved school order should be discharged, the girl remaining a voluntary patient in the hospital. The county council suggested that consideration should be given to the possibility of arranging for the girl to be committed to the care of the hospital authorities as a fit person, and agreed that the approved school order might be discharged.

While the county council's suggestion was under consideration, the acting medical superintendent of the hospital wrote to the Home Office saying that, while he did not regard the girl as a suitable case for indefinite retention in Hollymoor Hospital, he did not consider it advisable for her to be sent straight to an ordinary approved school. In view of this, the suggestion made by the Shropshire County Council was not pursued, but arrangements were made for a senior medical inspector of the Home Office Children's Department to visit the girl at Hollymoor Hospital and discuss her case with the hospital medical authorities. On visiting the hospital on April 8, he learned that medical opinion at the hospital considered the girl to be certifiable as mentally defective. The Home Office therefore invited the Shropshire County Council to present a petition to the judicial authority for the girl's certification. The county council agreed, and the medical superintendent of the hospital expressed his willingness to retain the girl at Hollymoor until a petition could be presented. The Birmingham Regional Hospital Board then endeavoured to find a vacancy in a suitable institution.

On August 29 the Shropshire County Committee of Trades Councils wrote to the Home Office saying that the girl's father had approached them, that the secretary of the committee had visited the girl in hospital on August 24 and was "quite satisfied, in conjunction with other competent hospital authority, that the girl is not insane," and that the Home Office should arrange for the girl's removal from the hos-

pital as a matter of urgency. On September 1 the chairman of the Hollymoor Hospital Management Committee wrote to the Home Office saying that, in his view, the girl was not suitable for either a mental hospital or a mental deficiency institution. The Home Office ascertained from the medical superintendent of the hospital that he still considered that the girl should be certified under the Mental Deficiency Acts. In view of these conflicting opinions, the management committee's requests for early removal, and the difficulty of finding a place for her, the Home Office decided in consultation with the Ministry of Health that the girl should be removed to a classifying approved school for observation and assessment.

Arrangements were made accordingly for the girl to go to the Shaw Classifying School, near Warrington, on September 28. It was learned subsequently that the girl's father had given the hospital authorities the requisite 72 hours' notice to withdraw his daughter, as a voluntary patient, from the hospital, and that he intended to take her home on September 26. Had the girl been taken home by her parents, it would have been necessary to remove her from her home in pursuance of the approved school order. In view of the disturbance which this would have involved for the child, the Home Office arranged for her to go to the Shaw School on September 25.

The Home Office had acted throughout with the girl's best interests in view, and the decision to remove her, in pursuance of the court order, to an approved school (despite the doubts about her suitability for approved school training) was not taken until it became clear that her continued retention in the hospital was not favoured by the hospital management committee. She was not allowed to return home, since the court had decided by the making of an approved school order that, in her own interests, she should be removed from her home environment, and that order was still in operation. There was no foundation for the suggestion that the girl's removal to an approved school in pursuance of an order of the court infringed the rights of the parents, and it was the order itself which restricted the girl's liberty. Both he and the Minister of Health were satisfied that, notwithstanding the unfortunate differences of opinion between the lay members of the hospital management committee and the medical authorities as to the girl's mental condition and as to the proper method of dealing with her, all the parties concerned acted throughout in what they believed to be the girl's best interests. The case illustrated the necessity for an inquiry into the methods of certification of patients suffering from mental troubles on the lines of the royal commission which the Prime Minister had announced.

"Smog" Warnings Proposed

The Minister of Housing and Local Government was asked by Mr. N. N. DODDS and Lieutenant-Colonel M. LIPTON on October 20 what action he was taking to combat fogs similar to those of last December, when many people died as a result of air pollution.

Mr. HAROLD MACMILLAN replied that so far as he knew the only practicable way of combating "smog" was to reduce smoke from chimneys. The problem was not one for which it was easy to devise emergency plans. He was awaiting the report of the Beaver committee. Meanwhile a special effort was needed by all those who burned coal to use it efficiently, and as sparingly as possible during fogs. This applied to householders no less than to industrial and other consumers.

Mr. DODDS said it was remarkable that the Government had no plan ready, in view of the heavy death roll, and, as much was known already about air pollution, would it not be possible to give a warning if similar weather conditions were likely, and to request that domestic open fires and certain industrial processes should be dispensed with during the danger period? Mr. MACMILLAN said that he welcomed this and any other suggestions. He also stated in further replies that the committee on air pollution, presided over

by Sir Hugh Beaver, which was appointed last July, had lost no time and intended to present an interim report shortly—within a few weeks.

Infant Mortality in British Guiana

Mr. O. LYTTELTON, Secretary of State for the Colonies, published a reply on October 21 giving the infant mortality rates in British Guiana for the years 1945-52. These were (per 1,000 live births): 1945, 101; 1946, 87; 1947, 87; 1948, 78; 1949, 77; 1950, 86; 1951, 77; 1952, 82.

In 1946, he stated, the expectation of life was calculated at 49 years for males and 52 for females. Since then there had been a downward trend in death rates, and an approximate calculation for 1952 gave an increase of four years.

Consumption of Milk

Dr. CHARLES HILL, Parliamentary Secretary, Ministry of Food, stated on October 21 that the average weekly consumption of milk per person in the first six months of this year was 4.65 pints. The corresponding figures for 1952 and 1951 were 4.73 and 4.83 pints respectively. The total consumption of full-price liquid milk by the public last August was about 108 million gallons, compared with 110 millions in 1952 and 112 millions in 1951.

Vital Statistics

Poliomyelitis

Poliomyelitis notifications (uncorrected) in the week ending October 17 (41st week of the year) were as follows: paralytic, 81 (107); non-paralytic, 45 (69); total, 126 (176). This is a decrease of 50 compared with the previous week, the figures for which are in parentheses. The seasonal fall seems now to be well under way.

Week Ending October 17

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,062, whooping-cough 2,096, diphtheria 20, measles 742, dysentery 232, and paratyphoid fever 11.

Infectious Diseases

Only small variations were recorded in the returns of infectious diseases in England and Wales during the week ending October 10. The largest were increases of 103 for whooping-cough, from 2,292 to 2,395, 70 for measles, from 621 to 691, and 55 for dysentery, from 212 to 267.

986 cases of scarlet fever were notified, 6 fewer than in the preceding week, and no variations of any size were reported in the local trends. The largest fluctuation in the returns of whooping-cough was a fall of 38 in Warwickshire, from 140 to 102. The largest rise in the number of notifications of measles was 39 in Lancashire, from 128 to 167. 24 cases of diphtheria were notified during the week, and these were 4 fewer than in the preceding week. The largest fluctuation in the local returns of diphtheria was a fall from 7 to 3 in Staffordshire.

The downward trend of the notifications of acute poliomyelitis was interrupted by a rise of 19 during the week. 176 cases were notified, and these were 28 more for paralytic and 9 fewer for non-paralytic cases than in the preceding week. The chief centres of infection were Lancashire 20 (Blackpool C.B. 5, Liverpool C.B. 4), London 14 (Lewisham 4, Woolwich 3), Somersetshire 14 (Clevedon U.D. 3, Long Ashton R.D. 3), Warwickshire 12 (Birmingham C.B. 4, Coventry C.B. 3), and Dorsetshire 11 (Blandford Forum M.B. 3, Wimborne and Cranborne R.D. 3).

The largest returns of dysentery were London 43 (Lewisham 9), Yorkshire North Riding 38 (Middlesbrough C.B. 38), Northumberland 26 (Gosforth U.D. 24), Lancashire 23 (Liverpool C.B. 10), Yorkshire West Riding 18, Middlesex 16, and Warwickshire 16 (Birmingham C.B. 10).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 10 (No. 40) and corresponding week 1952.

CASES in Countries and London	1953					1952

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Scientific Exhibition at Glasgow.—The Annual Meeting of the B.M.A. will be held in Glasgow next year, and arrangements are already being made to hold the Scientific Exhibition from July 5 to 9. The exhibitions at Dublin in 1952 and at Cardiff this year proved most popular, and it is intended that the exhibition at Glasgow should cover a wide field of medical practice and research. Any doctor, hospital, or medical school wishing to provide an exhibit should apply for a stand as soon as possible. The last date for receiving applications is December 31, 1953. Those who would like further details or application forms should write to the Secretary, B.M.A. House, Tavistock Square, London, W.C.1.

Synthesis of Oxytocin.—In a letter to the *Journal of the American Chemical Society* (October 5, p. 4879) workers from Cornell University Medical College, New York, claim to have synthesized oxytocin, the principal uterine-contracting and milk-ejecting hormone of the posterior pituitary. If their claims are confirmed this will be the first synthesis of a polypeptide hormone. The synthetic product has been shown to be active in both stimulating labour and inducing milk ejection in women. A dose of 1 γ intravenously caused milk ejection in 20-30 seconds.

Commission on Divine Healing.—The Archbishops of Canterbury and York have appointed a commission composed mostly of clergymen and doctors to consider "the theological, medical, psychological, and pastoral aspects of 'Divine Healing.'" The commission is asked to provide, in two or three years' time, a report "to guide the Church to clearer understanding of the subject; and in particular to help the clergy in the exercise of the ministry of healing and to encourage increasing understanding and co-operation between them and the medical profession." The medical members of the commission are Dr. J. A. Hadfield, Dr. R. A. Henson, Dr. R. Cove-Smith, Professor Alan Moncrieff, Sir James Paterson Ross, Dr. Denis Brinton, and Dr. D. Stafford-Clark. All communications to the Commission should be addressed to the Secretary, Lambeth Palace, London, S.E.1.

Society of Medical Officers of Health.—The presence of the Minister of Education, Miss Florence Horsbrugh, as guest of honour at the annual dinner of the Society of Medical Officers of Health on October 22 emphasized the importance of the school medical service. Referring to the period when she was Parliamentary Secretary of the Ministry of Health in 1939, Miss Horsbrugh said that she was very glad that the Chief Medical Officer of that Ministry was also Chief Medical Officer of the Ministry of Education. She was also pleased to note that that example was being followed throughout the country; less than a dozen authorities now had two medical officers, one for health and one for schools. In the school dental service there were now the equivalent of 928 full-time dentists, the highest number ever in that service. The President of the Society, Dr. C. Metcalfe Brown, also touched on the school medical service. He said that he deplored the tendency to depend upon the consultants of the regional hospital board, and he considered that these consultants should in fact be members of the school health services. The child's health could be achieved only by a team—the parents, teachers, school medical officers, and consultants. Dr. Metcalfe Brown also referred to health visits. He said that the infant mortality rate of an area was inversely proportional to the efficiency of the health visit service, and he wanted to point out that others had found the same. The health of the guests was proposed by Dr. George Buchan, and Sir George Mowbray and Mr. Arnold Walker made brief replies.

Pneumoconiosis Field Research.—The Coal Board began this month a 10-year field investigation into the prevention of pneumoconiosis among miners. The objects are to discover what level of dustiness is safe for a miner who may spend his whole working life in the pits, and also whether the nature of the dust, such as its silica content, affects the safety level. It is also hoped to gain some idea of the true prevalence and rate of progression of pneumoconiosis in Britain. Twenty-four pits, with widely varying physical characteristics, have been chosen as representative and will be studied by scientists and doctors. Two medical teams, based on Edinburgh and Cardiff, are to carry out radiological surveys of the miners in these pits every two years, and their results will be correlated with the prevailing conditions of dustiness. The scheme is being directed by Dr. J. M. Rogan, C.M.O. of the Coal Board, and the scientific adviser is Dr. A. Cochran, of the Medical Research Council's Pneumoconiosis Research Unit.

Jenner Medal.—At the recent joint meeting of the Epidemiology Section of the Royal Society of Medicine and the Society of Medical Officers of Health (see p. 991) Sir Francis Walshe, F.R.S., president of the Royal Society of Medicine, presented the Jenner Medal to Mr. A. T. Glenny, F.R.S., for his notable work on diphtheria prophylaxis while a member of the research staff of Messrs. Burroughs Wellcome & Co. Mr. Glenny's experimental work prepared the way for the successful use of alum-precipitated toxoid in man. The Jenner Medal was founded in 1896 by the Epidemiological Society of London, and it has been awarded only 12 times.

Operations on the Frontal Lobes.—The Rockefeller Foundation has made a grant of £7,800 to London University for a three-year study of the psychological effects of frontal lobe operations. The study is being directed by Professor H. J. Eysenck, of the Institute of Psychiatry, who for the last 12 years has been working on the development of objective methods of measuring the personality. Other Rockefeller grants this quarter go to the Universities of Manchester (\$45,000 for research on the chemistry of biologically important materials), Cambridge (\$25,000 for equipment for the school of biochemistry), and Oxford (\$7,500 for equipment for work directed by Sir Howard Florey, F.R.S.).

Leverhulme Research Fellowships, 1954.—Application is invited for Fellowships and grants in aid of research. These awards are intended for senior workers prevented by routine duties from carrying out research. They are limited to British-born subjects normally resident in the United Kingdom, but in exceptional circumstances the condition as to residence may be waived. Applications from groups of workers engaged upon co-operative programmes of research (particularly if long-term) will also be considered. The duration of the awards will not normally extend over more than two years or less than three months, and the amount will depend on the nature of the research and the circumstances of the applicant. Forms of application may be obtained from the Secretary, Miss M. Branney, Leverhulme Research Fellowships, 3-5, Salisbury Square, London, E.C.4. The last date for applications is December 31, 1953. Awards will be announced in May and will date from September 1, 1954.

New Warning System for E.B.S.—The London Emergency Bed Service has modified its warning system to hospitals so as to make it a more sensitive index of the difficulty of obtaining beds. In calculating the rate (percentage of applicants admitted) no account will be taken in future of cases admitted through the medical referee. It is expected that this will result in the warnings being both issued earlier and cancelled later than in the past. A white warning will be sent out when the admission rate as now calculated falls to 85%, a yellow warning when it reaches 80%, and a red at 75%. In addition, at the request of the Ministry of Health, the white warning may be given even earlier still if there is reason to suppose that a serious epidemic is developing.

A Doctors' Orchestra.—Dr. H. Ucko's appeal for music-loving members of the medical and dental professions in London to join him in forming an orchestra (*Journal*, September 26, p. 727) has been successful, and the orchestra had its first rehearsal last week. At present it consists of 53 players—21 violins, 3 violas, 10 celli, 1 double bass, 2 flutes, 4 oboes, 6 clarinets, 1 bassoon, 2 horns, 1 trumpet, 1 trombone, and one player of tympani. More players are wanted in every category. Rehearsals will be held weekly on Thursdays, and anyone interested should communicate with Dr. Ucko at 14, Upper Wimpole Street, London, W.1.

Royal College of Physicians of Ireland.—On October 19 Dr. Edward T. Freeman was elected President of the College and Dr. J. A. Wallace Vice-President.

Dangerous Drugs.—On November 1 N-allylnormorphine will come within the provisions of Part III of the Dangerous Drugs Act, 1951.

Drawing Conventions for Laboratory Apparatus.—The British Standards Institution has circulated a draft British Standard for Drawing Conventions for Laboratory Apparatus. The last date for the receipt of comments (which should be sent to the British Standards Institution, 2, Park Street, London, W.1) is December 1.

Family Doctor.—The November issue of *Family Doctor* is now available. It contains articles on the interpretation of dreams (Dr. T. Traherne), pneumoconiosis, chiropody as a career, alcoholism (Dr. G. K. Selborne), and the infectious diseases of childhood (Dr. T. Anderson). Topical subjects discussed are the prevention of draughts and feeding the family in winter (Dr. A. Porter).

COMING EVENTS

College of General Practitioners.—The first annual general meeting of the College of General Practitioners will be held on Saturday, November 14, at 2 p.m., in the Great Hall, B.M.A. House, Tavistock Square, London, W.C.1. Foundation Membership and Associateship will close on that day. The agenda for this meeting and the first annual report of the College were dispatched to all members and associates on October 23. Will anyone who has not received them please communicate with the secretary?

Contraceptive Technique.—A lecture and demonstration will be given by Dr. Marie Stopes, Ph.D., at the Mothers' Clinic, 108, Whitfield Street, London, W.1, on November 5, at 2.30 p.m. Admission free, but tickets must be obtained in advance.

Smoke and "Smog."—An exhibition on smoke and "smog" will be open from November 9 to December 5 from 10 a.m. to 5 p.m. on Mondays to Fridays, and from 10 a.m. to 12 noon on Saturdays, at the Museum of Hygiene of the Royal Sanitary Institute, 90, Buckingham Palace Road, London, S.W.1. Admission free.

The British Association of Sport and Medicine.—A meeting will be held at 5 p.m. on November 11 in the Meyerstein Theatre of the Westminster Hospital Medical School, Horseferry Road, London, S.W.1. Dr. H. N. Bleasdale will speak on "The Health and Minor Maladies of Swimmers and Divers," and Dr. Michael Ward on "Some Medical Aspects of the Everest Expedition, 1953."

Empire Rheumatism Council.—The guest speakers at the symposium on "butazolidin" on November 13 (see *Journal*, August 15, 1953, p. 403) will be Dr. Otto Steinbrocker, of New York, and Professor Domenjos, of the University of Saarbrücken.

The London Medical Exhibition will be held in the new hall of the Royal Horticultural Society, Greycoat Street, London, S.W.1, from November 16 to 20. It will be open daily from 11 a.m. to 6.30 p.m. Lord Horder will perform the opening ceremony at 11.30 a.m. on November 16.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Friday, October 30

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., clinical meeting for general practitioners. Mr. C. Gill-Carey: The Common Cold.

Monday, November 2

INSTITUTE OF PSYCHIATRY.—5.30 p.m., Dr. E. Stengel: lecture-demonstration.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. William Evans: The Electrocardiogram in Cardiac Pain.

ROYAL EYE HOSPITAL.—5.30 p.m., Miss J. M. Dollar: Management of Diseases of the Uveal Tract.

Tuesday, November 3

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor E. C. Amoroso: Biology of the Foetal Membranes and the Placenta.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Viral Diseases of the Skin.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Arris and Gale Lecture by Mr. H. A. Haxton: Sympathetic Supply of the Upper Limb.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. M. H. E. Hulbert and Dr. W. M. Levitt: X-ray Therapy in Gynaecology.

WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Dr. C. C. Edwards: neurological demonstration.

Wednesday, November 4

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Viral Diseases of the Skin.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. R. C. Higham: Enuresis.

MANCHESTER MEDICAL SOCIETY: SECTION OF MEDICINE.—At Medical School, Manchester University, 4.30 p.m., address by Dr. Denis Williams.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Dr. J. C. Gilson: Is Coal Dust Harmful to Man?

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—7.30 p.m., Mr. T. C. Denison, B.Pharm., Ph.C., F.R.I.C.: General Survey of the *British Pharmacopoeia*, 1953.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. F. V. Flynn: Na and K Metabolism.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Lord Amulree: Geriatrics.

SOCIETY OF APOTHECARIES OF LONDON.—4 p.m., Mr. J. B. Harman: Management of Inoperable Malignant Disease; 5.15 p.m., Dr. F. P. Lee Lander: Asthma and its Treatment.

Thursday, November 5

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. P. M. F. Bishop: Physiological Action of Sex Hormones.

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—At Glasgow University Union, 7.30 p.m., Dr. D. K. Adams: Food in Relation to Health and Disease.

● INSTITUTE OF CHILD HEALTH AND INSTITUTE OF NEUROLOGY.—At National Hospital, Queen Square, W.C., 5.30 p.m., Dr. E. A. Carmichael: Hemiplegia: Clinical Types, Diagnosis and Treatment.

● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Queen Charlotte's Hospital, 3.30 p.m., Professor A. M. Clay: The Forceps in Present-day Practice.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Symposium to be opened by Mr. A. Sutcliffe Kerr: Management of Paraplegia.

LONDON UNIVERSITY.—At Royal Society of Medicine, 5 p.m., Semon Lecture by Professor F. C. Ormerod: The Management of Cancer of the Larynx.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.—At Royal Society of Medicine, 2.15 p.m., 28th Maudsley Lecture by Earl Jowitt: Medicine and the Law.

ROYAL SOCIETY.—4.30 p.m., The Lecuwenhoek Lecture by Dr. K. M. Smith, D.Sc., F.R.S.: Some Aspects of the Behaviour of Certain Viruses in their Hosts and of their Development in the Cell.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor J. Glaister: Some Medico-Legal Trifles.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. Denis Williams: neurology demonstration.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—4.30 p.m., demonstration of clinical cases; 5.15 p.m., discussion of clinical cases.

Friday, November 6

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. B. F. Russell: Pyogenic Infections.

● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor W. Melville Arnott: Peripheral Vascular Disease.

ROYAL EYE HOSPITAL.—4.30 p.m., Mr. A. J. Cameron: Recent Advances in Retinal Detachment Surgery.

Saturday, November 7

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—11.30 a.m., Professor E. Luscher (Basle): Physical Factors in Ear, Nose, and Throat Diseases.

● INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Hammersmith Hospital, 12 noon, Mr. J. A. Stallworthy: Genital Tuberculosis.

MIDLAND TUBERCULOSIS SOCIETY.—3 p.m., Professor J. McMichael: Pulmonary Heart Disease.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Barter.—On October 23, 1953, at Queen Charlotte's Hospital, London, W., to Marjorie (formerly Stavely), wife of Dr. Antony P. Barter, a daughter—Suzanne.

Fisher.—On October 22, 1953, at the Royal Maternity Hospital, Belfast, to Sheila, wife of Oliver D. Fisher, M.D., M.R.C.P., a daughter—Amanda Jane.

Solomons.—On October 2, 1953, in Dublin, to Joan (formerly Maitland), wife of Michael Solomons, M.R.C.O.G., a son.

Stok.—On October 13, 1953, at Liverpool Maternity Hospital, to Pauline (formerly Jones), wife of Dr. E. Theodor Stok, a son.

Swan.—On September 12, 1953, at the Civil Hospital, Aden, South-West Arabia, to Veronica (formerly Donnelly), wife of Thurloc Swan, M.Ch., F.R.C.S.I., a daughter—Oonagh Mary.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Exchange Resins for Peptic Ulcer

Q.—What is the consensus on the status of anion exchange resins in the medical management of peptic ulcer? Which resin or type of resin is believed to be best, and in what dosage? Are there any toxic possibilities or contraindications?

A.—Anion exchange resins are large insoluble bases with the capacity to absorb the anion of an acid forming an insoluble resin salt; and in the alkaline small intestine the anion exchange is reversed. Amberlite 1 R-4 (particle size 200 mesh), a polyethylene polyamine substituted resin of diphenylol dimethyl methane and formaldehyde in basic form, has been used for the treatment of peptic ulcer, and up to 28 g. by mouth daily has been used without causing untoward effects.¹ The neutralizing efficiency is not impressive, comparable effects being obtained by 0.6 g. aluminium hydroxide and 3.2 g. of Amberlite 1 R-4, and there is evidence that it is in no way superior to other antacids. No definite ill effects have been noted, and constipation does not develop during its administration. Spears and Pfeiffer² found that all but one of a group of 30 patients experienced relief from pain, but this, however, was not synonymous with healing, and in some cases recurrence or complications occurred during treatment. Wirts, Sullivan, and Hammerly³ found that the effect of resin for duodenal ulcer was comparable to that of aluminium hydroxide gel, but did not notably surpass it. Similarly, Segal *et al.*⁴ achieved 65% clinical remission with chronic recurrent duodenal ulcer, but failed to get assistance in the more serious and protracted cases. On the whole, there seems remarkably little justification for its use in peptic ulcer.

Liquid Paraffin and Cancer of Bowel

Q.—What is the origin of the view that the continued use of liquid paraffin may cause cancer of the bowel? It crops up from time to time and is invariably denied in the medical journals.

A.—The belief that the long-continued use of liquid paraffin by the mouth as an aperient conduces to cancer of the intestine has no doubt been encouraged by, if it did not arise from, the most unfortunate term "paraffin cancer" applied to occupational cancers of the skin occurring in workers exposed to shale oil, petroleum, or products derived from them. "Aniline cancer" is another most misleading title.

The word "paraffin" has at least two meanings: in chemistry it is a quite exact term denoting a class of compound of the general formula C_nH_{2n+2} ; while in everyday life and in commerce it may be applied to a variety of mineral oils, especially to those used for heating and lighting, which may consist to a large but not to a specific extent of paraffins conforming to the chemical definition.

One may perhaps take some data, which are still relevant, from a paper published many years ago "On the Cancer-producing Factor in Tar" by E. L. Kennaway.¹ In the lignite tar and shale oil industries the workmen who have most to do with the most concentrated forms of chemical

paraffins are the least liable to affections of the skin. High-temperature coal tar, which, together with its pitch, produces far more cases of industrial cancer than do all other materials put together, is especially poor in paraffins, and contains less of them than does non-carcinogenic blast-furnace tar. The petroleum of Pennsylvania, Canada, Galicia, and Rumania contain especially large amounts (up to 85%) of chemical paraffins, but are not distinguished by producing many cases of petroleum cancer. Prosser White² says, "The writer has watched women and girls employed all their working hours, year after year, bedaubed with refined paraffin wax free from impurities, none of whom have ever experienced the least trace of inconvenience or distress."

So far as the writer knows, there is no evidence that the medicinal "liquid paraffin" taken by mouth has any carcinogenic action upon the alimentary tract or upon any other organs. The proverbial difficulty of proving a negative of course presents itself here. Anyone interested in this question could tabulate the deaths from cancer of various parts of the intestine given in the annual *Statistical Reviews* of the Registrar-General, and the standardized death rate given from time to time in these publications, beginning at the time when the ingestion of liquid paraffin became common. Possibly this date was somewhere about 1910, when "intestinal stasis" was very generally discussed and was alleged to be the cause of at least one common form of cancer. But no doubt the records of pharmaceutical firms would give the information required. If we have no data showing a direct carcinogenic action of paraffins upon the alimentary tract, we have no more, so far as I know, indicating any indirect action of this kind due to interference with the absorption of fat-soluble substances.

The name "paraffin" does not occur among the immense number of compounds named in Hartwell's *Survey of Compounds which have been Tested for Carcinogenic Activity*.³

Prevention of Amoebic Dysentery

Q.—Is the chemoprophylaxis of amoebic dysentery a practicable procedure? If so, what drugs are recommended, and are there any dangers?

A.—The chemoprophylaxis of amoebic dysentery is not a practicable procedure. If normal hygienic precautions in relation to food and drink are adopted, the risk of contracting amoebic dysentery is remote, and it is by such measures that infection should be avoided. Even if they had an effective prophylactic action, which is doubtful, amoebicidal drugs are not suitable for indefinitely repeated administration.

Antiseptics for Surgical Theatres

Q.—What antiseptics are recommended for (a) the storage of previously sterilized sharp instruments so that they can be used at a moment's notice; (b) the washing of basins, trolleys, and operating theatre floors? Do antiseptics have any advantages over soap or detergent and water for the latter purposes?

A.—(a) Liquor boracis et formaldehydi (borax 1.5 g., solution of formaldehyde 2.5 ml., phenol 0.4 g., water to 100 ml.) is effective. It is completely bactericidal (sporicidal effect included) and non-rusting. Instruments placed in it require rinsing in sterile water before use, and irritating vapour from it may be a drawback. Spirit, commonly used for this purpose, is at least theoretically unsatisfactory because it is not completely bactericidal; it may even contain living bacterial spores.

(b) Operating theatre furniture and floors which have been contaminated with septic material should be swabbed with a strong phenolic disinfectant such as 5% phenol or 2% lysol; this should be given 15 minutes to act before being

washed off. Unless any such specific contamination has occurred the use of disinfectants has no advantage over washing with soap and water. The practice of adding small quantities of odoriferous disinfectants to water used for washing is wasteful and useless; the amount required to produce an antiseptic smell is only a small fraction of that which would be necessary actually to disinfect.

Milk for Tuberculous Patients

Q.—I should be pleased to know the modern opinion regarding the value of milk for tuberculous cases. Is it given because it is an easily assimilable type of food, because of its relevantly high calcium content, or is it a medical fashion which has continued without any really sound therapeutic basis?

A.—The value of milk for tuberculous patients lies in the fact that it is a well-balanced food which is easily assimilated. It is of most value to the really ill patient, who may be able to take it more easily than an equivalent amount of solid food. During the rationing period, when protein foods suffered the greatest reductions, the allowance of two pints (1.1 litres) of milk daily to tuberculous patients was a wise provision, and until meat rationing is abolished patients with active pulmonary tuberculosis should be encouraged to take this amount of milk. On the other hand, if milk forms too large a part of the diet it is expensive and often indigestible, so that patients should be made aware that it possesses no specific virtues as a food in pulmonary tuberculosis.

Indrawn Nipples in Children

Q.—One of my daughters aged 9—healthy in every way—is showing signs of developing indrawn nipples. Is there any way of preventing this as she grows older?

A.—It is probably impossible to assess the situation accurately at such a young age, and post-pubertal development of the breasts may well alter the picture. In any case, nothing useful can be done now, and any attempt at treatment might well have unfortunate psychological effects on the girl; the condition should not even be brought to her notice. The question of treatment should be deferred until she is adult, and, in the writer's view, until she is pregnant.

NOTES AND COMMENTS

Corrections.—In the article by Mr. Patrick Clarkson and Mr. D. A. Campbell Reid entitled "Use of the Electrodermatome, with Special Reference to its Value in Serious Burns" (October 3, p. 763) the name Padgett in the first paragraph was wrongly spelt Paget. There was also a misprint in the description of the instrument. The current required to operate the instrument is 110 volts, not 10 volts as stated.

Mr. N. J. Ainsworth asks us to correct a statement in his appreciation of the late Mr. J. H. Badcock (*Journal*, October 24, p. 943). Mr. Badcock was not "the last remaining member of that group of great dental surgeons and teachers . . ." but only one of the last of the remaining members of that group, of which happily there are some still alive and well.

Sir Ewen Maclean was mistakenly said in our last issue (p. 941) to have provided the only instance of a Chairman of the Representative Body becoming President. Sir Henry Souttar held both these offices, and he has the distinction of also being an ex-Chairman of Council.

ISONIAZID IN COMBINATION WITH STREPTOMYCIN OR WITH P.A.S. IN THE TREATMENT OF PULMONARY TUBERCULOSIS

FIFTH REPORT TO THE MEDICAL RESEARCH COUNCIL BY THEIR TUBERCULOSIS CHEMOTHERAPY TRIALS COMMITTEE*

The Medical Research Council trial of isonicotinic acid hydrazide (isoniazid) in the treatment of pulmonary tuberculosis has been in progress since March, 1952; reports comparing clinical and bacteriological findings in patients treated with streptomycin plus P.A.S., isoniazid alone, and streptomycin plus isoniazid, and a report on bacteriological techniques, have already been published (Medical Research Council, 1952, 1953a, 1953b, 1953c). The present report compares the effects of two combinations of drugs—streptomycin plus isoniazid and P.A.S. plus isoniazid—on a total of 391 patients after three months' treatment in 50 hospitals. A list of the hospitals, and the names of the co-operating clinicians, bacteriologists, and pathologists, are given at the end of the report. The trial was co-ordinated by the late Dr. Marc Daniels and by Dr. Wallace Fox, of the Council's Tuberculosis Research Unit; Dr. Fox and Dr. Ian Sutherland (of the Council's Statistical Research Unit) analysed the present results and prepared the report. Radiological assessments were made by Dr. L. G. Blair. The isoniazid used throughout the trial has been supplied as "nydrazid" by E. R. Squibb and Sons.

I. PLAN AND CONDUCT OF THE TRIAL

The plan and conduct of the trial are only briefly referred to here, as they have been described in detail in the first two reports (Medical Research Council, 1952, 1953a).

1. Type of Case

Certain basic requirements were laid down for all cases accepted into the trial. At the start of treatment: (a) Tubercle bacilli must have been demonstrated, either in a direct smear from a sputum specimen taken within the previous two weeks or in a culture derived from a specimen taken not more than two months previously. (b) The tubercle bacilli must not, so far as is known, be streptomycin-resistant or P.A.S.-resistant. (c) The patient must not have had more than 15 g. streptomycin or 300 g. P.A.S. (sodium salt) within the previous three months, and not more than 3 g. isoniazid at any time. (d) The patient must not be undergoing pneumoperitoneum, nor have any form of collapse therapy for the lung requiring treatment.

*Members of the Committee: Sir Geoffrey Marshall (chairman), Professor J. W. Crofton, Professor R. Cruickshank, Dr. J. E. Geddes, Professor F. R. G. Heaf, Professor A. Bradford Hill, Dr. J. V. Hurford, Dr. D. A. Mitchison, Dr. W. D. M. Paton, Dr. J. G. Scadding, Dr. Norman Smith, Dr. P. D'Arcy Hart (secretary).

Cases satisfying the above requirements were admitted to the trial in one of three main disease groups: (1) acute rapidly progressive pulmonary tuberculosis believed to be of recent origin; (2) other forms of pulmonary tuberculosis considered suitable for chemotherapy; (3) chronic forms of pulmonary tuberculosis expected to make only a limited response to streptomycin plus P.A.S.

Group 1 cases were selected by a central panel of clinicians; cases in Groups 2 and 3 were, in the main, selected by the clinicians in the co-operating hospitals from the patients already under their care.

2. Treatment

When a patient has been accepted for the trial, treatment is allocated by the Tuberculosis Research Unit from confidentially held prearranged lists based upon random sampling numbers.

After admission to the trial and a preliminary week of investigation, all patients are kept under observation for six months. During the first three months the prescribed treatment is followed for every patient. During the second three months Group 3 patients continue on the same combination of drugs. For other patients the clinician is free to undertake any treatment he wishes.

In the present phase of the trial, which started on September 5, 1952, four treatments are being studied—namely:

SH: Streptomycin 1 g. daily, in one intramuscular injection, plus isoniazid 200 mg. daily, in two equal doses by mouth.

S2H: Streptomycin 1 g., in one intramuscular injection, twice a week, plus isoniazid 200 mg. daily, in two equal doses by mouth.

20 PH: P.A.S. (sodium salt) 20 g. daily, in four equal doses by mouth, plus isoniazid 200 mg. daily, in two equal doses by mouth.

10 PH: P.A.S. (sodium salt) 10 g. daily, in two equal doses by mouth, plus isoniazid 200 mg. daily, in two equal doses by mouth.

In one important disease subgroup (1A—acute rapidly progressive bilateral pulmonary tuberculosis of recent origin, in patients between the ages of 15 and 30) patients have been allocated only to the SH and 20 PH series. Every other patient has been allocated at random to one of the four treatment series.

The present report analyses the results after three months' treatment for 391 patients admitted to the trial

between September 5, 1952, and March 31, 1953. Over 200 more patients were admitted to the same four treatments between April 1 and July 31, 1953, when admissions to the trial were discontinued; the three-month results for these latter patients are not yet complete. It should also be noted that the results for the 142 SH patients previously reported (Medical Research Council, 1953a) do not appear in the present analysis because they formed part of an earlier comparison.

3. Number of Patients in the Present Analysis

Prior to exclusions, 125 patients were allocated to the SH treatment, 104 to S2H, 121 to 20 PH, and 82 to 10 PH. The larger totals in the SH and 20 PH series are accounted for by patients in subgroup 1A. The number of patients allocated to the S2H series is not intentionally larger than the number in the 10 PH series; the difference has arisen by chance as a result of the operation of random allocation in the 50 hospitals.

Forty-one patients were excluded from the analysis of the results for the following reasons:

- (i) Five patients were excluded before treatment was started:
 - 1 died before admission to hospital (20 PH);
 - 1 was too ill to be moved to hospital (S2H);
 - 2 discharged themselves against medical advice (2 20 PH);
 - 1, although admitted, did not start treatment, because no positive sputum was obtained (SH).
- (ii) Thirty-six patients were excluded after treatment had begun:
 - 2 were found to have had organisms resistant to streptomycin at the start of treatment (2 SH);
 - 4 were found to have had organisms resistant to P.A.S. at the start of treatment (3 20 PH, 1 10 PH);
 - 6 were found to have had excessive recent chemotherapy (1 S2H, 4 20 PH, 1 10 PH);
 - 1 was given the wrong treatment (20 PH);
 - 11 discharged themselves against medical advice—6 in the first and 5 in the second month (1 SH, 2 S2H, 2 20 PH, 6 10 PH);
 - 2 were transferred to other hospitals in the first month for investigations of non-pulmonary complaints (1 20 PH, 1 10 PH);
 - 1 was transferred to a mental hospital with a psychosis, in the second month (10 PH);
 - 3 had severe toxic reactions attributed to P.A.S. (3 20 PH);
 - 2 stopped treatment in the second month, one because of acute nephritis, the other because of persistent haemoptysis believed to be related to treatment (2 SH);
 - 2 had a change of treatment in the first month: for one 10 PH patient streptomycin was added after eight days, and the dosage of P.A.S. was doubled, because of the serious clinical condition; this case can scarcely be considered a failure of the prescribed chemotherapy; in one 20 PH patient streptomycin was added after 18 days because of radiographic deterioration; this patient had

1-minus deterioration at one month, and the deterioration at three months was still classed as 1-minus; despite the short period of treatment, this may represent a failure of the prescribed chemotherapy;

2 had a change of treatment in the second month (2 20 PH): one patient had deteriorated both clinically and radiographically and the treatment was changed to SH at six weeks; at ten weeks a radiograph showed 1-plus improvement compared with the condition on admission; the other patient deteriorated radiographically and streptomycin was added at six weeks, but there was 2-minus deterioration at three months.

Thus in the present series only 3 patients were removed from the trial because of drug toxicity; all were receiving 20 PH and were intolerant to the P.A.S. In 2 more (2 SH) drug toxicity could not be excluded as the cause of acute nephritis in one and persistent haemoptysis in the other, although in the latter patient the same chemotherapy was resumed after an interruption of five weeks without a recurrence of the haemoptysis.

Of the 4 patients in whom treatment was changed, 2, and possibly a third, all on 20 PH, might be classed as failures of treatment. On the other hand, it must be remembered that the combination P.A.S. plus isoniazid was a new treatment; it would be a natural inclination for clinicians to resort to a combination containing streptomycin for patients who deteriorated.

4. Plan of the Present Report

After the exclusions detailed above, the numbers remaining in the clinical analysis are 119 SH, 100 S2H, 101 20 PH, and 71 10 PH patients. The numbers in each disease group are set out in Table I. It should be noted, first, that in contrast to the earlier reports on the trial the total of very chronic patients (Group 3) is small and that the proportion of patients admitted to the trial who were suffering from acute forms of the disease has been higher in recent months than in earlier stages. Secondly, since patients in subgroup 1A (acute bilateral disease in young adults) were admitted only to the SH and 20 PH treatment series, a valid comparison of the relative clinical efficacy of all four treatments SH, S2H, 20 PH, and 10 PH can be made only after excluding the patients in subgroup 1A. When this is done, the clinical results of the four treatments are at present very similar, although the numbers of patients are too small for firm conclusions to be reached. A full comparison of the four treatments will be made when results on a larger number of patients are available.

In this report two comparisons are made. First, the clinical progress of patients on the SH and 20 PH treatments is compared, and for this purpose the 70 patients in sub-

TABLE I.—Number of Patients Admitted to the SH, S2H, 20 PH, and 10 PH Treatments from September 5, 1952, to March 31, 1953 (after exclusions)

	Treatment				All Patients
	SH	S2H	20 PH	10 PH	
	Streptomycin 1 g. Daily Plus Isoniazid 200 mg. Daily	Streptomycin 1 g. Twice a Week Plus Isoniazid 200 mg. Daily	P.A.S. (Sodium) 20 g. Daily Plus Isoniazid 200 mg. Daily	P.A.S. (Sodium) 10 g. Daily Plus Isoniazid 200 mg. Daily	
Group 1: Acute rapidly progressive pulmonary tuberculosis of recent origin	39	25	31	23	70
Group 2: Other forms of pulmonary tuberculosis suitable for chemotherapy	52	67	45	44	208
Group 3: Chronic forms of pulmonary tuberculosis expected to make only a limited response to chemotherapy	3	8	8	4	23
All patients	119	100	101	71	391

group 1A are included, but the 11 Group 3 patients are omitted because of their small number and unequal distribution between the two treatments; this leaves 116 SH patients and 93 20 PH patients. The results are presented in Section A of Tables II-VII. Secondly, a supplementary comparison of streptomycin plus isoniazid and P.A.S. plus isoniazid on a large number of patients is made by combining all the SH and S2H patients, numbering 219, and comparing their progress with that of all the 20 PH and 10 PH patients, numbering 172. Group 3 patients have been retained in this broad comparison, the results of which appear in Section B of Tables II-VII.

II. CLINICAL PROGRESS

1. Condition on Admission

The treatment which patients had received before entering the trial was analysed. Eight patients on SH (7%), 8 on S2H (8%), 6 on 20 PH (6%), and 3 on 10 PH (4%) had already received one or more courses of chemotherapy, but not within the preceding three months. For the patients in Groups 1 and 2 combined, the figures for the four treatments are 7 (6%), 4 (4%), 2 (2%), and 2 (3%), respectively. Thus most of the patients in the present analysis were receiving their first course of chemotherapy in this trial. Most were also newly diagnosed cases.

Table II shows the condition of patients before the start of treatment as reflected by their general condition (assessment by the clinician in charge), temperature, erythrocyte sedimentation rate (E.S.R. Westergren 200 mm. reading at one hour), and the extent of cavitation on a full-plate radiograph (as estimated by an independent radiological assessor, unaware of the treatment series of any patient). It can be seen that, judging by the factors listed, the SH and 20 PH patients (Section A of the Table) had a broadly similar distribution of severe and less severe illness, but that, particularly in Group 2, the SH patients appear to have been, on the average, rather less ill than the 20 PH patients. This possible disadvantage to the 20 PH treatment must be borne in mind in assessing the results. The patients in the SH and S2H series combined (Section B of the Table) had a distribution of severe and less severe illness similar to that of the 20 PH and 10 PH patients.

2. Mortality

There were two deaths among the 391 patients (0.5%) during the three months of treatment—one in an SH patient, the other in a 20 PH patient. The SH patient (in Group 1) died towards the end of the third month with renal failure secondary to acute nephritis, confirmed at post-mortem examination. This patient had slight clinical and radiographic deterioration at one month and showed further clinical and radiographic deterioration at the end of two months. The nephritis was diagnosed in the third month. The 20 PH patient (in subgroup 1A) rapidly deteriorated, and treatment was stopped after 20 days because the patient was incapable of swallowing; she died 10 days later.

3. Toxicity

Apart from the 3 exclusions due to P.A.S. toxicity, and the 2 doubtful toxic reactions described above, there is nothing new to report on toxicity. With the dosage used (200 mg. daily), there continues to be no evidence of serious toxicity from isoniazid therapy over a three-month period of administration. In one 20 PH patient treatment was stopped after 10 weeks because the leucocyte count fell progressively from 4,400 per c.mm. to 1,800 per c.mm., although the differential count remained normal. It was considered undesirable to continue chemotherapy, but the patient has been retained in the analysis at three months.

4. The Comparison between SH (Streptomycin 1 g. Daily Plus Isoniazid 200 mg. Daily) and 20 PH (P.A.S., Sodium Salt, 20 g. Daily Plus Isoniazid 200 mg. Daily)

General Condition.—Change in the patient's general condition was assessed by the physician in charge. Section A of Table III shows that a high percentage of patients on each treatment improved—89% of 116 SH patients and 88% of 93 20 PH patients. With each treatment there were more patients with 2-plus (considerable) improvement in Group 1 than in Group 2.

Weight Changes.—The weight changes for the three-month period are set out in Section A of Table IV. Only 6 of 113 SH patients (5%) and 9 of 90 20 PH patients (10%) failed to gain weight. A gain of 14 lb. (6.4 kg.) or more occurred in 45% of SH patients and 38% of 20 PH patients, and

* A patient was considered afebrile if every evening temperature in the pre-treatment week of investigation was below 99° F. (37.2° C.).

† Assessment on a single full-plate chest radiograph taken before treatment started. Tomograms were not taken into account.

‡ The sedimentation rate of one patient was not recorded.

the average weight gain for the former was 12.8 lb. (5.8 kg.), for the latter 10.8 lb. (4.9 kg.). These differences for Groups 1 and 2 combined do not attain statistical significance. However, in Group 1 alone, the difference in average weight gain is significant at the 1% level.

Temperature.—A patient was considered to be initially afebrile if the evening temperature was below 99° F. (37.2° C) on every day of the week of preliminary investigation. The same definition applied in the last week of the third month of treatment. Table V sets out the number of patients who were febrile in the pre-treatment week but afebrile at three months. The patients are grouped according to the initial level of pyrexia. Of 61 febrile SH patients, 79% were afebrile at three months, compared with 85% of the same number of febrile 20 PH patients. Of 54 SH patients who were afebrile in the pre-treatment week (not shown in the Table), 8, or 15%, had a low-grade pyrexia at three months (an occasional evening temperature above 99° F.). The corresponding figures for the 20 PH patients were 4 of 31, or 13%.

Sedimentation Rate.—Table VI sets out the number of patients with an initially elevated E.S.R. which was lowered to normal (10 or less) after three months' treatment. The E.S.R. was normal at the end of three months in 37% of 78 SH patients with an initial E.S.R. of 21 or more. The corresponding figures for the 20 PH series were 46% of 67 patients. The difference is not statistically significant. The E.S.R. rose from an initially normal level in 2 of 21 SH patients and 2 of 12 20 PH patients.

Radiographic Changes in the First Three Months.—Table VII sets out the radiographic changes at the end of three

months' treatment. The assessments were made at an independent reading of full-plate chest radiographs by a radiologist unaware of the treatment of any patient. In assessing improvement or deterioration three degrees were allowed in each—namely, 1-plus, 2-plus, and 3-plus, and 1-minus, 2-minus, and 3-minus. Of 116 SH patients 82% improved radiographically, compared with 76% of 93 20 PH patients. Two-plus and 3-plus improvement was more frequent under the SH treatment (54%) than the 20 PH treatment (42%). In Group 1, 23% of 64 SH patients showed 3-plus (considerable) improvement compared with 10% of 48 20 PH patients. These differences do not attain statistical significance. In all, there were two radiographic deteriorations and one death on each treatment.

Summary of the Comparison of SH with 20 PH

At the end of three months the two treatments had very similar effects on the general condition of the patient and on the temperature. The 20 PH treatment may have been slightly the more effective in lowering the E.S.R., and the SH treatment in fostering weight gain. Judging from the important assessment of radiographic response, the SH treatment appears to have been rather more effective, particularly in the cases with acute extensive disease in Group 1. The 20 PH patients were on an average more ill than the SH patients on admission to the trial (Table II), and so may have started at a disadvantage. On the other hand, it will be recalled that 3 20 PH patients, who deteriorated and had their treatment changed, were excluded from the analysis.

The x-ray films were subsequently lost.

* The assessments for one SH and one 10 PH patient were made by the clinician in charge. The x-ray films were subsequently lost.

5. The Comparison between Streptomycin Plus Isoniazid (SH and S2H) and P.A.S. Plus Isoniazid (20 PH and 10 PH)

General Condition.—Section B of Table III shows that the majority of patients—89% of 219 SH and S2H patients, and 88% of 172 20 PH and 10 PH patients—improved clinically.

Weight Changes.—Section B of Table IV shows that the average gain in weight of 214 SH and S2H patients was 13.4 lb. (6.1 kg.) and that 50% gained 14 lb. (6.4 kg.) or more. The average gain in weight for 168 20 PH and 10 PH patients was 11.6 lb. (5.3 kg.); of these patients 39% gained 14 lb. or more. The difference in average weight gain is significant at the 5% level.

Temperature.—Of 119 pyrexial SH and S2H patients 75% became afebrile, compared with 80% of 104 20 PH and 10 PH patients (Table V). Of 99 initially afebrile SH and S2H patients 11% showed a low-grade pyrexia at three months, compared with 9% of 67 20 PH and 10 PH patients.

Sedimentation Rate.—In 145 SH and S2H patients with an initial E.S.R. of 21 or more there was a fall to normal (10 or less) in 38%. For 119 20 PH and 10 PH patients the corresponding figure was 43% (Table VI). In 39 SH and S2H patients with an initially normal E.S.R. there was a rise to 11 or more at three months in 10%, compared with 7% of 27 20 PH and 10 PH patients.

Radiographic Changes in the First Three Months.—The percentages showing radiographic improvement were 77% of 219 SH and S2H patients, and 74% of 172 20 PH and 10 PH patients (Table VII). A higher proportion of the SH and S2H patients showed 2-plus and 3-plus improvement (49%) than of those on 20 PH and 10 PH (38%), the difference between these percentages being significant at the 5% level.

Summary of the Comparison of Streptomycin Plus Isoniazid With P.A.S. Plus Isoniazid

The patients on streptomycin plus isoniazid gained a little more weight and a higher proportion showed substantial radiographic improvement. In other respects the three-month results in the two treatment series are similar.

III. BACTERIOLOGY

This section presents an analysis of the bacteriological findings in those patients whose clinical progress has been reported above. The bacterial content of the sputum is studied after one, two, and three months of treatment. Evidence on the development of bacterial resistance after two and three months of treatment is presented. Resistance to

isoniazid is studied for patients under each of the four treatments, to streptomycin for SH and for S2H patients, and to P.A.S. for 20 PH and for 10 PH patients.

The procedure for taking specimens, the technique for sensitivity tests to each of the three drugs, and the definitions of resistance and sensitivity have been described in detail in previous reports (Medical Research Council, 1953a, 1953b). The examinations of bacteriological specimens and the sensitivity tests to isoniazid and to streptomycin were performed in the co-operating laboratories. The P.A.S. sensitivity tests on cultures from the 20 PH and 10 PH patients were all performed in the reference laboratory (see Acknowledgments).

The result of a bacteriological examination, or of a sensitivity test, for a given month was accepted only if it was performed on a specimen collected not more than seven days before or after the appropriate date. When more than one such result was available, the one referring to a specimen taken on or nearest to the appropriate date was selected to avoid bias. Thus in all the bacteriological tables each item represents a number of patients for each of whom a single test has been selected, and not a total of all the tests performed on a smaller number of patients.

1. Exclusions

In addition to the patients already excluded from the clinical analysis, a further 5 patients (3 SH, 1 S2H, 1 10 PH) have been excluded from the bacteriological analysis. No tubercle bacilli were seen or isolated from pre-treatment specimens for any of these patients, and although there was no doubt of the diagnosis they did not conform to the bacteriological requirements on entry to the trial. It will be recalled that 6 patients were excluded because they were found to have had bacilli resistant to at least one of the drugs on entry to the trial. The bacteriological as well as the clinical analysis is thus confined to patients whose organisms were sensitive at the start of the trial to both of the drugs they were receiving.

2. Bacterial Content of Sputum

The results at one, two, and three months of the selected single examinations of the sputum for tubercle bacilli are set out in Table VIII. At the end of one month's treatment specimens from 32% of 111 SH patients and 27% of 89 20 PH patients, in Groups 1 and 2 combined, were negative both on direct examination and on culture. At the end of the second month the corresponding figures were 51% of 104 SH patients and 43% of 91 20 PH patients. At three months the figures were 65% of 106 SH patients and 66% of 89 20 PH patients. The figures for the two treatments are ver-

‡ See note at foot of page.

similar. It will be noted, however, that at three months the patients with the more acute disease (Group 1) had not fared so well as the Group 2 patients.

Section B of Table VIII presents a supplementary comparison of the effects of streptomycin plus isoniazid and P.A.S. plus isoniazid in all patients. Of 203 SH and S2H patients, specimens from 69% were negative at the end of three months, both on direct examination and on culture, compared with 71% from 162 20 PH and 10 PH patients.

3. Sensitivity Tests

The results of the sensitivity tests at two and three months, on all the SH and 20 PH patients in Groups 1 and 2 combined, appear in Section A of Tables IX–XI.

So far in this report no separate information on the S2H or 10 PH series has been presented, since the numbers of results are at present rather small. These two treatments were included in the trial because they are more readily administered to, and tolerated by, the patient than the SH and 20 PH treatments respectively. However, since a crucial measure of the suitability of these combinations is their ability to prevent the emergence of drug-resistant bacteria, the data on drug resistance, although limited, are sufficiently important to be presented now for each of the four treatments separately. To make valid comparisons between the SH and S2H series, the SH patients in subgroup 1A (who have no counterparts in the S2H series) have been omitted. Similarly, the 20 PH patients in subgroup 1A have been omitted from the comparison between the 20 PH and 10 PH series. The small numbers of Group 3 patients have been retained in the analysis. The results of these comparisons appear in Section B of Tables IX–XI.

Isoniazid Sensitivity.—The results of the isoniazid-sensitivity tests are set out in Table IX. At three months results were available for 39 positive cultures from 106 SH patients; 2 of the cultures yielded resistant strains. The corresponding figures for 89 20 PH patients were 29 positive cultures, none of which yielded resistant strains. The incidence of isoniazid resistance for a period of three months is thus low with each treatment.†

Turning to the comparison between the SH and S2H treatments, and between the 20 PH and 10 PH treatments (Section B of Table IX), it will be seen that at three months cultures were found to be resistant from 2 of 18 patients on SH compared with 8 of 21 on S2H and from 0 of 18 on 20 PH compared with 1 of 16 on 10 PH. The least satisfactory figures are those for the S2H treatment, for which the resistant cultures at three months represent 38% of all positive cultures, compared with 11% for the SH series; they represent 9% of all the patients for whom cultures

were undertaken, compared with 3% for the SH series. At two months also the results for the S2H series are inferior to those for the SH series, 5 of 45 positive cultures from S2H patients being resistant to isoniazid, compared with 0 of 32 cultures from SH patients. The findings in the 10 PH series at two and three months, on the other hand, are almost as satisfactory as in the 20 PH series, although the numbers are small.

Streptomycin Sensitivity.—At two months 1 of 52 cultures from 104 SH patients was resistant to streptomycin (Table X). At three months there was one resistant strain among 38 cultures from 106 patients. The SH combination is thus effective for at least three months in preventing the emergence of bacilli resistant to streptomycin.

The comparison of the SH and S2H treatments in Section B of Table X shows that 0 of 18 cultures from 74 SH patients, and 3 of 22 cultures from 94 S2H patients, were streptomycin-resistant at the end of three months.

P.A.S. Sensitivity.—At two months 2 of 47 cultures from 91 20 PH patients were resistant to P.A.S. (Table XI). At three months there was 1 resistant strain among 28 cultures from 89 patients. The 20 PH combination is thus effective for a three-month period in preventing the emergence of bacilli resistant to P.A.S.

The comparison of the 20 PH and 10 PH treatments in Section B of Table XI shows that 1 of 18 cultures from 67 20 PH patients, and 1 of 14 from 65 10 PH patients, were P.A.S.-resistant at the end of three months.

‡ Special reference must be made to the results of isoniazid-sensitivity tests at two months in 3 20 PH patients. All were from one small centre which had recently entered the trial, and they represent the total contribution of the centre to the two treatment series receiving P.A.S. plus isoniazid.

The cultures from two of these patients were reported at the local laboratory as resistant to two months to isoniazid, and were submitted as usual to the reference laboratory for confirmation of the level of resistance. In the reference laboratory, however, both cultures were found to be sensitive to isoniazid. The two cultures were subsequently retested both locally and centrally and the results in both laboratories were sensitive. The culture from the third patient was accidentally discarded at the local laboratory and a test at the reference laboratory gave a sensitive result. However, a culture at six weeks on the same patient had been reported as resistant to isoniazid at the local laboratory, but sensitive at the reference laboratory. At three months specimens from all 3 patients were negative on culture, so that no sensitivity tests were possible.

It must be realized that the check-tests were made on cultures which had been kept for some while before testing, and in one instance on a subculture; any isoniazid resistance may have diminished in the interval. On the other hand no isoniazid-resistant strains, either in 20 PH or in 10 PH patients, were reported at two months from any other centre. In these circumstances it was decided with the local bacteriologist that the results of these tests should be regarded as equivocal. They have been entered as "Culture-positive, sensitivity test not available."

IV. DISCUSSION

In the first report of this trial (Medical Research Council, 1952) it was shown that isoniazid was an effective drug in the treatment of pulmonary tuberculosis, but that when it was used alone resistant bacteria emerged frequently and rapidly. This finding indicated the importance of combining isoniazid with other drugs active against tuberculosis, in order to find a treatment which was bacteriologically as well as clinically effective.

Accordingly, from September 5, 1952, four combined treatments have been investigated—namely, streptomycin 1 g. daily plus isoniazid (SH), streptomycin 1 g. twice a week plus isoniazid (S2H), P.A.S. (sodium salt) 20 g. daily plus isoniazid (20 PH), and P.A.S. (sodium salt) 10 g. daily plus isoniazid (10 PH). The dosage of isoniazid was 200 mg. daily in each treatment. Over 600 patients have now been given one of these four treatments, allocated concurrently and at random, and this report presents clinical and bacteriological results at three months on 391 of these patients who were admitted to the trial before March 31, 1953. For reasons given, the main comparison in the report is between the SH and 20 PH treatments, the results at the end of three months being summarized in Table XII. Over this limited period the two treatments were of comparable efficacy in improving the general clinical condition, in lowering the sedimentation rate, in resolving pyrexia, and in suppressing tubercle bacilli in the sputum. Patients on the SH treatment gained more weight and a rather higher proportion showed substantial radiographic improvement, but on present totals the differences are not statistically significant.

In the second report of the trial (Medical Research Council, 1953a) it was concluded that streptomycin 1 g. daily plus isoniazid 200 mg. daily was clinically the most effective anti-tuberculosis chemotherapy yet investigated in the trial, although its superiority to streptomycin 1 g.

See Tables III-IX for the numbers of patients on which these percentages are based. See Tables X and XI for the results of the streptomycin-P.A.S. sensitivity tests.

daily plus P.A.S. (sodium) 20 g. daily was not great. T new information now presented on the clinical efficacy of P.A.S. (sodium) 20 g. daily plus isoniazid indicates that this combination is a powerful addition to acceptable drug treatments of pulmonary tuberculosis over a three-month period. Further evidence of

efficacy of combining P.A.S. with isoniazid is provided by the supplementary analysis of the progress of the 20 PH and 10 PH patients combined, which presents results for a much larger number of patients.

It was also shown in the second report that the combination streptomycin 1 g. daily plus isoniazid effectively hindered the emergence of bacilli resistant either to isoniazid or to streptomycin; the present report confirms these findings on a further series of patients, who were on the whole suffering from more acute forms of the disease. At three months 39 cultures from 106 patients were isolated and tested for isoniazid sensitivity, and 2 were resistant; 1 of 38 cultures from the same number of patients was resistant to streptomycin. The combination P.A.S. (sodium) 20 g. daily plus isoniazid is no less effective in preventing the emergence of strains resistant either to isoniazid or to P.A.S. At three months 29 cultures from 89 patients were tested for isoniazid sensitivity, and all were sensitive; 1 of 28 cultures from the same number of patients was resistant to P.A.S. For a three-month period the 20 PH treatment is thus bacteriologically as well as clinically effective. As an indication of the ability of the 20 PH combination to prevent the emergence of isoniazid-resistant strains, it will be recalled that in an earlier stage of the trial 64% of 132 positive cultures from 243 patients on isoniazid alone were resistant at three months (Medical Research Council, 1953c).

Before a valid comparison of the relative efficacy of the four treatments SH, S2H, 20 PH, and 10 PH could be made, it was necessary to exclude the patients in subgroup 1A, who were allocated only to the SH and 20 PH treatments. When this was done, no marked differences in clinical response were apparent between patients on each of the four treatments, but a full clinical evaluation must await the results for the larger number of patients now under study. However, the bacteriological information already available, although based upon small numbers, is of sufficient importance to warrant discussion.

The results of sensitivity tests for the 20 PH and the 10 PH patients at three months showed practically no

development of bacterial resistance, either to isoniazid (see Chart) or to P.A.S., in patients on either of these treatments. The finding that 10 PH appears to be bacteriologically an effective treatment should lend particular interest to the detailed study, in due course, of the clinical findings in 10 PH patients.

The preliminary comparison of the results of sensitivity tests for the SH and S2H patients at three months indicates a less satisfactory situation for the latter treatment. Although the development of streptomycin resistance was largely prevented by each combination, the incidence of isoniazid-resistant strains at three months (see Chart) was noticeably greater for the S2H than for the SH patients. If, on larger numbers, this difference is confirmed, it will represent a definite disadvantage of the combination streptomycin 1 g. twice a week plus isoniazid.

In conclusion, this analysis has demonstrated that P.A.S. (sodium) 20 g. daily plus isoniazid 200 mg. daily, when used for a three-month period, is very effective, both clinically and bacteriologically, in the treatment of pulmonary tuberculosis. It ranks with the most efficacious chemotherapeutic combinations so far tested in this trial—namely, streptomycin 1 g. daily plus isoniazid 200 mg. daily and streptomycin 1 g. daily plus P.A.S. (sodium) 20 g. daily. It possesses an advantage over these two established treatments in that both drugs are administered by mouth.

V. SUMMARY

As part of a clinical trial of isoniazid (isonicotinic acid hydrazide) in the treatment of pulmonary tuberculosis, 391 patients were studied in 50 hospitals: 119 were treated with streptomycin (1 g. daily) plus isoniazid (100 mg. twice a day), 100 with streptomycin (1 g. twice a week) plus isoniazid (100 mg. twice a day), 101 with P.A.S. (sodium salt, 5 g. four times a day) plus isoniazid (100 mg. twice a day), and 71 with P.A.S. (sodium salt, 5 g. twice a day) plus isoniazid (100 mg. twice a day). When submitting a case the physician did not know which treatment the patient would receive, this being determined by random allocation. The present report analyses results at the end of three months' treatment.

Three main groups were observed: Group 1, acute rapidly progressive disease of recent origin; Group 2, other forms considered suitable for chemotherapy; Group 3, chronic disease considered unlikely to respond to chemotherapy.

For reasons given, the principal comparison in the report is between the patients in Groups 1 and 2 on streptomycin 1 g. daily plus isoniazid 200 mg. daily (SH) and those on P.A.S. (sodium) 20 g. daily plus isoniazid 200 mg. daily (20 PH). (A full comparison of all four treatments will be made when results for more patients are available.)

On admission, these two treatment series had a similar distribution of patients with severe and less severe illness. At the end of three months the general condition had improved in 89% of the SH patients and 88% of the 20 PH patients. The average gain in weight during the period was 12.8 lb. (5.8 kg.) for the SH patients and 10.8 lb. (4.9 kg.) for the 20 PH patients. The temperature fell to normal in 79% of febrile SH patients and 85% of febrile 20 PH patients. In patients with an E.S.R. of 21 or more before treatment the rate fell to 10 or less in 37% of those on SH, compared with

Results of isoniazid-sensitivity tests at three months.

46% of those on 20 PH. Changes in radiographic appearances were independently assessed by a radiologist unaware of the treatment of any patient. Two-plus or three-plus improvement was seen in 54% of SH and 42% of 20 PH patients. There were two radiographic deteriorations and one death on each treatment. None of the above differences is statistically significant.

The proportion of patients bacteriologically negative, both on direct examination and on culture, at a single examination at three months was 65% for the SH series and 66% for the 20 PH series.

Bacillary resistance to isoniazid was found in 2 of 39 culture-positive SH patients tested at three months, compared with 0 of 29 similar 20 PH patients. Bacillary resistance to streptomycin was found in 1 of 38 culture-positive SH patients, and to P.A.S. in 1 of 28 similar 20 PH patients.

It is concluded, *judging solely from the results at three months*, that P.A.S. (sodium) 20 g. daily plus isoniazid 200 mg. daily is a very effective combination of drugs, both clinically and bacteriologically; it ranks with the most efficacious treatments so far studied—namely, streptomycin 1 g. daily plus isoniazid 200 mg. daily and streptomycin 1 g. daily plus P.A.S. (sodium) 20 g. daily.

A supplementary clinical comparison of all the 219 patients on streptomycin plus isoniazid and all the 172 on P.A.S. plus isoniazid confirms the clinical efficacy of combining P.A.S. with isoniazid. However, patients on streptomycin plus isoniazid gained a little more weight, and a higher proportion showed substantial radiographic improvement.

A preliminary analysis of results of sensitivity tests on each of the four treatments shows that P.A.S. (sodium) 10 g. daily plus isoniazid 200 mg. daily may prove to be a bacteriologically effective combination for at least three months. On the other hand, treatment with streptomycin 1 g. twice a week plus isoniazid 200 mg. daily is apparently less effective than streptomycin 1 g. daily plus isoniazid 200 mg. daily in preventing the development of bacterial resistance to isoniazid over a three-month period.

ACKNOWLEDGMENTS

The hospitals and the doctors co-operating in the phase of the trial reported here are as follows:

Hospitals.—Aberdeen City Hospital; Ainuree Hospital; Ashludie Hospital; Moffat; Ayrshire Central Hospital; Irvine; Bangour Hospital, West Lothian; Black Nole Hospital, Braintree; Brierton Hospital, West Herts; British Legion Sanatorium, Nantland; Brompton Hospital; Broomfield Hospital, Chelmsford; Canadian Red Cross Memorial Hospital, Taplow; Clare Hall Hospital, Herts; Connaught Military Hospital; Cumberland Hospital, Surrey; Dumfries and Galloway Sanatorium; East Fortune Hospital, East Lothian; Edgware General Hospital; Edinburgh City Hospital; Foxhall Hospital, Ipswich; Glenafton Hospital, Ayrshire; Hammer-smith Hospital; Heathcote Hospital, Leamington Spa; Heathfield Hospital, Ayrshire; Hillingdon Hospital; Hollywood Hall Sanatorium, Bishop Auckland; Inverurie Hospital, Aberdeen; Kettlewell Hospital, Kent; King Edward VII Sanatorium, Midhurst; King George V Hospital, Godalming; King George's Sanatorium for Sailors, Hants; Lenham Sanatorium, Kent; Manawyan Hospital, Denbigh; Mearns Kirk Hospital, Renfrewshire; Mount Pleasant Hospital, Middlesbrough; Newcastle General Hospital; North Middlesex Hospital; Poole Sanatorium, Middlesbrough; Robroyston Hospital, Glasgow; Romsley Hill Sanatorium, Worcestershire; Royal Victoria Hospital, Edinburgh; St. Albans City Hospital; St. Helen's Hospital, Ipswich; St. Helier Hospital, Surrey; Seaham Hall Sanatorium, Sunderland; Southfield Hospital, Edinburgh; Westcliffe Hospital; West Heath Sanatorium, Birmingham; Woodend Hospital, Aberdeen; Wooley Sanatorium, Northumberland; Yardley Green Hospital, Birmingham.

Physicians.—Drs. P. G. Arblaster, M. Barry, D. Bell, W. Biagi, W. M. Borden, J. T. Boyd, L. E. Burkman, K. M. Chalmers, J. A. Chamberlain, C. W. Clayton, R. C. Cohen, A. H. C. Couch, Professor J. W. Crofton, Drs. R. Cunningham, V. Davies, V. F. Dawkins, M. K. Dhole, J. W. Duerden, T. A. Watkin Edwards, I. Elmalie, W. J. Ferraby, P. Forgacs, M. A. Foulis, R. Fraser, M. A. Gallagher, J. E. Geddes, I. W. B. Grant, J. G. H. Greenfield, L. A. Hardie, W. C. Harris, H. F. Harwood, M. Hemmings, E. V. Hess, J. A. Hill, F. Hodgkiss, N. W. Horne, J. V. Huxford, G. Hurrell, J. E. M. Hutchinson, Lieutenant G. J. Jones, Drs. G. Perkin Jones, R. Sinclair Kennedy, G. M. Lewis, G. M. Little, L. C. Lyon, E. G. Sta Lumen, G. R. W. N. Luntz, Lieutenant-Colonel J. Mackay-Dick, Drs. W. MacDermid, N. MacFarlane, D. G. McIntosh, G. R. McNab, A. T. Mason, W. T. Miller, K. Murray, W. A. Murray, P. J. O'Rourke, J. P. Parkinson, Hayden J. Partington, W. C. Pinkney,

Stradling, G. F. Summers, J. Sumner, J. O. Taubman, D. Teare, H. E. Thomas, O. F. Thomas, B. C. Thompson, H. R. Thomson, Sir Geoffrey S. Todd, Dr. H. J. Trenchard, F. W. A. Turnbull, M. Walton, W. F. Wheeler, A. B. White, F. L. Wollaston, W. L. Yell, D. van Zwanenberg, and the consultant staff of Brompton Hospital (Registrar, R. N. Johnston).

Bacteriologists and Pathologists.—Drs. C. S. Anderson, D. F. Barrowcliff, R. Blowers, D. M. H. Cogman, R. T. Cooke, J. E. Craik, P. B. Cron, J. C. Dick, Professor A. W. Downie, Drs. J. M. Dunbar, W. J. Godden, T. E. W. Goodier, W. I. Gordon, J. Harper, J. F. Haggie, E. D. Hoare, Captain C. H. Jones, Drs. E. R. Jones, P. Kidd, M. Laidlaw, G. Laws, J. T. A. Lloyd, A. Macdonald, J. Marks, P. H. Martin, A. Messer, D. A. Mitchell, Squadron-Leader A. D. Moore, Dr. E. Nassau, J. W. Nicholas, W. H. A. Picton, R. Pilsworth, Squadron-Leader J. S. Porterfield, Dr. A. I. D. Prentice, I. A. Purdie, K. Rafinski, R. W. Riddell, J. M. Robertson, B. R. Sandiford, F. E. T. Scott, A. G. Signy, T. Skeoch, J. Smith, P. J. Taylor, W. K. Taylor, A. T. Wallace, R. F. Welch, W. Whitelaw. The bacteriologists and pathologists form a laboratory sub-committee under the chairmanship of Professor R. Cruickshank.

Dr. E. H. Bailey, Southern Group Laboratory, supplied culture medium where desired. Dr. D. A. Mitchison's laboratory, Postgraduate Medical School of London, served as reference laboratory for drug-resistance tests.

The above cannot be a comprehensive list of all the doctors who have contributed to the results reported here, nor has it been possible to name the many laboratory technicians who have done detailed and valuable work. The Tuberculosis Chemotherapy Trials Committee expresses its thanks to all members of hospital staffs who have assisted in the investigation, particularly for their willing response to the urgent requests for information for inclusion in this report.

The Research Committee of the Tuberculosis Society of Scotland was of considerable assistance in initiating the trial in Scotland. The Edinburgh team is in receipt of a research grant from the Royal Victoria Hospital Tuberculosis Trust. The figure was drawn by Miss P. Carter, of the Department of Medical Illustration, Guy's Hospital.

DESENSITIZATION TO STREPTOMYCIN AND P.A.S.

BY

JOHN CROFTON, M.D., F.R.C.P.

From the Department of Tuberculosis and Diseases of the Respiratory System, University of Edinburgh

It is not proposed to discuss in detail in this paper the symptoms of hypersensitivity to streptomycin or P.A.S. (para-aminosalicylic acid), but only to emphasize that desensitization is possible. In patients sensitized by treatment with streptomycin or P.A.S. desensitization is usually easy, and has been referred to briefly elsewhere (Crofton, 1953). It is much more difficult to desensitize individuals sensitized to streptomycin by handling it in the course of their work, and I have seen no previous report of this being successfully accomplished.

Desensitization of Streptomycin-handlers

The recent statement from the Ministry of Health (1953) indicates that a number of people whose duty involves the handling of streptomycin become sensitized to the drug. In many cases the degree of sensitivity is very high; a nurse may not only be unable to administer streptomycin injections but may be unable to work in a ward where they are given or enter a room where the injections are prepared. The previous literature on this subject has been well reviewed in the Ministry of Health report and will not be recapitulated here. The present report is only to emphasize that even individuals highly sensitive to streptomycin can be desensitized, and to describe two cases in which this has been done.

Case 1

A ward sister aged 37 had no family or personal history of allergy. Two years before admission to hospital she had begun giving streptomycin injections, and during the five

months before the onset of symptoms one year previously she had been giving injections daily to between two and nine patients. She had not worn rubber gloves. One year before admission she began to notice swelling of the periorbital tissue of the right eye, which reached its maximum two hours after giving streptomycin injections. (She had previously lost her left eye in an accident.) These symptoms gradually increased, and eight months before admission a patch test with streptomycin was done on her back. This resulted in severe local reaction and also local redness and swelling around her right eye. By this time she had become so sensitive that she was liable to develop the reaction whenever she went into the ward, and she had to be put off work. Even then she found that a flare occurred in the eye if she went to visit one of her friends who was changing after coming off duty.

At the time of admission she had not been in contact with streptomycin for some time, and there were no abnormal physical signs. An intradermal test with 50 µg. of streptomycin in 0.1 ml. produced a local reaction with oedema 4 by 4 mm. in diameter and an erythema 20 by 18 mm. at six hours. One hour after the injection there was a reaction in the eye, with reddening and itching of the right cheek. She was placed on diphenhydramine hydrochloride, 50 mg. three times a day, and then two injections of distilled water were given, without reaction, on successive days. Thereafter she had a first injection of 10 µg. of streptomycin. The next day she said she felt slightly unwell, but there was no local reaction. It was thought that this feeling might be due to overdosage with diphenhydramine, and this was reduced to 50 mg. twice a day. On the following two days intramuscular injections of 20 and 50 µg. successively of streptomycin were given without incident. On the 4th day 100 µg. was given, but 16 hours later she developed redness and oedema of the right eyelids. This lasted for two days. No streptomycin was given until the evening of the second day, and diphenhydramine was increased to three times a day.

On the 6th day after starting treatment the dosage of streptomycin was reduced to 50 µg. On the 7th and 8th days no injections were given as there was still slight desquamation of the right eye but no oedema. On the 9th day 100 µg. was given again with no reaction. On the 10th day 200 µg. produced oedema and redness of the upper eyelid six hours later. On the following day this dose was repeated with an extra dose of diphenhydramine and there was no reaction. On the 12th day the dose was stepped up to 300 µg. and produced no reaction. On the 13th day, following 500 µg., there was marked swelling and oedema of the right eyelids, and 2½ hours after the injection she was hardly able to open the eye. At the same time the patch test on her back which had been done eight months previously became red and hot. On the 14th day this reaction had subsided and the 500-µg. dose was repeated. The reaction in the back and eye occurred again, but less severely than previously, and on the evening of the 15th day the 500-µg. dose was repeated with no reaction. With the succeeding doses of 600, 800, 1,000, and 1,250 µg. there was no reaction, but with 2-, 3-, and 4-mg. doses there was very slight swelling and itching of the eyelids.

On the 23rd day 6 mg. produced no reaction, but there was a slight one with the 10-mg. dose the next day. This had subsided by the evening of the 25th day and 12 mg. was given. Thereafter 20, 30, 50, and 100 mg. were given without incident, but 0.2 g. on the 30th day was followed by redness and itching. There was no reaction to 0.3 g. on the 31st day, but there was a slight reaction to 0.5 g. on the 32nd. Thereafter 0.7 g. and 1 g. were given without any reaction. Diphenhydramine was then stopped. For a couple of days she complained of headache and nausea, but this was relieved by giving 50 mg. of diphenhydramine on the third day. The next day there was some recurrence, which was relieved by giving glucose in a diphenhydramine capsule. Thereafter there was no further trouble. A further injection of 1 g. was given after the cessation of diphenhydramine treatment, and there was no reaction.

The intradermal test with 50 µg. of streptomycin was then repeated and there was no reaction whatsoever. Gauze soaked in 50% streptomycin solution was strapped on her back for 24 hours with no reaction. She was therefore regarded as having been desensitized, and returned to work in tuberculosis wards. Three years later she has had no recurrence of trouble. She has on the whole avoided giving streptomycin injections herself, but has occasionally done so, taking the precautions we have previously outlined (Crofton and Foreman, 1948).

Summary of Case 1.—A nursing sister aged 37 became sensitized to streptomycin after giving injections for about a year. The sensitivity consisted of redness and swelling around the right eye, and was so severe that she was unable to enter a room in which one of her colleagues was changing after coming off duty. Skin tests confirmed the streptomycin sensitivity and desensitization was carried out by giving ascending daily intramuscular injections of streptomycin over 35 days, the first injection being 10 µg. and the last 1 g. Minor reactions occurred during the course of desensitization. She has subsequently worked for three years in tuberculosis wards without incident. This patient was a sensible woman and could probably have been desensitized as an out-patient, but she was admitted to hospital, partly because I had not carried out such desensitization previously and partly because the sanatorium in which she worked was situated a long way away.

Case 2

An assistant nurse aged 47 had no personal or family history of allergic conditions. In February, 1948, she had begun giving streptomycin injections, up to about 28 a day. Rubber gloves were available but were seldom worn. In November, 1948, she began to develop conjunctivitis and periorbital swelling. In January, 1949, a streptomycin patch test was said to have been positive. Subsequently she did not handle streptomycin herself, but continued to work in the tuberculosis wards. In May, 1949, the condition recurred and by September she had also developed a dermatitis of the arms and hands. Thereafter she ceased work in the wards and during this time had almost no trouble. In January, 1952, she had a recurrence on the eyes and on the arms. Just before the onset of this she had passed through a room where streptomycin injections were being prepared. An intradermal injection of 25 µg. of streptomycin resulted in an erythema 9 by 10 mm. at 24 hours, almost no reaction being present at six hours. The patient had a difficult personality. It did not prove possible to desensitize her as an out-patient and she was consequently admitted to hospital.

Mepyramine maleate, 100 mg. three times a day, was given and desensitization was begun with an intramuscular dosage of 50 µg. Daily doses of 75, 100, 200, and 400 µg. were given without incident. When given 500 µg. and subsequent doses of 800 and 1,600 µg. the rash became a little worse, with slight itching on the forehead. The 1,600-µg. dose was therefore repeated for five days, until the reaction subsided. On the 14th day 2 mg. was given. There was again some reaction, so 1.6 mg. was given on the 15th day and no injections on the 16th or 17th. Owing to the persistence of reactions three further injections of 2 mg. were given between the 18th and 20th days, 2.5 mg. on the 21st, 3 mg. on the 22nd, and 3.5 mg. on the 23rd and 24th. On the 25th to the 29th days no injections were given, because of persistent dermatitis. Then 3.5 mg. was again given.

Subsequently the dose was raised slowly with occasional intermissions of a day or two days and on several occasions repetition of doses. The doses (in mg.) on successive days were 4, 4, 4, 4.5, nil, 5, 5.5, nil, 5.5, 6, 6.5, 7, 7.5, nil, nil, 7.5, 8, 8.5, 9, nil, nil, 9, 9.5, 10, 12, 14, 16, nil, 18. At this stage there was again a slightly more severe reaction, exaggerated by her difficult personality, and no injections were given for three days. The reaction subsided and injections were resumed: 18, 19, 20, 22, 24, 25, 27, 30, 32, 34, 38, 43, 50, 70, 75, 85, 100, 120, 120, 150, 180, nil, nil, 180,

nil, 200, nil, 220, 240, 260, 280, 300, 330, 360, 380, 400, 420, 450, 500 mg. At this point an error was discovered, most unfortunate but of some interest. It was found that, by mistake, desensitization had been carried out with dihydrostreptomycin sulphate instead of with streptomycin sulphate. Streptomycin sulphate was substituted and, foolishly, the same dose as the previous dose of dihydrostreptomycin was given—that is, 500 mg. There was a very severe reaction. Although the temperature rose only to 98.8° F. (37.1° C.), there was a brisk generalized rash, erythema, slight oedema of the eyes, and great exacerbation of the peripheral dermatitis. Injections were stopped for five days until the reaction had subsided and everyone had calmed down.

Desensitization was then recommenced with streptomycin sulphate, starting with 50 µg. It was found possible to increase the dose quite rapidly, indicating that the dihydrostreptomycin had at least partially desensitized the patient to streptomycin. The dose was increased from 50 µg. to 5 mg. within nine days. There was a slight reaction at this stage, and subsequent doses of 5, 8, 10, 15, and 25 mg. were given without reaction. A dose of 45 mg. resulted in a slight reaction lasting three days, but the dose was increased from 45 to 140 mg. within the succeeding week. At 140 mg. a small patch of dermatitis appeared on the chin and no injections were given for four days. Over the next 25 days the doses were increased from 150 mg. to 1 g. with no significant incidents. Mepyramine maleate was then stopped and intradermal tests were repeated with 100 µg. of streptomycin. There was no reaction. A piece of gauze soaked in 50% streptomycin was then applied to the back for 24 hours without any reaction. Desensitization had therefore apparently been accomplished. Unfortunately, in spite of this, the patient refused to return to work in the wards, and it has not been possible to test out in practice the success of the desensitization.

Summary of Case 2.—An assistant nurse aged 47, who had developed a streptomycin dermatitis and who was highly sensitive to the drug, was desensitized to dihydrostreptomycin by being given daily intramuscular injections, rising from 50 µg. to 0.5 g. over fifteen weeks. At this stage streptomycin was substituted, resulting in very severe reaction. Desensitization was recommenced with streptomycin over the succeeding eight weeks, in which the intramuscular dose was increased gradually from 50 µg. to 1 g. Intradermal and patch tests of streptomycin were negative at the end of the desensitization period, but the patient refused to return to work in tuberculosis wards.

Comment

It seems clear, therefore, that desensitization in individuals whose skin has become sensitized to streptomycin by contact is quite feasible, although it may take several months and minor reactions may occur. It is probable that the patient's mentality may have something to do with the speed with which desensitization is attained. In the first case the patient was a sensible woman and, in spite of some minor reactions, desensitization was readily achieved in a period of 35 days, excluding the time utilized in doing tests. The second patient had a difficult personality and tended to exaggerate her reactions. In consequence, even allowing for the error over dihydrostreptomycin, desensitization took much longer. It was apparent that there was some cross-desensitization to dihydrostreptomycin and that the initial use of that substance for desensitization had resulted in partial desensitization to streptomycin, for subsequent desensitization to streptomycin itself took only eight weeks. It is felt that, with a sensible individual, it should be quite feasible to carry out desensitization on an out-patient basis. This in fact has been done elsewhere, using methods similar to those described (personal communication, Dr. Michael Gibson).

Desensitization of Patients

In patients undergoing treatment with streptomycin and P.A.S. hypersensitivity reactions are well known. The com-

monest manifestation is fever, usually occurring 10 to 25 days after starting treatment. Any fever at this stage of treatment should be regarded as a hypersensitivity reaction until proved otherwise. Rashes may be seen, with or without fever. When such a reaction occurs chemotherapy should be stopped. Continuation in spite of a warning fever has resulted in severe liver damage, encephalitis, or other serious hypersensitivity reactions, especially in the case of P.A.S. When the reaction has subsided one may test for hypersensitivity by giving 0.5 g. of streptomycin. If the patient is hypersensitive symptoms such as mild fever, a rash, or itching of the skin occur within an hour or two. If there is no reaction a dose of 1 g. is given in order to make certain. When the reaction, if any, has subsided, a half-dose of P.A.S. (usually 2.5 g.) is given, for the patient may be sensitive to both drugs. Again a reaction will usually occur within an hour or two. If there is none a full dose (5 g.) is repeated two or three times to make certain.

Desensitization is then begun. If the patient is sensitive to both drugs it is well to desensitize to P.A.S. first, as resistance to this drug develops less readily; after desensitization normal doses of P.A.S. can then be used to cover the desensitization to streptomycin. It is usually adequate to start with 0.5 g. of P.A.S., working up to the full dose by daily increments over 10 to 14 days. With streptomycin an initial dose of 0.1 g. is usually low enough, and this can be increased to 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, and 1 g. in the succeeding days, desensitizing over 10 to 14 days. In both cases, if there is any reaction the last dose is repeated after the reaction has subsided.

Personally I have encountered no difficulties in a large number of patients desensitized; it is a very much easier matter than the desensitization of streptomycin-handlers. The following patient is an example. She was sensitive to both drugs and was a little more difficult than usual to desensitize, but presented no major problems.

Case 3

A female schoolteacher aged 23 was admitted with pulmonary tuberculosis of recent origin. She was started on streptomycin, 1 g., and P.A.S., 15 g. daily, the latter being increased to 17 g. within a few days. She had a slight fever up to 99° F. (37.2° C.) or a little above. On the 22nd day the temperature rose to 100.6° F. (38.1° C.) in the evening; it was normal the next morning, but rose to 104° F. (40° C.) that evening, with a bright red morbilliform rash over the body. P.A.S. was stopped and the next day the temperature subsided. That evening she received the normal dose of streptomycin and the temperature again rose to 104° F. (40° C.), with rigors, exacerbation of the rash, and Raynaud's phenomenon in the fingers. Streptomycin was then stopped also and an antihistamine drug given. The temperature was normal next day and the rash cleared within two days. A test dose of 2.5 g. of P.A.S. resulted in a faint rash and itching of the skin one hour later. Two days later a test dose of 0.5 g. of streptomycin resulted in pains in the arms and flushing of the face and conjunctivae. Both these reactions subsided within 12 hours.

Desensitization to P.A.S. was begun with 0.5 g. the first day in a single dose, 0.5 g. four times on the 2nd day, 0.5 g. five times on the 3rd day, 1 g. four times on the 4th day (slight itching of skin). On successive days the following doses were then given, each five times a day: 1.5, 2, 2.5 and 3 g. On the last-mentioned dose there was slight prickling of face and legs lasting one to two hours after each dose, but the dose was maintained and within ten days could be raised to 17.5 g. a day. Desensitization to streptomycin was then begun with 0.1 g. on the first day. Slight prickling of the legs occurred with this dose and with the 0.2-g. dose the next day. The latter was repeated, as was the 0.4-g. dose a few days later, but the full 1-g. dose was reached on the 12th day. P.A.S. was continued throughout the desensitization to streptomycin. Thereafter there was

no further trouble. Chemotherapy was continued for over a year, during which she had a segmental resection of the residual disease.

Summary of Case 3.—A female patient aged 23 developed a high temperature and a morbilliform rash after 22 days on streptomycin and P.A.S. Test doses proved she had become sensitive to both drugs. The daily dose of P.A.S. was gradually increased from 0.5 g. to 15 g. over 11 days; 10 days later it was raised to 17.5 g. Streptomycin doses were increased from 0.1 to 1 g. daily over 12 days. Subsequently she continued both drugs for over a year without incident.

Summary

Desensitization of streptomycin-handlers who have become hypersensitive to the drug is difficult but quite feasible. Two cases are reported.

By contrast, patients who acquire hypersensitivity to streptomycin or P.A.S. during treatment are usually readily desensitized. As an example a case is described of a patient hypersensitive to both drugs.

My thanks are due to the residents and nursing staff at Hammersmith Hospital, London, the Northern General Hospital, and Southfield Hospital, Edinburgh, who carried out the day-to-day treatment of these patients.

EFFECT OF HEXAMETHONIUM BROMIDE ON THE CEREBRAL CIRCULATION IN HYPERTENSION

BY

H. A. DEWAR, M.D., M.R.C.P.

Assistant Physician, Royal Victoria Infirmary,
Newcastle-upon-Tyne

A. R. JENKINS, B.Sc.

Late Assistant Biochemist, Royal Victoria Infirmary,
Newcastle-upon-Tyne

The fall in total peripheral resistance which occurs after the administration of the ganglion-blocking agent hexamethonium bromide is not distributed equally between the vascular areas of the body; there follows, therefore, a redistribution of peripheral blood flow. Thus the flow to the foot and toes is greatly increased, while that to the calf segment of the leg muscles is diminished; vascular resistance in the liver decreases enough to maintain the blood flow at its previous level (Freis *et al.*, 1952). The more complex changes in the kidneys have been described by these and other authors (Kirkendall and Culbertson, 1952; Mackinnon, 1952; Miles *et al.*, 1952; Moyer *et al.*, 1952). The effects upon the cerebral and coronary circulations are of particular importance, considering how serious might be the risk of impairment of the blood supply to heart or brain in hypertensive patients. Crumpton and Murphy (1952) have shown that in dogs with experimental renal hypertension the vascular resistance in the coronary system is slightly re-

duced by hexamethonium and that the mean coronary blood flow is maintained. These authors have further outlined the results of their studies of the cerebral circulation in six patients with hypertension and grade III to IV retinopathy before and after blood-pressure reduction with hexamethonium bromide. The present investigation covers the same field in a series of hypertensive patients, in all of whom the changes in the fundi were classified as grade II (Keith-Wagener-Barker) with the exception of one case of malignant hypertension and grade IV retinopathy (Patient 2).

Methods

The studies were carried out on six patients with arterial hypertension who had been admitted to hospital for treatment with subcutaneous hexamethonium bromide. The nitrous oxide technique of Kety and Schmidt (1945, 1948) as modified by Scheinberg and Stead (1949) was employed, constant-rate samples over the ten-minute periods being withdrawn by means of an electrical device (Dewar *et al.*, 1953). In three cases cerebral venous blood was sampled through a needle introduced direct into the superior jugular bulb (Myerson *et al.*, 1927; Gibbs *et al.*, 1945); in the remainder cerebral venous blood was obtained through a cardiac catheter inserted into the left antecubital vein, the technique of which has been described elsewhere (Dewar *et al.*, 1953). Mean cerebral blood flow (C.B.F.) was calculated according to the formula:

$$C.B.F. = \frac{CV_{10} \times S \times 10}{\int_0^{10} (A-V) dt}$$

C.B.F. in ml. per 100 g. brain per minute =

where CV_{10} is the concentration of nitrous oxide in the cerebral venous blood in volumes % at the end of the ten-minute period, S is the partition coefficient of nitrous oxide between brain tissue and blood (known to be unity), and $\int_0^{10} (A-V) dt$ is the integral of the arterial-cerebral venous nitrous oxide difference for the period as determined from the difference between the nitrous oxide concentrations of the integrated arterial and cerebral venous samples.

Blood-pressure readings were made by the auscultatory method in the arm held at heart level, and the mean arterial blood pressure (M.A.B.P.) for each ten-minute period was calculated by adding one-third of the average pulse pressure to the average diastolic reading. The cerebral vascular resistance (C.V.R.) was taken as the quotient of M.A.B.P. divided by the mean C.B.F. In four cases analyses for oxygen content were made on the integrated arterial and cerebral venous samples and the cerebral oxygen consumption ($CMRO_2$) calculated by dividing the product of the mean arterio-venous oxygen difference ($A-VO_2$) and mean C.B.F. by 100. The gas analyses were made in a Van Slyke-Neill manometric apparatus, and were all performed by one of us (A. R. J.). Two estimations of blood flow were made on each patient, separated by at least 25 minutes. The conditions of the second were identical with those of the first except for the prior administration of hexamethonium bromide by intravenous or subcutaneous injection in a dose sufficient to cause significant blood-pressure reduction. The second estimation was not begun until the blood pressure had stabilized at its new level. The results of the studies are shown in the Table.

Hexamethonium bromide produced an average fall in the M.A.B.P. of 30% ($t = 4.7$, $P < 0.01$). This was accompanied by a 28% decrease in the C.V.R. ($t = 3.7$, $P < 0.05$), which in four instances fell to a value within the normal range (Kety and Schmidt, 1948). No significant change occurred in the mean C.B.F. during the period of blood-pressure reduction, successive estimations showing close agreement. (In each pair this was in fact within the range of twice the theoretical standard error of the method as performed by us—Dewar *et al.*, 1953.) In the four cases in which this was estimated, no essential alteration occurred in the $A-VO_2$ difference, nor in the rate of $CMRO_2$. These results agree with those obtained by Crumpton and Murphy

C = Control observations.

E = Observations following the administration of hexamethonium bromide.

M.A.B.P. = Mean arterial blood pressure (mm. of mercury) over ten-minute period.

C.B.F. = Mean cerebral blood flow (ml. blood per 100 g. brain per minute) over ten-minute period.

C.V.R. = Mean cerebral vascular resistance (mm. mercury per ml. blood per 100 g. brain per minute) over ten-minute period.

A-VO₂ = Mean arterial-cerebral venous oxygen difference (ml. O₂ per 100 ml. blood) over ten-minute period.CMRO₂ = Mean cerebral oxygen consumption (ml. O₂ per 100 g. brain per minute) over ten-minute period.

(1952) in their group of six hypertensive patients with grade III to IV retinopathy; they found no significant alteration in the C.B.F., A-VO₂, and CMRO₂ values after reduction of the M.A.B.P. and C.V.R. with hexamethonium by 29% and 30% respectively.

It seems unlikely that hexamethonium lowers the abnormal cerebral vascular tone in hypertension by blocking sympathetic impulses to the cerebral vessels, since it has been shown that, while unilateral and bilateral procaine injections of the stellate ganglion produce no alteration in C.V.R. in hypertensive conditions (Harmel *et al.*, 1949; Scheinberg, 1950), such relaxation follows various procedures which result in decrease in the systemic arterial pressure—namely, the administration of dihydroergocornine, thoraco-lumbar sympathectomy, and differential spinal sympathetic block (Hafkenschiel *et al.*, 1950; Shenkin *et al.*, 1950; Kety *et al.*, 1950). The nature of the mechanism by which increased cerebral vascular resistance is maintained in hypertensive states, and by which it falls when the arterial pressure head is reduced, is not fully understood, but it appears to be a homeostatic response on the part of the cerebral circulation, which tends to maintain the cerebral blood flow and metabolism within normal limits.

These findings imply that cerebral nutrition and metabolism will not ordinarily be impaired by the treatment of hypertensive patients with hexamethonium bromide, since cerebral vascular relaxation to a degree sufficient to maintain adequate cerebral blood flow and oxygen consumption accompanies blood-pressure reduction of the order obtained above. Whether this mechanism is able to compensate for the more drastic and sudden hypotension which may sometimes follow the administration of this drug in sensitive patients is less certain, since it has been shown that the acute hypotension consequent upon differential spinal sympathetic block diminishes mean C.B.F. values (Kety *et al.*, 1950). Further, the possibility of an increased likelihood of cerebral thrombosis in patients in whom arterial disease favours the occurrence of such a complication cannot be considered to be eliminated by the present findings; a decrease in C.V.R., assuming blood viscosity and intracranial tension to remain constant, implies increased vessel calibre and increased blood volume per unit weight of tissue. This, if the mean C.B.F. does not alter, will cause slowing of the linear flow rate and prolongation of the local circulation time. It remains possible that such a result would contribute to the development of intravascular thrombosis.

Summary

The cerebral blood flow has been estimated by a modification of the nitrous oxide method in six patients suffering from arterial hypertension before and after administration of hexamethonium bromide. The mean arterial blood pressure fell by an average of 30%, but no significant change occurred in mean cerebral blood flow. The rate of cerebral oxygen utilization was

measured in four of these patients and showed no essential alteration. The practical implications of these findings is briefly discussed.

We wish to acknowledge our indebtedness to Mr. H. Campbell, of the Department of Industrial Health, King's College, Durham University, for help with the statistical analysis, and to Mr. T. Copeland for much technical assistance.

The Royal Medico-Psychological Association's journal, the *Journal of Mental Science*, celebrates its centenary this month. It was in 1852 that the Association of Medical Officers of Asylums and Hospitals for the Insane decided at a meeting held in Oxford to establish a special asylum journal; and in November, 1853, the first issue of the *Asylum Journal*, as the *Journal of Mental Science* was then called, was published. Its aim was to "afford a medium of intercommunication between men engaged in the construction and management of asylums, in the treatment of the insane, and in all subsidiary operations. . . . It will be a record of improvements and experiments in psychotherapeutics." An editorial article in this issue was devoted to "The Headress of Pauper Lunatic Men." A stone-coloured fustian forage cap was recommended as peculiarly well suited for the use of the insane—"Its weight is 4½ oz., its cost, home made, 7d." (only a penny more than the *Asylum Journal*). It was admitted that the cap's appearance became "perhaps a little odd" when the fustian washed out white. "By no means an ill-looking cap," however, it was strongly advocated for epileptics subject to frequent and heavy falls. This was a modification of the old-fashioned epileptic ring, which "certainly had a somewhat uncouth appearance and suggested . . . the belt of Saturn or the halo of Saint," and was a chamois leather ring, stuffed with curled horsehair, somewhat in the shape of a narrow quoit and covered with grey serge—evidently an early type of crash helmet.

DETECTION OF ACHLORHYDRIA
WITHOUT INTUBATION

BY

HUGH CONWAY, M.B., B.Sc., M.R.C.P.

AND

R. W. MEIKLE, M.B., M.R.C.P.

(From the Gardiner Institute of Medicine, University of Glasgow, and the Western Infirmary, Glasgow)

Intubation of the stomach to obtain samples of gastric juice for examination has two major disadvantages. Even with expert assistance it often proves distressing to the patient, and the act of swallowing the tube tends to alter the composition of the juice. Thus, nausea and retching inhibit the secretion of gastric hydrochloric acid in dogs even when histamine is injected every ten minutes (Grossman *et al.*, 1945), and the presence in the stomach of excessive saliva reduces the acid content (Zaus and Fosdick, 1934).

The most important information which the clinician wants from a gastric analysis is the ability or otherwise of the stomach to secrete hydrochloric acid. This can now be obtained by a simple test which does not involve the passage of a tube. This paper describes the origin of the test, its use by other workers, and some personal results.

Rationale and Development of Test

Following the work of Adams and Holmes (1935) on synthetic ion-exchange resins, H. L. Segal, of Rochester, New York, became interested in their use as antacids (Segal *et al.*, 1945). The therapeutic trials were disappointing, but in 1948 he and his co-workers began to develop the idea that an ion-exchange resin to which a special indicator cation was attached could be used to detect gastric hydrochloric acid without intubation.

The preparation and use of such a compound was first reported by Segal *et al.* (1950a). Starting with the resin "amberlite XE-96," which has the general formula

now marketed under the trade name of "diagnex," was produced by replacing the hydrogen ions of the carboxylic acid groups with quininium ions. Studies *in vitro* showed that the displacement of the quininium cations of this compound by cations in solution depended on various factors, the most important being the hydrogen-ion concentration. Sodium, potassium, and calcium replaced quinine only slightly, but magnesium was more powerful in this respect. When the compound was given orally to patients the hope that quinine would be easily liberated by the hydrogen ions of the hydrochloric acid present in gastric juice was confirmed. The quinine set free was rapidly absorbed and approximately a third excreted in the urine (Goodman and Gilman, 1941). The time of appearance, as well as the amount of quinine in the urine, was noted to avoid misinterpretation resulting from later ionic exchange in the small intestine.

In their preliminary clinical study Segal *et al.* (1950a) gave the quininium indicator compound orally in 2-g. doses with 50 ml. of 7% alcohol to 63 patients whose gastric secretory response to alcohol had been determined by the usual intubation technique on a previous day. In 34 of the 38 patients with free gastric hydrochloric acid quinine was found, on qualitative testing, in the urine excreted during

the first, second, and third hours after the administration of the compound, whereas none of the 25 with achlorhydria showed quinine in the first-hour urine and 20 also failed to excrete it in the second. They concluded that the appearance of quinine in the urine during the first and second hours indicated the presence of free gastric hydrochloric acid, and delay in its excretion until the third hour was compatible with achlorhydria. A few patients passed quinine only in the second and third hours and not in the first; quantitative testing by a photofluorimetric technique was then necessary to confirm the presence or absence of free hydrochloric acid.

Further experiences with the test were described by Segal *et al.* (1950b), Segal (1951), and Segal *et al.* (1953). It was established that achlorhydria could be differentiated from the presence of free hydrochloric acid by the total quantity of quinine excreted in the first two hours after the ingestion of diagnex. Out of 257 subjects who were known to secrete hydrochloric acid and 85 with proved achlorhydria, only four gave inconsistent results by the tubeless technique.

Other favourable reports, in smaller series of cases, were published by Malach and Banks (1952) and Flood *et al.* (1953). Harkness and Durant (1953) made an indicator exchange compound similar to diagnex and showed that patients with free gastric hydrochloric acid excreted considerably more quinine than those with achlorhydria.

Present Investigation

Method.—The patients, none of whom had been ingesting vitamins or drugs containing calcium, magnesium, iron, or aluminium during the previous 24 hours, were investigated in the following manner. After an eight-hour fast the bladder was emptied and the urine saved. Immediately afterwards 0.5 mg. of histamine acid phosphate was injected subcutaneously and 2 g. of diagnex, in 4 oz. (114 ml.) of water, given orally with instructions to avoid chewing the granules. Thereafter the bladder was emptied at the end of one and two hours. The volumes of all three urine specimens were noted and each was treated with ether and sulphuric acid according to the method described by Kelsey and Geiling (1942) for the extraction of quinine. The final acid extracts were compared with a standard solution of quinine sulphate in a Hilger fluorimeter; the natural fluorescence of the night urine (expressed as µg. of quinine) and the amount of quinine in each hourly specimen were then calculated.

Material.—Twenty-two patients were investigated. Intubation studies were performed, usually 24 hours before the diagnex test, in all but four, the exceptions being two with peptic ulceration, one with gastric carcinoma, and one with a partial gastrectomy. For assessing the results of the diagnex test the patients were divided into two groups. Group 1 contained 11 with proved histamine-fast achlorhydria (Addisonian pernicious anaemia, 4; iron-deficiency anaemia, 3; partial gastrectomy, 2; gastric carcinoma, 1; anxiety state, 1), and, in addition, 2 who were not examined by the intubation method (partial gastrectomy, 1; gastric carcinoma, 1). The last two patients were included in this group because it was considered that free hydrochloric acid was more likely to be absent than present. Group 2 comprised 9 patients who were known, or expected, to secrete hydrochloric acid (active peptic ulceration, 6; partial gastrectomy, 2; refractory anaemia, 1).

Results.—In group 1 the total urinary output of quinine in the first two hours after the administration of diagnex ranged from 5.1 to 19.1 µg., and for 8 patients in group 2 from 57 to 319 µg. The Chart shows the wide separation between the mean curves of the urinary fluorescence in the two groups. The remaining patient in group 2 was exceptional in that only 12.8 µg. of quinine was excreted. This patient had a partial gastrectomy, and the fasting juice, when examined previously by the tube method, contained 6.4 clinical units of hydrochloric acid.

Discussion

In this small series of cases the existence of achlorhydria coincided with an excretion of less than 20 µg. of quinine in the total two-hour urine, while, with one exception, the presence of free gastric hydrochloric acid was associated with an output of more than 50 µg. Flood *et al.* (1953) reported similar findings except that the upper limit of urinary quinine in the achlorhydric cases was 25 µg. After long experience with the test, Segal *et al.* (1953) concluded that a firm diagnosis of achlorhydria depended on an excretion of not more than 15 µg. of quinine. These slight differences in the interpretation of the significant urinary quinine level are possibly due to minor variations in the extraction technique. In the group 2 patients no quantitative relationship was demonstrated between the amount of quinine in the urine and the units of acid present in the stomach.

The diagnex test, although still in the experimental stage, promises to be a valuable clinical method of gastric investigation. The patient who refuses or fails to swallow a tube is in no way upset by a procedure which involves only the ingestion of a non-toxic tasteless compound, an injection of histamine, and the collection of urine samples. If further simplification is desired, histamine can be omitted in the first test, but without artificial stimulation a low output of quinine cannot be accepted as evidence of achlorhydria. The test must then be repeated after several days with the addition of histamine. Diagnex itself does not promote acid production to any appreciable extent, and the routine use of histamine is desirable to save time.

Apart from its convenience in patients who are apprehensive about passing a stomach tube, the test has other clinical applications. It is eminently suitable for investigating the incidence of achlorhydria in the general population (Segal *et al.*, 1953), and Malach and Banks (1952) advocate its use, in preference to the conventional tube method of gastric analysis, after recent bleeding from the upper gastro-intestinal tract and after the operation of partial gastrectomy. They report excellent correlation between the diagnex test and the ordinary aspiration technique in nine patients after gastric resection. In the present study four such patients were examined by both methods and the results were conflicting in one: hydrochloric acid was demonstrated by aspiration, but the output of quinine suggested achlorhydria. This may have been due to too rapid emptying of the diagnex, or the hydrochloric acid, from the gastric stump. The interpretation of the standard fractional gastric analysis in patients who have had a partial gastrectomy is often

suspect because of doubt about the position of the tube in the gastric remnant, and it is unfortunate that the tubeless method does not appear to be a completely reliable alternative. Much more experience with such cases is required before the status of the tubeless technique can be properly evaluated.

In the laboratory the only problem concerned the possible significance of natural urinary fluorescence as a source of error. Extraction of normal urines obtained under the exact conditions of the test, except that diagnex was omitted, showed, however, that it did not have an important influence on the results. Apart from the concentrated night urines, the fluorescence did not exceed the equivalent of 3 µg. of quinine in any specimen. Segal *et al.* (1953) recommended that the night urine should be discarded and a control specimen collected an hour later immediately before the administration of the diagnex. This will serve for the recognition of fluorescence due to the ingestion of riboflavine, nicotinic acid, or quinine.

At present the diagnex test is likely to be used only in selected patients, especially those who object to swallowing a stomach tube. Eventually, however, it may become the routine method of gastric analysis, if only for the sake of the patients' comfort.

Summary

The development of a quininium cation exchange indicator compound called "diagnex" and its use to detect achlorhydria without intubation are reviewed.

Experience of the test in 22 patients is described. Achlorhydria was associated with an output of less than 20 µg. of quinine in the urine passed during the first two hours after the oral administration of diagnex.

In general, the results agreed well with those obtained by the aspiration technique, but a discrepancy occurred in a patient who had a partial gastrectomy.

The clinical advantages and applications of the test are discussed.

We wish to thank E. R. Squibb and Sons, New York, for a small supply of diagnex, and Dr. H. L. Segal for stimulating our interest.

The World Health Organization has published a *World Directory of Medical Schools* (1953) which lists over 500 institutions arranged under countries. Information given includes name and place of each institution; year founded; details of administration; length of the academic year; conditions governing admission of students; numbers of full-time and part-time teachers; total enrolment, by sex; number of new students admitted each year; language in which instruction is given; degrees obtainable and time required to obtain them; annual number of graduates; and annual tuition fees. Information is given in both English and French. The directory reveals that the U.S.A. has 79 medical schools, the U.S.S.R. has 61, Japan 46 (of which 21 have been created since the war), India 34, United Kingdom 27, France 25, and Italy 21. It is obtainable in Britain from H.M. Stationery Office, price 25s.

"LENTE" INSULIN (INSULIN ZINC SUSPENSION): FURTHER STUDIES

BY

WILFRID OAKLEY, M.D., F.R.C.P.

Physician, King's College Hospital

A preliminary trial of "lente" insulin was reported by Lawrence and Oakley (1953). The present paper gives the results of further experience with this insulin in the treatment of diabetics, both in the ward and in out-patients, in the Diabetic Department of King's College Hospital.

The researches of Hallas-Møller, Petersen, and Schlichtkrull (1952) in the Novo Laboratories in Copenhagen, and the characteristics of their three new long-acting insulin preparations, "semilente," "lente," and "ultralente"—insulin zinc suspension (amorphous), insulin zinc suspension, and insulin zinc suspension (crystalline)—were briefly described in the account of the preliminary trial. The first clinical studies of these new zinc insulin preparations with prolonged action were carried out by Hallas-Møller, Jersild, Petersen, and Schlichtkrull.

The results now presented are those obtained with lente, the intermediate form; for reasons given later, we have concentrated at King's on the therapeutic trial of this preparation. The trial has been carried out on two series of cases: (1) in-patients, old and new cases; and (2) out-patients, old and new cases.

In-patients

In all, 29 patients have now been studied, of which 21 were treated and 8 untreated diabetics.

(a) Old Cases

The results obtained in the first 11 cases were described by Lawrence and Oakley (1953). In that paper the conditions necessary for the therapeutic trial of any insulin preparation were laid down.

In the cases described the patient was first stabilized on two injections of soluble, a single mixed injection of soluble and P.Z.I., or a single dose of P.Z.I. or globin insulin, and then changed over to a single dose of lente, equal in size to the total previous dose. The urine was examined for

TABLE I.—Comparison Between Lente Insulin and Other Insulin Preparations

sugar and ketone bodies at 7 a.m., 8 a.m., 11 a.m., noon, 6 p.m., and 9 p.m., and blood-sugar estimations were carried out at 8 a.m. (fasting), noon, 6 p.m., and 9 p.m. These results are summarized in Table I.

In the remaining 10 cases no attempt was made to compare by means of serial blood sugars the degree of control obtainable by the use of lente with that with the older insulins. The total dose of soluble insulin, P.Z.I., or mixture was converted into lente and an attempt then made to control the diabetes by adjusting the dose of lente. Six of these patients received comparable doses of different batches of lente with a view to determining the extent of batch-to-batch variation.

Good control was obtained in five cases, in two the result was fair, in two poor, and in one lente completely failed to control the hyperglycaemia; it is perhaps significant that the only satisfactory method of stabilizing this patient was by means of two relatively large doses of soluble insulin.

In these cases the results are not quite so good. One reason for this is that in the six who received different batches of lente it was essential not to vary the dose even if it proved inadequate at any time during the experiment; temporary shortage of lente insulin at this time also made good stabilization difficult, and, had more been available, at least one case classified as fair would almost certainly have been good.

(b) New Cases

Eight cases of severe untreated diabetes have received lente insulin in hospital; in seven of them no previous insulin therapy was given. Details of this series are shown in Table II.

Heavy glycosuria and hyperglycaemia exceeding 250 mg. per 100 ml. was present in every case, and in all but one there was also severe ketosis. The glycosuria after treatment is expressed qualitatively, the figure representing the mean result of six tests a day over the last four days of treatment. Control was regarded as good if the blood sugar before breakfast was 150 mg. or less, before the midday meal 180 mg. or less, and there was no evening relapse. As judged by these standards the control in six cases was good, in one fair, and in one poor. In the two latter cases 60 units of lente failed to produce good control; in one this was in part due to the fact that the patient was one of those used to compare the action of different batches of lente insulin, and the dose had therefore to be kept at a constant level until there was insufficient time left to study the effect of larger doses, but even allowing for this the response was not good.

In two of these cases five blood-sugar estimations were carried out during the twenty-four hours in order to follow the action of lente (Fig. 1). The course of the fasting and noon blood sugars, glycosuria, ketosis, and dosage of lente insulin is shown in two of the new cases whose control

FIG. 1.—Blood-sugar estimations in two new cases treated in hospital with lente insulin.

was classified as good. Glycosuria is expressed in the same way as in Table II (Figs. 2 and 3). In both instances there is seen to be a gradual fall in the level of the blood sugar, disappearance of ketosis, and a reduction in glycosuria; there were no hypoglycaemic reactions. The ketosis persisted for three days in one case and four days in the other, which is a little longer than is usual when two injections of soluble insulin are used at the onset of insulin therapy. All cases classified as good showed a satisfactory gain in weight.

Out-patients

A small series of 14 out-patients have been treated with lente; ten of these were new untreated diabetics and four relatively mild long-standing cases.

The out-patient treatment of new cases of moderately severe and severe diabetes has proved remarkably easy and successful. The results obtained in 6 out of the 10 cases are shown in Table III, and are all regarded as good. In the remaining four cases two were as good as those shown, one was fair, and one looks as if it will be good, but has not yet been on treatment long enough to warrant classification.

The four long-standing cases were all on a single morning dose of P.Z.I., which controlled the blood sugar in the

fasting state but not during the day. In three cases lente improved the control in this respect, and in one the results were unreliable owing to complete disregard of diet.

Batch Variability

It must be realized at the outset that in moderately severe and severe diabetes there is likely to be a day-to-day variation in the course of the disease, and exact similarity of results between different batches of any insulin cannot be expected. It should also be remembered that, from the point of view of this investigation, the degree of control is not of great importance, provided that conditions remain constant and there is no ketosis.

The results of this investigation are shown in Table IV and are regarded as indicating a reasonably close similarity between the hypoglycaemic action of the different batches of lente insulin tried.

Local and Hypoglycaemic Reactions

There have been no significant local reactions to lente insulin in our series of cases. In one patient a change to lente completely relieved persistent painful reactions to P.Z.I.

Fig. 2.—Fasting and noon blood sugars, glycosuria, ketosis, and dosage of lente insulin in a male patient aged 40. New case; control good.

Fig. 3.—Fasting and noon blood sugars, glycosuria, ketosis, and dosage of lente insulin in a female patient aged 20. New case; control good.

There have been remarkably few hypoglycaemic reactions either in the in-patients or in the out-patients. Such reactions as have occurred have been quite typical and relatively mild, except in one or two instances in which the dose given has been clearly too large and had to be greatly reduced.

Reactions have been observed at 10 a.m., three hours after injection, and at noon in the same patient, but not on the same day. The commonest times at which patients on lente insulin before breakfast are liable to have hypoglycaemic reactions appear to be during the morning or afternoon. Nocturnal reactions are uncommon in our experience, and hypoglycaemia rarely occurs in the early hours of the morning.

Conclusion

The reason why we have concentrated on lente insulin is that we think it is the most generally useful of the three preparations and the one which, if any, should be put on the market in the near future. We feel that further knowledge is required to determine whether or not ultralente has, for practical purposes, the same action as P.Z.I. and semilente the same action as globin insulin; if this is shown to be the case then it would seem reasonable to suggest that, if and when these two insulins of the lente series are put on the market, P.Z.I. and globin insulin should be simul-

taneously withdrawn so as to lessen the confusion which would inevitably result from having seven insulin preparations available to doctors and patients at one and the same time.

I wish to thank Dr. R. D. Lawrence for his unfailing interest and advice, and the Novo Laboratories of Copenhagen for generous supplies of lente insulin.

THE NEW INSULINS—LENTE, ULTRALENTE, AND SEMILENTE

BY

IAN MURRAY, M.D., F.R.C.P.Ed., F.R.F.P.S.

AND

ROBERT B. WILSON, M.B., B.Sc., M.R.C.P.

From the Department of Metabolic Diseases, Victoria Infirmary, Glasgow

Much interest has been aroused in the new insulin preparations of the Novo Therapeutisk Laboratories in Copenhagen (Hallas-Møller *et al.*, 1952a, 1952b; Lawrence and Oakley, 1953; Nabarro and Stowers, 1953). Through the courtesy of Dr. Hallas-Møller supplies of these insulins were made available to us in October, 1952, and since then we have investigated the effects in 28 patients. We have endeavoured to compare the action of these new insulins with that of insulins in current use, and to consider, in the event of their proving to be superior, whether such superiority was sufficient to warrant their introduction for general usage.

Initially, study was made on in-patients in hospital suffering from diabetes of considerable severity but well controlled with various combinations of soluble insulin and protamine zinc insulin, in order to compare the action of these with that of Novo insulins—"semilente," "lente," and "ultralente." Later we tried the new insulins on some patients in whom control was difficult, in the hope that these might give better results.

TABLE IV.—Comparison Between the Hypoglycaemic Action of Different Batches of Lente Insulin.

The investigation was then extended to include a number of out-patients. We hesitated to ask well-controlled patients to stay off work and come into hospital simply for the purpose of trial of a new insulin, while, on the other hand, we thought that a better comparison might be made with the patient continuing under ordinary working conditions. Those selected could be relied upon to carry out accurately all instructions about diet and urine-testing. Several of these out-patients were chosen either because it had been found that in their cases protamine zinc insulin did not have a sufficiently prolonged action, or because they were particularly subject to local insulin reactions.

All the patients were on a measured intake of carbohydrate in the diet, the amount being regulated by appetite but having regard for the maintenance of proper body weight. The daily allowance of carbohydrate was distributed in three roughly equal portions, at breakfast, lunch, and tea, with snacks between and a small late supper—for example, 285 g., distributed as follows: 8 a.m., 75 g.; 10 a.m., 15 g.; 12.30 p.m., 75 g.; 2.30 p.m., 15 g.; 5 p.m., 75 g.; 9 p.m., 30 g. Protein and fat in the

diets were not measured, since the quantity of these consumed varies so little from day to day.

Blood-sugar estimations were carried out by the method of Nelson (1944). Urine tests were done on samples collected before meals and after the bladder had been emptied half to one hour previously. In the case of out-patients, control was estimated largely by the result of urine tests, but in some of these, as in all in-patients, blood-sugar estimations were made.

Results

Details of the 28 patients investigated are summarized in Table I. It will be seen that they varied in age from 14 to 72 years, and that the length of time they had been diabetic varied from a few months to over 20 years. Of these patients 15 were female and 13 male. The results of blood-sugar estimations are shown in Table II. Some of the values were low, but were not associated with hypoglycaemic symptoms.

Lente.—From our observations we concluded that lente insulin had an action similar to that of a mixture of soluble and protamine zinc insulins. In every patient formerly controlled on a mixture of these, control was at least equally

good when lente was administered, while in a number of cases rather more even control throughout the 24 hours was noted. There was some advantage in that with the use of lente the trouble of making a mixture of two insulins was avoided.

The results obtained in two of these patients are shown in Figs. 1 and 2. It will be noted that, while they were well controlled with lente, in Case 3 previous control had not

FIG. 1.—Chart of Case 1.

FIG. 2.—Chart of Case 3.

been completely satisfactory. The blood-sugar values given in Table II for Case 8 would seem to show that the results obtained with lente were much inferior to those with a mixture of soluble and protamine zinc insulins. Actually we concluded that control was equal by either method, but this patient showed great variability. Although no other series of blood-sugar estimations was carried out while she was having the mixture, occasional examinations on various days gave values at least as high as those with lente.

In three cases in which lente was used the patient had previously been having morning and evening injections. In one (Case 18) the result was extremely satisfactory. In the other two (Cases 14 and 16), although the fasting blood-sugar level was normal, the levels during the early part of the day were too low.

FIG. 3.—Chart of Case 21.

Ultralente.—We found that ultralente had a more prolonged action than protamine zinc insulin, but when used alone it failed to control hyperglycaemia for several hours after injection. It is apparent in Fig. 3 that control on protamine zinc was poor. The explanation is that, although the patient was continued on this insulin, the dose, on account of hypoglycaemic attacks each afternoon, was reduced until these were eliminated.

Semilente.—We have used semilente in an insufficient number of cases to be able to draw definite conclusions, but its action appears to resemble that of soluble insulin.

Local Allergy.—Troublesome local insulin reactions are commonly encountered, as has been pointed out by Paley and Tunbridge (1952). This was a feature in eight of our cases, all of which had been receiving protamine zinc insulin either alone or in a mixture. On changing to lente or ultralente local allergy was immediately eliminated in every case.

Use of a Mixture.—Recently we have tried in one case (Case 26) a mixture of ultralente with lente, and in another (Case 27) ultralente with semilente. In the former, protamine zinc failed to control the man properly, urine tests were bad, and he became thirsty at night. The thirst was relieved on change to ultralente, but the tests still showed considerable glycosuria. He was then given a mixture of 52 units lente with 32 units ultralente, and he is now under better control than ever before. In the other case, a woman who has been diabetic for 22 years, control was very variable. Best control was obtained with separate injections of protamine zinc 44 units and soluble 16 units. She was then given 68 units ultralente. With this she became thirsty in the late afternoon and tests were bad, but in the early morning the urine was almost sugar-free. Eventually she was given a mixture of semilente 28 units with ultralente 48 units. This was a very definite improvement, as judged by urine tests, and she remained symptom-free and without hypoglycaemic attacks, of which she was always afraid.

It will be observed from Table I that no conclusion has been made regarding control with novo insulin of five patients (Cases 15, 20, 21, 23, and 28). In the first four of these the results seemed to suggest that a mixture of lente with ultralente might have proved very satisfactory, and until this has been tried it seems premature to judge the efficacy of novo insulins in these cases. The remaining case showed such fluctuations in control, associated with frequent asthmatic attacks, that comparison between different types of insulin was impossible.

Failures.—In two cases, previously well controlled, change to novo insulin was followed by rapid deterioration. Both were out-patients, and with the reappearance of diabetic symptoms they, on their own initiative, abandoned the new insulin and resumed that which they had been taking before. The first (Case 17) was a very intelligent man, a research chemist, extremely careful about diet and accurate in urine tests. On changing from globin insulin to lente he steadily became worse, and even a considerable increase in the dose of lente failed to correct this. With resumption of globin control was regained. The other patient (Case 25) was tried with ultralente because she was having much trouble with "lumps." All the urine tests very soon became bad and she developed thirst. Within two days of the resumption of protamine zinc control was restored. We have not so far had an opportunity of investigating the cause of the failure of novo insulin in these cases.

Conclusions

We considered that control obtained with the new Novo insulins was rather better in 14 and equally good in 7 of the 28 diabetic patients in whom trials were made. In two cases the results were definitely worse.

In four of the remaining five cases we have not felt justified in drawing definite conclusions on the relative merits of the old and new types of insulin, since the possibility of control with a mixture of lente and ultralente has not yet been investigated.

Lente insulin appeared to have an action similar to that of a mixture of soluble and protamine zinc insulins and thus had the advantage of avoiding the trouble of making such a mixture. In some cases it seemed to exert a more even action than such a mixture.

Ultralente was found to have a more prolonged action than that of protamine zinc insulin, but when used alone it rarely effected control in the early part of the day. It has the advantage that a small dose of semilente can be added without losing the effect of the latter, thus avoiding the necessity for separate injections.

Semilente appears to have an action similar to that of soluble insulin.

The Novo insulins available to us were in a strength of 40 units per ml. only, thus necessitating a bulky injection in many cases, but we understand that they may be introduced in double this strength.

The complete absence of local allergic reactions when using the new insulins was striking. In no instance was there any evidence of this, and, even in the eight cases in which insulin "lumps" had previously been troublesome, change to Novo insulin gave immediate and complete relief.

Having due consideration for the necessity of serious reflection before recommending the introduction of any insulin in addition to the series in current use, and admitting that further investigation especially regarding the use of mixtures of lente and ultralente insulins is required, we would nevertheless advise that lente and ultralente insulins be made available for general use. It seems probable that these insulins could control the large majority of diabetics and render unnecessary the use of protamine zinc and globin insulins.

ADDENDUM.—This paper was read at the meeting of the Diabetic Association in Leeds on July 17, 1953. Since that date it has been possible to make further observations on three of the patients (Cases 20, 21, and 23) in whom it was hoped better results might be obtained with the use of a mixture.

Case 20.—On changing from a dose of 120 units lente to a mixture of lente and semilente, 60 units of each, blood-sugar values were: fasting, 175 mg. per 100 ml.; noon, 47 mg.; 4 p.m., 156 mg.; 8.30 p.m., 140 mg. In view of the sharp drop in blood sugar before lunch the dose was altered to semilente 40 units, lente 80 units. Judged by urine tests, control was extremely satisfactory and there have been no hypoglycaemic incidents.

Case 21.—After the trials with lente and with ultralente he was discharged from hospital on his former regime. Later, as an out-patient, he was given lente and ultralente as a mixture, with 20 units of each. With this, control was better than ever before. The tendency to insulin reactions was entirely overcome. Blood-sugar results were: fasting, 64 mg. per 100 ml.; 11.45 a.m., 70 mg.; 4.30 p.m., 57 mg.; 8.30 p.m., 105 mg.

Case 23.—This man has now been taking a mixture—lente 40 units, ultralente 60 units—for six weeks, with satisfactory results.

We are in no doubt that in these three cases the use of a mixture has brought about definite improvement in control.

Investigation of the cause of failure with this insulin in Cases 17 and 25 has not yet been possible.

We are indebted to Messrs. Hendon Laboratories Ltd. and to Evans Medical Supplies Ltd. for supplies of the Novo insulins.

A study of European methods of dealing with air and water pollution caused by the chemical industry is being carried out by a technical assistance mission arranged by the Organization for European Economic Co-operation. The mission visited various chemical firms in the United Kingdom during the week October 25–31. The Board of Trade emphasized that the mission is confined to studying the problem of pollution caused by the chemical industry. It is not dealing with the problem of "smog," which is not a special problem of the chemical industry, being caused by the combustion of coal in general.

THE INSULIN ZINC SUSPENSIONS

BY

J. D. N. NABARRO, M.D., M.R.C.P.

AND

J. M. STOWERS, M.D., M.R.C.P.

Medical Unit, University College Hospital Medical School

The insulin zinc suspensions are a group of long-acting insulins recently developed by Hallas-Møller and his colleagues (1952b) at the Novo Laboratories in Copenhagen. They contain insulin precipitated with zinc and resuspended in an acetate buffer. The duration of the hypoglycaemic action depends chiefly on the size and form of the insulin particles. Two basic suspensions were prepared. One, with amorphous insulin particles, had a hypoglycaemic action lasting up to 16 hours, and was called "semilente" (insulin zinc suspension—amorphous). The second contained crystalline insulin, had an action lasting up to 30 hours or more, and was called "ultralente" (insulin zinc suspension—crystalline). Mixtures of the two suspensions remained stable and had the same effect as separate injections. By varying the proportions in the mixture it was possible to obtain insulins with a wide range of duration of action. Clinical trials in Denmark showed that most diabetic patients could be controlled with a single daily injection of a mixture containing 3 parts of the amorphous to 7 parts of the crystalline suspension (Hallas-Møller *et al.*, 1952a). This mixture was called "lente insulin" (insulin zinc suspension), and it is to be noted that the ratio of the two suspensions in this standard mixture was decided after trials in Denmark, using diets somewhat different from those customary in Great Britain. The descriptive features of these three preparations are tabulated below.

British Name	Danish Name	Duration in Hours	Strengths Available (Units/ml.)
Insulin zinc suspension	Lente	app. 24	40 and 80
Insulin zinc suspension (crystalline)	Ultralente	30+	40
Insulin zinc suspension (amorphous)	Semilente	12–16	40

Through the courtesy of the Novo Laboratories we have been studying the actions of these new insulins in the Diabetic Clinic at University College Hospital since October, 1952. The introduction of three new insulin preparations will complicate the management of patients with diabetes, and we have been investigating the possibility of shortening the action of I.Z.S. and I.Z.S. (crystalline) by the addition of soluble insulin instead of I.Z.S. (amorphous), thus making it unnecessary to release the latter as a separate preparation.

Clinical Trials

For the initial studies of the insulin zinc suspensions patients were admitted to hospital. Most of them were selected because they required large doses of insulin and morning and evening injections. They were given a strictly controlled diet with a distribution of carbohydrate suitable for the I.Z.S. (lente) (see Fig. 1). When the insulin dose had been adjusted, blood-sugar levels were studied over a 24-hour period. Capillary blood samples were collected at 8.15 a.m., 10 a.m., 12 noon, 2.15 p.m., 6 p.m., and 11 p.m., and the sugar content was estimated in duplicate by the Nelson modification of Somogyi's method (Nelson, 1944). Urine was collected in six-hour fractions and the glucose content measured by Benedict's method. The insulin was

injected 45 minutes before breakfast. In many of the patients the blood-sugar levels were studied on a number of occasions with different doses and combinations of I.Z.S., I.Z.S. (amorphous), and I.Z.S. (crystalline). At least one clear day was allowed between a change of insulin and investigation of the blood sugars. When repeated studies were made on a single patient the distribution of dietary carbohydrate was kept constant to simplify comparison of the results obtained, although the distribution was primarily devised for use with I.Z.S. and was not really ideal for some of the combinations.

Of the 22 patients studied, 19 were found to need more than 48 units a day of I.Z.S. The three milder cases and 9 of the 19 more severe ones were adequately controlled with I.Z.S. alone. This insulin proved unsatisfactory in

FIG. 1.—Diurnal variations in the blood sugar in patients with severe diabetes poorly controlled on I.Z.S. alone. Mean of six patients. Dose range, 48 to 108 units (mean 72). On the left I.Z.S. alone. On the right the same patients on combinations of I.Z.S. and I.Z.S. (crystalline) in the ratio 1:1 (two patients) and 2:1, 3:1, 4:1, and 5:1 (one patient each). Glucose equivalent of the diet = g. carbohydrate + 58% g. protein + 10% g. fat.

10 patients, all needing more than 48 units a day. One had a very variable insulin requirement, and in another the insulin action in the early part of the day was inadequate. The defect in the remaining eight was an evening and early morning hyperglycaemia. In six it was found that this could be prevented by the use of a combination of I.Z.S. and I.Z.S. (crystalline) in ratios varying from 5:1 to 1:1. These results are shown in Fig. 1. In the two other cases combinations of I.Z.S. and I.Z.S. (crystalline) were not used owing to the high doses needed and the consequent large volume of injection (over 3 ml.) using 40 units insulin per ml.

Thirteen of the 22 patients have subsequently been maintained as out-patients on I.Z.S. or a combination of I.Z.S. with I.Z.S. (crystalline); in addition a further eight have been given the new insulins as out-patients. In one of these the trial was unsuccessful because at the dose level needed with I.Z.S. alone (120 units a day, 80 units per ml.) the patient had nocturnal thirst and polyuria, and it was considered impracticable to use the appropriate combination of I.Z.S. with I.Z.S. (crystalline), as the latter is at present available only in the strength of 40 units per ml. In 15 patients observed over an adequate period as out-patients, the dose of the new insulins can be compared with that previously required. Of the remaining five, one had not needed insulin before and the other four have not been followed for long enough. The dose is almost identi-

cal (± 4 units) in five; in eight the dose of the new insulins is greater (mean +19 units, or 139% of the previous dose); in two the dose is smaller (10 and 24 units less).

A few hypoglycaemic attacks following the insulin zinc suspensions have occurred in hospital. In each case there was good warning and a gradual onset. This experience has been confirmed by out-patients who have had similar attacks.

There have been no local reactions to the injections of the insulin zinc suspensions. I.Z.S. was given to three patients who were having local reactions to soluble or globin insulin; there were no reactions with the new preparation.

Mixing of Insulin Zinc Suspension with Soluble Insulin

The insulin zinc suspensions are preparations at body pH and are designed to cover a range of duration of action from about 12 to 30 or more hours, but, since soluble insulin will always be needed, the question arises whether the action of I.Z.S. could not be shortened by mixing it with soluble insulin, thus dispensing with the need for I.Z.S. (amorphous). There is no phosphate in British soluble insulin, so the danger of precipitating the zinc in I.Z.S. as zinc phosphate does not exist. Soluble insulin, however, is kept at the acid pH of 3 to 3.5 to obtain optimal stability, and the pH would therefore be variable on mixing I.Z.S. and soluble insulin in different preparations. This factor of pH was shown by Hallas-Møller *et al.* (1952b) to control the form and size of insulin zinc particles and thus their prolongation of effect. Insulin exists as a precipitate in the presence of zinc (0.5 to 2 mg. per 1,000 units) in the pH range of roughly 4.5 to 8, and with a pH of between 5 and 6 the precipitate is in the crystalline long-acting form. If insulin zinc crystals are suspended in buffers between a pH of 4.5 and of 8 they remain crystalline, but when amorphous insulin zinc particles are buffered between a pH of 5 and of 6 they slowly become crystalline, and, furthermore, insulin precipitated from added soluble insulin will also be crystalline. Thus the addition of soluble insulin at this pH, so far from shortening the duration of action, will actually prolong it by increasing the proportion of the crystalline particles. This can be seen from the curves shown in Fig. 2. It can also be seen in this figure that the pH of a mixture of a soluble insulin and I.Z.S. cannot be

FIG. 2.—Comparison of blood-sugar curves obtained in a patient on a constant diet using varying proportions of I.Z.S. and soluble insulin, given by separate injection (on right) and premixed in phial for 24 hours (on left). Curves obtained with soluble insulin alone and I.Z.S. alone are shown at the top. The pH of the mixtures is recorded.

reliably predicted from the proportions of the two insulins mixed. This is presumably because there is a variable amount of free hydrochloric acid in soluble insulin. If successful mixing of soluble and I.Z.S. is to be achieved, the I.Z.S. must be buffered effectively outside the range at which crystalline precipitation occurs. We have been able to do this with 0.1 M acetate buffer at pH 4.8 added in equal volume to 80 units I.Z.S. per ml. (see Fig. 3).

FIG. 3.—Action of buffered I.Z.S. and mixtures of buffered I.Z.S. and soluble insulin. Top: Comparison of the effects of plain and buffered I.Z.S. Middle: Comparison of the mixtures of soluble with plain and buffered I.Z.S. In the former (final pH 5.19) the prolonged hypoglycaemic action suggests that additional I.Z.S. (crystalline) has been formed. Below: Comparison of mixtures of soluble and buffered I.Z.S. and I.Z.S. (amorphous) and buffered I.Z.S., showing that the addition of soluble insulin has the same effect as the addition of I.Z.S. (amorphous).

The final concentration of zinc in the mixture is important. Hallas-Møller *et al.* (1952b) have shown that the minimum effective concentration is about 0.5 mg. per 1,000 units, and the preparations of I.Z.S. to be put on the market contain 2 mg. per 1,000 units. To lower the zinc concentration below the critical level at least three volumes of soluble insulin would have to be added to one of the suspension, and this would be most unlikely to be required in practice. In mixtures of soluble insulin with I.Z.S. buffered at pH 4.8 the soluble insulin is at once precipitated, and at this pH the precipitate is in the amorphous form. Further study of this buffered I.Z.S. is required, but it seems likely that with its introduction it should be possible to dispense with the I.Z.S. (amorphous) as a separate preparation.

Discussion

The introduction of three new insulins will complicate the management of patients with diabetes mellitus and should be done only if there is good evidence that they are an improvement on the preparations at present in use. P.Z.I. alone is suitable for the control of mild diabetes but in the more severe cases soluble insulin is also necessary in the morning and sometimes in the evening as well. The varying excess of protamine in P.Z.I. makes it unwise to mix soluble insulin and P.Z.I. in the syringe or to inject them at the same site; for efficient and consistent control separate injections are required. A single dose of globin insulin given one hour before breakfast is effective in many patients needing less than 48 units a day, but in more severe diabetes early morning hyperglycaemia necessitates a second injection in the evening. Both P.Z.I. and globin insulin contain foreign protein, and sensitization reactions at the site of injection are not uncommon. Isophane (N.P.H.)

insulin has recently been made available in this country. It does not contain any excess of protamine and can therefore be satisfactorily mixed with soluble insulin. There is some evidence that the duration of action of isophane insulin is too short for a proportion of severe diabetics: it contains a foreign protein and may give rise to allergic reactions. The most outstanding defect of the long-acting insulins at present available is that most diabetics who need more than 48 units a day require morning and evening injections.

The originators of the insulin zinc suspensions claim that a single daily injection is enough for the great majority of diabetics requiring insulin. The standard mixture I.Z.S. (lente) is reported to be suitable for 85 to 90% of cases (Hallas-Møller *et al.*, 1952a); in the remainder a combination with I.Z.S. (amorphous) or I.Z.S. (crystalline) is necessary. These claims were confirmed by Lawrence and Oakley (1953), who obtained good results with I.Z.S. in 11 patients, 7 of whom needed more than 48 units a day. We have made detailed studies of the action of the insulin zinc suspensions in 22 diabetic patients in hospital. Our findings suggest that a single daily injection of the new insulins will be satisfactory in over 90% of diabetics, but in 40% of the more severe cases I.Z.S. (lente) used alone had too short an action, and a combination of I.Z.S. with I.Z.S. (crystalline) was required. The composition of the standard I.Z.S. mixture (lente insulin) was decided on the results of trials in Denmark using diets in which slightly more than half of the day's allowance of carbohydrate was taken before 2 p.m. In a recent memorandum published by the Novo Laboratories it is recommended that the ratio of carbohydrate taken at breakfast and lunch to that taken later in the day should be 120 : 80 or 3 : 2. In the diets in use at the diabetic clinic at this hospital the ratio is 1 : 1. It seems possible that although the standard I.Z.S. mixture with three parts I.Z.S. (amorphous) to seven parts I.Z.S. (crystalline) is optimal for the Danish dietary habits, a ratio of 2 : 8 would be more suitable in this country.

The duration of action of the standard I.Z.S. mixture can be lengthened by combining it with I.Z.S. (crystalline) in varying proportions. We have supplied our patients on such mixtures with phials of the premixed insulin so that the technical difficulties of mixing in the syringe are avoided. Use of these combinations in severe cases is limited by the strength of I.Z.S. (crystalline) available. The patients who might benefit most from the insulin zinc suspensions are those at present requiring large doses of insulin and two injections a day. However, unless the I.Z.S. (crystalline) is made available in the strength of 80 units per ml., many of them will be unable to take advantage of the new preparations.

Our studies have confirmed the value of the new insulins, but have indicated minor modifications that might simplify their introduction. In this country a standard mixture with two parts of amorphous to eight of crystalline may prove more suitable than the present lente mixture, and mean that fewer patients will require combinations of two types. If the standard mixture can be suitably buffered it may be possible to shorten its action, when this is necessary, by the addition of soluble insulin, thus dispensing with the need for I.Z.S. (amorphous). In only one of our patients has it so far proved desirable to shorten the action of I.Z.S. The I.Z.S. (crystalline) should be made available in a strength of 80 units per ml.

Indications for the Use of the Insulin Zinc Suspensions

Diabetics at present well controlled on a single daily injection of P.Z.I. or globin insulin are unlikely to benefit in any way from transfer to the new insulin zinc suspensions, unless their present insulin causes allergy. We consider that the indications for trial of the new insulins are: (1) poor control on present insulin; (2) patients at present needing morning and evening injections; (3) patients requiring P.Z.I. and soluble insulin in the morning by separate injection; and (4) patients who show allergic reactions to other types of insulin.

There are also certain contraindications. "Brittle" diabetics whose insulin requirement varies from day to day or during the day will usually be better controlled with morning and evening injections. Patients needing more than 80 units a day are likely to be disappointed with the insulin zinc suspensions at present available, because if they need a combination of I.Z.S. and I.Z.S. (crystalline) they will have to use it in the strength of 40 units per ml.

We have had little experience in the use of insulin zinc suspensions in patients being given insulin for the first time. With P.Z.I. and globin insulin severe local reactions may occur between three and nine months after the injections are started. It seems likely that these will be avoided by the use of the insulin zinc suspensions, and in many new diabetics treatment may begin with the new preparations.

Transfer to the Insulin Zinc Suspensions

It will often be found necessary to adjust both the diet and the insulin dosage when the patients are transferred to the new preparations. The carbohydrate in the diet should be distributed so that the greater part is taken at lunch and tea to cover the period of maximum insulin action. The amount of carbohydrate needed at breakfast-time has varied considerably. We have usually restricted it initially, but in some cases it has had to be increased later on account of morning hypoglycaemia. In all cases we have started with I.Z.S. and the previous total insulin dose. The patients are advised to make the injection 45 to 60 minutes before breakfast, and the importance of shaking the bottle well before withdrawing the insulin is stressed.

Patients are asked to test their urine four times a day during the period of adjustment (before breakfast, lunch-time, and suppertime, and at bedtime). Results of all urine tests are recorded and brought to the clinic on the weekly visits, which are considered desirable during this period. The patients are requested to adjust their own insulin dose if this appears necessary between visits. If the urine contains 2% or more sugar for 48 hours they are advised to increase the dose by 10%. If they experience any hypoglycaemic reactions a comparable reduction is authorized. Reactions may occur at any time of the day, but seem to be most common in the late morning and during the afternoon. They usually indicate the necessity for adjustment of the diet.

In a number of our patients it has become clear after the first few weeks that, although good control can be achieved with I.Z.S. alone during the day, glycosuria is present at bedtime and in the early morning. This suggests that the action of the I.Z.S. should be prolonged by the addition of I.Z.S. (crystalline), and we try first a 1 : 1 mixture, in which the ratio of I.Z.S. (amorphous) to I.Z.S. (crystalline) is 1.5 : 8.5. Some patients can be provided with sterile rubber-capped bottles and allowed to prepare their own mixtures; others have to have this done for them, and special arrangements are required for this in a busy clinic.

Summary

The action of the insulin zinc suspensions has been studied in 22 diabetic patients in hospital. Repeated blood-sugar estimations were performed over a 24-hour period. Insulin zinc suspension (lente) proved unsatisfactory in 10 out of 19 patients requiring more than 48 units a day. In most of these patients the duration of action was too short, and better control was achieved with a mixture of insulin zinc suspension and insulin zinc suspension (crystalline). For this purpose it is recommended that insulin zinc suspension (crystalline) should be made available in a strength of 80 units per ml.

Studies were undertaken to ascertain whether the action of insulin zinc suspension could be shortened by mixing it with soluble insulin, thus dispensing with

the need for insulin zinc suspension (amorphous). It is suggested that this would be possible if the properties of the acetate buffer in insulin zinc suspension were altered, but that further studies are required.

The indications for the use of the insulin zinc suspensions are described, and a plan is outlined for changing patients to the new preparations.

We wish to thank the Novo Laboratories in Copenhagen and Evans Medical Supplies Limited, their distributors in this country, for very generous supplies of these insulins for use in this trial. We would also like to thank Miss A. Moxham, who performed most of the blood-sugar estimations, and the dietitians, sisters, and nurses for the great help they have given us.

THE CLASSIFICATION OF VARIOUS INSULINS

BY

F. GERRITZEN, M.D.

(From the Department of Endocrinology and Diseases of Metabolism, University Hospital Medical Department, Leyden, Holland)

In an annotation in the *British Medical Journal* (1953) in which the Novo insulin preparations were announced, attention was drawn to the confusion that might arise when a larger variety of insulins became available. This problem needs extensive consideration for several reasons.

In some cases the new insulin preparations show no superiority over those already in use, but in others they are a distinct improvement. Most doctors who treat diabetic patients use a special brand of insulin, and thus do not take advantage of the intensive research that is going on in the laboratories of the insulin manufacturers.

To choose the right insulin for a certain diabetic patient is not a simple matter. It requires a thorough study of the particular manifestations of the case and a knowledge of the characteristics of the various insulins existing, to adapt the insulin therapy to the individual need. It would be of great value, therefore, if the physician could be guided in the choice of the most suitable insulin, or, if the patient is already using insulin, in making a change that might be of benefit in the particular case.

Principles Involved in Choosing Type of Insulin

In this study a method is recommended which has been described earlier (Gerritzen, 1952), but it might be useful to recall attention to the principles that led to its adoption. Though insulin is used almost exclusively in diabetics, no reliable information can be had from an investigation of diabetic patients because they vary widely in sensitiveness to it. The results obtained would tell us more about the variation in sensitiveness of the patients than about the insulin itself. The same consideration would apply if, in the standardization of insulin, diabetic instead of healthy rabbits were used. The results would be far more uncertain if diabetic rabbits with different degrees of the metabolic

disorder served as test animals. Evidently the diabetic patient would not be a suitable subject for testing the properties of different insulins. Even the average of several diabetics, if an average could be calculated, would not be better, as the average diabetic does not exist.

Insulin is measured in terms of the decrease of the blood sugar after injection. This means that if the decrease in the blood sugar is representative of the action of insulin, all other factors influencing the blood sugar must be excluded. Fasting and exercise, which tend to depress the blood sugar, must be avoided; in addition, emotions and meals, which cause an increase of blood sugar, should also be excluded. Elimination of exercise is easy in the human, as the test persons can be kept in bed. The requirements to exclude meals and to avoid a fasting state led me to give a constant amount of carbohydrate every hour, a method that is not practicable in test animals, because the emotion of forced feeding would undoubtedly influence the blood sugar. Test animals in a state of fasting would get low blood-sugar values when insulin was injected, and a regulating mechanism, of which adrenaline is the most important component, might come into action, thus making the results of insulin action very uncertain.

For these reasons I choose healthy students as test persons. The results obtained in regard to duration and character of the action of insulin would not, of course, apply to diabetics, but they would tell us something about the qualities of the various insulins. This has become of special importance since Hallas-Møller *et al.* (1952a, 1952b) published their method of testing insulin in diabetics. In a great number of diabetics they classified the reaction to different insulins as types A, B, and C; type B being the ideal one, as it gives a flat blood-sugar curve throughout the day. It is necessary to give the A-type (✓) patient an insulin that has a more prolonged action with less intensity during the first few hours after injection, while patients of type C (✓) require an insulin of shorter and more intense action.

This logical attempt to adjust the insulin to the type of reaction of the patient presupposes a knowledge of the differences that exist between the various insulins. This study is an effort to classify the insulins in regard to the duration and character of the action.

The persons tested were lying down from 11 p.m. the night before the experiment started and during the experiment. From 6 a.m. on the day of the experiment they ate 50 g. of mashed potatoes (about 10 g. of carbohydrate) and drank 30 ml. of water every hour. From 7 a.m. the blood sugar was determined hourly by the Hagedorn-Jensen method, until the end of the experiment, which was considered to be reached when the average blood sugar had returned to its original level at 8 a.m.

By this method I was able to classify 13 different insulins without difficulty into four categories according to the duration of the action. Differences in the intensity of the action, as measured by the depression of the blood-sugar level, are shown in Figs. 1-4. The insulin mixtures are described in my previous study (Gerritzen, 1952), but are not considered here.

In an earlier investigation (not published) I found that the sensitivity of healthy students to insulin does not vary throughout the day. Therefore the fact that the prolonged insulins act throughout the evening and night does not affect the results.

Duration of Action

Category 1.—Duration, eight hours. Only two insulins were tested—regular

Fig. 1.—Category 1. Duration of action, 8 hours. Both insulins act during the same period of time. Regular insulin (Organon) reaches its maximum in one hour. Alt-insulin (Horm) acts less acutely.

insulin (Organon) and alt-insulin (Horm)—the former acting somewhat more acutely than the latter. In the literature the normal duration of the action of regular insulin in diabetics is given as eight hours, so one may take this value to be well founded (Fig. 1).

Category 2.—Duration, 10 hours. To this category belong N.P.H. insulin (Organon), N.P.H. 50 (Lilly), depot insulin (Horm), semilente (Novo), and zinc insulin "neutrale" (Organon). These show only minor differences in character. The first three insulins are protamine zinc insulins: N.P.H. insulin and N.P.H. 50 being cloudy suspensions and depot insulin (Horm) a clear solution. The last two insulins are zinc insulins, consisting of zinc and insulin only (Fig. 2).

Fig. 2.—Category 2. Duration of action, 10 hours. These five insulins have a nearly identical action—only minor variations in intensity.

Fig. 3.—Category 3. Duration of action, 16 hours. Of the insulins of this class, lente has the smoothest action.

Fig. 4.—Category 4. Duration of action, 18 hours. These insulins have the most prolonged action of all the insulins at present on the market.

diabetic patients (Figs. 3 and 4). This is a question of individual sensitivity more than an indication of the character of the insulin. Hallas-Møller's method of arriving at the most suitable insulin seems logical, but a knowledge of the differences existing between the various insulins, measured under standard experimental conditions in an identical test material, is a prerequisite for its practical application.

The description of these insulins, which comprise only a few of those on the market, leads to the question whether one preparation is preferable to another of the same category. This question I have not tried to answer.

Summary

Thirteen different insulins have been tested in young healthy students under standard experimental conditions—that is, absolute rest and a constant hourly intake of carbohydrate and water.

These insulins have been classified into four categories, according to the duration of the action, with the object of simplifying the choice of the most suitable insulin.

I have to thank Miss S. P. I. Hoogveen for accurate and numerous blood-sugar determinations, and the managements of Burroughs Wellcome, Hormonchemie, Novo, and Organon for financial support.

Medical Memoranda

An Early Fatal Reaction to Blood Transfusion

Fatal haemolytic transfusion reactions due to specific incompatibility between the blood of the donor and recipient are fortunately rare. The fatal haemolytic reaction here recorded was the result of confusing the recipient's name with that of the donor's label, both donor and recipient having the same surname. The duration of the reaction, which was four hours, must be regarded as one of the shortest on record.

CASE REPORT

After an abdomino-perineal excision of the rectum for carcinoma on February 10, 1953, a man aged 54 received 2 pints (1,140 ml.) of blood of his own group, O rhesus-positive, followed by intravenous dextrose-saline. In the early hours of February 11, on account of bleeding from the perineal wound, the night sister, thinking that the patient required more blood and acting on unreliable information that the blood had been prepared and would be available in the pathological laboratory, went to the blood bank about 3.30 a.m. and, on finding a bottle with a donor's label bearing the name Moon (which was the patient's name), took it to the ward and began the transfusion. The blood was group B rhesus-positive, and did not bear a compatibility label. It ran very slowly from 4 to 5 a.m., when it stopped. The resident doctor, after relieving the blockage in the needle, allowed the blood to flow rapidly from 6 to 6.20 a.m., when the patient had a severe rigor lasting 10 minutes. He had pyrexia and a rapid pulse, and seemed distressed. For the next three and a half hours, until his death at 10 a.m., he had suffered from severe shock, with pyrexia, rapid pulse, increased respirations, and epigastric pain. He had survived four hours after receiving a rapid transfusion of about 300 ml. of incompatible blood.

Post-mortem Examination.—This was conducted about two hours after death and revealed little retroperitoneal haemorrhage. The blood serum was very haemolysed. When anti-B serum was mixed with the patient's cells there was no agglutination, indicating that complete, or almost complete, destruction of all the transfused cells had taken place. A comparison of pre- and post-transfusion titres to anti-A and anti-B in the patient's serum was made. (1) The titre of anti-A was 1:8 in both pre- and post-transfusion

samples: this served as a control for the second test. (2) The titre of anti-B was 1:8 in the pre-transfusion sample, and 1:2 in the post-transfusion sample, indicating the absorption of large quantities of circulating anti-B on the transfused cells.

Histology.—The changes in the kidneys suggested a haemolytic reaction: the intertubular blood vessels were dilated and engorged with blood containing clumped masses of red blood cells; the tubular epithelium showed degenerate changes, and the lumina contained brownish granular material and pigment casts; there was oedema of the interstitial tissue. The sinusoids of the liver contained granular pigmented material and clumped red cells. The cerebral capillaries, mainly in the subcortical white matter, showed marked clumping of red cells, with amorphous granular deposits of haemoglobin. There were numerous small perivascular haemorrhages, the red cells in one instance being seen passing through a damaged capillary wall.

Dr. A. F. Ollerenshaw did the blood tests.

A. A. MILLER, M.D.,
Group Laboratory, Royal Infirmary, Preston.

Headaches Caused by Nasal Obstruction

The following case is unusual enough to be worthy of record.

CASE REPORT

A girl aged 18 was first seen in 1946, complaining of frequently recurring severe headaches, localized in the frontal area of the head above and behind the right eye. The headaches were so bad that she often had to stay home in bed, missing school two or three times a week. Inquiry revealed that there had never been any accident to the nose or head. When she was 11 two different ophthalmologists found her eyes to be normal.

On examination the nasal septum was found to be deflected to the right side, high up, causing pressure against the middle turbinate and obstruction in the upper part of the nose. It was thought that the headache was due to frontal sinus obstruction, and the patient was referred to an E.N.T. surgeon, who gave drops to put in the nose. These gave temporary relief and nothing further was done. An x-ray examination was not thought necessary.

The patient was referred to me again in April, 1951. During the intervening four years she had had frequent headaches, to cure which the tonsils and adenoids had been removed once, and the adenoids a second time. The headaches had become continuous day and night for the past six weeks, and had necessitated injections of "omnolon," in addition to codeine and phenacetin tablets, and various headache powders. In February, 1951, she again visited an ophthalmologist and had been fitted with glasses, which improved the eyesight but did not relieve the headaches.

FIG. 1.—Lateral view showing needle in position.

Recently the mother recollected an accident that occurred when the patient was 9 years old. While running down some steps at school she had run into a girl who was holding a knitting needle. Thereafter, her nose bled freely for a few hours. She was, however, able to return to school the next day. This story was dismissed as of no consequence, and as having no bearing on the headaches.

On examination some obstruction in the right side of the nose high up was again found. There was ptosis of the right eyelid. The blood pressure was 120/72. The urine, the cardiovascular and gastro-intestinal systems, and the reflexes were normal. Again a diagnosis of frontal sinus obstruction was made, but on this occasion she was sent for an x-ray examination of the skull. The result was indeed surprising. The radiologist's report was as follows: "A metallic foreign body, some 3 in. (7.5 cm.) in length, projects posteriorly and upwards with a slight lateral inclination from the right nostril. The point has penetrated the base of the skull and lies within the middle cranial fossa lateral to the sphenoid sinus. The ethmoid, sphenoid, and frontal sinuses appear normally translucent and show no evidence of infective change or other abnormality. Both maxillary antra are normal in appearance and no evidence of infection is seen" (Figs. 1 and 2). On clinical grounds it seemed most improbable that the needle was penetrating into the middle fossa and brain, but it was obvious that an operation had to be done at once, and the patient was admitted to hospital.

FIG. 2.—Radiograph showing position of needle and clear antra.

It was thought wise to give penicillin and streptomycin for 48 hours before operation, because of the possibility of a cerebral abscess forming and to prevent post-operative infection. The patient had constant headache and increasing ptosis of the right eye, and she was drowsy, lay curled up on her right side, would do nothing, took no interest in anything, and avoided the light. The leucocytes numbered 8,500, neutrophils 73%, monocytes 6%, lymphocytes 18%, eosinophils 2%, basophils 1%.

Under general anaesthesia the needle was removed through the nose. It was lying on the nasal plate of the maxilla, under the inferior turbinate, and was covered with a thin layer of bone, which had to be broken away before the end of the needle could be freed. When about 1 in. (2.5 cm.) of the needle was exposed it was grasped firmly with forceps and extracted. It was necessary to pull with some force before the needle—2½ in. (6.3 cm.) long—suddenly came away intact. A petroleum jelly and sulphonamide plug was placed in the nose and the patient returned to bed.

For four days headaches continued, but with periods of freedom. From the fifth day onward there were no further headaches. The penicillin and streptomycin were continued up to the tenth day, when the patient was so well that she was discharged from hospital, with the wound in the nose soundly healed. She has since then been completely free of headache, and feels better than she has done for years. The mother states that her outlook on life and disposition have greatly improved.

I wish to thank Dr. E. R. Hafner, under whose care the patient had recently come, for permission to publish this case.

Reviews

SOCIETY AND GENETICS

The Facts of Life. By C. D. Darlington. (Pp. 467; illustrated. £1 15s.) London: Allen and Unwin. 1953.

This book contains two components—an account of the mechanism of reproduction and inheritance, and Professor Darlington's views on the relevance of this mechanism to certain social and moral questions. It therefore has to be judged on two criteria—its accuracy and lucidity as a piece of popular science, and its perception and originality as a synthesis of biology and sociology.

The so-called laws of heredity, and the remarkable parallelism between the observed behaviour of chromosomes and the segregation of Mendelian "factors," are familiar to all who have read biology, both amateurs and professionals. There are already a dozen good popular books on the subject. Professor Darlington's book has two advantages over earlier ones—namely, that it includes some recent work on the genetics of micro-organisms and on the evolution of immunity to disease; and that it has a good chapter on "the genetic underworld," which summarizes those phenomena of inheritance which pass through the protoplasm and not the nucleus. Unfortunately (we say "unfortunately" because Professor Darlington has great authority as a cytologist, and he could have written an authoritative popular account) these are the only two advantages of *The Facts of Life*. The author evidently underrates the intelligence of people who read scientific books, for he refrains from burdening his readers with many of the facts of life or (for that matter) with many facts. In place of a lucid and thorough exposition of modern views on the genetics and physiology of reproduction, he pads the exposition with what he himself in the preface calls "light entertainment," in the form of quips about incidents in the Old Testament, Russian politics, virgin birth, and Mr. Arnold Toynbee. The chapters are peppered with the sort of querulous pertness one remembers in Samuel Butler's notebooks: only in those days it was a novelty.

Every man to his humour: it may just be the reviewer's sour prejudice to like his science straight. Suffice it to say that, as an exposition of the facts of reproduction and heredity, Professor Darlington's book is of fair average quality, with some new material, but otherwise without any special merits to distinguish it from a dozen others. Therefore the value of the book must rest on the way Professor Darlington develops his thesis that the great questions of society—love and courtship, marriage and divorce, immortality and free will—can be answered, or at any rate brightly illuminated, by reference to the behaviour of chromosomes and the genes they carry, and to the influence on genes of natural selection. Professor Darlington belongs to that almost extinct variety of thinkers, scientific determinists. He is utterly confident that science can analyse not only efficient causes but final causes too. He really does believe that the marriage and divorce laws would be better if they were drawn up by biologists. He summarizes the complex emotional and mental reactions based on pituitary, gonads, and central nervous system, leading through courtship to consummation; "it is to these," he says artlessly, "that we give the name of love." He predicts that on genetic grounds "some five or ten per cent of marriages will fail." He asserts that low agricultural production in England is due to the genetic unfitness of tenant farmers. He provides a genetic reason for the "great illusion" of immortality.

From time to time scientists have to be iconoclasts and they should not respect even the most precious beliefs if these are contrary to fact. But there are rules for scientific iconoclasts. Rule One is never to extrapolate, never to carry your conclusions beyond your data. Nietzsche extrapolated Darwinism beyond the dogs and pigeons and fishes to

European society; and the dreadful fallacy of that extrapolation was demonstrated from 1939 to 1945. Darlington, in a word, offers the reader of *The Facts of Life* a faintly similar extrapolation of Mendelism. Only we are now in a colder intellectual climate than Nietzsche was, and the attempt is not ominous: it simply falls flat. Rule Two for iconoclasts is to break images in the name of the Truth and all the Truth. Now on several occasions Professor Darlington does what he is far too good a scientist to do in his research: he omits relevant evidence. Take, for example, the discussion of twins. Darlington cites in full the observations of Lange on criminal twins, published 25 years ago. This work provides evidence in favour of genetic determinism among identical twins. But, although he quotes one reference in his bibliography, Darlington does not mention that Newman and many others have done work since 1929 which greatly weakens Lange's opinion that the social behaviour of identical twins is almost entirely a matter of nature, not of nurture. In this and in other instances Darlington makes dogmatic assertions without disclosing to his readers that there is evidence inconsistent with his dogmatism. He precedes his book by a pretty Japanese picture and quotations from Chaucer, Montaigne, and Gibbon. It would have been well if he had added Amiel's warning: "An error is the more dangerous in proportion to the degree of truth it contains."

One sometimes hears it said that in a scientific age scientists should have a greater influence in government. Professor Darlington's book should be widely read if only as an awful warning of the horrors which await us if we ever get a scientific oligarchy.

ERIC ASHBY.

CLINICAL ENDOCRINOLOGY

Clinical Endocrinology. By Allan William Spence, M.A., M.D.(Cantab.), F.R.C.P. (Pp. 696; 59 figures. £2 10s.) London: Cassell and Co. 1953.

This outstanding publication has been written by a wise and experienced general physician who at the same time is a first-class endocrinologist with personal experience, over a number of years, in the experimental laboratory and in the wards of a great hospital. It is the best book that has appeared in this field for some years and it will become a standard work for students, postgraduates, and all physicians interested in the subject. The historical notes are brief but fascinating, and the notes on the standardization of hormones give us a mathematical and scientific basis for therapy. The author discusses each gland in a separate section and comprehensively. He considers Cushing's syndrome in its latest aspects, and draws attention to such features as atrophy of the opposite gland in the presence of an adrenal tumour and the therapeutic results of bilateral adrenalectomy, a procedure initiated on a systematic scale at the Mayo Clinic. The basic work of Sheehan in enlarging the scope of our knowledge of Simmonds's disease is well presented. Fröhlich's syndrome appears in proper perspective and the differential diagnosis is discussed with illumination. The hypothalamus finds its appropriate place both in its own right and in relationship to pituitary disorders.

In view of the author's pioneer work with Marine in America and later with Scowen at St. Bartholomew's Hospital, it is not surprising that the thyroid section excels in its account of the physiology and the application of this knowledge to clinical disorders of the thyroid gland. Unfortunately, it has not been possible to add anything reassuring to our present views on the treatment of that very difficult condition exophthalmic ophthalmoplegia, but the author draws attention to radiotherapy of the orbital tissues. This gives some benefit, perhaps paradoxically, in the most advanced cases with considerable oedema of the conjunctiva. The more recent indication that A.C.T.H. may be of value in these cases has not been sustained by further experience. The section on the thymus gland faithfully records the work of Rowntree and his colleagues on the effect of thymic

extracts in successive generations of rats, inducing precocity of growth and development, and the author notes that other investigators have failed to confirm the results. It is now known that there is little likelihood of these experiments being repeated with the same result and that the laboratory circumstances were such as were apt to mislead the original workers. It would therefore be better not to cite this series of experiments any longer, since needless confusion may result. This does not mean that thymic extracts may not have actions as yet unelucidated. The work would not have been quoted so often had not the research workers been men of outstanding ability and integrity who have achieved a great deal in other endocrine fields.

In some respects the chapter on miscellaneous disorders is the most fascinating, and among other subjects the author considers intersexuality, hermaphroditism, sexual precocity, various forms of hypothalamic disorders, adipose gynandrisms, sterility, and hyperinsulinism. The references are comprehensive and the index is clear and adequate.

S. LEONARD SIMPSON.

E.N.T. INTRODUCTION

Ear, Nose, and Throat Diseases for Medical Students. By William McKenzie, M.B., B.Chir.(Cantab.), F.R.C.S. (Pp. 260; 95 figures. £1 1s.) Edinburgh and London: E. and S. Livingstone. 1953.

In his preface the author states that this book is designed to be interesting rather than exhaustive. In the space of only 250 pages are included sketches of the diseases of the upper respiratory tract, oesophagus, and bronchi, and it is striking how much instruction is conveyed in that space. It is evident that the work is founded on the author's own experience, and he makes full use of it in all sections of the subject, though the chapter on deafness stands out as most comprehensive and lucid. A feature of the book is the frequent interpolation of short case histories to illustrate mistakes and successes in diagnosis and treatment, a sure way of interesting the student. The style is naturally didactic and there are some statements which might have been modified to suit the student. The statement that syphilis is a rare disease in this country would better read that throat manifestations of syphilis are now rare. "The function of the semicircular canals and vestibule is that of maintaining the position of the body in space" really means maintaining the knowledge of the position.

The only operations described in detail are tonsillectomy, tracheotomy, and antral lavage, and the accounts are excellent. At the end of each chapter are two or three questions to focus the student's attention on its contents, and at the end of the book come E.N.T. questions from the Conjoint Board examination papers. With his inherited knowledge of E.N.T. history why does the author displace the names of Patterson-Brown Kelly by Plummer-Vinson? The book is a novel elementary introduction to the specialty.

W. M. MOLLISON.

DIAGNOSTIC RADIOLOGY

Modern Trends in Diagnostic Radiology. (Second Series.) Edited by J. W. McLaren, M.A., M.R.C.P., F.F.R., D.M.R.E. (Pp. 413; 359 figures. £3 10s.) London: Butterworth and Co. 1953.

Dr. McLaren, in presenting the second edition of *Modern Trends in Diagnostic Radiology*, might almost have called it "Modern Scandinavian Trends," since seventeen of its thirty contributors come from countries that combine to produce *Acta Radiologica*. This is no bad thing, and the volume reflects the outstanding work that has come from these countries during the past five years.

J. W. Pierce has contributed a valuable survey of the pulmonary manifestations of fungous diseases occurring in Britain and in America. Recent technical developments in rapid film changers, outlined by Schonander early in the

book, give point to a critical résumé by Wegelius and Lind of the problems in cardiac physiology and pathology to which angiocardiology can supply the answer. The reviewer's only regret on reading this section is that space was not found for a more detailed presentation of this work on two-plane simultaneous angiocardiology with synchronous electrocardiographic records. The cases illustrated in this article show clearly how necessary the E.C.G. record may be for an accurate angiocardiological study of the dynamics of the heart. Gunnar Jönsson has contributed an important article on selective angiocardiology and thoracic aortography, with many illustrative cases.

A welcome contribution on the colon comes from Arthur Singleton, of Toronto, and the editor himself writes an admirable survey of the recent work on the small intestine. Frimann-Dahl has by his recent monograph shown himself to be an authority on the radiology of the acute abdomen, and it is fitting that he should have been asked to write on this subject. Other Scandinavian articles of great interest include those by Lindblom on arthrography, Lindgren on abdominal aortography, and Engset and Kristiansen on cerebral angiography.

It is sobering to realize that in 1952 nearly nine million x-ray examinations were carried out in England and Wales, a million more than the year before; and this readable and informative book, with authority in every article, helps to explain that massive increase. The first edition set a high standard, and Dr. McLaren is to be congratulated in having raised it in this second edition.

S. COCHRANE SHANKS.

PARASITIC ANIMALS

Parasitic Animals. By Geoffrey Lapage, M.D., M.Sc., M.A. (Pp. 351; 113 figures. £1 1s.) London: Cambridge University Press. 1951.

The aim of this book, as stated in the author's preface, "is to give, from the biological rather than the economic point of view, an outline of the general principles which govern the lives of parasitic animals." Its title has been chosen to indicate that the kind of parasites concerned are those belonging to the animal kingdom, so that other parasitic organisms such as viruses and bacteria are excluded. In describing, therefore, how parasitic animals live, the scope of the work is limited, if such a word can be used in a field of this magnitude, to certain parasitic species selected from the groups arthropoda, protozoa, and helminths; and, although "not in any sense a text-book of economic parasitology," reference is made chiefly to those parasites which are harmful to man and his domestic animals.

The first two chapters are concerned with a definition of the term "parasitic animal" and a general description of the routes of entry and movements of parasites inside the host's body. Representative life-cycles selected from the three groups are then described in detail. These are illustrated by diagrams which will delight the student of parasitology by their originality and clarity and are certain to arouse the interest of the intelligent general reader. Five chapters are devoted to various aspects of the host-parasite relationship, which include some very interesting and instructive discussions on the effects of parasitism on the parasite and the effects of the parasite on its host. The subjects of host tissue reactions and host immunity are discussed competently. An account of the main principles in the control of parasitic infections follows, and in his conclusion the author discusses a philosophical viewpoint to parasitism and in this reveals an eloquence of style which is in abeyance in his presentation of the factual matter of the preceding chapters. This book contains a wealth of information on the parasites the author has chosen to illustrate his main thesis, and, taken as a whole, is one to be recommended to students and teachers of parasitology, while the general reader will find much interesting material within its pages.

J. J. C. BUCKLEY.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 7 1953

PROGRESS IN ANTIBIOTICS

We are able to print on p. 1043 an account of a symposium on antibiotics held in the latter part of last week at the U.S. Department of Health, Washington. Contributors to this included many leading authorities in the U.S.A., which has been the birthplace and first testing ground of almost every new important antibiotic since penicillin. The commercial enterprise responsible for this leadership is well known: the immense resources of American pharmaceutical houses have enabled them to conduct costly surveys of many thousand samples of soil from all parts of the world in the hope of discovering new and valuable antibiotic-producing organisms. This has probably been the most rapidly expanding American industry of the past few years, and one in which the reward of success is an immense prosperity which may nevertheless be of short duration. Either some unexpected drawback to the use of the drug may be discovered after the first burst of therapeutic enthusiasm, or mounting bacterial resistance may diminish its value; at any moment, too, something else better may be discovered by someone else. It is this fierce competition which has given us the almost bewildering series of new antibiotics of the past few years.

The news about erythromycin, of which only small quantities for research and other special purposes have yet reached England, is much as might have been expected. This substance, and carbomycin, which closely resembles it, have a range of activity corresponding more closely to that of penicillin than that of their predecessors. Erythromycin has been successfully used for streptococcal infections and pneumonia, but for these conditions penicillin itself remains available. It appears to be unsuccessful in endocarditis except in combination with another drug—streptomycin—in a series of cases reported at this meeting. Its main sphere of usefulness is the treat-

ment of staphylococcal infections resistant not only to penicillin but to aureomycin and terramycin. It should perhaps be reserved for this and any other strictly specific indications, in view of a report from Chicago on the effects of its general use in a hospital. Within a few months the majority of the staff became nasal or throat carriers of a staphylococcus highly resistant to it, and this organism began also to cause infections in patients. Although there are no precise data on the point, it may be suspected that resistance to erythromycin among staphylococci is acquired more rapidly than to its predecessors. If so, this drug should evidently be held carefully in reserve and not used promiscuously.

The principal new antibiotic announced was tetracycline, which is simply the same molecule as that of aureomycin and terramycin (chlortetracycline and oxytetracycline) without either of the attachments which characterize these antibiotics. It has not only been prepared by the dehalogenation of aureomycin, but has been obtained from a new species of mould. It is unusual for the action of a chemotherapeutic agent to be improved by removing something from the molecule: most developments in the past have been elaborations rather than simplifications. It may well be wondered whether further modifications of the basic molecule of tetracycline may not be possible by way of addition rather than subtraction, which will confer superior properties on it. In therapeutic activity tetracycline differs little from its cousins. Its chief advantage is a substantially smaller liability to cause nausea or vomiting and diarrhoea, an improvement for which any patient having to take these drugs for some length of time, as in the treatment of brucellosis, will undoubtedly be grateful. On the other hand, novelty must also be counted one of its principal assets.

Apart from other novelties of little clinical importance, the symposium was devoted largely to discussing better ways of using existing drugs. There are new "dosage forms" of penicillin, and the possibilities of combined treatment have been further explored. The use of two drugs together is now regarded as obligatory in the treatment of tuberculosis, and there are other important indications for it. On the other hand, "blind" therapy with two or more drugs was strongly condemned. There is no doubt that the first condition for success in the use of antibiotics is diagnosis, which can then be followed by the deliberate choice of treatment known to be appropriate.

ISONIAZID WITH P.A.S. OR STREPTOMYCIN

The fifth report of the Tuberculosis Chemotherapeutic Trials Committee of the Medical Research Council on the use of isoniazid in pulmonary tuberculosis is published on another page. Previous reports¹⁻³ have shown that isoniazid is an effective drug and almost devoid of toxicity in the doses used, but that, if given alone, drug-resistant organisms emerge in a high proportion of patients. It has also been established that the combination of streptomycin 1 g. daily with isoniazid 100 mg. twice daily reduces the incidence of streptomycin resistance to a degree comparable with that obtained by combining the same dose of streptomycin with 5 g. of sodium *para*-aminosalicylate (P.A.S. (sodium)) four times a day.

The present report compares the clinical effectiveness of isoniazid 100 mg. twice a day for three months when combined either with streptomycin 1 g. daily (SH group) or with P.A.S. (sodium) 5 g. four times a day (20 PH group). The comparison was made in patients with widely differing types of lesion, though excluding those with chronic disease who, before admission to the trial, were thought unlikely to make any significant response to chemotherapy. As in previous trials, once patients were accepted for the trial they were allotted at random to the different treatment groups. There were 116 in the SH group and 93 in the 20 PH group; the distribution of patients with severe and less severe disease was similar in the two groups, though on the whole the 20 PH patients were rather more ill. The clinical results at the end of three months were very similar. In both groups 90% of patients improved in general condition. Average weight gain in the SH group was a little greater, 12.8 lb. (5.8 kg.) as compared with 10.8 lb. (4.9 kg.). Moderate or considerable improvement in the radiograph occurred in 54% of SH as compared with 42% of 20 PH patients. On the other hand slightly more of the febrile patients in the 20 PH group became afebrile (85% as compared with 79%), and of those with raised erythrocyte sedimentation rate rather more returned to normal (46% as compared with 37%). There was no difference in the rate of sputum conversion as measured at a single examination by direct smear and culture after three months' treatment. It appears, therefore, that isoniazid 100 mg. twice a day given with P.A.S. (sodium) 5 g. four times a day is a very effective treatment, and comparable in results to strepto-

mycin 1 g. daily combined with isoniazid 100 mg. twice a day or with P.A.S. (sodium) 20 g. a day. That 20 PH may be an effective treatment over longer periods than three months is suggested by the very satisfactory results of the tests for drug resistance. In the SH group, in accordance with previous experience, isoniazid-resistant organisms were isolated after three months only from 2 out of 106 patients, or 2 out of the 39 whose sputum remained positive on culture. It had previously been reported that, after three months on isoniazid alone, resistant bacilli were isolated from about 35% of all patients and 65% of those with positive cultures.³ No isoniazid-resistant bacilli were isolated from 89 patients in the 20 PH group, though 30 had positive cultures at three months. Streptomycin-resistant organisms were isolated from only 1 of 106 SH patients. At three months P.A.S.-resistant bacilli were obtained from only 1 of the 89 20 PH patients, though resistant organisms had been detected in 2 at two months. In view of these results and the excellent clinical progress of the cases, the combination of isoniazid 100 mg. twice a day with P.A.S. (sodium) 5 g. four times a day seems assured of an important place in the treatment of tuberculosis. Being spared frequent injections will please the patients, and the value of the combination for home treatment is self-evident.

In the report a supplementary clinical comparison is made in which 100 patients treated with streptomycin 1 g. twice weekly plus isoniazid 100 mg. twice a day (S2H group) are added to the SH cases, and 71 patients treated with 5 g. P.A.S. (sodium) twice a day plus 100 mg. isoniazid twice a day (10 PH group) are added to the 20 PH group. In this way a large group of patients on streptomycin and isoniazid are compared with a second large group on P.A.S. (sodium) and isoniazid. Clinical progress at three months was similar in the two groups, though those treated with streptomycin and isoniazid gained on average rather more weight, and more of them showed considerable improvement in the radiograph.

The preliminary drug sensitivity results in the 10 PH group are promising; isoniazid-resistant bacilli were obtained from only 1 patient after three months. The numbers are at present small, and this combination should not be generally used until more results become available. Most patients can tolerate 10 g. of P.A.S. (sodium) a day without difficulty, and if the early results are confirmed on larger numbers this treatment should prove of great value in domiciliary work and also in backward areas abroad. On the other hand the early drug sensi-

itivity results in the group given streptomycin 1 g. only twice a week combined with isoniazid 100 mg. twice a day provide a warning against the general adoption of this treatment. Isoniazid-resistant tubercle bacilli were obtained at three months from 1% of these patients and 38% of those with positive cultures.

The successive reports from the Medical Research Council on this subject continue to give us information which is notable both for its reliability and for the speed with which it is produced. Great credit is due to those who design the trials, co-ordinate them, and analyse the results. We must also pay tribute to the large number of clinicians, bacteriologists, nurses, and technicians throughout the country, without whose unselfish co-operation the trials, and the benefit they have conferred on patients all over the world, would have been impossible.

INSULIN ZINC SUSPENSIONS

Within recent weeks diabetic patients, encouraged by reports in the newspapers and on the radio, have besieged their doctors and chemists with questions about the insulin zinc suspensions recently developed by the Novo Laboratories in Copenhagen and soon to be available in Britain. Those who have experienced some difficulty in answering will find guidance in the four papers which appear elsewhere in this issue, and in the comment¹ we made nine months ago when Drs. R. D. Lawrence and Wilfrid Oakley² published the results of a small therapeutic trial of "lente" insulin in this *Journal*. The introduction of three new insulin preparations may be welcomed by some because it will improve and widen the scope of insulin therapy, but it is clear that the dangers resulting from confusion between different preparations will be much increased, and correspondingly greater care will have to be taken to ensure that mistakes do not occur. The task of choosing the best preparation or mixture of insulins for the individual patient will now be more difficult, but the principles will remain the same. The duration of activity of an insulin dictates the manner of its use, and Dr. F. Gerritzen (see p. 1030) has performed a useful service by classifying thirteen insulins according to their duration of action, using normal students as subjects. But it must be remembered that insulin often has a longer action in a diabetic than in a healthy person.

The insulin zinc suspensions are not a "new" insulin as many patients may suppose, but are simply the old, familiar insulin in a series of new

garbs. The healthy pancreas secretes insulin in response to a rise in the blood sugar, and there is no reason to suppose that insulin zinc suspensions can imitate this intermittent activity any more closely than those preparations to which we are now accustomed. On the eve of the arrival of the suspensions for general use it is important to consider what advantages they offer. First, they are the only long-acting preparations which contain no protein other than the hormone itself, and it is clear from the papers in this issue that they do not cause allergic reactions in patients who are sensitive to protamine or globin. There is thus a definite indication for the use of an insulin zinc suspension in such patients. Secondly, the combined use of soluble and protamine zinc insulins, as a mixture or by separate injections, has been invaluable in many cases, but it is an inconvenient method, and sometimes inaccurate because of the variable behaviour of mixtures. In such cases it appears that a single daily injection of an insulin zinc suspension may give comparable or even better control with greater convenience. It has usually been considered unwise to administer a single dose of a long-acting insulin in excess of 60 units because of the danger of profound hypoglycaemia, and there is no evidence that the suspensions will be immune from this risk. In the series of cases reported on by Drs. I. Murray and R. B. Wilson (p. 1023), some of the patients receiving doses of 100 or more units had very low blood sugar concentrations at some time in the day, though no hypoglycaemic reactions seemed to have occurred.

Dr. Wilfrid Oakley (p. 1021) has shown very clearly that insulin therapy can be satisfactorily initiated in a new diabetic with insulin zinc suspension (lente), but that the diabetes is controlled less rapidly than it would be with soluble insulin. It is evident that we must continue to use soluble insulin in any patient who is severely ill and when rapid control is essential. The insulin zinc suspensions cannot oust soluble insulin from its traditional place as the insulin for diabetic emergencies. While supplies remain inadequate there is little point in altering the treatment of those patients who are already well controlled by a single dose of protamine zinc insulin. When it comes to choosing between the three suspensions it will probably be found that the mixture containing amorphous and crystalline suspensions—named insulin zinc suspension or "lente"—is the most generally suitable, but it may well prove that the suggestion of Drs. J. D. N. Nabarro and J. M. Stowers (p. 1027) is wise in that a mixture of 8 parts of the crystalline suspension to 2 parts of the amorphous will be better suited to the British diet,

¹ *British Medical Journal*, 1952, 2, 735.

² *Ibid.*, 1953, 1, 521.

³ *Lancet*, 1953, 2, 217.

¹ *British Medical Journal*, 1953, 1, 266.

² *Ibid.*, 1953, 1, 242.

with its emphasis on a late afternoon or evening meal of starches washed down by tea, than the mixture designed for use in Denmark. The plea of the same authors that the insulin zinc suspension (crystalline)—or “ultralente”—should be made available in a strength of 80 units per ml. also deserves commendation.

There will be ample scope for further work in the investigation of these new preparations. For example, it may happen that many severe diabetics can be well controlled by insulin zinc suspension (amorphous)—or “semilente”—given alone night and morning. It remains to be seen whether the Novo insulins can entirely replace any of the preparations of insulin now in common use.

CAUSES OF BLINDNESS

Although by its own nature blindness may command a degree of interest and sympathy disproportionate to any objective assessment of the personal hardships and communal economic loss entailed, nevertheless it represents an outstanding problem and a challenge. The magnitude of the challenge and the nature of the problem are sharply focused in a recent survey¹ by Professor Arnold Sorsby of the causes of blindness in England, which together with his earlier surveys of conditions in England and Wales² and in the wider international field³ provides statistical material of considerable sociological no less than medical importance. The first point which emerges from a study of his most recent review is that the number of registered blind persons in England has in recent years shown a marked increase, standing in 1951 at 83,464. This increase is probably not as depressing as at first sight it might appear, reflecting as it does the increasing longevity of the population, the increasing public recognition of the social and economic benefits accruing from blind certification, the realization that it is not—in some cases at least—an irrevocable acceptance of permanent disability, and the increasing latitude of certifying examiners in registering borderline cases.

Of much greater interest and significance are the figures relating to age and disease distributions. The steady downward trend in those registered during the first five years of life, for which antenatal and neonatal supervision and the efficiency of modern antibiotic and chemotherapeutic agents was responsible, has, as was foreshadowed, come to an end. Indeed the numbers in this age group have shown a slight increase, for which the new, or newly recognized, disease of retrolental fibroplasia added to the hard-core residuum of congenital defects and neoplasms may be at least partially responsible.

¹ *The Causes of Blindness in England, 1948-50, 1953*, London, H.M.S.O.
² *The Causes of Blindness in England and Wales, 1950*, Medical Research Council Memorandum, No. 24, London, H.M.S.O.
³ *The Incidence and Causes of Blindness: An International Survey*, Supplement XIV, *Brit. J. Ophthalmol.*, 1950.

In the years between youth and old age there has been little change of emphasis in the operative causes of blindness, among which myopia, congenital and abiotrophic defects, diseases of the central nervous system, iritis and iridocyclitis, and injury are the most prominent. Of these, probably the first two groups can be alleviated, if at all, only through long-term biological and genetic research, and the last three by early diagnosis and treatment.

In the older age groups there is, as must be expected, a small increase in the numbers of those blind from diabetes and vascular lesions, but perhaps one of the most startling revelations of this survey is that three affections only—cataract, senile macular degenerations, and glaucoma (all afflictions primarily of old age)—are to-day responsible for no less than some 60% of newly registered blindness, and that cataract, an essentially tractable disease, accounts for one half of this larger proportion. Blindness is indeed becoming an increasingly geriatric problem. These three diseases present biological and possibly genetic problems. Senile macular degeneration, in so far as it is not susceptible to control by mechanical means, must for the time being remain insoluble. In glaucoma the main difficulty is that of early diagnosis, which affords the best, but by no means a certain, prospect of controlling visual deterioration. It is disturbing to learn that more than one half of patients blinded from glaucoma had had treatment described on the certifying form as “complete,” although there is no means of assessing at what stage of the disease such treatment was instituted. It may well be that in those in whom the diagnosis was established at an early stage the outlook was much happier.

It is even more disturbing to read that of those newly registered as blind from cataract (some 3,350 annually) no fewer than 4 out of 5 have had no treatment whatever; while those still blind after the completion of treatment number only one in 30 cases. It may be not sufficiently recognized either by practitioners, or perhaps even by those undertaking certification, that the modern operation for cataract is not so much a matter of physical endurance (it does not nowadays involve ten days' complete immobilization and misery) as of morale—to which the prospects of recovery of the ability to read and of a considerable measure of independence will surely contribute very highly. The small risk of loss of the eye to be operated on and the even smaller risk to life involved in the operation must be weighed against the personal happiness and the far-reaching economic amelioration resulting from its successful outcome. It is in a judicious appreciation of these factors, and in the early diagnosis of glaucoma and other tractable diseases, that the profession as a whole can best help.

STUDIES OF MORBIDITY

Our knowledge of disease is at present heavily biased by conclusions reached after studying the more advanced cases to be seen in hospital. The terminal stages are apt to be better known than the initial stages,

and whereas abundant information is available on the distribution of causes of death—in Great Britain at least—the distribution of causes of morbidity is much more a matter of speculation. It is therefore not surprising that epidemiologists, vital-statisticians, and others are looking with some envy on the records kept by general practitioners of their Health Service patients, or the family doctor is uniquely placed to gather data about the earliest features of disease and about those many causes of ill-health that entail misery for the patient but no hospital investigation. Nor are general practitioners unresponsive to the call for more data about the many diseases that are at present escaping the trained research worker's attention. Some are carrying out their own investigation; others would certainly do so if provided with certain necessary facilities; others again would no doubt join them if given the encouragement from a senior that hospital doctors often so enthusiastically acknowledge at the end of their scientific articles. For there is little doubt that, as Dr. W. P. D. Logan says in a report¹ published this week, general practitioners' records “potentially constitute one of the most valuable sources of information on morbidity.”

As a pilot experiment, the doctors in eight general practices have co-operated with Dr. Logan by keeping full records of the work they have done for their patients. The period covered by the report is the twelve months from the beginning of April, 1951, but the doctors are continuing to keep records in order to extend the study. The practices were carefully selected to provide a wide variety of conditions. While it would be rash to draw any very firm conclusions from the morbidity data obtained from eight practices over only one year, the experiment has served several useful purposes. The first is that different forms of record keeping were tried and some experience was gained on the best methods of collecting the data. Secondly, the investigation has confirmed the presupposition that such records as general practitioners will have time to keep can yield valuable information about morbidity. Thirdly, it already points to several lines of study worth following up with more intensive research. As an example of this, the extraordinary differences between the practices in the numbers of patients reporting with the common cold may be cited. The consultation-rate for all the practices combined—that is, the number of patients consulting per 1,000 patients in the practices—was 130 for the common cold. This rate is far above that for any other disease—and indeed sharpens those criticisms that some doctors have made about the trivial uses to which the Health Service is sometimes being put. But more remarkable still is the fact that the rate for one practice was 213 while the rate for another was only 19. The lower rate is one-tenth of the higher, yet for all consultations combined the rate for the second practice was only between one-third and one-quarter of the first. The common-cold rates for the other six practices lay between 80 and 140. Such a wide dis-

parity as that between the highest and the lowest figures can clearly not reflect the incidence of the disease in question but points to some other circumstance. The practice with the high rate is in “a lower working class neighbourhood” of Liverpool, whereas the one with the low rate is a rural N.H.S. practice in Hampshire, so that distance from the doctor probably plays some part. But how great a part it plays is something that might well be worth further inquiry, for in this Liverpool practice of 7,700 souls 1,636 patients consulted the doctors 3,625 times for the common cold in the twelve months covered by the report.

The records of at least another twelve months are to be tabulated in due course to find out how far they confirm those already obtained. A type of investigation that has yet to be carried out is into case histories extending over many years for a few patients. Again, families may be studied as units from such records as these. The College of General Practitioners has been showing a lively interest in research in general practice and might well consider whether it can help in such investigations. Meanwhile, a report of the second twelve months' records will be awaited with interest, and Dr. Logan and his colleagues are to be congratulated on carrying out such an instructive experiment. In the collection of accurate mortality statistics England led the world, and we may hope to do so again in the collection of reliable information on morbidity.

SCIENTIFIC EXHIBITION AT THE ANNUAL MEETING

After the successful exhibitions at Dublin last year and Cardiff this year the scientific exhibition is now well on the way to becoming a permanent and popular feature of the Annual Meetings of the B.M.A. The two exhibitions already held have shown that modern clinical and laboratory investigations, as well as public health field work both at home and abroad, lend themselves well to demonstration by visual methods. The attention of the eye can often be more effectively caught than that of the ear, but the success of an exhibit depends largely on whether the interest aroused by the first glance is stimulated by a closer look. It is here that the exhibitor can exercise his skill and imagination. At the Annual Meeting at Glasgow in 1954 the scientific exhibition will be held from July 5 to 9. It will cover a wide field of medical practice and research. But space is limited, and those who would like to take part should apply for details to the Secretary of the Association as soon as possible. The last date for receiving applications for a stand is December 31.

The next session of the General Medical Council will open on Tuesday, November 24, at 2 p.m., when the President, Sir David Campbell, will take the chair and deliver an address.

CLINICAL PATHOLOGY IN GENERAL PRACTICE LUMBAR PUNCTURE

BY

WILLIAM GOODDY, M.D., F.R.C.P.

Physician, Neurological Department, University College Hospital; Assistant Physician, the National Hospital, Queen Square, London

Lumbar puncture was first used as a clinical method by Corning in 1885. Within a few years Quincke in Germany and Wynter in England developed improvements for the relief of raised intracranial pressure. Quincke devised a technique generally similar to that used to-day, and was the first to measure pressures and have the spinal fluid analysed.

In adults the spinal cord ends at the level of the lower border of the first lumbar vertebra. In children it ends at a lower level, and in infancy may reach the level of the third lumbar vertebra. The arachnoid membrane continues down to the level of the second sacral vertebra. There is therefore in the cavity of the lower lumbar vertebral canal a sac containing cerebrospinal fluid (C.S.F.) and the lower spinal nerve roots. Into this sac a needle may be inserted without danger of injuring the spinal cord. The sac is surrounded by a venous plexus. In lumbar puncture the needle enters the sac posteriorly. After passing through skin, interspinous ligaments, and posterior vertebral muscles the needle is guided between two adjacent spinous processes (usually lumbar 3 and 4) through the posterior longitudinal ligament of the vertebral column into the lumbar sac.

The C.S.F. has a circulation in and about the central nervous system. A sample taken from the lumbar region will, with a fair degree of accuracy, indicate the conditions throughout the pathways of circulation. Being so closely related to the central nervous system, the spinal fluid reflects changes in nervous tissue and its accessory parts, the meninges and blood vessels.

From consideration of abnormalities in pressure, cellular content, and chemical composition it is often possible to establish a diagnosis which could not be otherwise made.

Lumbar Puncture in Diagnosis

Lumbar puncture provides *direct* information from the pressure and composition of the spinal fluid; *indirect* information is obtained by the injection of air or opaque media into the subarachnoid space. Lumbar puncture may be combined with puncture of the C.S.F. system elsewhere (ventricles, cisterna magna).

Direct information may be obtained in:

- Infectious Diseases:* meningitis; abscess; encephalitis; myelitis.
- Neoplastic Diseases:* benign tumours; primary or secondary malignant tumours. (Note that lumbar puncture may be dangerous in cases in which the intracranial pressure is significantly raised.)
- Vascular Diseases:* haemorrhage; thrombosis or embolism; haematoma.
- Neurosyphilis.*
- Demyelinating Diseases.*
- Degenerative and Congenital Conditions.* In this group, which includes such conditions as Friedreich's ataxia, amyotrophic lateral sclerosis, and the lipoidoses, curiously enough the spinal fluid is usually normal.

Lumbar puncture should be used only to settle definite questions of differential diagnosis. Routine lumbar puncture is to be deplored. Certain conditions are sometimes aggra-

vated by lumbar puncture: cerebral or spinal tumours when the local pressure and circulation are reaching critical levels; disseminated sclerosis; and psychoneurosis, "hysteria," depression, and cases in which compensation is a factor.

Lumbar puncture may be of special importance in those cases of difficult and obscure illness in which it is all too easy to label the condition as functional or hysterical. The presence of definitely abnormal C.S.F. findings very strongly supports a diagnosis of organic disease.

Lumbar puncture may be used for injection of air, other gases, or opaque substances into the subarachnoid space. By appropriate manoeuvres the medium can be used to show abnormalities within the skull or vertebral canal. Growths and other obstructive lesions give positive findings. Cerebral atrophy is shown by air in dilated ventricles or widened sulci.

For Therapy

Prognosis in the "malignant" forms of meningitis, such as pneumococcal, tuberculous, and influenzal, has greatly changed for the better since intrathecal antibiotic therapy began. Penicillin and streptomycin are now in general use. The maximum intrathecal dose of penicillin is 20,000 units; of streptomycin, 0.1 g. The use of fibrinolytic agents is at present considered hazardous.

The injection of saline under moderate pressure has been advised for those cases of subdural haematoma in which, after the removal of the clot, the brain does not regain its normal shape and position.

The intrathecal use of anaesthetics is a well-established specialized practice. Occasionally serious spinal cord damage occurs after spinal anaesthesia.

Contraindications.—Lumbar puncture is contraindicated: (1) If the practitioner has no positive problem which may be solved as a result of the findings. (2) If there is no prospect of a successful puncture owing to spinal deformity or disease. (3) If it is judged either on the history of the illness (headaches, vomiting, visual blurring) or physical signs (papilloedema, slow pulse, lowered state of consciousness) that the patient has an expanding cerebral lesion (tumour or abscess) which will, if the intracranial tension is suddenly altered, cause complete and irreversible obstruction to the C.S.F. or blood circulation (pressure cone). Occasionally the patient in such a state may die while the puncture is being carried out. Often death is delayed for some hours and the connexion between death and lumbar puncture may escape the unobservant. In these difficult circumstances, ventriculography is necessary. (4) If there is a gross spinal lesion already causing obvious nervous and vascular damage. A complete transverse lesion may rapidly follow puncture. In doubtful cases a neurosurgeon should first be consulted.

Apparatus

At the National Hospital for Nervous Diseases a standard set of instruments, dressings, and towels is provided. The set consists of a cloth container folded in two and tied with tape. The tape is undone by an assistant with sterile forceps. The operator then turns the upper fold back to expose towels on the right, and the instruments and dressings on the left (Fig. 1).

The instruments are kept in a row of pockets. The manometer lies in the centre of the package. Instruments available are: two Greenfield needles with three-way taps and stylets—they are best kept in a metal tube to prevent pene-

tration of the cover and subsequent sepsis; a glass manometer reading up to 300 mm., with a short rubber tube for attachment to the needle; one 2-ml. and one 10-ml. hypodermic syringe, with hypodermic needles to fit the small syringe. A specimen bottle may be included. The package is laid out on a sterile cloth on top of a trolley, with a sterile kidney dish, pair of forceps, pair of gallipots for antiseptics,

FIG. 1.—Standard set of instruments for lumbar puncture.

and a bowl for extra dressings. On the lower shelf of the trolley are kept: Cheate's forceps in antiseptic; 1-ml. ampoules of 2% procaine hydrochloride; bottles of methylated spirit and 2½% iodine in methylated spirit; and specimen bottles.

Technique

The following method has proved reliable in the hands of a large group of operators over many years, but satisfactory modifications are well known. Before starting, the physician or surgeon should remind himself of a few simple but important facts.

- (1) Lumbar puncture is unpleasant and frightening, not usually from the pain of the procedure but because of apprehension, ignorance, and "old wives' tales," and because the patient cannot see what is happening. He should not be kept in suspense for hours or days. It is best to carry out the puncture as soon as consent has been obtained and the outline of the process explained. Patient and simple explanation repeated as often as necessary, with quiet warning of each move in good time, help greatly in decreasing the strain of the investigation.
- (2) Lumbar puncture may result in an infected spinal fluid, even if the operator is scrupulously careful. If anything is to be injected into the subarachnoid space, the operator is advised to use full aseptic surgical technique, including cap, mask, gown, and gloves.
- (3) The most important single detail in the procedure is the patient's position.
- (4) Haste and force indicate lack of experience and sympathy. They contribute to failure.
- (5) Consideration should be given to the convenience of the pathological services so that specimens arrive in good time for examination.

After due warning to the nursing staff, the operator should carry out his work punctually. He should expect to find the patient behind screens, suitably clothed, and not in a draught. Incontinent patients should be in clean beds. All concerned with the actual puncture should wear masks.

Reliable nursing assistance is essential. If the patient is violent, restless, or confused it is useless to attempt lumbar puncture until an adequate amount of restraint can be provided. Colleagues, students, male nurses, porters, and even other patients may on occasion be required. Many sisters and nurses are efficient in holding restless patients, but if possible they should be spared from duties beyond their physical

powers. The operator should never find himself in the middle of a scrimmage. In extreme cases the patient will have to be overpowered until an anaesthetic can be administered intravenously. The operator should explain the need for the patient being rendered quiet and placed in the right posture for puncture. He should not start at the lumbar puncture until he is sure of a reasonable time for safe work. Calm and deliberateness are essential. Happily, the great majority of punctures are carried out simply and uneventfully.

Patient's Position.—Great care should be taken in ensuring correct posture before anything further is done. The spine must be horizontal and fully flexed. The patient is drawn to the right side of the bed for right-handed operators. His back is exposed. He is told to lie on his left side with his knees up to his chin, his head well bent, and his arms below his knees. One pillow for the head may be useful (Fig. 2). The operator should be prepared to play an active part in this positioning until he is satisfied. The patient is requested to keep quite still in this position. The operator then masks himself and scrubs his hands for five minutes with soap and running water. He returns to the bedside and satisfies himself that the patient is still in the correct position. The assistant undoes the fastenings of the instru-

ment packet and opens it with sterile forceps taken from the lower shelf of the trolley. Small amounts of methylated spirit and 2½% iodine are poured into the sterile gallipots. An ampoule of procaine hydrochloride 2% is opened. Specimen bottles are kept in readiness and material for intrathecal injection should be easily accessible. The operator dries his hands on a sterile towel. (Those experienced in medico-legal work advise the use of sterile gloves, but many operators do not use them for single diagnostic punctures.) The patient is draped in sterile towels, one over his back to the left of the exposed lumbar area, one between his left loin and the bed, and one over his right (upper) loin, hip, and buttock. He is then warned that his back is to be rubbed with methy-

FIG. 2.—Position for lumbar puncture.

lated spirits and that this may be cold. The lumbar region is carefully cleansed, especially in the central area.

Site of Puncture.—The space between the third and fourth lumbar vertebrae is most commonly used. A space higher or lower may be used if difficulties are encountered or if previous use of a space has made the patient's back tender. A line joining the highest points of the iliac crests normally passes between the third and fourth lumbar spines. If necessary the iliac crest can be felt through the sterile towel and the landmarks emphasized by a dab of iodine. A small syringe is filled with local analgesic and fitted with a short fine sharp needle. The patient must be warned that a local analgesic "to make the skin numb" is about to be used and that a prick, in the skin only, will be felt. The skin over the

third and fourth vertebral spines is then firmly stretched by the fingers and a small $\frac{1}{4}$ -inch (1 cm.) diameter subcutaneous weal is raised. A longer needle is slowly inserted through the weal into the deeper tissues, local analgesic being expelled throughout the needle's progress. The patient should be told that one of the worst parts of the procedure is now over.

The Puncture.—The spinal needle is inserted through the centre of the weal. A little firm pressure is sometimes needed to get the point through the interspinous ligament. Subsequent greater pressure on the needle should never be used, for resistance means bony obstruction which must be by-passed and not penetrated. The needle should then be pressed forward, its cutting edge in the same plane as the longitudinal (head to foot) fibres of the dura and ligaments. The point should be directed *slightly* upwards (towards the head). Usually the needle goes in to a depth of about 4.5 cm. with a firm smoothness. Then a ligamentous resistance is easily overcome, with a feeling of a slight "click." If the stylet is withdrawn, C.S.F. may flow from the butt of the needle. If it does not, the stylet must be reinserted and the needle gently and slowly advanced up to 0.5 cm. more. Another "click" may be felt, and C.S.F. then be easily obtained. If none appears, rotation of the needle through a quarter or a half turn may be effective. Lack of immediate success should not dismay the operator. On occasion he may prick a strand of the cauda equina, causing the patient pain in the foot. He may at times repeatedly encounter a vertebral bone. He may find pure blood instead of C.S.F. coming from his needle. Under such circumstances he should not use force or advance the needle further. (The needle should never be inserted so deep that less than 1 cm. remains between the skin and the connexion with the tap.) It must be withdrawn 2-3 cm. and a slightly different line taken. If the patient has complained of pain in the right leg or foot the point has clearly been too far to the right of the midline. If the needle is not withdrawn far enough before reinsertion it is likely to take the same course twice. Rarely it may be advisable to try an insertion slightly lateral, or in a space above or below, after suitable analgesia.

FIG. 3.—Taking the pressure.

the same course twice. Rarely it may be advisable to try an insertion slightly lateral, or in a space above or below, after suitable analgesia.

Pressure Readings

As soon as a free flow of fluid is obtained the manometer should be attached to the needle and the tap turned so that the fluid passes up the tube held vertically (Fig. 3). The patient may be told to relax his tension slightly but not to move his back. The initial pressure may now be read. A slight oscillating rise and fall is normally seen. This variation is due to cardio-respiratory effects. If, with the patient relaxed, the pressure is over 200 mm. of fluid the tap should

be turned further so that the manometer fluid escapes into the specimen bottle, but no further C.S.F. is withdrawn from the theca. The needle should be removed.

Queckenstedt's test consists of compression and release of the jugular veins, first unilaterally and then bilaterally. The operator must be sure that he does not get false-positive results from local obstruction by nerve roots. Normally, such compression causes a brisk rise of pressure up to 300 mm., bilateral compression naturally causing a more rapid effect than unilateral. Release is accompanied by a fall in pressure. In cases of obstruction to the C.S.F. circulation, rise and fall in pressure may be slow or absent. In cases of lateral sinus or jugular thrombosis, compression of the jugular vein on the diseased side causes no change; compression on the healthy side alone causes pressure changes equal to those to be expected from bilateral pressure in a normal subject.

When pressure tests have been completed, one or more specimens are collected in sterile bottles. If the outside of the bottle is not sterile, it should be unstoppered by the assistant and held below the needle butt to catch the fluid, without touching the needle. For routine examination 5 ml. should be taken. If extensive tests are to be carried out a larger specimen should be bottled.

With the needle still in position, injection of any necessary substance may be carried out, using the 10-ml. syringe. No active agent such as streptomycin should be injected all at once. C.S.F. should be aspirated into the syringe to dilute the injection material. A number of to-and-fro movements of the piston ensure adequate dilution. If air is being injected, a good fit of syringe to needle is essential, if escape is to be avoided.

Pressing the skin firmly through a swab with the left hand, the operator smoothly and swiftly withdraws the needle. If any bleeding is seen the flow should be stopped by firm pressure. No further attention to the site is necessary. (Some like to apply a small dressing, but this often causes slight irritation and inflammation.)

The patient should be informed of the success of the proceeding and allowed to return to a normal position in bed.

The specimens, labelled, dated, and numbered, should be sent for analysis at once.

Aftercare and Complications

To avoid trouble a nursing routine for all cases is advisable. The patient is allowed only one pillow, and stays in bed till the following day. Plenty of fluid should be taken. The following complications may be encountered:

(1) **Headache** is uncommon: it is usually slight and transient. More severe headache in the absence of obvious disease suggests a leakage of C.S.F. through the site of puncture and low intracranial tension. Saline fluids, flavoured with lemonade, are helpful. The foot of the bed should be put on blocks. Analgesics are to be used.

(2) **Backache** at the site of puncture is occasionally noted. The site should be inspected for signs of infection in the skin or muscles.

(3) **Fever** up to 100° F. (37.8° C.) may be seen on one reading in the 24 hours after puncture. It generally subsides without treatment.

The above symptoms very rarely indicate the disaster of meningitis due to septic puncture. Careful watch should always be kept for the possibility. If there is infection it must be admitted so that treatment can be started at once. There may be medico-legal consequences.

(4) Injected solutions too strong for the nervous system may cause *convulsions* or *local cord damage*. *Hopeless paraplegia* may result.

(5) **Ruptured intervertebral disk** may follow too deep a puncture, especially if repeated.

(6) **Subdural haematoma** has been reported after lumbar puncture.

(7) **Collapse and death** may occur during puncture or within 12 hours if the patient's state of disease is advanced (see contraindications).

Lumbar Puncture in Children

Commonsense modification of the above methods is necessary for carrying out lumbar puncture in children. Pre-operative sedation is often of value. An uncooperative child will need to be firmly and expertly held in the fully flexed position by a trained person at the opposite side of the bed. It is best to put one arm round the patient's neck and the other under his knees. The spinal theca is closer to the skin and may, in an emergency, be reached with a suitable hypodermic needle. A needle of finer gauge than is used for adults should be used, especially if pressure readings are not essential. The Harris or Howard Jones pattern is pleasant to use.

Next article on Clinical Pathology.—"Taking Swabs," by Dr. Robert Cruickshank.

Refresher Course Book.—The first collection of articles in the Refresher Course for General Practitioners (fully revised) are available as a book containing 55 chapters, price 25s. Copies can be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

WASHINGTON SYMPOSIUM ON ANTIBIOTICS

[BY A SPECIAL CORRESPONDENT]

A symposium on antibiotics, intended to be the first of an annual series, and sponsored by the Antibiotics Division, Food and Drug Administration, U.S. Department of Health, and by the journal *Antibiotics and Chemotherapy*, was held in Washington on October 28 to 30 in the magnificent auditorium of the Department of Health. Introductory addresses were given by HENRY WELCH, director of the Division of Antibiotics, CHESTER S. KEEFER, now special assistant to the Secretary for Health and Medical Affairs, and by F. MARTI-IBANEZ, international editor of *Antibiotics and Chemotherapy*, who paid a tribute to the pharmaceutical manufacturers, among whom free competition had been the spur responsible for rapid progress. In discussing the impact of antibiotics on medicine, and the profound change resulting in the natural history of disease, he suggested that chairs of chemotherapy should be created in medical schools throughout the world in order that the subject might be more adequately studied. (It may have occurred to other hearers that many distinguished physicians in the U.S.A. are working very much as if they held such chairs without the trouble of their creation or the restrictions which this would imply.)

The number of papers read during the three days of the symposium was 102, many being contributed by well-known authorities, and together they must fairly represent the latest acquisitions of knowledge and trends of opinion in a country which has advantages over all others in this sphere. The following is some account of what was said on the more important topics.

Misuse of Antibiotics

There seemed to be universal agreement that antibiotics were being grossly misused. PERRIN H. LONG (New York) picturesquely described the American populace as "an enormous sponge with an infinite capacity for absorbing antibiotics." MAXWELL FINLAND (Boston) referred dis-

approvingly to the common practice of administering many drugs successively or together for no more precise indication than fever, and blamed advertising pressure for some of this. SIDNEY ROSS (Washington) described the profession as being "inundated literally with a plethora of drugs," and made a plea for a return, for many purposes, to an earlier, simpler, cheaper, and often no less effective treatment; he asked his hearers not to "write off an obituary of sulpha drugs in the current high-power antibiotic era."

Acquired Bacterial Resistance

A great deal of such need as there is for new antibiotics is due to the waning power of their predecessors, which is a result of the acquired resistance of bacteria to them. As Finland pointed out, penicillin is fortunately unique in its exemption from this defect. The only possible instance, in his opinion, of a general diminution in sensitivity to this drug might be seen in the larger doses required to cure subacute bacterial endocarditis, owing, on this hypothesis, to the effect of ten years' use on the world's salivary streptococci.

It is true that penicillin resistance in staphylococci is now common and disastrous, but this is not the result of acquired resistance. To almost all other antibiotics all susceptible bacteria tend to become resistant and to remain so. Several speakers gave recent figures for the proportion of strains of common organisms found resistant to the principal antibiotics in use: these figures differed little from others recently published. The most disturbing change is evidently a pronounced increase, said by Ross to have been sharply accentuated recently, in the proportion of strains of staphylococci resistant to aureomycin and terramycin (one figure given for this proportion was 40%). An opinion expressed by several speakers was that the danger occasioned by these changes had been exaggerated. HARRY DOWLING (Chicago) took comfort from observations which were said to show that exposure to another antibiotic, or cultivation with a sensitive organism of another species, might render a resistant organism sensitive again: he cited an instance in which the substitution of another antibiotic in a hospital for one to which a high proportion of strains of an organism had become resistant was followed by a fall in this proportion. WALSH McDERMOTT (New York) believed that this problem was important only in connexion with tuberculosis, urinary infections, and infections by staphylococci, and that tissue destruction and the consequently greater difficulty of eliminating the organism was a factor. He also regarded the problem as a "hard core remaining unsolved" rather than as a threatening catastrophe, and believed that it was not one which could in any case be solved by drugs alone.

Combined Therapy

Although, as Dowling said, rapid elimination of the organism is the only certain way of preventing acquired resistance, combined therapy with two or more drugs may delay or minimize it: such treatment may also be indicated for the sake of a synergic effect, or contraindicated because of an antagonistic effect. ERNEST JAWETZ (San Francisco) gave an account of the conditions under which such effects might be expected, as defined largely by his own work, and GLADYS L. HOBBS (Brooklyn) described an extensive series of experiments on combined action *in vitro* which seemed to illustrate the difficulty of laying down any general rules in this connexion. Among combinations recommended for clinical use were the triple combination of penicillin, chloramphenicol, and a sulphonamide for pyogenic meningitis (another author being cited as having lost only 7 out of 80 cases on this treatment), erythromycin and streptomycin for coccal endocarditis (referred to later in connexion with the former drug), and polymyxin with terramycin for *Ps. pyocyanea* infections (this suggestion was based only on an *in vitro* demonstration of synergism, and another speaker had failed to confirm this finding).

Mode of Action

In an essentially practical and mainly clinical meeting few papers dealt with pure theory or fundamentals, but two outstanding exceptions must be mentioned. HARRY EAGLE (Bethesda) reported studies with radio-penicillin which showed that the amount of penicillin bound by the bacterial cell was closely correlated with its sensitivity: sensitive cells concentrated the drug within themselves, the amount bound varying little with the concentration of the solution used. Since the effect was the same whether the radioactive element was C or S, and these were far apart in the penicillin molecule, the probability was that the entire molecule is bound and not some part of it. He also showed that extracts of sensitive cells bound more penicillin than those of insensitive cells, a finding which suggested that sensitivity might depend on the reactivity with penicillin of certain cell constituents, possibly enzyme proteins. On the other hand, combining power was unchanged in cells rendered artificially resistant. Another suggestive observation was that extracts of mammalian cells had little combining power: the possible connexion with low toxicity was evident. From the same institution came a report by ARTHUR K. SAZ and RITA B. SLIE on interference by aureomycin with the reduction of the nitro groups of chloramphenicol and *p*-nitrobenzoate to the corresponding arylamines by cell-free extracts of *E. coli*—the first example of such an effect which has been described.

New Antibiotics

ERYTHROMYCIN AND CARBOMYCIN

Of these two recent and very similar antibiotics, the former appears to be the more active and has been subjected to more extensive clinical trial. EMITT H. SHOEMAKER and ELLARD M. YOW (Houston, Texas), employing a daily total dose of 20–25 mg./kg. body weight, had obtained almost uniform success with it in pneumonia and haemolytic streptococcal infections, but less regularly successful results in staphylococcal infections. They explained both their failures and the failure of the organism to develop resistance to the drug in terms of non-penetration into such lesions as empyema and osteomyelitis. From the same institution LLOYD C. JONES and ELLARD M. YOW reported on the treatment of bacterial endocarditis resistant to other therapy: erythromycin alone had only a temporary suppressive effect, but given in combination with streptomycin it achieved cure in 5 out of 7 cases—one caused by a staphylococcus, the remainder by various streptococci. In 1 patient with a streptomycin-resistant infection treatment with erythromycin and bacitracin was successful. W. M. M. KIRBY (Seattle) referred to 100 cases of pneumonia, 12 having positive blood cultures, in which the response to erythromycin was uniformly good and the blood levels attained higher than those with similar antibiotics. Jawetz protested against the trial of a new antibiotic in "a disease in which any hard evil look will eradicate the organism" (gonorrhoea was referred to, but it is a testimony to the achievements of chemotherapy that this picturesque expression could be intelligibly used in reference to any disease).

A somewhat discordant note was struck by M. H. LEPPER and his colleagues (Chicago), who observed that, within one month of the adoption of erythromycin for general use in a hospital, strains of staphylococci resistant to it began to appear in the nose and throat of the staff: after five months the carrier-rate of highly resistant strains reached 75%. The use of the drug was then discontinued, and the carrier-rate fell to 37% two months later. These resistant organisms were also recovered from the trachea of patients tracheotomized for poliomyelitis. The obvious moral was that the use of erythromycin should be restricted to patients for whom no other treatment was available, which was equivalent to saying those with staphylococcal infections resistant to all earlier antibiotics.

TETRACYCLINE

This was the surprise of the meeting, and calls for some preliminary explanation. It is now known that the molecular structures of aureomycin (chlortetracycline) and terramycin (oxytetracycline) differ only in the possession of a chlorine atom by the former and an OH group by the latter, and the new antibiotic is simply the same molecule without either of these attachments. Descriptions of its properties were given by members of the research staffs of the manufacturers of both chlortetracycline (Lederle Laboratories) and oxytetracycline (Chas. Pfizer and Co.), and of the staff of the Heyden Chemical Corporation, who have isolated a *Streptomyces* from a Texas soil which directly forms tetracycline itself. Its preparation from chlortetracycline was described by J. H. BOOTH and others (Lederle Laboratories), dehalogenation being achieved by treatment with palladium on charcoal in the presence of hydrogen: the company proposes to name the new drug "Achromycin."

It appears, as might perhaps be expected, that there are only minor differences between the activity of tetracycline and that of its two near relatives, either *in vitro* or in the experimental animal. It is much more stable than chlortetracycline and has a rather lower acute toxicity. Satisfactory blood levels are attained, and penetration of the blood-brain barrier is good: it has also been shown to appear in cord blood, saliva, and serous effusions. It was claimed that resistance to it develops more slowly than either of the others, and that it does not stimulate the growth of *Candida*, as chlortetracycline is said to. Proof of its lack of toxicity is fully adequate, and Finland reported having used it in 102 patients with streptococcal, pneumococcal, staphylococcal, and urinary infections with good results.

The main claim of tetracycline to superiority depends almost entirely on its lesser liability to cause gastro-intestinal disturbance. Figures cited by several speakers indicated a substantially lower incidence of nausea, vomiting, and diarrhoea than that produced by either of its predecessors.

Search for New Antibiotics

Something was heard of the present extensive search for antibiotics active against the smaller viruses, but it does not seem that this has yet been rewarded by any discovery of immediate therapeutic importance. There were papers on fumagillin, which is highly active against *Entamoeba histolytica*, and on nystatin, which is antifungal. Among other named antibiotics, hygromycin and streptogramin are broad-spectrum antibacterial substances of some promise; ruticin and streptocardin seem unpromising; and puromycin has been shown to have a retarding effect on the growth of certain tumours.

Treatment of Individual Diseases

Tuberculosis.—WILLIAM B. TUCKER (Minneapolis) reported a study of the chemotherapy of tuberculosis, an interesting finding in which was that, when P.A.S. was combined with isoniazid, not only were clinical results almost as good as with isoniazid and streptomycin, but resistance to isoniazid developed less than with the other combination. In patients intolerant of P.A.S. terramycin had been given with streptomycin, and acted like P.A.S. in preventing streptomycin resistance. Viomycin given in 2-g. doses twice weekly together with daily P.A.S. had been found useful in streptomycin-resistant cases.

Syphilis.—M. J. ROMANSKY (Washington) had treated 62 patients in various stages of syphilis with aureomycin with satisfactory results, and presented less extensive evidence that, if it were necessary, this disease could probably be treated with any of the other similar antibiotics. CHARLES R. REIN (New York) emphasized the facility with which syphilis could now be treated with penicillin, a single dose of a long-acting preparation being adequate in the early stages. The latest product contained potassium penicillin, procaine penicillin, and dibenzylethylenediamine dipeni-

cillin, giving a slowly falling gradient of blood concentration lasting over a long period (one patient had a detectable blood concentration 66 days after the last of multiple doses).

Peritonitis.—It is notorious that owing to the difficulty of carrying out satisfactory comparative trials little information exists about the relative merits of different forms of chemotherapy in peritonitis. EDWIN J. PULASKI (Washington) had tried to remedy this deficiency so far as possible by experiment. Peritonitis was produced in rats and dogs by perforating the caecum and at the same time introducing mucin into the peritoneum. The results in both species pointed clearly to the superiority of penicillin with streptomycin over either chlortetracycline or oxytetracycline. To achieve 90% recovery (no treatment saved all the animals) these drugs had to be given both intravenously and intraperitoneally.

Toxic Effects of Antibiotics

In a paper on sensitivity reactions PERRIN H. LONG pointed out that penicillin is the only antibiotic to which reactions have been known to be fatal, and although there was some disagreement about the frequency of this effect a natural reluctance to report it may well have obscured the occurrence of considerable numbers of such cases. Patients exhibiting these alarming reactions, fatal or not, had always had penicillin before and often previous reactions to it, suffered from asthma or some other allergic condition, and were sometimes sensitive to procaine. Inquiry about these predisposing factors should serve to identify patients in whom reactions were to be expected.

There is evidently no general agreement about the extent to which the use of bacitracin is justified despite its renal toxicity, and conflicting views were expressed on the maximal safe intrathecal dose of polymyxin.

Miscellaneous

A number of speakers read papers on antibiotic supplements in animal feeds. It does not seem that the mechanism by which these promote growth is yet fully understood. A process known as "bacillation" was demonstrated by colour film: this consists of implanting a pellet of bacitracin subcutaneously in young pigs with a syringe-like instrument (the "bacillator"). The good effect of this on survival and weight gain presumably results simply from suppressing infection and not on any hitherto imperfectly understood effect on the bowel flora. Another new development described is the use of antibiotics for prolonging the "shelf life" of perishable foods. Finally, the strange phenomenon of antibiotic dependence in bacteria is being turned to account. MORTON REITMAN and WARREN P. IVERSON (Camp Detrick) have obtained a dihydrostreptomycin-dependent variant of *Salm. typhi*, and used it as a living vaccine: this is non-pathogenic in animals and protects against subsequent inoculation with a lethal dose of normal culture in mice.

The International Sanitary Regulations governing trade and travel are now in force in 136 countries. Eight other countries have accepted the regulations with reservations, on certain articles. Only 9 countries are not bound by this international pact, and 34 others have as yet taken no definite stand. The W.H.O. Committee on International Quarantine, now holding a 3-week session in Geneva, under the chairmanship of Dr. M. T. Morgan, Medical Officer of Health to the Port of London, has been reviewing the working of the new regulations since they came into force on October 1, 1952. The regulations replaced 13 different international sanitary conventions, which were simultaneously in force. Adoption of the regulations marked the culmination of a century of effort begun in 1851 in Paris at an international conference, which attempted to establish on an international level an agreement to limit the spread of pestilential diseases such as plague, cholera, and smallpox.

IMMUNIZATION IN YOUNG CHILDREN

CONFERENCE AT WHITTINGTON HOSPITAL

A conference on immunization in young children was held at the Highgate Wing of Whittington Hospital, London, on October 31, the chair being taken by Dr. J. A. Scott, medical officer of health to the London County Council. The first speaker was Dr. W. C. COCKBURN, of the Central Public Health Laboratory. He said that no antigen was entirely free from risk, and clinic medical officers and general practitioners should always be on the watch for remote, untoward sequelae, even when using antigens which were considered safe. Geffen's findings on cases of poliomyelitis apparently associated with injections of mixed alum-precipitated antigens were an example of the value of careful observation.

The available prophylactics in England and Wales were sheep lymph for smallpox, diphtheria toxoids, and pertussis vaccines. Children should be vaccinated against smallpox in the first year of life, when the risk of encephalomyelitis was lowest and when generalized vaccinia seemed less common. Lymph should be used as soon as it was received and should be administered by the multiple-pressure method.

Diphtheria and Pertussis Immunization

For diphtheria immunization, A.P.T. in two spaced doses gave excellent results, but for children over 10 years of age, who should also have Schick tests first, T.A.F. was safer. No community could be considered adequately protected unless 70% of the population in the 1–15 age group was immunized and reimmunized at four- to five-year intervals. Most of the statistics in diphtheria immunization gave a false picture of the adequacy of immunization at present.

Good pertussis vaccine gave good protection for at least two and a half years, but no adequate standardization of vaccines was yet possible. The United States of America had accepted an intracerebral mouse test for standardization, and this test was being exhaustively tried out here. Three doses of a plain-suspension vaccine should be used for primary vaccination against pertussis. There was insufficient evidence about the need for reinforcing doses, though many medical officers of health gave a reinforcing dose at 3–5 years of age. Pertussis vaccination should be offered only to children who were fit and well at the time and who had no history of convulsions, epilepsy, or encephalitis. A mixture of diphtheria and pertussis antigens reduced the number of injections and did not appear to interfere with the potency of the diphtheria components. The effect on the pertussis component could be studied only in field trials, and such a trial was in progress in Battersea and Wandsworth.

There was no need to immunize children against diphtheria below 8–12 months of age, for in 1952 only three cases were in children under the age of 1. In pertussis there was a case for early immunization, but the effectiveness of the response of very young babies and the duration of the immunity were not yet known. Vaccination of children over 6 months of age would screen the very young baby from infection. Provided tetanus toxoid did not interfere with the potency of the pertussis component of a mixed vaccine, there was no reason why it should not be added, but it was necessary to ensure that reinforcing doses were given at about five-yearly intervals. Some method of indicating to a busy casualty officer or general practitioner whether an injured patient had been adequately immunized was required.

Administration of an Immunization Scheme

Dr. S. KING, divisional medical officer to division 4 of the London County Council, described the arrangements which were made for immunization in his area. Under Section 26 of the National Health Service Act, 1946, practitioners were encouraged to undertake vaccination and immunization, and the local health authority also did this work in welfare centres and schools. Whooping-cough vaccination was

available at the clinics, but in the absence of an authoritative statement on the effectiveness of available vaccines this procedure was not urged, as was the case with vaccination and immunization.

In Dr. King's division all notified births were entered in a register, a page being allotted to each day. Entries relating to children who died or moved from the area were deleted, and children moving in were added. As records of vaccinations and immunizations were received entries were made against the children's names. Invitations to parents to get their children protected could therefore be directed to the right people at the appropriate time—that is, for vaccination when the child reached 3–4 months, and for diphtheria immunization at 7–8 months—and health visitors were given lists of defaulters for follow-up until definite refusal was established. The schools were visited in turn, and lists were made of children needing immunization or boosting. Parental consent having been obtained, immunization sessions were held in the schools, or, if less than 20 children required injections, these were done at the end of a medical inspection.

Dr. King suggested that the suspension of whooping-cough vaccination and "soft-peddling" on diphtheria immunization when poliomyelitis was prevalent were unsettling. He asked whether it would not be better to have a "close season," say from June to October, and avoid cessation of injections, sometimes in the middle of a course.

B.C.G. Vaccination

Dr. T. M. POLLOCK, of the Tuberculosis Research Unit of the Medical Research Council, spoke about B.C.G. vaccination. Although B.C.G. had been used for over 30 years, and many millions of people had been vaccinated, controversy about its value still persisted. This was partly due to the fact that tuberculosis morbidity rates were subject to a large number of influences which were difficult to assess independently, and also because the death rate from tuberculosis had been falling for some years in many countries, irrespective of whether the vaccine had been widely used or not. Trials of the vaccine so far carried out, although criticized on statistical grounds, suggested that it was of value to those in contact with the disease, and also in communities with a high tuberculosis morbidity rate and a low standard of living. Further knowledge of the value of its widespread application in communities with a high standard of living and a moderate or low tuberculosis rate was required. It was hoped that the current trial of the vaccine being carried out by the Medical Research Council would produce such evidence, particularly about the degree of protection and length of time it lasted.

Immunization during Poliomyelitis Epidemics

In the discussion which followed the opening papers several speakers questioned the necessity of stopping injections during the poliomyelitis season, although most medical officers of health had succumbed to the general pressure. Dr. HARDING felt that if injections could be given at more than three-monthly intervals this would obviate the need for interruption. Dr. BUTLER had found that infants of 4–5 months had good antibody response, at least with the suspended vaccine, and that combined antigens gave as good response as separate antigens. Dr. THOMPSON pointed out that the greatest difficulty in general immunization of the very young infant was administrative. He also reminded the audience that severe diphtheria was still liable to occur when the general level of immunity was low, and quoted a recent example from the Midlands. In such instances even immunized children might get diphtheria, although the disease was milder in these children. Dr. BATTEN wondered whether it was worth giving a booster whooping-cough injection at 5 or 10 years. He felt it would be better to let children of this age catch the disease. Dr. POWELL said that continuous propaganda was necessary, and asked for the family doctors to take an active part in immunization and in the campaign.

In reply, Dr. COCKBURN agreed that injections should not be suspended except when a local epidemic of poliomyelitis occurred. Current surveys would reveal the size of this problem and indicate which antigen was most responsible. He felt that prolonging the space between injections to three months or more was less valuable than shorter intervals. As far as immunization of very young infants was concerned, there was some doubt about the antibody response at this age. If immunization of older children was complete the youngest would be screened from contact with the disease. He looked forward to as complete elimination of whooping-cough as of diphtheria once an antigen of measurable potency was easily producible.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Carcinoma of the Female Breast

SIR,—There is obviously nothing sacrosanct about surgery in the treatment of carcinoma of the breast, and surgeons must be prepared to consider judiciously any criticisms either of the indications for surgery or of technique.

In recent years surgery has been criticized from two opposing points of view: the first that the misleading term "radical mastectomy" is too radical; the second that it is not radical enough. On the one hand, it has been argued that routine sacrifice of the pectoralis major or surgical dissection of the axilla is unnecessary; on the other hand, that it is illogical to confine surgical attention to one route of lymphatic spread—the axillary—to the neglect of another possibly almost as important—the internal mammary.

But the advocates of these views too must be prepared to submit them to critical examination, and it is in this spirit that I would like to raise a few questions on the interesting article of Dr. I. G. Williams, Mr. R. S. Murley and Mr. M. P. Curwen (*Journal*, October 10, p. 787). The essence of their case is that removal of axillary glands is unnecessary or undesirable and should be replaced by radiotherapy, limiting surgery to removal of the breast. Now a considerable amount of histological material is available on the effect of irradiation of invaded axillary glands. Surgeons are frequently clearing axillae after they have been submitted to full courses of irradiation, and it is striking how often the glands still contain apparently viable growth histologically in spite of the irradiation. This difficulty of sterilizing the axilla by irradiation is a common experience of those who have studied the question with histological control, and it was one of the points that emerged in an informal conference on carcinoma of the breast in London a few years ago. Have Dr. Williams and his colleagues any evidence that their experience is different or is failure to sterilize the axilla unimportant?

Anatomical and surgical details do not fall within the scope of the article by Dr. Williams and his colleagues, but are pertinent to the argument. The pectoral axillary glands are in such close relation with the axillary tail of the breast that removal of the one usually means removal of the other. Moreover, removal of a primary in the upper and outer quadrant often involves such impingement of invaded pectoral glands that even advocates of avoidance of axillary surgery advise their removal with the breast. practice, therefore, the question that has been posed, grant that the whole breast should be removed, is not whether axillary glands should be treated surgically or by radiotherapy, but whether the treatment should be complete axillary dissection or limited axillary dissection with radiotherapy.

Dr. Williams and his colleagues briefly refer to the spread of carcinoma by the internal mammary lymphatic route

a route largely ignored by both surgeons and radiotherapists until the work of Handley and Thackray. They appear to assume that irradiation of the internal mammary chain is efficient, and surgical attack unjustified. Have they any evidence of the efficiency of irradiation, or, in the case of these glands too, is the presence of apparently viable carcinoma after irradiation of no significance? It is obvious that if irradiation can deal efficiently with the invaded mammary chain it is preferable to surgery. But is it justifiable to condemn out of hand a trial of surgical methods without such evidence? At the very least, surgery has a place in the histological control of irradiation treatment. And, if surgery were as successful in dealing with the local disease in the internal mammary chain as it is in dealing with the local disease in the axilla, can we yet say for certain that this would have no influence on the course of the disease? Incidentally, Dr. Williams and his colleagues perhaps underestimate the extent of interest in the development of methods of surgical attack on the internal mammary chain. Apart from work in the United States to which they refer, it has for some time been the subject of wide inquiry and experiment, particularly in France and Scandinavia, and is also being explored in this country.

Finally, Dr. Williams and his colleagues note that in the procedures they advocate the "local recurrence index" is higher, but they do not appear to attach much importance to this. It may be that when general methods of control of malignant disease become more efficient the question of sterilization of its local manifestations will become unimportant. But at the present time, and with the bulk of the evidence suggesting that both surgery and irradiation are purely local in their effect, is not local persistence or recurrence of the disease the fairest test of the efficacy of such local forms of treatment?—I am, etc.,

London, W.1.

DAVID PATEY.

Cough Syncope

SIR,—The use of some neutral and descriptive term such as "cough syncope" in place of "laryngeal epilepsy" is to be welcomed; and all those interested in this syndrome are indebted to Professor E. P. Sharpey-Schafer (*Journal*, October 17, p. 860) for demonstrating so clearly a physiological mechanism for its production. However, in implying that this explains all cases of loss of consciousness or fits following coughing, he claims too much. There are cases in the literature, and within my own experience, where the preceding cough was neither violent nor prolonged. In some it was subjectively different from the patient's "ordinary" cough and was recognized as heralding an attack. These cases should probably be regarded as primarily epileptic with coughing as an aura.

His further far-reaching statement that a "fit can occur in any normal subject if the blood flow to the brain is sufficiently reduced" may be true. However, some procedures, such as venepuncture, used to reduce cerebral blood flow experimentally, will also affect cerebral mechanisms directly via more than one sensory pathway. The range of sensory stimuli which may on occasion produce reflex epilepsy is wide; and the evidence for some cerebral abnormality in these cases is considerable. If such stimuli occur together with reduced blood flow, and a fit ensues, it seems arbitrary to assign the role of "cause" to the vascular change, and to assume cerebral normality.—I am, etc.,

Oxford.

Milk and Protozoal Infections

SIR,—We have read with great interest the communication on the effect of various diets on *Trypanosoma congolense* infections by Miss Audrey A. N. Keppie (*Journal*, October 17, p. 853), and we should like to add some details to the general story of milk and protozoal infections. We had not intended to publish the results below, but we feel now that the bare facts should be made known in order to prevent duplication of effort.

We have found that a pure milk diet has no suppressive activity against *T. rhodesiense* infections in rats when milk is offered three days before infection until death. The *T. rhodesiense* infestation was in fact somewhat more intense in milk-fed rats than in control normal diet-fed rats. This variance from the results obtained with *T. congolense* may be due to the swift multiplication of the human parasite in rats when compared with the more chronic strain of *T. congolense* used by Miss Keppie. The same diet effectively controlled normal and pyrimethamine-resistant strains of *P. berghei* under the same conditions.

Further, we have found that a diet of 2% casein hydrolysate in 50% glucose solution effectively suppresses *P. berghei* malaria in mice when offered in the same manner as milk. However, the effect is not so abrupt as with pure milk diets. Multiplication is permitted for six days before suppression becomes effective, but, once active, the diet reduces the parasites to negligible numbers. This is in contrast to the immediate results obtained with milk diets. The effect of casein hydrolysate diet is partially reversed by addition of *p*-amino-benzoic acid and almost completely reversed by addition of a mixture of most of the B vitamins.

May we say in conclusion that on examining all the facts we are not convinced that the inhibition of protozoal infections by milk or milk products is due wholly to a lack of any essential metabolite or of *p*-amino-benzoic acid in particular? The activity of milk as a whole is greater than such of its parts as have been tested in malarial infections, and the reversal of the effect by the addition of *p*-amino-benzoic acid is not always complete. We feel that this question is likely to be much more complex than at first it may seem.—We are, etc.,

M. A. REFAAT.
R. S. BRAY.

London, W.C.1.

SIR,—I was very interested to read the communication of Miss Audrey A. N. Keppie (*Journal*, October 17, p. 853) concerning the effect of various diets on *T. congolense* infections in mice. You may be interested to learn that we have unfortunately failed to observe any such suppressive effect of a milk diet on *T. rhodesiense* infections in mice. On the contrary, we have found that animals placed on an exclusive diet of milk for a week before infection, and subsequently left on the diet, die at about the same time and with the same degree of blood infection as do animals on the ordinary laboratory diet of cubes and water. Moreover, parasites appear in the blood on the same day after infection in both groups.

So far, in fact, we have not been able to demonstrate any effect of milk on parasites other than those of malaria. For instance, whereas a milk diet gives rise to suppression of *P. berghei*, *P. cynomolgi*, and *P. knowlesi*, it has no effect on *Babesia canis* in puppies, although the latter exists within the erythrocytes.

Recent experiments have led us to believe that the suppressive effect of milk on malaria parasites may be a good deal more complicated than has been suggested. We have, for instance, noted that at about this time of the year or a little earlier the local milk may fail completely to protect rats against a strain of *P. berghei* which on other occasions has proved to be highly sensitive. It may be that this represents some change in the cow's diet reflected in the milk and arising possibly from change in pasture.

When we first reported the suppressive effect of milk in *P. berghei* malaria¹ we suggested that a similar phenomenon might explain the commonly reported low incidence of malaria in very young (breast-fed) infants. Since the publication of our paper I have been informed that in certain areas of Africa infection of breast-fed infants is sometimes quite common. Perhaps this may also be a reflection of the mother's diet at the time of breast-feeding. It would be possible to explain this variation in the suppressive power of milk in terms of variation in the amount of some essential factor such as *p*-aminobenzoic acid, but it seems to me too early on the evidence available to interpret the action of milk exclusively in terms of deficiency of *p*-aminobenzoic acid or any other metabolites. We have broadly confirmed

the action of *p*-aminobenzoic acid on milk-suppressed berghel² and knowlesi infections, but the effect is not always complete. Moreover, we have now some evidence that other substances besides *p*-aminobenzoic acid may at times have similar effects on milk-suppressed malaria.—I am, etc.,

Liverpool, 3.

"Smog"

SIR,—The recommendation of the London Local Medical Committee to wear gauze masks during a fog may not be acted on by many people, but it seems likely that a loose plug of cotton-wool in each nostril would act fairly efficiently provided there is no mouth breathing. While possibly neither efficient nor advisable in young children, the value of this method can be tested by anyone using it in their coal cellars for a time and then examining the plugs, when the coal dust will be found limited to the outer parts. If a cleaner test is preferred an attempt may be made to inhale snuff—or even pepper—through them.—I am, etc.,

Ferndown, Dorset.

W. MCNAUGHTAN.

SIR,—Apropos the recent minor conflict between the London Local Medical Committee and the Ministry of Health on the subject of the efficacy of a gauze mask as a barrier against the solid particles in "smog," the following personal experience may be of some interest.

Some few weeks ago I decided to shift a quantity of coal, which was blocking the entrance of the coal shed, to the far end of the shed. Before commencing the work I donned a mask, which was of the usual pattern used in operating theatres, in the hope that much of the coal dust would be stopped thereby. To my surprise, at the end of the operation I found that most of the coal dust was deposited on the inner surface and amazingly little on the outer.

The lesson is obvious. The mask, being tied over the bridge of the nose and under the chin, left a wide gap along the upper border through which the coal dust had been aspirated, testimony for which was provided, in this instance, by the liberal coating of coal dust along the alae nasi.

I very much doubt whether such a mask would afford any measure of protection against "smog" particles.—I am, etc.,

St. Helens, Lancs.

L. CRAWFORD.

SIR,—In connexion with the much-discussed problem of "smog," I have met with several patients who have undoubtedly been suffering from varying degrees of carbon-monoxide poisoning. They have been drivers of cars and held up in traffic jams, owing to dense fog. In view of the tragic number of deaths which occurred as a result of the "smog" last winter, every effort should be made to lessen the collection of noxious gases in a motionless atmosphere. One way of doing this would be to switch off motor engines when there is a hold-up of more than a few minutes. It is very simple to switch on again when traffic begins to move.

I personally have suffered nausea and severe headache from petrol and diesel oil fumes when in a traffic block for 20 minutes, irrespective of fog, so how much greater will be the concentration in still air?—I am, etc.,

Chigwell, Essex.

CONSTANCE P. F. THOMAS.

Clinical Pathology in General Practice

SIR,—Dr. A. J. N. Warrack's comments (*Journal*, October 24, p. 935) on my account of the facilities provided for the general practitioner by the Public Health Laboratory Service (*Journal*, October 10, p. 823) should encourage us to think a little more carefully about what we mean by a consultant service in clinical pathology.

Even in the best hospitals, I doubt whether every request for a laboratory examination is preceded or followed by a discussion of the case between the clinician and the pathologist. Occasionally, it is true, the clinician will approach the pathologist to ask for advice before planning his investigation, but such consultations arise more commonly after one or more examinations have been carried out. Indeed, in most cases no such personal consultation takes place, because the results of the laboratory tests have provided the information the clinician requires. The essential elements in the situation are that the clinician should know that he can approach the pathologist when he needs advice, and that the pathologist should seek every opportunity to tender advice when his results suggest that it is needed. There is no reason why the position of the general practitioner in relation to the laboratory should be in any way different from that of the hospital doctor. He, too, should be able to learn when to begin by consulting the pathologist and when to submit specimens first.

Dr. Warrack deplores the division of clinical bacteriology into "infectious" and non-infectious," but this is the way in which the pathological services are divided in the National Health Service. The hospital service deals essentially with the curative, the public health service with the preventive side. In practice the division seldom leads to serious trouble, and most of the apparent anomalies which Dr. Warrack instances can be settled quite easily by the heads of the laboratories concerned. Close co-operation between the two services is essential, but the form it takes must depend on local circumstances. The aim is to site the two laboratories together so that they may work under the same favourable conditions as Dr. Warrack enjoys at Sheffield.—I am, etc.,

Manchester.

M. T. PARKER.

Prolapse of the Urethra in Young Girls

SIR,—May I be permitted a brief comment on the case recorded by Mr. H. H. Fouracre Barns (*Journal*, October 3, p. 765)? I have met with several instances of this lesion over the years.

In the aetiology it should not be forgotten that a urinary infection with transient cystitis and straining may be an important factor, and in the treatment simple conservative measures, if patiently pursued, can, in my experience, prove entirely successful. They should be given an extended trial before any operative interference is resorted to. An account of this somewhat rare condition will be found in *The Urology of Childhood*.¹—I am, etc.,

Deal.

T. TWISTINGTON HIGGINS.

The Human Foot

SIR,—It was interesting for those of us in the School Health Service to read the two articles (*Journal*, October 3, pp. 745 and 749) and the annotation (p. 772) on foot defects. Such research is perhaps useful corroboration of what is virtually self-evident when the question of shoes and feet is seriously considered. In old China binding of women's feet was accepted without question as a social convention. We still accept it here—for both sexes—admittedly in a lesser degree. It is impossible to buy ready-made shoes which fit the natural shape of the feet except in a few expensive brands for younger children. For adults such shoes do not exist. The inner border of the shoe should be straight. Almost all shoes have a curved inner border, with the result that they act as a permanent splint tending to mould the hallux into a valgus position. It is strange that this obvious fact was omitted from all three papers. It is a fact greatly disliked by the shoe trade and one which they try to conceal as much as possible. It will be time for the real research to begin when it is possible for the population to obtain

naturally shaped shoes. When this happy time comes, we may suspect that there will be little clinical material left to investigate.

The figures given of hallux valgus incidence in both papers are astonishingly low and contradict everyday experience. It is alleged that only 13.9 cases of hallux valgus per thousand were found in recruits of 17–19. My own experience in boys of 15 would be nearer 50%. In the Ealing survey the percentages in senior boys and girls were given respectively as 4% and 22.4%. My experience would indicate nearer 50% and 90% respectively. This is probably a question of standards. I submit that this acceptance of low criteria is deplorable, however much it may be welcomed by the shoe trade. Let us all press for action in this matter.—I am, etc.,

London, W.8.

GEOFFREY G. SHERRIFF.

SIR,—Although it is very clear, and all too obvious, to Mr. John Hanby (*Journal*, October 24, p. 935) with his long experience of foot troubles that the incidence is shockingly high and that very many have their origins in childhood, it is only recently that the public as a whole have begun to appreciate these facts. It is also only comparatively recently that we, as a medical profession, have made any efforts to put the problem on an epidemiological basis and have had the benefit of scientific and statistical studies such as those of Dykes *et al.*,¹ Hardy and Clapham,² and Craigmile.³

It would surely be unrealistic to approach the problem on the basis of Mr. Hanby's first suggestion, that the sole of a shoe or its equivalent leads to a lack of sensory stimuli to the small muscles of the foot and thereby causes retraction of toes, etc. Many feet that have had these restrictions have not developed these defects and it would surely be impossible to discard shoes.

On his second point—namely, the anomalies of the normal foot—as a result of the recent work we are in a much better position than ever before to realize the enormous range and variety of normal foot shapes. It is now surely clear that feet are as various as faces, and it is evident that the casing of a growing foot is no simple matter. If possible, every child's foot should have a made-to-measure shoe and this should be changed every three or four months. We have been experimenting with the possibility of shoes made from plaster casts for children—without much assistance from the boot and shoe trade—during the last year. This form of course would be the ideal solution. Alternatively, surely the least we can ask is that every child should have a proper fitting and not be subjected to a 1-in-3 chance of getting it—as at present. Until shoes are supplied on the lines of the scheme run under Dr. Doris A. Craigmile's supervision in Ealing there can be no possibility of normal foot development.—I am, etc.,

Ealing, W.5.

Succinylcholine Chloride for Casualty Anaesthesia

SIR,—Drs. Terence Vaz and J. M. Bishop have proposed (*Journal*, October 17, p. 885) the use of intravenous succinylcholine chloride "as a simple and effective method of obtaining relaxation during manipulations in the casualty department."

Such manipulations may be required in two classes of patients—those who are requested to attend at a stated time, having been instructed to take no food, and emergencies who come in "off the street." In such cases anaesthesia will presumably be postponed for 3–4 hours after the last meal. The stomach is then presumed to be empty. It is not uncommon, however, for this belief to be unfounded. While vomiting is regrettable in association with a simple

gas-and-oxygen anaesthetic, it is seldom disastrous, as the protective reflexes are seldom far away. How different is the situation if succinylcholine chloride is given also.

I suggest, Sir, that it should be made clear that the technique suggested by Drs. Vaz and Bishop is indefensible in emergency cases, although admirable for "arranged" cases.—I am, etc.,

Glasgow.

R. CECIL BROWN.

SIR,—In their letter (*Journal*, October 17, p. 885) suggesting the use of succinylcholine chloride for casualty anaesthesia, Drs. Terence Vaz and J. M. Bishop do not mention how their patients are prepared pre-operatively. If this technique is used on emergency cases for the reduction of fractures, then this is an important omission. Such cases have often had a recent meal, and mental and physical shock may have delayed the emptying time of the stomach. Morton and Wylie¹ have described how, in these conditions, regurgitation of stomach contents is likely to accompany the injection of thiopentone or relaxant drugs. If the use of muscle-relaxants in casualty departments is to be advocated, then this danger must be stressed, for it is often with the more trivial accident cases that the greatest care must be taken. If it is certain or even probable that there is material in the stomach, then the anaesthetist must postpone operation for not less than five hours, or wash out and empty the stomach before inducing anaesthesia. Drs. Vaz and Bishop say that the patient may safely go home after the technique described, but I am sure that, if this is so, then it must be a rule that he is neither unaccompanied nor in charge of transport.

Whilst these observations are obvious, they must be emphasized continually if this trend in casualty anaesthesia develops.—I am, etc.,

London, E.C.1.

ROBERT I. W. BALLANTINE.

The Diploma in Public Health

SIR,—I read with considerable interest Dr. Max Park's letter (*Journal*, October 3, p. 778) in which he discusses the present course for the Diploma in Public Health. Although some of his criticisms are undoubtedly of great importance in considering any revision of the course, I would like to take issue with Dr. Park on one or two points.

It must be remembered that, although current changes in public health practice in Great Britain were brought about largely as a direct result of the National Health Service, in many other parts of the world the public health physician will continue to concern himself with the communicable diseases and their treatment. Therefore a real knowledge of bacteriology, parasitology, entomology, vector control, and related subjects is most necessary for such a health officer, especially those working in tropical and sub-tropical countries. Not all the latter wish only to hold the D.T.M.&H., and others may prefer to have the D.P.H. in any case. Surely there is no reason why lectures and demonstrations on these subjects need be tedious repetitions of undergraduate material. A little imagination on the part of the instructors is all that is needed.

Presumably Great Britain still wishes to retain her position as an international teaching centre, and her universities and colleges to serve students from abroad as well as her own sons and daughters. If so, the course for the Diploma in Public Health must be so orientated. However, there is surely no reason why a wider choice of subjects should not be allowed (as is done in the American schools of public health) in addition to the basic subjects which must be taken by all candidates for the diploma. Review of the course for the diploma is excellent, and, provided any revision undertaken is carried out with reasoned conservatism, this can only be to the good. Dead wood must be chipped away if progress must be made, but make sure

that it is really dead first. Through exercise of the choice system the "local" man can choose the subjects he feels are necessary for his work in the British Isles, while the foreign or Commonwealth man can follow the broader line.—I am, etc.,

Ayer, Massachusetts.

KENNETH I. E. MACLEOD.

The Broken Acrylic Head

SIR,—We read with interest Mr. K. H. Pridie's letter (*Journal*, October 24, p. 939). Work which we have carried out on the Judet heads which have been sent following our request (*Journal*, May 2, p. 993) for broken prostheses has shown that the problems involved are far more complex than Mr. Pridie's letter would suggest. His assumption that the skirt breaks first and throws extra load on the stem is not a major consideration. The skirt is not designed to take the weight of the patient. Even if the metal rod is increased in diameter—and some makers do use large-diameter rods—breakages still occur. Moreover, it is doubtful whether, in the operative procedure, the surgeon is able to fit the prosthesis in such a manner as to obtain a pre-determined distribution of load between the skirt and the stem of the acrylic prosthesis. Reorganization of bone in the immediate post-operative period will result in redistribution of load beyond anyone's control. It can be demonstrated that a proportion of the failures of British manufactured Judet prostheses are due to lack of knowledge of the behaviour under fatigue stress conditions of polymethyl methacrylate in combination with metals. It is only since the introduction of the Judet prosthesis that metals have been used for purposes where they will be continuously exposed to fatigue stress. Very little thought has been given to the possibility of stress corrosion of metal in the human body. Static loading tests at room temperature do not demonstrate the ability of a composite structure to withstand fatigue stress at body temperature after sterilization by boiling. A study of the biomechanics of this problem seems to suggest that the angle at which the prosthesis is inserted is critical. The use of more extensive prostheses, which Mr. Pridie suggests, may prove to be a step forward in the treatment of pathological conditions of the hip-joint.

There is no doubt that plastics and metals have their place in orthopaedic surgery, provided the materials used, the design of the prosthesis, the condition of the bone to which it is attached, and the situation in which it is to operate are carefully considered. Large-animal experiments can give a great deal of valuable information and should be performed prior to the nation-wide use of new devices. The present trend of devising and modifying all manner of prostheses, coupled with the apparent lack of research facilities of those who manufacture them, will only increase the sufferings of the patient with which Mr. Pridie is so rightly concerned.—We are, etc.,

Stanmore.

Site for Vaccination

SIR,—For some three years past I have been vaccinating female infants on the sole of the foot in those cases where the mother, for cosmetic reasons, has requested that the upper arm should not be used. The percentage of "takes" does not appear to differ from that where vaccination is on other sites. The advantages would appear to be: (a) a concealed scar (as compared with vaccination on the thigh); (b) the vaccination site is well away from faecal and urinary contamination; and (c) the mothers inform me that the bathing of the baby is facilitated.

Whilst not for one moment claiming to be the originator of the technique, I have so far not met anyone using this site for vaccination purposes. The views of other practitioners would be much valued, with especial reference to any disadvantages of using this site for vaccination.—I am, etc.,

Faversham, Kent.

J. CANTOR.

Obituary

Sir NORWOOD EAST, M.D., F.R.C.P.

Sir Norwood East, whose death took place at his home at Crowthorne, Berkshire, on October 30, celebrated as recently as last Christmas his eightieth birthday, when he received many tributes, including one in this *Journal*, in which his noteworthy career in the prison medical service was set out.

William Norwood East was born in 1872, the son of a hotel-keeper at St. Martin's-le-Grand in the City of London. He was educated at King's College School and King's College, and received his medical training at Guy's, qualifying in 1897 and proceeding M.D. (London) in 1901. He entered the prison medical service in 1899, and served at several of the larger prisons—Portland, Manchester, Liverpool, and finally as senior medical officer at Brixton. In 1924 he was promoted medical inspector of H.M. prisons in England and Wales, and six years later was appointed H.M. Commissioner of Prisons and director of convict prisons. He retired in 1938, but returned to his task and was reappointed Prison Commissioner for seven months in 1940–1, while his successor was seconded elsewhere. After his retirement he was appointed lecturer in forensic psychiatry at the Maudsley Hospital.

In the course of a career extending over 50 years, Sir Norwood East made an outstanding contribution to the solution of the ever-debated problems of crime and punishment, the causes of crime, and the treatment of offenders. He brought to his task the precise mind of a scientist, the practical outlook of an administrator, and the balanced judgment of a lawyer. He did much to enhance the efficiency of the prison medical service and to humanize the prison hospital, while his study of criminal psychology led to a new understanding of the criminal. During his later career psychiatry became increasingly prominent in both the trial and the treatment of criminals, and East, who understood as few men did the psychiatric approach, never dismissed it as irrelevant, but on the other hand he was not prepared to support excessive claims of psychiatry in dealing with criminal cases. The lawyer's standpoint that society must be protected was fully appreciated by him.

Norwood East was at one time or another president of the Medico-Legal Society, the Society for the Study of Addiction, and the Psychiatric Section of the Royal Society of Medicine, and he was a corresponding member of various medico-legal societies abroad. He had a prolific pen. The first of his writings was in 1901, in the *Journal of Mental Science*, when he wrote of physical and moral insensibility in the criminal. His *Introduction to Forensic Psychiatry in Criminal Courts*, published in 1927, was the first work of its kind. One of his last publications was *Society and the Criminal*, a book which appeared in 1949. One of several investigations which he organized was into the cause

Nov. 7, 1953

OBITUARY

BRITISH
MEDICAL JOURNAL 1051

of delinquency among adolescents, based on material comprising 4,000 cases. He analysed 1,000 consecutive cases of attempted suicide, and another inquiry of his was into the susceptibility of criminals to atmospheric changes.

His various important tasks included those of an inspector under the Inebriates Act and membership of the Departmental Committees on prison dietary and on persistent offenders. He was also very frequently called in as assessor to give an opinion on the sanity or otherwise of murderers after conviction.

In a service which can be sustained only by an exceptional sense of vocation because of the unresponsive and often repulsive human material with which it has to deal, he kept his own sense of vocation to the very end and continually impressed upon the young doctors who came into the service the high moral demand which such work would make upon them.

His knighthood was announced in the Birthday Honours, 1947, for services to the study of criminal psychology. Lady East, whom he married 53 years ago, survives him with one daughter, the wife of Dr. J. S. Knox, the deputy superintendent at Broadmoor.

W. E. TUCKER, M.B., F.R.C.S.

Dr. William Eldon Tucker, a leading figure in Bermuda, died at the age of 81 in the King Edward VII Memorial Hospital, Bermuda, on St. Luke's Day, October 18. His death brought to an end a life of service and great achievement, not only in his profession, which awarded him one of its highest honours, but in the field of sport and community affairs.

William Eldon Tucker, the son of the late Venerable Archdeacon George Tucker, was born on August 17, 1872. From Trinity College School, Port Hope, Canada, where he was a classical scholar and head of the school, he went on to Caius College, Cambridge, and soon won fame in the Rugby world, playing for Cambridge and England. Even in the 1920s many of the college servants still remembered his feats of strength, for he had gained the reputation, among other things, of being one of the strongest men ever to be at the University. In 1894 he captained the Cambridge

(Frederick L. Hamilton, Bermuda)

fifteen, the same year as the late G. M. Carey was captain of Oxford, and the result of that year's game was a draw. Both captains played in the England team, together with such great players as A. F. Todd, S. M. J. Woods, and Frank Mitchell, and were firm friends. Altogether Tucker played five times for England. He also played cricket and rowed for his college for four years. From Cambridge he went to St. George's Hospital and qualified in 1899. While at hospital he played rugby for Blackheath, and was in the team that won the county championship in 1897.

After holding a number of house appointments at St. George's, he graduated M.B., B.Chir. at Cambridge and returned to Bermuda to set up in general practice there. Before his arrival only two major operations

were known to have been performed in the islands. But through his efforts and those of the late Dr. D. C. Trott the time came when several hundred patients were treated each year by major surgery in the local hospital. During the first world war Tucker acted as surgeon to the Military Hospital, Bermuda, and on one occasion a ship-load of frost-bitten West Indian troops arrived from the north in winter, and he then performed about 150 amputations within a period of a month.

A practitioner of the old school, Dr. Tucker was loved and respected throughout the islands, and he rendered invaluable service to the King Edward VII Memorial Hospital as a member of the medical staff from the day it was opened. Motor-cars for general use were not permitted into Bermuda until 1947, so he visited his patients on horseback or bicycle or by horse-drawn carriage. Although he was a man of strong personality and definite views, it was largely because of a combination of gentleness and frankness that he made few enemies but many friends. In later life he became crippled with osteoarthritis of the hip-joints and arteriosclerosis of the vessels of both legs, which compelled him to give up practice in 1949. Nevertheless, he bore his disabilities with a stout heart and did not complain.

Tucker worked hard to improve the standards of the medical profession in Bermuda. He served at various times on the Board of Health, as medical attendant at the leprosarium, as chairman of the hospital advisory committee and of the medical examining board, and he was a past president of the Bermuda Branch of the British Medical Association. In April this year he flew to London to receive the Fellowship of the Royal College of Surgeons of England, conferred on him in recognition of his surgical work. It was with great pride that he received this honour, which put the seal on his full and useful life. Dr. and Mrs. Tucker celebrated their fiftieth wedding anniversary last year. His widow, two daughters, and two sons survive him. His elder son, Mr. W. E. Tucker, is an orthopaedic surgeon in London and, like his father, a former captain of the Cambridge Rugby fifteen and an old England player. In 1925 Dr. Tucker saw his son lead the Cambridge side against Oxford at Twickenham.

We are indebted to Professor R. J. WILLAN for the following appreciation: In 1938 I had a pleasant holiday in Bermuda, largely contributed to by the kindness and hospitality of Dr. and Mrs. W. E. Tucker. Perhaps few know of the responsibility Dr. Tucker shouldered during the pioneer days in the islands, before easy—and particularly rapid—travel communication was possible. The pre-early rapid—travel communication was possible, when even sea air-travel era is particularly referred to, when even sea transport was limited, and New York was 700 miles distant from Bermuda. Dr. Tucker was a good all-round surgeon and operator: countless patients—not only Bermuda residents but visitors to the islands who developed acute surgical emergencies—owed their lives and health to Dr. Tucker for his skilful diagnosis and surgical treatment. The recent award of the F.R.C.S. gave great pleasure to his many friends in Bermuda, in Great Britain, and in the American continent. His passing has left a gap in Bermuda and in the surgical world.

Dr. ARCHIBALD OGG died at his home at Wolverhampton on October 12 at the age of 60, after an illness lasting only two days. His death, which occurred shortly after his return from holiday, was a great shock to his friends and colleagues, but he died, as he hoped he would, in harness. Archibald Ogg was born on May 24, 1893, and was educated at Glasgow University, where he graduated first as M.A. in 1919 and then as M.B., B.Ch. in 1924. He took the D.P.H. in 1927 and proceeded to the M.D. in 1934.

After qualifying he held the appointments of house-physician at Glasgow Royal Infirmary and assistant physician at the Glasgow Fever Hospital, later becoming resident medical officer at the Leicester Isolation Hospital and Sanatorium. A period in private practice and at the tuberculosis dispensary at Nuneaton followed, and he was then appointed tuberculosis officer to the Staffordshire, Wolverhampton, and Dudley Joint Board for Tuberculosis. He was at first in charge of the dispensaries in the north of the county, where he rapidly won the affection and gratitude of those under his care. His interest in his patients was not limited to their physical condition; indeed, he spent much of his private time in seeking added comforts and personal necessities for them. This was before work on the care of the tuberculous was widely organized by local authorities and voluntary societies as a necessary part of their schemes. In 1941 Dr. Ogg asked to be transferred to the Wolverhampton district, where he worked without sparing himself and continued until the time of his death. The long hours of strain during the war years in the very busy clinics undermined his health and probably contributed to his relatively early death. His loss will be widely mourned, for he regarded his work as being essentially personal in nature. He belonged to the early generation of tuberculosis officers whose efforts had, of necessity, to be concentrated on the environmental conditions of the patients, and though he kept himself strictly up to date clinically this outlook aided and enhanced the value of his treatment of his patients. His type is becoming rare, but it is to be hoped that his outlook will be held by his successors. He leaves a widow, to whom our deepest sympathy is extended.

We are indebted to Dr. R. L. MACKAY for the following appreciation: Dr. Archibald Ogg was an undergraduate in arts at Glasgow University when the first world war broke out. Like so many of that generation, he abandoned his studies to serve as a private in the ranks of his local regiment, the Cameronians (Scottish Rifles). While with his battalion he was seriously wounded, lying in no-man's-land for a day and a night. His company commander tried to bring him in, but was killed in the attempt, but later his platoon sergeant, displaying the greatest bravery, succeeded, for which act he was awarded the Victoria Cross. No higher tribute to Ogg's qualities and character could have been paid in those distant days than that these sacrifices should have been made for him. Although he never spoke of his war service, Ogg's life showed that he never forgot those two men. Thereafter he was commissioned in the Machine Gun Corps, and later returned to complete his arts course in 1919 and to commence in medicine. As a student he was quiet and a steady worker, preferring to let others talk and play. After graduating in medicine he dedicated his professional life to the study of phthisis and the battle against that disease. The citizens of Wolverhampton will long remember him for his quiet, untruffled demeanour, his attentiveness to their stories, and his sympathetic and skilled handling of their problems. Where administration would fall short, Ogg's smile and encouragement would fortify and revivify. His counsel was sought and much valued by his colleagues in the hospitals of the district. He was a great reader, interested in history and music and with a philosophical bent; his conversation attracted listeners, and a certain pawky humour stimulated talk but repelled pettiness. He is greatly missed by a legion of friends and patients.

Dr. ALICE M. HUTCHISON died at her home at Jordans, Buckinghamshire, on September 29 at the age of 79. Alice Marion Hutchison was born at Dalhousie, India, on August 12, 1874, the daughter of the late Dr. John Hutchison, and was educated at Moffat and Bridge of Allan and at Edinburgh University, where she graduated M.B., Ch.B. in 1899. She proceeded to the M.D. in 1905, and was admitted M.R.C.P. in 1921. Soon after graduation, Dr. Hutchison returned to India for a time and held an appointment at the Dow Memorial Hospital at Gujrat in the Punjab. She then held

various posts in Edinburgh, including those of resident medical officer at the Hospice, medical officer to George Watson's Ladies' College, and physician to the Edinburgh Hospital for Women and Children, until the outbreak of war in 1914, when she helped to organize a hospital unit under the Scottish Women's Hospitals and accompanied the unit to Serbia. In 1917 she was transferred to the R.A.M.C., and remained with the Corps until 1920. For her services Dr. Hutchison was awarded the Serbian Order of St. Sava and the Belgian Order of the Palm Leaf. After the war she settled in practice in London and held the appointments of assistant physician to the South London Hospital for Women, senior clinical assistant at the Hospital for Sick Children, Great Ormond Street, and physician to the children's department of the Tavistock Clinic, the latter appointment indicating her interest in the psychological aspect of children's diseases, in which she specialized. She had also been medical officer to infant welfare centres in Bermondsey and Peckham. She was the author of *The Child and His Problems and Motives of Conduct in Children*.

We are indebted to Dame LOUISE MCILROY for the following appreciation: The sudden and tragic death of Dr. Alice Hutchison has come as a shock to all her friends, of whom she had many. It seems a very short time since I met her at a Serbian reunion, at which she looked so well. Dr. Hutchison was one of the first British women doctors to take out a hospital unit under the Scottish Women's Hospitals to help the Serbian soldiers in 1915. She and her staff stood up most bravely to the dangers and vicissitudes of war, and for a number of months they were prisoners of war in Central Europe. Dr. Hutchison served most of her time on the Serbian front, and was much beloved by her staff and her soldier patients. She kept up the morale of all who were under her care. Later, when the Serbian Army had become scattered, she and her staff looked after Serbian women and children in Corsica, and did excellent work in that way. I can only inadequately express the regard and admiration which I had for Dr. Hutchison and her wonderful unselfish devotion to duty and her kindly attention to anyone in trouble during the war years, with their consequences.

Medical Notes in Parliament

NATIONAL SERVICE BOARDS INQUIRY

Sir WALTER MONCKTON, Minister of Labour, gave the House of Commons on October 27 the results of his inquiry into the work of medical boards examining men for national service.

He stated that he and the Parliamentary Secretary had visited a number of boards. He had had discussions with chairmen of other boards, and officials had attended meetings of chairmen in all regions. These investigations had satisfied him that the medical men who comprised the National Service Medical Boards were fully alive to their responsibilities.

Nevertheless, he continued, some errors in grading had occurred. Special investigation had revealed about 20 such cases, which was not a large number in relation to an annual rate of about 300,000 examinations. The most common factor resulting in a man being placed in too high a grade was the failure on the part of the man to disclose his full medical history. To correct this source of error the notice summoning the man had been revised and now advised him to bring to the board medical evidence of any past disabilities and ailments.

In a few cases there had been a lapse on the part of the board in applying the proper medical standards, and in other cases there had been clerical errors. He proposed to relieve the chairmen of any non-medical work which might be a distraction. As a further safeguard, in future every man summoned to a medical board would be informed by notice that if he had any reason to think he had been given a wrong grading he might appeal in writing within 14 days, enclosing with his appeal any medical evidence. Such

appeals would be referred to the regional medical officer of the Ministry of Health for advice whether medical grounds existed to justify re-examination. Ordinarily any re-examination would be undertaken by a different board.

The boards' task was not easy, and he could assure the House that they had maintained the high tradition of their profession.

Mr. H. R. GOWER, recalling a previous assurance that medical boards would in every case of reasonable doubt refer to the previous medical history of the man concerned, asked if the innovation had been successful. Sir WALTER MONCKTON said that one of the main difficulties—and it was very much to the credit of some of these men—was that they were most anxious not to disclose something to prevent them from doing service. They were trying to ensure that the medical officers had a fair start by knowing the background.

Mental Disorders Inquiry

Mr. D. DONNELLY asked the Minister of Health on October 26 whether he would recommend the extension of the terms of reference of the Royal Commission on the laws relating to mental disorders, so as to enable the commission to consider improvements in the present law and medical treatment of homosexuals. Mr. IAIN MACLEOD replied that it would not be appropriate to extend the terms of reference to cover the law with regard to these cases and their medical treatment. In so far, however, as they might be suffering from mental illness or mental defect their position as regards certification, detention, and care would be covered in the same way as that of other persons so suffering.

Milk-borne Disease

Dr. A. D. D. BROUGHTON asked what progress had been made in the specification of areas under the Food and Drugs (Milk, Dairies, and Artificial Cream) Act, 1950, and the Milk (Special Designations) Act, 1949, for the purpose of protecting the public against milk-borne diseases. Dr. CHARLES HILL replied on October 26 that 48% of the population of England and Wales and 63% of the population of Scotland resided in areas specified by orders which had been made or which were now laid, in draft, before Parliament. Surveys were proceeding with a view to specification of further areas.

Dr. BROUGHTON asked for the approximate date by which the public would be protected against the dangers of bovine tuberculosis, by the whole milk supply being either pasteurized or coming from tuberculin-tested herds. Dr. HILL said he sympathized with the purpose, but it was impossible to forecast when the work of surveying the country would be completed.

Tuberculosis Nursing in R.A.F.

Mr. G. WARD, Under-Secretary for Air, stated in answer to Mr. I. MIKARDO on October 28 that an extra 3s. a day was paid to nursing officers of Princess Mary's R.A.F. Nursing Service below the rank of wing officer when employed full-time on nursing pulmonary tuberculosis cases. Airmen on this work were given an extra 6d. a day, and airwomen an extra 5d.

Mr. MIKARDO commented on the "sharp difference" between 3s. and the other rates, and asked what justification there was—in so far as one could compensate with money for the special risks involved in this work—to compensate with different levels of money. Mr. WARD pointed out that they were dealing with Princess Mary's Nursing Service on the one hand and uniformed airmen and airwomen on the other; but careful precautions were laid down, and taken, and all had to undergo careful medical examination before being accepted for this work.

Mr. A. WOODBURN said that the health authorities did not regard it as desirable that it should be suggested that nurses in this type of nursing were open to any greater risk than they were in an ordinary accident ward, where a proportion of the patients might be suffering from tuberculosis. Mr. WARD agreed, and said that practice in the R.A.F. was in conformity with the practice in civil hospitals.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 17 (No. 41) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1953					1952

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

‡ Includes puerperal pyrexia.

Vital Statistics

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in September was 117, compared with 110 (revised figure) in the previous month, and 119 (revised figure) in September, 1952.

The number of cases of industrial diseases in the United Kingdom reported during September was as follows: lead poisoning, 1; other poisoning, 1; anthrax, 1; epitheliomatous ulceration, 14; chrome ulceration, 17; total, 34. There were no deaths.—*Ministry of Labour Gazette*, October, 1953.

Scotland in 1951

The birth rate in Scotland, as elsewhere in Great Britain, has been falling since 1947, and in 1951 it was 17.7 per 1,000 population as compared with 22.0 in 1947 and 17.7 in 1938.

The death rate in 1951 was 12.86 per 1,000 population. The infant mortality rate at 37.4 per 1,000 live births was the lowest ever reported in Scotland. The decline in the number of deaths from tuberculosis continued, the mortality rate being 43 per 100,000 of the population as compared with 54 in 1950 and 67 in 1949.—*97th Annual Report of the Registrar-General for Scotland, 1951* (H.M.S.O., 11s.).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus ————. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The largest variations in the number of notifications of infectious diseases in England and Wales during the week ending October 17 were increases of 76 for scarlet fever, from 986 to 1,062, and 51 for measles, from 691 to 742, and a decrease of 299 for whooping-cough, from 2,395 to 2,096. Only small fluctuations were recorded in the local trends of scarlet fever. An increase of 51 in the number of notifications of measles in Staffordshire, from 49 to 100, was the only large rise in the local incidence. The largest decreases in the incidence of whooping-cough were 67 in Essex, from 178 to 111, and 40 in London, from 167 to 127. 20 cases of diphtheria were notified during the week, and this was the same total as in the preceding week.

126 cases of acute poliomyelitis were notified, and these were 26 fewer for paralytic and 24 fewer for non-paralytic than in the preceding week. The largest returns were Lancashire 16 (Preston C.B. 3), Yorkshire West Riding 12 (Bradford C.B. 3), Warwickshire 11 (Birmingham C.B. 5), London 8 (Lewisham 3), Kent 8, and Middlesex 7.

232 cases of dysentery were notified; these were 35 fewer than in the preceding week. The chief centres of infection were London 35 (Chelsea 9), Northumberland 28 (Gosforth U.D. 19), Lancashire 26 (Liverpool C.B. 12), Yorkshire North Riding 24 (Middlesbrough C.B. 24), Yorkshire West Riding 22 (Bradford C.B. 9), and Middlesex 14.

Week Ending October 24

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,265; whooping-cough 2,190; diphtheria 29; measles 861; dysentery 310; paratyphoid fever 17; and typhoid fever 3. Poliomyelitis notifications were as follows: paralytic, 89 (81) non-paralytic, 46 (45); total, 135 (126). This is an increase of 9 compared with the previous week, the figures for which are in parentheses.

The Services

Surgeon Captain J. B. Oldham, V.R.D., R.N.V.R., has been appointed Honorary Surgeon to the Queen, in succession to Surgeon Captain G. McCoull, O.B.E., V.R.D., R.N.V.R., who has been placed on the Retired List.

Medical News

Annual Meeting at Toronto.—In 1955 the Annual Meeting of the B.M.A. will be held jointly with the Canadian Medical Association in Toronto on June 20-25. There will be a special religious service on Sunday, June 19, and members attending from Britain may wish to assemble in Toronto on June 18. Scientific Sections and Plenary Sessions will meet, and attractive excursions are to be arranged. Special currency allowances for 10 days covering the period of the meeting will be available for a moderate number to attend the meeting from Britain. The following rates are approximate figures:

By Air	
London to Toronto return	£230 first-class
	£190 tourist
Surface Route	
From British port to Toronto and return ..	£160 first-class
	£120 tourist
Combined, air route one direction, reverse surface route	£305 first-class
	£230 tourist

Hotel charges in Toronto have to be paid in dollars and range from approximately 12 dollars a day. The Canadian Medical Association has generously offered to provide private hospitality in Toronto for those who would like it.

Since preliminary arrangements for transport and accommodation should now be made, members who are considering attending the meeting are invited to inform the Secretary of the Association of their intentions, or provisional intentions, as soon as possible. It is particularly important to ascertain at an early date how many may wish to accept the offer of private hospitality in Toronto, and it would be helpful if an indication could be given of the travel arrangements preferred. The Secretary will be glad to supply further information about currency. No assurance can yet be given that dollars will be available for all applicants. The Annual Representative Meeting in 1955 will be held in London. The date has not yet been decided.

Nobel Peace Prize.—Dr. Albert Schweitzer, medical missionary, theologian, and musician, has been awarded the Nobel Peace Prize for 1952. The only other medically qualified recipient of the Peace Prize is Lord Boyd-Orr (1949), though Henry Dunant (1901) received it for his work on behalf of the Red Cross, and Fridtjof Nansen (1922) had made important contributions to neurohistology before taking first to exploration and later to diplomacy.

Albert Schweitzer was born in Alsace on January 14, 1875, the son of the vicar of Günsbach. He studied for the church and became a licentiate of theology in 1900, having obtained his Ph.D. two years earlier. For a short time he held a curacy at St. Nicolaus, Strasbourg. From an early age he was interested in music; he studied under the Parisian organist Widor and from 1903 to 1911 was organist of the Bach Society in Paris. His considerable studies of the works of Bach make him to-day one of the greatest living authorities on that musician. In 1903 Schweitzer was appointed principal of the College of St. Thomas, part of the University of Strasbourg, where he taught theology and wrote many books on this subject, chief of which was his *Quest of the Historical Jesus*, 1906 (English translation 1908).

(Camera Press, Ltd., London)

After a few years Schweitzer became discontented at his inability to give greater service to humanity. He decided to become a medical missionary, began the study of medicine in 1903, and gained his M.D. in 1912. On Good Friday, 1913, he left with his wife for French Equatorial Africa, where he was assigned to the mission station at Lambaréné on the Ogowe River. There he built his own hospital, overcoming immense difficulties. To-day it has beds for nearly 400 in-patients and deals also with a vast number of out-patients. Apart from periodic breaks in Europe, usually to raise funds for his hospital by means of organ recitals, Albert Schweitzer has spent the rest of his life in Lambaréné. He has found time to write many philosophical and theological works, and in them has repeatedly advocated a return to fundamental Christian principles as the only remedy for what he regards as the decline of civilization.

The British Occupational Hygiene Society.—The first conference of this society was opened by Sir Walter Monckton at the London School of Hygiene and Tropical Medicine on November 2. In his address Sir Walter spoke of the need for close collaboration between industrial research and industrial health research, and for the inclusion of education in industrial hygiene in the training of engineers, scientists, medical men, and all others who are concerned with the welfare of the worker. In his presidential address Dr. Thomas Bedford outlined the development of occupational hygiene in Great Britain and defined its scope. He emphasized the need for close team-work between medical men and those trained in other sciences, and spoke of the responsibilities of employers and employed as well as of scientists in ensuring more healthy conditions of work. Three papers were read at the conference. Mr. S. A. Roach dealt with the measurement of the worker's environment, discussing in particular the estimation of the dust hazard in coal mines. Dr. D. G. Harvey spoke on problems of chemical toxicity, and finally Mr. J. E. Braham, in a paper on occupational hygiene and the industrial designer, showed how at nearly every stage of design the requirements of hygiene and of safety demand consideration.

Fog Disaster.—The London Local Medical Committee on October 27 passed the following resolution:

That this committee, representing the 6,000 doctors of London (1) looks forward with deep anxiety to a possible recurrence of the London fog of December last year which directly caused the deaths of over 4,000 persons in Greater London, and serious illness, not recorded in the returns of notifiable disease, to tens of thousands more, flung an unnecessary strain on the public health and general medical services of the capital, disrupted communications and ambulance services, and prevented doctors from reaching patients who urgently needed them;

(2) is profoundly alarmed at the lack of any effective response from official quarters to what can truthfully be described as a national disaster;

and (3) calls upon the Government to take immediate action to prevent a repetition of this disaster.

R.A.F. Medical and Dental Branches Dinner.—The twenty-third annual dinner was held on October 23 with a record attendance of 250. The Director-General of R.A.F. Medical Services, Air Marshal Sir James Kilpatrick, announced the presentation of the Lady Cade Medal to the Royal College of Surgeons by Sir Stanford Cade for annual award to a Royal Air Force medical officer in recognition of outstanding services in a field of Royal Air Force medicine. Sir James went on to emphasize the value of the existing excellent relationship with the Royal Navy, the Army, and the Air Forces of the other members of the Commonwealth and the United States. Wing Commander C. C. Barker, A.F.C., in proposing "The Guests," illustrated the co-operation between the Services and civilian medicine. In reply Mr. H. E. Harding, Dean of the Westminster Medical School, emphasized the contribution of national service to the security of the nation.

Christmas Seals for decorating letters and parcels are once again being offered for sale by the National Association for the Prevention of Tuberculosis, at a cost of 4s. per hundred. The Association is also selling Christmas cards (6s. per dozen, including envelopes). Supplies of both may be obtained through the N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1. All proceeds from sales will be devoted to the work of the association.

Drunkenness in England and Wales.—According to a White Paper issued recently by the Home Office 53,888 cases of drunkenness were proved in courts in England and Wales during 1952. Of these, 48,694 concerned males and 5,194 females. Each year since 1946 the rate of "proved drunkenness" per 10,000 of population aged over 15 years has risen—from 6 in 1946 to 15.8 last year. The present level is about what it was in the two years before the 1939-45 war, but the curve is now showing signs of flattening out. Methylated spirits is said to have accounted for 569 cases, which is about two-thirds the number in 1938 and double that in 1945, when the low level of 273 cases was recorded. The London City Police District had a rate of 228 per 10,000 of population over 15 years, which compares with 74 for Middlesbrough, the next on the list, and 29 for the Metropolitan Police District. Newcastle-upon-Tyne City and Liverpool City had rates respectively of 68.5 and 61.

Sir Gordon Holmes, F.R.S., the consultant neurologist, was on October 20 presented with the gold medal of the Royal Society of Medicine.

COMING EVENTS

The Bradshaw Lecture will be delivered on November 12 at 5 p.m. at the Royal College of Physicians by Professor E. J. Wayne. His subject will be "The Diagnosis of Thyrotoxicosis."

National Association for Mental Health.—The 10th Inter-clinic conference will be held on November 21 at the Queen Mary Hall, Y.W.C.A., Great Russell Street, London, W.C.1. The conference is limited to professional members of child guidance staffs. Further details may be obtained from the conference secretary, 39, Queen Anne Street, London, W.1.

Leeds University Medical School.—The 63rd annual dinner of past and present men students will be held at the Metropole Hotel, Leeds, on November 27 at 7 for 7.30 p.m. Sir Henry Cohen will be the guest of honour. Tickets and further information from Mr. D. A. Youdale, The Medical School, Leeds, 2.

NEW ISSUES

British Journal of Ophthalmology.—The next issue (Vol. 37, No. 11) is now available. The contents include:

BULBAR PRESSURE TEST IN GLAUCOMA. P. L. Blaxier.
CATARACTS IN GALACTOSAEMIA. F. D. McAuley.
DEGENERATION OF VISUAL ACUITY. M. Gilbert.
DEGENERATIONS OF THE DOG RETINA. III: RETINOPATHY SECONDARY TO GLAUCOMA. H. B. Parry.
ANTERIOR FLAP SCIERTOMY WITH BASAL IRIENCLISIS. H. B. Stallard.
CONGENITAL TOXOPLASMOSIS. James Hill.
STANDARDIZED TOMOMETERS IN GREAT BRITAIN. C. R. S. Jackson.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, November 9

MEDICAL SOCIETY OF LONDON.—8.30 p.m., discussion to be introduced by Mr. E. S. Horning, M.A., B.Sc., and Sir Stanford Cade: Hormones in Relation to Cancer.
● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Professor G. W. Pickering: Concept of Essential Hypertension.
ROYAL EYE HOSPITAL.—5.30 p.m., Professor Thomas Nicol: Surgical Anatomy of the Orbit and Ocular Adnexa.

Tuesday, November 10

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor E. J. King: Alkaline and Acid Phosphatases.
CHELSEA CLINICAL SOCIETY.—At South Kensington Hotel, 7.30 p.m., dinner, followed by a discussion: Electronics in Industry and Medicine, to be opened by Mr. P. E. Henderson and Dr. P. Bauwens.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. D. F. O'Neill: Stress in Relation to Diseases of the Skin.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—3.45 p.m., Erasmus Wilson Demonstration by Mr. W. H. Jayne: Slide Culture of Malignant Cells.
ROYAL EYE HOSPITAL.—5 p.m., Mr. T. M. Tyrrell: Pitfalls in Refraction.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., Dr. E. Roban Williams and Mr. H. G. E. Arthur: Obstetric Pelvis.
WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Mr. G. C. Knight: Diagnosis and Treatment of Spinal Compression.

Wednesday, November 11

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Benign Epithelial Tumours of the Skin.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. D. Ferguson: Prostatic Cancer.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Dr. H. Bickel: Observations on Lignac-Fanconi Disease, Wilson's Disease, and Phenylketonuria.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. J. Greenwood Wilson: Care and After-care—The Cardiff Interpretation (Illustrated).
ROYAL SANITARY INSTITUTE.—2.30 p.m., Discussion to be opened by Dr. E. T. Wilkins, M.Sc., Ph.D.: Air Pollution and the London Fog of December, 1952.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—At Wright-Fleming Theatre, 5 p.m., lecture-demonstration by Dr. D. F. O'Neill: Psychological Medicine.
SOCIETY OF APOTHECARIES OF LONDON.—4 p.m., Professor C. H. Gray: Fluid and Electrolyte Balance; 5.15 p.m., Mr. F. A. Williamson-Noble: Early Treatment of Eye Diseases.

Thursday, November 12

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Dr. Thomas F. Cotton: Psychological Element in Cardiac Disease.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. R. L. M. Synge, F.R.S.: Principles of Chromatography.
HONYMAN GILLESPIE LECTURE.—At University New Buildings, Edinburgh, 5 p.m., Professor J. W. Crofton: Chemotherapy of Pulmonary Tuberculosis.
● INSTITUTE OF CHILD HEALTH AND INSTITUTE OF NEUROLOGY.—At National Hospital, Queen Square, W.C., 5.30 p.m., Dr. Helen E. Dimdale: Syndromes Involving the Basal Ganglia: Clinical Types, Diagnosis, and Treatment.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Pathogenesis of Tinea Capitis.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. M. T. Morgan: Modern Developments in Rodenticides and Insecticides in Port Health and Quarantine Administration.
ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Bradshaw Lecture by Dr. E. J. Wayne: Diagnosis of Thyrotoxicosis.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Cecil Joll Lecture by Mr. Geoffrey L. Keynes: Investigations into Thyroid Disease and Tumour Formation.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Mr. A. W. Wilkinson: Reactions to Injury.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Sir Paul Maitlandson: Psychiatry demonstration.

Friday, November 13

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. D. F. O'Neill and Dr. G. B. Mitchell-Heags: Neurodermatoses.
LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.—7.30 p.m., clinica meeting.
OSLER CLUB OF LONDON.—At 11, Chandos Street, W., 7.45 p.m., Professor L. Edelstein, Ph.D.: Karl Sudhoff's Contributions to Medical History.
Professor J. Trueta: Michael Servetus.
● POSTGRADUATE MEDICAL SCHOOL OF LONDON.—4 p.m., Dr. L. G. Pugh: The 1953 Everest Expedition.

Saturday, November 14

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, St. Mary's Hospital Medical School, 11.30 a.m., scientific papers.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Freeth.—On October 24, 1953, at the Central Middlesex Hospital, London, N.W., to Joan, wife of Derek Freeth, M.D., M.R.C.O.G., a daughter.
Yule.—On October 15, 1953, at the Simpson Memorial Maternity Pavilion, Edinburgh, to Nora (formerly Rendell), S.R.N., S.C.M., wife of D. Robert Yule, a son.

MARRIAGES

Thompson—Logan.—On October 24, 1953, at the Brompton Oratory, London, S.W., Dr. J. H. Thompson, of Croydon, Surrey, to Margaret A. (Gret) Logan, of Darlington, Co. Durham.

DEATHS

Birks.—On October 2, 1953, at The Brackens, Beech, Alton, Staffs, A. Herrenden Birks, M.B., B.Ch., formerly of Dorney Reach, Taplow, Bucks and Woodbridge, Suffolk.
Cairns.—On October 6, 1953, at Green Lea Hospital, Huddersfield, David Louis Cairns, M.D., J.P., of Ashfield, Cedar Avenue, Huddersfield, Yorks, aged 78.
Fraser.—On October 6, 1953, at Torosay, St. John's, Newfoundland, Nutting Stuart Fraser, O.B.E., M.D., aged 89.
Garland.—On October 17, 1953, at 114a, Hampton Road, Bristol, Edwin Blake Garland, M.B., C.M., aged 86.
Harry.—On October 7, 1953, at Saltash, Cornwall, Norman George Harry, M.B., B.Ch.
McKendrick.—On October 7, 1953, at 33, Woodside Grange Road, Finchley, London, N., William McKendrick, M.B., aged 74.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Stress and Arterial Disease

Q.—What part do stress and strain play in the aetiology of arterial disease, particularly of the coronary and cerebral arteries?

A.—This question is difficult to answer, because there are insufficient scientific data on the point. The Ministry of Pensions admits that stress and strain may aggravate hypertension, and allows this in certain cases if it can be shown that symptoms did in fact arise during service. On the other hand, the Ministry does not agree that stress and strain play any part in the development of coronary or cerebral atherosclerosis and their complications, and has been in the habit of quoting opinions of eminent cardiologists who have held this view in the past. These opinions are rarely based on statistical evidence.

It has long been known that there is a loose relationship between atherosclerosis and hypercholesterolaemia, whether the latter is spontaneous, hereditary, or a complication of diabetes mellitus, myxoedema, xanthomatosis, or nephrosis. The work of John Gofman shows that there is a closer relationship between atherosclerosis and certain large fat molecules which can be identified in the blood stream by a special ultracentrifuge technique. It is highly improbable that there can be any relationship between stress and strain and the concentration of these large fat molecules in the blood stream. It is believed, however, that the deposition of lipids in the intima depends not only on the concentration of these substances in the plasma but on some structural, functional, or biochemical change in the intima which favours the penetration and laying down of fatty substances. Such structural changes have been demonstrated under the microscope.¹

The idea that stress and strain aggravate or accelerate atherosclerosis and precipitate its complications has grown up not only as the result of the experience of some physicians but also as a result of at least three careful statistical studies, the first by Ryle and Russell,² the second by Yater *et al.*,³ and the third by Morris, Heady, and Barley.⁴ These three studies have one thing in common: they all demonstrate a relationship between occupation and the incidence of angina pectoris or coronary thrombosis. The statistics presented by Ryle and Russell appeared to show that coronary disease was about 10 times more common in professional men whose occupations involved mental stress and responsibility than in manual labourers. Although this remarkable difference did not apply to the wives of such men, this work has been criticized because it was based on the Registrar-General's figures compiled in 1932, for at that time coronary thrombosis had been recognized in Great Britain for only about eight years, and it was felt that professional men might have been more accurately diagnosed. From the U.S. Army Institute of Pathology, Yater *et al.* obtained impressive evidence that coronary disease was twice as common in the relatively young men entering the Army from civil occupations carrying mental stress and high responsibility, as in those whose previous work was of a lower order. The statistical analysis presented by Morris and his colleagues seems to show that coronary disease is twice as common in general practitioners as in other doctors.

If the relationship between occupation and coronary disease is admitted, and it surely must be, the nature of the relationship is still obscure. While Ryle and Russell

believed that stress and strain were the operative factor, the Ministry of Pensions holds that there is no proof of this. Thus it might simply be that the professional classes are better fed or have a more fatty diet, or, being more sedentary, tend to store fat more readily. This is really the crux of the matter, and the problem has not yet been solved.

Congenital Lymphoedema

Q.—A female child, now aged 4½, was noted at birth to have oedema of both hands and both feet. In about a month's time the hands were fairly normal but the feet were still swollen, and at 5 months old the feet, while still a little swollen, were much improved. At a year old the child had intermittent swelling of the right arm and hand, and slightly of both feet. This became less frequent, and for several years nothing abnormal was observed. The mother now complains that in the evenings the child's right foot and ankle swell. When seen in the morning the foot appears perfectly normal. The child is small for her age, but otherwise there is no abnormality. The urine is free from albumin. A cousin of the mother's is said to have marked oedema of the feet and legs which came on at the age of 14 (she is now 40) and is thought to be due to "bad circulation." I would welcome advice on this case.

A.—It is a little dangerous to give an opinion on such a question without seeing the child, but the likely diagnosis is congenital lymphoedema. This condition may be present from birth or appear later, and the degree of oedema of the limbs may vary considerably. It is possible that the swelling in this case never completely disappeared, as this is the commoner finding.

The cause is not clearly understood, apart from the fact that some abnormality of the lymphatics is present, which may be an undue permeability or an obstruction to the lymphatic return. This may be local or generalized. There is some evidence that the exuded lymph is damaging to living cells and causes the dense fibrosis which later invades and causes permanent swelling of the limbs. It is therefore possible that restriction of the oedema in early life by rest in bed or bandaging may help to diminish later irreversible changes, but it is generally considered to be hardly worth while. Plastic surgery in early adult life or late childhood can greatly improve the appearance of badly swollen limbs by removing the fibrosed subcutaneous tissues.

Postponing Menstruation

Q.—I have been asked by a patient, shortly to be married, whether I can stop her period, which is due during her honeymoon. I believe it is possible to do this with stilboestrol or allied compounds. If this is so, I should be grateful for information on the following points: (a) Is it safe? (b) Is the period suppressed or merely delayed? (c) What is the best compound dosage and correct time for starting? This patient goes two weeks and four days between periods. (d) Are any effects to be expected on her libido?

A.—It is often but not always possible to postpone a menstrual period with oestrogens, provided a large dose is given. Different techniques are employed, but one of the most reliable is to give not less than stilboestrol 1 mg. three times a day beginning at the conclusion of a menstrual period and continuing until there is no need to delay the bleeding any longer. When treatment is suspended uterine haemorrhage will begin within a few days and it will probably be anovular in type. Moreover, it is likely to be prolonged and heavy. A further disadvantage is that the stilboestrol may cause nausea and vomiting to the extent of interrupting treatment, and this precipitates oestrogen withdrawal bleeding at an inconvenient time. The risk of vomit-

ing is reduced by giving ethinyl oestradiol instead of stilboestrol, the dose being 0.05 mg. three times a day.

Treatment of this kind will not materially affect libido, and it can hardly be described as unsafe. Nevertheless it does interfere with the natural ovarian and uterine rhythm, and the ultimate bleeding can be troublesome. There should therefore be a good reason for its application, and the one stated in the question is, in the writer's opinion, inadequate. The various emotional changes associated with marriage often temporarily disturb the menstrual cycle and render calculations inaccurate. It may well be that the expected clash between honeymoon and menstruation will not occur. If it does, it matters little. It is better to face embarrassment than to meddle with physiological processes, while interruption of coitus for a few days can be an advantage if the partners experience the usual difficulties associated with the consummation of marriage.

Alcohol and Barbiturates

Q.—There have been two recent reports of death caused by barbiturates following the consumption of alcohol. Is this a common occurrence? How does it affect the taking of normal doses of barbiturates by heavy drinkers, and conversely the consumption of alcohol by constant users of barbiturates?

A.—The available evidence suggests that it is unusual for death to be caused by a combination of a barbiturate and alcohol. Both these substances are depressants to the respiratory centre, and death occurs from their combined action in the same way as it would if a large dose of ether were administered after a full dose of thiopentone. There is some evidence that patients who have taken barbiturates may die with blood alcohol levels in themselves insufficient to cause death.¹ It is probable that heavy drinkers can take normal doses of barbiturates and that constant users of barbiturates can take their usual dose of alcohol without danger to life. But the margin of safety is lowered in both instances. It is wise to warn patients receiving barbiturates in doses above the maximum official dose that they should be sparing in their consumption of alcohol. It is also dangerous to attempt to wean a chronic alcoholic from his drink by substituting barbiturates unless one can be sure that he will not indulge in an alcoholic bout. Further information on this subject will be found in a recent annotation.²

Routine Lumbar Puncture in Primary Tuberculosis

Q.—Frequently one hears the opinion that children with primary tuberculosis should have routine lumbar punctures in order to detect cases of meningitis very early. Do you think it likely that this procedure might cause meningitis by releasing the pressure over an unsuspected subcortical tubercle so that it ruptures into the C.S.F.?

A.—The incidence of tuberculous meningitis in primary tuberculosis is so low that routine lumbar puncture is justifiable only when miliary disease is present, and perhaps in a case of primary tuberculosis running a persistently high fever.

A number of people have seen cases of tuberculous meningitis develop a few days after routine lumbar puncture. Bernard and his colleagues¹ in Paris investigated this point in a large series of cases of miliary tuberculosis, but the incidence of meningitis was no higher in those who had routine lumbar punctures. If routine lumbar puncture is performed in the types of cases indicated above, it will enable meningitis to be detected in its earliest and most treatable stage.

Action of the Sternomastoids

Q.—What is the combined action of both sternomastoid muscles and does it differ when they are acting against resistance? What is the full action of a single sternomastoid? I am interested in congenital torticollis and find some confusion in the literature as to the position necessary to stretch this muscle—that is, whether to flex or extend the neck.

A.—The combined action of the sternomastoids is to flex the head on the trunk. Their action against resistance is not essentially different, but if the neck is kept rigid by the extensor muscles the sternomastoids can act as accessory muscles of respiration—for example, in a severe poliomyelitis with paralysis of the intercostals.

When one sternomastoid acts it laterally flexes the head towards the same side and rotates the face away from that side. Stretching of a tight sternomastoid is accomplished by laterally flexing the head away from the affected side and flexing the neck. Rotation of the head does not affect the length of the muscles to any important extent.

NOTES AND COMMENTS

Otitis Externa in the Tropics.—Dr. IAIN M. M. MACLEAN (London, S.E.4) writes: Having experience of various climates, for example, arctic and tropical, I think that the name otitis externa is not quite accurate ("Any Questions?" October 17, p. 896). The condition has many local names such as "Panama ear," and I am of the opinion that it—that is, otomycosis—should be described technically as either otitis externa diffusa or desquamative external otitis, as it does differ from the otitis externa in other climates. In the acute stage I noticed that the pain was always worse at night (but the cause was not always of a clinical nature) and was accompanied by moderate pyrexia. When the canal is not obliterated, I found (apart from what you have said) that gauze soaked in 10% glycerin and ichthammol helped if combined with daily swabbing with spirit and painting with, say, Castellani's fuchsin. An ammoniated mercurial ointment was used to treat the excoriations. While non-fungus infections of the canal occur, are they not usually seen in those who have recently returned from a temperate climate?

OUR EXPERT writes: The desquamative external otitis seen in the Tropics was very clearly described by Daggett.¹ This condition, though common in the Tropics, is indeed sometimes seen in temperate climates. Fungus infections are also on the increase in temperate climates, and this may be due to the use of certain antibiotics which allow fungus infections to develop.

VALVOTOMY IN THE TREATMENT OF MITRAL STENOSIS

BY

T. HOLMES SELLORS, D.M., M.Ch., F.R.C.S.

Thoracic Surgeon, the Middlesex Hospital; Surgeon, London Chest and Harefield Hospitals

D. EVAN BEDFORD, M.D., F.R.C.P.

Physician, the Middlesex and National Heart Hospitals

AND

WALTER SOMERVILLE, M.D., M.R.C.P.

Assistant, Department of Cardiology, the Middlesex Hospital; Cardiologist, Harefield Hospital

The selection of patients who need surgical treatment for mitral stenosis is a problem which is no longer confined to special centres for cardiac surgery. If patients who are in greatest need of surgical treatment, and who are most likely to benefit from it, are to be given priority, selection must start with the practitioner and in the general medical clinic.

The advent of valvotomy as a method of treatment has stimulated an intensive investigation of the pathological physiology of mitral stenosis by means of cardiac catheterization and related technical procedures. This has led in turn to a renewed interest in the interpretation of clinical signs and symptoms. Many physical signs which have been a source of speculation since the early days of auscultation can now be more precisely interpreted in the light of surgical experience and of recent haemodynamic research. Many of the patients in the present series, and a great many others judged unsuitable for operation, have been investigated by cardiac catheterization, and, at the start, the information so obtained often fortified the decision for or against operation. But with increasing experience we are now seldom influenced by catheter findings in selecting favourable cases for surgery. Admittedly, in extending the scope of surgery to less favourable cases, full investigation is still desirable.

The low mortality and good results of mitral valvotomy are already well known, and it is with the indications for operation that we are now mainly concerned. In this respect we were guided from the start by the pioneer work at Guy's Hospital (Baker, Brock, and Campbell, 1950) and in the United States (Harken *et al.*, 1948; Bailey, 1949), but our present views have been moulded largely by personal experience.

SELECTION OF CASES FOR VALVOTOMY

Basic Indications.—The aim of surgical treatment of mitral stenosis is to remove or reduce valvular obstruction without thereby creating serious valvular incompetence. Provided the fused mitral cusps are split or cut along the line of the commissures, as advocated by Brock, the degree of incompetence need not be increased, and may even be diminished, by valvotomy. The basic

indications for mitral valvotomy may therefore be simply stated as follows: (1) Severe stenosis of the mitral orifice, the anatomical conformation of which must be suitable for surgical correction. (2) The patient's symptoms must be disabling enough to warrant the risks of surgery. (3) We must be satisfied that the symptoms are entirely or mainly due to mitral obstruction, and not to myocardial or other valvular lesions, or to extra-cardiac causes.

Degree of Mitral Stenosis and its Anatomy

If mitral stenosis were a purely mechanical constriction of the valvular orifice, of unvarying anatomical form, and superimposed on an otherwise healthy heart, it would be a relatively simple matter to assess its degree, but in practice the problem is far more complex. We have to take account of the anatomical form of the valvular structures, of secondary changes in the lung vessels, and of complicating factors such as myocardial damage, auricular fibrillation, and associated aortic and tricuspid valve lesions. Nevertheless, in many cases the rheumatic damage falls mainly on the mitral valve cusps.

The ideal type of stenosis for surgical correction is the *diaphragmatic valve* well described by Balfour (1898) as follows: "The condition of the valve generally associated with the presystolic murmur is that usually termed a diaphragmatic valve in which the two segments of the mitral valve are united and stretched like a diaphragm across the auriculo-ventricular opening. This diaphragm, as we may call it, is thickened especially at the edges of the central opening. . . . Apart from the thickened orifice, the mitral diaphragm as a whole may be relatively pliant, and it can be split so as to re-create mobile and supple valve flaps, and so that obstruction is relieved without incompetence resulting (Type I, Fig. 1). The diaphragmatic valve, which is formed mainly by the large antero-medial or aortic cusp, cannot open or close, but, if still pliant, it balloons like a sail towards the auricle in systole, and billows back towards the ventricle in diastole. This sudden tension of the mitral diaphragm, first in one direction and then in the other, gives rise to important physical signs, which are discussed below.

Sometimes the valve sheet as a whole is indurated and thickened so that ballooning is reduced and at the same time valvotomy made more difficult technically (Type II, Fig. 1). Most valves in this category cannot be completely divided, but an adequate result may be achieved if one commissure is split and the other only partly split. Here the extent of shortening or fibrosis of the chordae tendineae is greater than in Type I, and mobile cusps cannot be reconstructed.

More severe rheumatic damage may fuse the cusps, chordae, and papillary muscles into a rigid, fibrous, funnel-shaped structure directed towards the ventricle (Type III, Fig. 1). If cases for surgery are carefully selected, the surgeon seldom encounters this type of stenosis, which features so prominently in textbooks of pathology. Here little can be done by operation, yet digital dilatation has occasionally produced unexpected clinical improvement.

Deformed and retracted cusps producing a permanently gaping and incompetent orifice, even though some degree of stenosis may be present, are not amenable to surgical reconstruction. Graham Steell (1906) and Carey Coombs (1924) regarded mitral regurgitation as due mainly to dilatation of the left ventricle and of the mitral ring from myocardial damage during the active phase of rheumatic carditis, so that subsequent fibrosis of the cusps failed to constrict the enlarged orifice appreciably. Others regarded the left ventricular enlargement as the result rather than the cause of mitral regurgitation. Whichever view is taken, and both may be correct under different circumstances, the fact remains that left ventricular enlargement and mitral incompetence go together, and both are probably incompatible with a severe degree of mitral stenosis. An enlarged left ventricle should be regarded as evidence of myocardial damage, whether of inflammatory or of mechanical causation.

Clinical Signs

The clinical signs of a pliant diaphragmatic valve are, first and foremost, the snapping first sound, and the

characteristic apex beat described by Broadbent (1897) as "tapping," an adjective originally applied to the first sound by Sansom (1892). Carey Coombs described the apex beat of mitral stenosis as follows: "The hand placed over the praecordium feels the apex bang suddenly and sharply against the chest wall, then sink away from it as suddenly as it arrived." These signs relate to a sudden tension of the pliant mitral diaphragm as it is ballooned upwards into the auricle in systole, and can be felt by the surgeon's finger. We may well speak of this sign as the "closing snap" of the mitral valve. So long as a snapping first sound is audible, and it is best heard with the patient lying and inclined toward his left side, serious mitral incompetence and a hopelessly rigid valve are unlikely, and a systolic murmur may be ignored.

Another important sign of a diaphragmatic valve is the opening snap, a sharp click which follows closely after the second sound and which is best heard over the mesocardium often internal to or above the apex beat. The opening snap, formerly described as a double second sound at the apex, was first recognized by Sansom as originating at the mitral valve, and the term "claquement d'ouverture" is generally attributed by French writers to Potain. It may be supposed that the opening snap is caused by sudden tension of the pliant mitral diaphragm in a reversed direction to that responsible for the snapping first sound—namely towards the ventricle at the start of diastole. We believe that a loud opening snap of clicking quality is a reliable sign of mitral stenosis with a pliant diaphragmatic valve.

and that it constitutes important evidence of operability. The opening snap is absent in predominant mitral regurgitation, and is uncommon or lacks a loud clicking quality in severe mitral calcification (Mounsey, 1953; Wyn 1953).

In regard to murmurs, loud rumbling diastolic and pr systolic murmurs completely filling diastole constitute reliable evidence of considerable mitral stenosis, though it does not necessarily imply an operable valve. The absence of an impressive mitral diastolic rumble does not exclude severe stenosis, and Levine and Love (1952) have drawn attention to the occasional absence of all diastolic murmur in this condition. The intensity of the diastolic murmur depends not only on the degree of stenosis but also on the flow through the mitral orifice, and active pulmonary vasoconstriction acts as a barrier to mitral flow. In cases with

FIG. 1.—Types of mitral stenosis. The features of each type are described in the text.

severe pulmonary hypertension the mitral diastolic murmur may be quite insignificant, though the opening snap tends to persist.

A mitral systolic murmur need not imply serious incompetence in the presence of a snapping first sound and an opening snap; it may be ignored unless there is evidence of left ventricular hypertrophy in the form of an apex beat with a localized and sustained thrust, the "choc en dôme" of Bard. If the first sound is diminished or replaced by a systolic murmur, and the left ventricle is enlarged, the case is probably unsuitable for valvotomy. The electrocardiogram and radiograph are valuable in identifying left ventricular hypertrophy. In evaluating left ventricular enlargement *vis-à-vis* the mitral valve, due regard must be given to the presence of aortic incompetence.

The pulse in severe mitral stenosis is of small volume and sustained in character, and, like the small aorta, is evidence of a restricted output from the left ventricle. It is especially small in cases with active pulmonary hypertension, when the cardiac output is further reduced by a second mechanical barrier in the lungs. In predominant mitral regurgitation the pulse has a more jerky character.

A small hypoplastic aorta is the rule in severe mitral stenosis developing before adult life, and the aortic knuckle is small in the radiograph, situated well below the clavicles, and sometimes invisible in the anterior view.

To sum up, we regard the following clinical signs of mitral stenosis as indicative of a pliant diaphragmatic valve amenable to valvotomy: a snapping apex beat; a snapping first sound (closing snap); and a loud opening snap of clicking quality. Additional evidence of severe mitral stenosis is provided by intense diastolic and presystolic murmurs; a small sustained pulse; and a small hypoplastic aorta in the radiograph.

Signs of Right Ventricular Enlargement

When the right ventricle enlarges, the infundibulum is first involved, causing a palpable systolic impulse on the left of the sternum, usually in the third interspace and well above the apex beat. A diastolic shock due to forcible closure of the pulmonary valves is also felt over the enlarged infundibulum.

The main cavity of the right ventricle enlarges towards the left, displacing the left ventricle posteriorly away from the chest wall. In pure mitral stenosis, therefore, an apex beat displaced to the left is evidence of right ventricular enlargement. The right ventricle seems to strike the chest broadside, so that the apex beat resembles a blow with the open hand, compared with a blow by the closed fist from the left ventricle, which strikes the chest head on. Instead of a localized thrust, the enlarged right ventricle causes a diffuse and less-sustained pulsation between sternum and apex beat which, in mitral stenosis, also has a snapping quality.

In radiographs, right ventricular enlargement gives the heart a square shape with blunted apex, compared with the pointed oval of left ventricular enlargement. Right heart enlargement may also be identified in the left oblique view.

Symptoms

Breathlessness is the earliest symptom in the majority of cases and its onset is usually gradual. Patients notice that they can no longer keep pace with their friends, carry their shopping, or perform their usual domestic duties without distress, and their disability is best assessed in terms of their capacity for these simple everyday tasks. Sometimes attention is first called to the heart by more dramatic symptoms of a characteristic kind.

In 1921, and more fully in 1934, Gallavardin described the occurrence of paroxysmal pulmonary oedema in certain cases of mitral stenosis, which he called "le rétrécissement mitral oedémateux," and this particular syndrome was also

described by Oppenheimer and Schwartz (1933) and by McGinn and White (1934). It is encountered especially in women aged 25 to 35 years with long-standing mitral stenosis. The paroxysms of dyspnoea are often provoked by effort or emotion, but may also occur spontaneously at night, and tend to be aggravated during the menstrual period, during pregnancy, and in cold weather. Gallavardin noted that in such patients the heart was little if at all enlarged, the rhythm was regular, and digitalis was ineffective in controlling the breathlessness.

Careful interrogation is necessary to identify minor paroxysms provoked by effort; once dyspnoea attains a certain degree the following symptoms appear—oppression in the chest, severe palpitation, tracheal bubbling and wheezing, cough, and blood-stained expectoration. These symptoms subside gradually with rest. Spontaneous or nocturnal attacks tend to be more severe, may be accompanied by circulatory collapse, and may prove mortal. Sooner or later these patients become orthopnoeic, require extra pillows for sleep, and exhibit some degree of persistent pulmonary congestion. The patient with "oedematous mitral stenosis" is severely incapacitated and offers a marked contrast to the patient with a huge heart, auricular fibrillation, and congestive failure reasonably controlled by digitalis, who may lead a relatively comfortable though restricted life.

Paroxysmal pulmonary oedema is explained by a sudden increase in pulmonary capillary pressure above the level of the colloid osmotic pressure of the plasma. Opposed by severe mitral obstruction, any increase in the output of the right ventricle—for example, on exertion—must elevate the pressure in the pulmonary veins and capillaries. In the past it was difficult to explain why pulmonary oedema should occur in certain cases of severe mitral stenosis and not in others, often with far larger hearts; the probable explanation is that in some cases the pulmonary arterioles are constricted, thus limiting the output of the right ventricle and so protecting the lung capillaries from any sudden overdistension. In mitral stenosis with pulmonary oedema, pulmonary hypertension is a purely passive process, due to a rise in pressure behind the obstructed mitral valve, and the absence of cardiac enlargement and of auricular fibrillation indicates that the myocardium is relatively intact. This combination of severe mechanical obstruction and a sound myocardium represents the ideal condition for surgical intervention.

Classification of Cases for Surgical Purposes

For the purpose of deciding suitability for valvotomy and for assessing its results, a classification based purely on symptoms or the degree of incapacity is unsatisfactory. A patient with symptoms of great severity may be most eligible for surgical relief, whereas another far less troubled may be entirely beyond it.

The pulmonary arterial pressure at a given moment is not a reliable basis for deciding on surgical treatment unless it is interpreted in relation to the clinical signs and symptoms, and a complete haemodynamic investigation is not always practicable even in expert hands. We believe that, eventually, suitability for valvotomy will usually be decided on the basis of routine cardiological examination rather than on catheter findings. The primary indication for valvotomy is severe mitral obstruction with an operable valve, and in this respect the clinical signs of a pliant diaphragmatic valve are significant. Next in importance is the size of the right ventricle. If tricuspid disease is excluded, right ventricular enlargement provides the best measure of the degree of permanent damage resulting from mitral stenosis, and thus it is the best guide in regard to the prospect of surgical relief. At the Middlesex, having selected the cases with operable valves, we graded them for surgical purposes into three classes, identifiable by routine cardiological examination:—Class I: cases without or with minimal signs of right ventricular enlargement; class II: cases with con-

FIG. 2

FIG. 3

FIG. 4

FIG. 2.—Mitral stenosis with clinical signs of slight right ventricular enlargement (class I). The patient, a woman aged 36, in sinus rhythm, had several attacks of pulmonary oedema. Valvotomy was performed with a good symptomatic result (Case 55). FIG. 3.—Mitral stenosis with clinical and electrocardiographic evidence of right ventricular enlargement (class II). The pulmonary artery and its hilar branches were dilated. Mean pulmonary arterial pressure was 54 mm. Hg. The patient, a woman aged 28, was considerably restricted by breathlessness. A good result followed valvotomy. FIG. 4.—Mitral stenosis with considerable cardiac enlargement (class III). Cardio-thoracic ratio 68%. Mean pulmonary arterial pressure was 48 mm. Hg. The patient, a woman aged 48 with auricular fibrillation, had recurrent attacks of congestive failure which improved with treatment.

siderable right ventricular enlargement, but without congestive failure; class III: cases with gross right ventricular enlargement and congestive failure.

Class I.—Regular rhythm was more common than auricular fibrillation, the pattern of right ventricular hypertrophy was seldom present in the electrocardiogram, and radiography showed a mitral configuration without much increase in transverse diameter of the heart. There was often perihilar congestion, but without great dilatation of the pulmonary artery (Fig. 2). The mean cardio-thoracic ratio in this group was 51%. Paroxysmal pulmonary oedema was common. The mean pulmonary arterial pressure averaged 35 mm. Hg.

Class II.—Right ventricular enlargement was evident clinically, radiologically, and in the electrocardiogram. Normal rhythm was more common than auricular fibrillation, and paroxysmal pulmonary oedema was less frequent than in class I. In some cases, episodes of congestive failure occurred, due to the onset of fibrillation or to pulmonary infarction, but failure was not persistent. Dilatation of the pulmonary artery and its hilar branches was evident in radiographs, but perihilar oedema was often absent (Fig. 3). The mean cardio-thoracic ratio was 55%. The mean pulmonary arterial pressure averaged over 50 mm. Hg, indicating active pulmonary hypertension. These patients have severe mitral obstruction with some myocardial damage.

Class III.—The heart was considerably enlarged, the cardio-thoracic ratio exceeding 65% (Fig. 4). Aortic valve

disease was present in some cases, and often tricuspid incompetence. Auricular fibrillation was invariable, and congestive failure was recurrent or could not be completely relieved by treatment. The liver was permanently enlarged and presumably damaged. Patients in this class posed the problem of whether the mitral obstruction played a sufficiently important part in the overall picture to justify mitral valvotomy. If the signs of a pliant diaphragmatic valve were present it was thought that some measure of surgical relief was at least possible.

Table I presents an analysis of the first 72 cases operated on at the Middlesex Hospital, classified as described.

Results

Mitral valvotomy has been performed on 150 patients—87 at the Middlesex Hospital and 63 at Harefield Hospital and the London Chest Hospital. There were 31 men and 119 women, a ratio of 1 to 4. The youngest patient was 19 and the oldest 57; 78% were between 30 and 49. The heart rhythm was regular in 88 patients (59%), and auricular fibrillation was present in the remaining 62 (41%). The incidence of certain other clinical features is mentioned below.

Four of the 150 patients operated on died as a direct result of the operation—that is, within four days—an immediate operative mortality of 2.7%. Four others died after an interval of one month or longer. Details of these fatalities are given later.

operated on within the past three months. All have made satisfactory progress to date, but it is too early to assess the results.

In each case the result was assessed in relation to the pre-operative disability. A good result indicates relief from symptoms such as paroxysmal dyspnoea, orthopnoea, and haemoptysis, and a considerably increased capacity for effort. For example, a more or less bedridden patient is able to sleep flat and to get about in comfort; an ambulant patient whose activities had been much restricted is able to lead a reasonably normal life or to return to work. A fair result implies an obvious and worth-while relief of disability, but short of the optimum improvement. A poor result means slight, doubtful, or no benefit.

Results in Relation to Classification of Cases.—The number of patients in each class is too small to allow of any far-reaching conclusions, but the results indicate a trend. Provided that clinical signs of a pliant diaphragmatic valve are present, the outlook after operation differs little in classes I and II, though in class II the right ventricle is larger and the pulmonary arterial pressure is correspondingly higher. Those in class III have the largest hearts and there is usually a history of recurrent congestive failure; they fare less well and carry a higher operative risk than cases in classes I and II.

SPECIAL FEATURES

Pulmonary Hypertension

The pulmonary arterial pressure by itself does not provide an indication of the degree of mitral stenosis. In cases with paroxysmal pulmonary oedema the mean pulmonary arterial pressure at rest may be little raised, and again in the later stages of mitral disease, when auricular fibrillation and failure have supervened, it need not be greatly elevated. On the other hand, the size of the right ventricle reflects the cumulative effect of pulmonary hypertension on the heart, and is more informative than the level of the pulmonary arterial pressure at a given moment.

The factors responsible for pulmonary hypertension complicating mitral stenosis are beyond the scope of this paper. We were concerned, however, in observing whether pulmonary hypertension influenced the result of mitral valvotomy. The good and poor results in classes I and II were of much the same order, though the degree of pulmonary hypertension was far higher in class II. The outcome of operation was equally favourable in the six patients with

the highest pulmonary arterial pressures and greatly increased pulmonary vascular resistance, and in the six with the lowest pressures recorded in this series who had only slightly raised pulmonary resistance (Table III).

Pulmonary arterial pressure has been measured approximately one year after operation in two patients (Nos. 9 and 1) included in Table III. In both, the mean pressure had fallen, the cardiac output increased, and the total pulmonary vascular resistance lowered by 50% and 60% respectively of their original values. The final figures were still well above normal, yet symptomatic improvement was satisfactory. Similar findings have been reported by other authors (Holling, 1952; Baker, Brock, Campbell, and Wood, 1952).

In mitral stenosis with gross right ventricular enlargement other factors than pulmonary hypertension have to be considered—namely, rheumatic myocardial damage, the effects of auricular fibrillation, and the possibility of associated tricuspid valvular disease.

Rheumatic Myocardial Damage

The relative importance of a defective valve and of rheumatic myocardial damage in the causation of cardiac enlargement and failure is an old-standing problem. Experience of the results of valvotomy has proved that the valvular factor is often far more important than Mackenzie and others believed and taught.

Nevertheless, a grossly enlarged right ventricle implies a damaged myocardium, and whether the damage is rheumatic or whether it is due purely to mechanical stress, it is unlikely to be reversible. The degree of benefit to be expected from valvotomy when the myocardium is permanently damaged is always problematical and the operative risks must be increased. Provided that tricuspid disease is excluded and there are signs of severe mitral stenosis with an operable valve, surgery need not be contraindicated if the age and other circumstances are favourable.

Auricular Fibrillation

So long as the operation was indicated on other grounds, we have disregarded auricular fibrillation entirely in selecting our cases. Indeed, fibrillation offers the advantage of a heart rate controlled by digitalis, whereas in normal rhythm tachycardia may be uncontrollable. In so far as fibrillation is commoner in the advanced than in the early stages of the disease, so those with fibrillation are more often unsuitable for valvotomy than those with regular rhythm. For the same reason the operative mortality would be expected to be higher amongst the fibrillators. Of the entire series of 150 patients, 41% had auricular fibrillation, including three of the four patients who died at operation or within four days of it. Four fatalities occurred later; one of these was fibrillating at the time of operation and three were in sinus rhythm. Otherwise the functional results were as good in those with fibrillation as in those with sinus rhythm.

During the actual valvotomy, bizarre auricular and ventricular arrhythmias were recorded as often in sinus rhythm as in auricular fibrillation.

Auricular fibrillation developed within one to three days of operation in 13 out of 48 patients in sinus rhythm who were operated on at the Middlesex Hospital. In anticipation of this, pre-operative digitalization was carried out as a routine in all cases irrespective of rhythm. In three instances the arrhythmia was related to a small area of pulmonary atelectasis, and sinus rhythm returned promptly when the lung re-expanded. A fourth patient reverted spontaneously before quinidine was given. In seven of the remaining nine cases quinidine restored sinus rhythm, usually after 10 to 15 gr. (0.65 to 1 g.) by mouth; the largest daily dose needed was 30 gr. (2 g.). Post-operative auricular fibrillation was irreversible in two patients. In addition, we have encountered one instance of established auricular fibrillation initiated by cardiac catheterization. Heparin

was given before and during quinidine therapy in two cases, but it is not used as a routine. There has been no instance of embolism related to quinidine therapy. Attempts to abolish post-operative fibrillation with quinidine during the first 10 days after operation were unsatisfactory and resulted in sinus rhythm vacillating with fibrillation. Quinidine is more likely to restore permanent sinus rhythm after the fourteenth day. When auricular fibrillation was established before operation we did not attempt to abolish it, and we have not encountered spontaneous reversion to normal rhythm in such cases.

Embolism

There was a history of embolism in 14 (9%) of the entire series of 150 cases. At operation a thrombus in the left auricle was encountered in only one of these cases (No. 22—auricular fibrillation); an old adherent clot was dissected away from the appendix with some difficulty. The patient died 12 hours after operation from cerebral embolism. In another case a fatal pulmonary embolism occurred one month after operation.

Post-operative embolism occurred altogether in nine patients; the details are set down in Table IV. Left auricular thrombi were noted at operation in 14 cases; in 11 of these the thrombus was in the appendix and in three in the body of the auricle.

TABLE IV.—*Mitral Valvotomy: Details of Post-operative Emboli in Nine Patients*

Case No.	History of Previous Embolus	Clot in Left Auricle	Site of Post-op. Embolus	Rhythm	Interval after Op.	Clinical Course

87	"	"	Cerebral	Auric. fib.	"	"

Two patients (Cases 17 and 42) died some months after operation from multiple pulmonary emboli under circumstances which deserve comment. In both patients the operation was technically satisfactory and a good result was anticipated on discharge from hospital. One and three months respectively after operation, during unusually severe foggy weather, they developed bronchitis and rapid auricular fibrillation, complicated by phlebothrombosis of the legs and repeated pulmonary emboli; both developed intractable cardiac failure. The third patient encountered a similar train of misfortunes one month after operation. Death in these three cases followed massive pulmonary embolism. Since this experience we have taken special care to warn the practitioner of the dangers of bronchitis complicating the early post-operative period and of the importance of detecting and treating phlebothrombosis in such patients.

Congestive Cardiac Failure

Congestive (right ventricular) failure had been present at one time or another in 29 of the complete series of 150 patients. Operation was undertaken in these cases only after long deliberation, since factors other than mitral stenosis, such as myocardial damage, might have contributed to the failure to a predominant degree. The majority of them responded favourably to medical treatment, but in a minority (class III) failure was recurrent or a state of borderline failure persisted. The deciding factors in favour of valvotomy were unquestionable signs of a diaphragmatic valve.

The Middlesex Hospital series of 87 cases included 19 with a history of right ventricular failure in whom valvotomy was deemed worth while. In eight of them failure had been related to the onset of auricular fibrillation or an intercurrent lung infection. When the exciting cause was treated the signs of failure disappeared and the heart became smaller, so that these patients were then included in classes I or II. The remaining 11 belonged to class III.

Three of the 19 patients died, one at operation from a tear of the auricular wall and two within a few days of operation. The result of valvotomy was good in four patients and poor in three. The remaining nine have been operated on within the past few months; all have survived, but the interval is too short to allow evaluation of the results. In a few cases the venous pressure increased and oedema developed within 10 days of operation. No cause was discovered, and the signs of failure disappeared spontaneously.

Calcification of the Mitral Valve

A grossly calcified mitral valve is likely to be rigid and is often incompetent. Yet the signs of a pliant diaphragmatic valve may exist with calcification which stands out conspicuously on radioscopy. Calcification was obvious in 9 of the 87 patients treated at the Middlesex Hospital. Small flecks of calcium perceived only after long scrutiny were disregarded. In one instance of gross calcification it appeared that valvotomy would be impossible; yet, because the signs of an operable valve were present, operation was proceeded with. Massive calcification involved the valve ring and invaded the cusps, which, however, were mobile. The commissures were split with ease and the functional result has been gratifying.

In addition to the nine instances of calcification discovered by radioscopy, a further 18 of varying degree were noted at operation, making a total of 27, or 31% of the Middlesex Hospital series. So far calcification by itself has not prevented operation, although often a knife had to be used to split the commissures. Emboli occurred in two of these cases; in one, transient hemiplegia developed after successful splitting of a slightly calcified valve; in the other it followed unsatisfactory widening of a heavily calcified valve.

Associated Valvular Disease

Mitral Incompetence.—Free mitral regurgitation is almost always a contraindication to valvotomy, but we believe that serious incompetence is incompatible with severe stenosis presenting signs of a pliant diaphragmatic valve. In such cases a systolic murmur may be ignored unless there is left ventricular enlargement. Expansile pulsation of the left auricle visible in the anterior view on radioscopy, and evident on both right and left heart borders should be taken as evidence of significant mitral incompetence. We have seldom found the diagnosis of mitral incompetence a difficult problem except in cases with gross right ventricular enlargement as already discussed.

Aortic Valve Disease.—In the presence of signs of tight mitral stenosis, we have ignored slight and occasional moderate aortic valve disease. One-third of the Middlesex Hospital cases had aortic incompetence and three of the also had aortic stenosis. However, mitral stenosis was always the dominant lesion. Free aortic incompetence with a thrusting apex beat, a jerky pulse, and left ventricular enlargement contraindicates mitral valvotomy. The result has been good in 15 of the 24 patients with slight aortic incompetence and fair in seven; two have died.

Tricuspid Valve Disease.—The possibility of organic tricuspid disease must always be considered when the right ventricle is greatly enlarged. It should be suspected when the signs of tricuspid regurgitation occur in the absence of congestive failure, when there is a noticeable tricuspid systolic murmur or thrill, and when the right auricle is unduly large. Tricuspid stenosis may sometimes be demonstrated by cardiac catheterization. The absence of pulm-

any congestion and relative freedom from dyspnoea and orthopnoea, in the presence of gross right-sided cardiac enlargement, especially if associated with liver swelling and ascites, is characteristic of tricuspid disease. We have regarded this condition as a contraindication to valvotomy. One patient with proved tricuspid stenosis and incompetence was submitted to mitral valvotomy on grounds of her hopeless disability and at her express wish, but unfortunately she died from post-operative embolism, so that the experiment was inconclusive. Functional tricuspid incompetence which disappears when failure responds to treatment is no bar to operation.

Pulmonary Complications

When mitral stenosis is complicated by chronic bronchitis and emphysema it is difficult to decide whether the symptoms are mainly cardiac or pulmonary, and long and careful observation may be necessary. We have performed mitral valvotomy on nine patients with well-marked chronic bronchitis and emphysema; the result was good in two and fair or poor in four. Two died and one case has not been followed up. Two out of three patients with extensive pulmonary haemosiderosis have done well after operation, and the radiological appearance of the lungs has shown a tendency to improve.

Pregnancy

Valvotomy was successfully performed during pregnancy in two patients who developed repetitive paroxysms of pulmonary oedema starting at the third and fourth months. The operation was done in one case at the fourth month, and in the other at the 32nd week, shortly after the patient first came under our care. Great improvement resulted and pregnancy continued normally to term.

Acute pulmonary oedema complicating mitral stenosis is the most important cardiac cause of death actually during pregnancy, and when it occurs after the third month a situation of the utmost gravity arises. Digitalis and other medical measures are unlikely to prevent a recurrence of the attacks if pregnancy continues, so that the choice lies between mitral valvotomy and termination of pregnancy by abdominal hysterotomy. Valvotomy has the double advantage of affording immediate relief to the underlying cause of the pulmonary oedema and of a good chance of preserving the life of the child. Late in pregnancy, however, it must carry a risk of precipitating premature labour in the post-operative period.

We have little doubt that immediate valvotomy is the method of choice in dealing with the emergency which arises when a patient with mitral stenosis develops pulmonary oedema after the third month of pregnancy. This does not imply that, in general, valvotomy renders those with severe mitral stenosis capable of undergoing pregnancy with safety, or that we should encourage such a belief in these patients.

Contraindications to Mitral Valvotomy

The current contraindications, in summary, are as follows:

Age.—Few patients under the age of 20 present with the indications for valvotomy. Because of the danger of activating the rheumatic state, operation should be postponed in these cases unless the symptoms compel immediate surgical relief. We have generally regarded 50 as the upper limit, although six of our patients had passed this age.

Acute Rheumatism.—We have never attempted valvotomy if clinical evidence of acute carditis was present.

Associated Valve Disease.—Predominant aortic valve disease, free mitral incompetence with left ventricular enlargement, and organic tricuspid disease are contraindications to valvotomy.

Myocardial Damage.—This is assessed from the size of the heart and the presence or absence of congestive failure. Gross right ventricular enlargement is a relative contraindication and gross left ventricular enlargement an absolute contraindication to valvotomy. One of our patients who had a coronary occlusion and left bundle-branch block in the electrocardiogram was nevertheless operated on successfully and with benefit.

Pulmonary Disease.—Severe emphysema, chronic bronchitis, and bronchiectasis have proved to be unfavourable.

Congestive Cardiac Failure.—If right ventricular failure cannot be relieved by treatment, mitral valvotomy is unlikely to be successful.

Giant Left Auricle.—Aneurysmal dilatation of the left auricle is often associated with mitral incompetence and with pericardial adhesions. In spite of the huge size of the heart, these patients may remain free from congestive failure for years on digitalis, and their disability is often far less than in cases of severe mitral stenosis with smaller hearts. Valvotomy is contraindicated in such cases.

Anaesthesia for Mitral Valvotomy

Non-explosive agents have been used throughout. Induction and intubation are performed with minimal doses of thiopentone and curare, after which narcosis is maintained by endotracheal gas-oxygen. Approximately 1 g. of procaine hydrochloride in saline is given over the period of an hour by intravenous drip. Topical local analgesic agents are not used. Further small doses of barbiturate and curare are added as required.

Cardiac irregularities of serious import were uncommon and demanded urgent attention on only two occasions. Continuous electrocardiograms, which were taken in the first 30 cases, are now recorded only for special reasons.

Technique of Mitral Valvotomy

The postero-lateral fifth-rib incision is preferred to the antero-lateral, the patient being tilted somewhat towards the supine position. The pericardium is freely opened parallel to the phrenic nerve to expose the lateral aspect of the heart.

Direct auscultation of the heart is carried out with a sterile stethoscope. The auricle and its appendix are gently palpated for thrombi, and if these are absent a light clamp is placed across the base of the appendix. Then, without using any sutures, the tip of the appendix is cut off and the incision enlarged to leave an opening one and a half times the diameter of the surgeon's index finger.

As the clamp is removed the finger is inserted gently. Sometimes the isthmus between the appendix and body of the auricle is unduly narrow and has to be stretched gradually. With the finger now well in the auricle, the tip can be swept over the aortic cusp and carried laterally until the roughened edges of the stenosis are felt. More posteriorly and laterally the wide mouth of the pulmonary vein can be identified. Attention is paid to the following points: ballooning of the antero-medial mitral cusp in ventricular systole, the size of the stenotic opening, the presence of calcification, and the existence of a regurgitant jet.

The actual valvotomy has often been described; it consists in engaging the side of the finger-tip in the opening and trying to fracture the commissures antero-laterally and postero-medially as far as the valve ring, a structure whose presence is inferred rather than felt (Fig. 5).

With the diaphragmatic type of valve, the posterior commissure, which is usually shorter, should be ruptured first; if the anterior commissure is split first, the resulting loss of tension makes the posterior commissure more difficult to deal with. When both commissures have been split (and considerable force may have to be used) the valve cusps are palpated for mobility, the finger is passed down the fan of the chordae tendineae on to the papillary muscles to exclude any cross-fusion, and, finally, a regurgitant jet is again sought for.

The finger is then withdrawn as the auricular clamp is reapplied, and the incision sutured with fine thread. The heart is auscultated again. The pericardium is loosely closed after flushing out with saline, and the chest closed. Temporary water-seal drainage of the chest is maintained for 24 to 48 hours to avoid the effects of a sudden accumulation of pleural fluid.

Matters are not always so straightforward, and the following complications may be encountered:

Auricular Thrombosis.—The incidence of thrombosis in the left auricle or its appendix in this series was 9%. Great caution should be exercised if the auricle does not pulsate and clot is felt within it. The tip of the appendix can be incised and the resultant gush of blood may sweep out a recent clot. Organized clot may be dissected out of the appendix if a light clamp is applied to the base. The danger lies in separating a piece of organized clot as the clamp is applied. If the thrombus is firmly attached, the operating finger may be worked carefully around without disturbing it. A small or thrombosed appendix or a thrombosed auricle may preclude the normal entry, and, if so, access may be gained through the pulmonary vein. The distal branches are held in check ligatures while a clamp is placed at the base of the vein. An oblique incision over the main trunk allows the finger to be introduced, and at the com-

plete of the operation simple suture is used to close the incised vein. In one case the auricular thrombosis was so extensive that it was impossible to introduce a finger or instrument into the heart. The pulmonary vein was too small, and direct incision through the auricular wall showed a thick layer of clot which could not be penetrated.

FIG. 5.—Necropsy specimen of mitral stenosis after valvotomy with (left) assumed appearance before operation. The patient (J. O.) died one month after operation from multiple pulmonary emboli.

Embolism.—The separation of clot or calcified fragments may produce embolism in the cerebral vessels, but this is seldom recognized until the patient recovers consciousness. Where a thrombus is palpable in the auricle, the anaesthetist compresses the carotid arteries in the neck during the actual valvotomy. This temporarily arrests the flow into these vessels, and any emboli may be swept along with the active blood flow and avoid the brain. This method is more simple than temporary occlusion of the innominate and left carotid arteries within the thorax.

Tearing of the Auricle.—The incision in the appendix sometimes splits, particularly if the auricular wall is thin. This should be recognized before the finger is withdrawn, as it permits insertion of control sutures before the clamp is applied. The loss of blood from an unsuspected tear can be catastrophic.

Rigidity of the Stenosis.—The finger may fail to rupture the commissure despite the application of considerable force; if so, the greatest care must be exercised to avoid tearing into the aortic cusp or pulling off a papillary muscle. Either of these events may produce a severe regurgitation. If the finger fails, a knife-like instrument attached to the finger can be used, care being taken to avoid injury to surrounding structures.

Haemorrhage.—In a straightforward operation the loss of blood does not exceed 1–2 oz. (28–57 ml.). If much manipulation is required or if the auricular wall is torn, urgent measures are necessary to replace the blood loss. A

Influence of Technical Result of Operation on Functional Result

An assessment has been made of the technical result of each valvotomy performed. When free splitting of the commissures was achieved without producing incompetence, 84% of the patients obtained a good functional result, compared with only 46% when the valvotomy was less complete. If the tiny slit of the stenosis is enlarged even by a few square millimetres, the volume of blood passing through the valve may be considerably increased. This may account for the early benefit experienced by certain patients in whom the technical result of the operation was poor in so far as the commissures were split to only a limited degree or a funnel-shaped valve could be merely dilated by the finger.

Summary and Conclusions

The basic indication for mitral valvotomy is disability from mitral stenosis of an anatomical form which is amenable to surgical correction. This type of stenosis, in which there is a *pliable diaphragmatic valve*, gives rise to characteristic clinical signs by which it may be recognized and which are described.

The most important consequence of pulmonary hypertension is right ventricular enlargement, and the size of the right ventricle, as determined by clinical radiological, and electrocardiographic findings, provides a more valuable index to the degree of pathological change

due to mitral stenosis than does the level of the pulmonary arterial pressure at a given moment. Cardiac catheterization is no longer required as a routine measure in the selection of cases suitable for mitral valvotomy. Selection may now be made on a basis of the symptoms and of the data provided by routine cardiologic examination.

Mitral valvotomy has been performed on 150 patients of whom 31 were men and 119 women. Their ages ranged from 19 to 57 years. Four patients died as direct result of the operation, an immediate mortality of 2.7%. Four died from various causes some time after the operation.

The results in 111 patients followed up for five months to two and a half years have been good in 74% and only fair or poor in 20%. Patients with auricular fibrillation (41% of the series) did as well as those with sinus rhythm, but three of the four operative fatalities were in fibrillation.

Cases selected for operation on grounds of an operable valve were classified according to the size of the right ventricle and the presence of congestive failure. Patients with large hearts, and congestive failure who failed to respond to treatment, benefited least from valvotomy. When free splitting of the commissures was achieved, 84% of the patients obtained good symptomatic relief, whereas when valvotomy was judged to be less satisfactory only 46% of the patients obtained relief. Nevertheless, partial splitting of the valve does not preclude satisfactory clinical improvement.

Clinical Material

Thirty-six cases of bronchiectasis in all, aged 3 to 15 years, have been treated with chloramphenicol. Judged by the quantity of sputum obtained while the patients were being treated by physiotherapy, 22 were severe and 14 were mild cases. Fifteen cases were able to produce an indefinite amount of sputum, 10 with involvement of at least four lobes. Among eight unilobar cases, only two are included in the severe group.

The first observations concern 15 cases, aged 5 to 10 years, in the Meath School of Recovery at Ottershaw (Invalid Children's Aid Association). In 11 the sputum grew *H. influenzae* alone, and in four *H. influenzae* with pneumococci. All had first been treated by a physiotherapist for many weeks, and eight of the cases could cough up a limitless quantity of purulent sputum at any time during the day. The dose of chloramphenicol was 500 mg. eight-hourly in capsules by mouth, equivalent to between 20 and 30 mg. per lb. (44 and 66 mg. per kg.) body weight daily. The quantity of sputum lessened dramatically, and by the third or fourth day of treatment it became difficult to obtain a specimen; cultures were sterile.* After seven days the drug was stopped in 10 and continued in five of the cases. The mildest case had no more sputum after this week of treatment and remained well and symptom-free for a whole year following discharge home. In the other nine cases sputum cultivated on the sixth day after the end of treatment showed a return of the original organism, while sputum from the five cases still under treatment remained sterile in four and grew pneumococci in one. Two cases continued treatment at half the original dose for two further weeks, the sputum remaining sterile, while two very severe cases, treated on half the original dose for five and six months, later increased the quantity of sputum to 1 to 1 oz. (14 to 28 ml.) daily (compared with 6 to 8 oz. (170 to 230 ml.) collected easily before treatment) and the sputa grew bacteria from time to time, but never *H. influenzae*. In all the severe cases *H. influenzae* regained its ascendancy in the sputum within 10 days of the end of treatment, though cough and the quantity of sputum were less than before treatment began.

Three cases had 250 mg. of chloramphenicol twice a day for one, two, and five months (approximately 10 mg. per lb. (22 mg. per kg.) daily), and pneumococci, streptococci, and staphylococci appeared from time to time without *H. influenzae*. In seven cases three doses of 250 mg. eight-hourly for one day of each week were given for one month in one case, for three months in five cases, and for five months in one case (12 to 24 mg. per lb.: 26 to 53 mg. per kg.). Cultures of sputum were sterile on the day after treatment, but grew various bacteria, including *H. influenzae*, by the sixth day, so that weekly treatment failed to produce constant sterility of the sputum. Assessment of the 15 cases one year after starting treatment showed a maintained improvement in seven; two are somewhat better, and in the six clinically most severe cases lessening of the sputum occurred only while chloramphenicol was actually being given.

A second observation at the Meath Home concerned eight patients from 3 to 8 years old. Six sputa grew *H. influenzae* and one sputum grew *H. influenzae* with *N. catarrhalis*. In one case there was a pure growth of pneumococci, and this is the only case in the study from whose sputum *H. influenzae* was not grown. Six cases were given 250 mg. eight-hourly for 18 days (13 to 21 mg. per lb. (29 to 46 mg. per kg.) daily). On this dose, two-thirds of that given in the previous test, there was the same dramatic change in the quantity and character of the sputum from the third or fourth day, with the same return of organisms within a few days of the end of treatment. Sputum from

*This term is used for the sake of brevity to describe cultures containing no colonies of any pathogen and very few colonies of commensals.

Good results were obtained alike in those with greatly elevated pulmonary arterial pressures and in those with a slight or moderate elevation.

The following are regarded as contraindications to operation: active rheumatic carditis, severe myocardial damage as revealed by gross right ventricular enlargement and intractable congestive failure, predominant aortic valve disease, organic tricuspid valve disease, mitral incompetence associated with left ventricular enlargement, and a giant left auricle. Chronic bronchitis, emphysema, and other pulmonary complications prejudice the success of the operation.

The technical details of mitral valvotomy and the operative complications are briefly described.

We wish to thank many colleagues in hospital and in practice, particularly Dr. K. Shirley Smith and others at the London Chest Hospital, who have kindly referred patients needing valvotomy. We are especially indebted to Mr. J. R. Belcher, who has taken an active part in the surgical management of the Middlesex Hospital patients.

CHLORAMPHENICOL TREATMENT OF BRONCHIECTASIS IN CHILDREN

BY

A. WHITE FRANKLIN, M.B., B.Ch., F.R.C.P.

AND

L. P. GARROD, M.D., F.R.C.P.

(From St. Bartholomew's Hospital, London)

Although most acute bacterial infections are now readily amenable to chemotherapy the problem of chronic infection based on structural changes remains unsolved. Whatever the prime cause or causes of bronchiectasis, the main symptoms in childhood result from chronic or recurrent infection of damaged lung. The damage is almost certainly permanent, yet follow-up studies suggest that the infection, as evidenced by clinical signs and symptoms, may die out towards adolescence. Cultures of sputum show the frequency of infection with *H. influenzae*, and, as this is an organism highly susceptible to chloramphenicol, a study has been made of the effect of this drug on the course of bronchiectasis. The study has been brought to an end by the recognition of the possible dangerous action of chloramphenicol on bone marrow. Sufficient knowledge had already been gathered to shed light on two problems—the nature of the infection, and the response, bacteriological and clinical, to chemotherapy; and these observations are reported here.

four of the cases given the same daily dose twice a week was not kept sterile.

Only two children, both with extremely severe symptoms, aged 3½ and 4 years, were given chloramphenicol palmitate, at first in doses of 12 and later of 24 mg. per lb. (26 and 53 mg. per kg.) daily, but the sputum failed to lessen in quantity or to become sterile in either. The death of one of these patients is referred to later.

Thirteen other cases of bronchiectasis have been treated with chloramphenicol capsules by mouth in the wards of St. Bartholomew's Hospital and Osterhills Hospital, St. Albans. Ages ranged from 4 to 15 years, eight cases being severe and five mild. Again *H. influenzae* was the predominant and usually the only organism cultivated from the sputum, and again daily doses of 12 to 15 mg. per lb. (26 to 33 mg. per kg.) sterilized the sputum in three or four days, with the same recurrence after treatment, the more rapidly the severer the case. The five mild cases have been treated periodically with one or two weeks of chloramphenicol—20 mg. per lb. (44 mg. per kg.) daily divided into three doses—particularly at the time of any acute respiratory symptoms; and under this regime school life and health have been little upset.

The following laboratory data are based on findings in 27 of the cases here described, examination in the remainder not having been performed by one of us (L. P. G.).

Sputum Findings

The characters of the sputum in these patients were strikingly uniform. It consisted of thick yellow odourless mucus. Except in the one case, already noted, which had a pure pneumococcus infection, a stained film invariably showed large numbers of minute Gram-negative rods, and culture gave a growth consisting almost entirely of *H. influenzae*. The only other identifiable pathogen in the sputum of untreated cases was *Str. pneumoniae*: this was found in 10 cases, but in relatively very small numbers.

Sensitivity to Antibiotics of Strains of *H. influenzae* from Cases of Bronchiectasis

Antibiotic	Total No. of Strains	Minimum Inhibitory Concentrations (µg./ml.)					
		0.25	0.5	1	2	4	8
Chloramphenicol ..	37*	2	16	19			
Penicillin ..	22		2	15	3	1	1
Streptomycin ..	22			3	2	16	
Aureomycin ..	22	2	3	17			
Terramycin ..	22	1	8	13			

Figures are numbers of strains inhibited by each concentration.
* Includes 10 strains from similar but untreated cases.

The sensitivity of the strains of *H. influenzae* to chloramphenicol and other antibiotics is stated in the Table. These determinations were made by incorporating the antibiotic in falling dilutions (two-fold differences) in plates of heated blood agar, the surface of which was inoculated with a small loopful of heated blood-broth culture, diluted approximately 1:500, in each of eight areas—that is, eight strains per plate were tested. The concentrations stated are those completely inhibiting growth after 24 hours: the next lower always showed diminished growth and the next full growth. All the strains tested were inhibited by 1 µg./ml., 16 by 0.5 µg./ml., and 2 by 0.25 µg./ml. of chloramphenicol.

The further tests with other antibiotics were done later with 22 strains which had been preserved in the dried state, the same method being used.

The sputum of patients under adequate treatment with chloramphenicol was distinguishable at a glance from a pre-treatment specimen. It was white in colour and less cellular, contained no *H. influenzae*, and at first yielded no significant growth. Two other species tended to appear during treatment: *Str. pneumoniae* (in 11 patients), which was

shown in three patients whose sputum had originally contained it in small numbers to have diminished in its sensitivity to chloramphenicol; and a chloramphenicol-resistant *Staph. pyogenes*. Sputum containing these organisms became more cellular, but in neither purulence nor quantity did it attain the characters of pre-treatment sputum.

Estimations of Drug in Sputum.—A method for this was devised, depending on two convenient facts: that chloramphenicol is heat-stable, and that the air passages and mouth usually contain no sporogenous or other heat-resistant bacteria. Specimens were accordingly placed in a water-bath at 60° C. for one and a half hours, then diluted 2-, 4-, 8-, and 16-fold in heated blood broth, and inoculated with *H. influenzae* itself. The organism grew well in all dilutions of control tests with non-drug-containing sputum, and was inhibited to the expected dilution in control tests in which chloramphenicol had been added. Whether the inoculum had multiplied was determined by plating after one day's incubation.

The results of such tests in 15 specimens showed the presence of 8 µg./ml. chloramphenicol in five and 4 µg./ml. in six who were receiving chloramphenicol, and less than 2 µg./ml. in four specimens from two patients receiving chloramphenicol palmitate, in whom this compound had failed to eliminate *H. influenzae* from the sputum.

Acquired Bacterial Resistance

Habituation to chloramphenicol was attempted *in vitro* by repeated transfers in heated blood broth containing increasing concentrations. Of three strains of *H. influenzae*, two showed a fourfold and one a twofold increase after five transfers. Of three strains of *Str. pneumoniae* two showed a fourfold increase and one no change after 10 transfers. Each of three strains of *Staph. pyogenes* underwent a fourfold increase in resistance in 10 transfers.

Acquired resistance *in vivo* was observed with three strains of *Str. pneumoniae*, the difference being fourfold in each case (inhibitory concentration increasing from 2.5 to 10 µg./ml.), and in three strains of *H. influenzae*, originally inhibited by 0.25, 0.5, and 0.5 µg./ml., and found after treatment in each case to require 2.0 µg./ml. One of these patients was given diminishing doses, which eventually failed to suppress the infection, and two were treated with chloramphenicol palmitate, which also failed to eliminate the organism. There is thus some suggestion that inadequate treatment tends to encourage the acquisition of bacterial resistance.

Toxic Effects

One patient, a female aged 4 years, was given 125 mg. of chloramphenicol palmitate three times a day for 20 days, followed by 250 mg. thrice daily for 29 days (total, 29.25 g.). Pallor was noted at the end of this course: eight days later there was generalized purpura. Despite vigorous treatment she died with multiple haemorrhages and an aplastic marrow 26 days after the appearance of purpura. (We are permitted by our colleague, Professor R. V. Christie, to mention that an aplastic anaemia also developed in a man under his care who had had prolonged chloramphenicol treatment for *H. influenzae* bronchitis: this patient, after many transfusions, is apparently recovering.)

Discussion

The effects of chloramphenicol when 20 mg. per lb. (44 mg. per kg.) is given by mouth daily, divided into three doses, is consistently to diminish the quantity of sputum and to sterilize it in three or four days. Continued treatment may be accompanied by a later increase in the quantity of mucoid sputum up to 2–3 oz. (57–85 ml.) daily despite the absence of pus and bacteria. The abnormal physical signs characteristic of active infection persist even when sputum disappears altogether. Bacteria reappear when the dose drops below 20 mg. per lb. per day or is

THE IN-VITRO SENSITIVITY OF *H. INFLUENZAE* TO FIVE DIFFERENT ANTIBIOTICS

BY

K. ZINNEMANN, M.D.

Senior Lecturer in the Department of Bacteriology, School of Medicine, University of Leeds

At times clinicians find it difficult to select and bacteriologists to suggest the antibiotic most effective in some of the less common bacterial infections until detailed sensitivity tests have been carried out, with the result that there is a delay of at least 24 hours in administering the one regarded as most suitable.

This situation occurs particularly often in infections due to *Haemophilus influenzae* (Mulder, 1952). This organism causes both acute infections—for example, meningitis, obstructive laryngo-tracheobronchitis, pneumonia, empyema (Rivers, 1922; Alexander, 1943; Zinnemann, 1947), and also chronic infections with acute exacerbations, such as otitis, sinusitis, and bronchiectasis (Hirsch, 1912; Mulder, 1940; Allison, J. Gordon, and Zinnemann, 1943; Bjuggren and Tunevall, 1952; Tunevall, 1952). It is sensitive in some degree to all antibiotics easily available in this country (M. Gordon and Zinnemann, 1945; Hewitt and Pittman, 1946; Alexander, Leidy, and Redman, 1949).

Few comparative assessments of the more recent antibiotic drugs against *H. influenzae* have been made, and these mostly on a small number of strains (Alexander *et al.*, 1949; Long *et al.*, 1950; McCrumb *et al.*, 1951; Schoenbach *et al.*, 1952). Recently two larger series have been published (Mulder *et al.*, 1952; Tunevall, 1951): see Table I. Mulder *et al.* recorded only the

upper and lower limits of the minimal *in-vitro* inhibiting doses for *H. influenzae* as did all authors quoted above, with the exception of Tunevall, whose findings will be discussed in detail later. The results obtained have not led any of the authors to make specific recommendations for the choice of an antibiotic drug in *H. influenzae* infections. The figures of Mulder *et al.*, however, are slightly favourable to chloramphenicol, whereas those of Tunevall suggest aureomycin.

During our routine determinations of the sensitivity of *H. influenzae* strains to antibiotics the impression was

given less often than eight-hourly. Pneumococci and staphylococci seem to reappear during long courses of treatment, but not to persist. In most cases, once the *H. influenzae* returns the other invading bacteria quickly die out. Mild and unilobar cases may remain symptom-free for many months after a course of two weeks' treatment (eight cases). Severe cases have always relapsed within 10 days of ceasing treatment, and sometimes the relapse is heralded by an acute febrile illness lasting one or two days. In every case another course of treatment has produced another remission. The question arises whether in severe cases the *H. influenzae* remains deep in the tissues of the bronchiectatic lung, ready to reappear in the sputum when the drug is stopped, or whether reinfection occurs. The larger doses that might reduce the risk of relapse on the first hypothesis have not been regarded as safe in these observations.

Unfortunately the possibly toxic effect of chloramphenicol on bone marrow, responsible for one death in the cases treated in this series, makes the prolonged use of the drug unwise. Some of the cases reported here have taken as much as 100 g. in six months without apparent ill effect, and repeated blood examinations might give warning of trouble in time for the drug to be stopped, before changes in the marrow become irreversible. We do not, however, intend to persist with this treatment. We feel that our results must be recorded to show that there is a place—if now vacant—in the medical treatment of bronchiectasis in children for an antibiotic sharing with chloramphenicol the power of rapidly reaching a high enough concentration in the respiratory tract to destroy *H. influenzae* without inducing resistance, so that recurrent infection may be successfully treated in the same way. Such a drug would combine safety with the power to dry up sputum and to make bacteriologically safe surgical procedures on lower respiratory tract or on upper respiratory tract, so often the site of disease causing persistence of symptoms; secondly, would be suitable for routine preventive treatment in severe bronchopneumonia in infancy, especially in association with pink disease and whooping-cough; thirdly, would keep the mild unilobar case free from recurrences following intercurrent influenza or other acute respiratory infections; and, fourthly, would give periods at least of freedom from endless cough and sputum in the severest cases where five lobes are diseased in early childhood, and where even the boldest thoracic surgeon must refuse surgical help. For those who believe that *H. influenzae* is responsible for the persistence of symptoms in the majority of cases of bronchiectasis, and that bronchiectasis is a disease with a tendency towards improvement and dying out of symptoms in time, the situation urgently demands a safe antibiotic with the remarkable powers of chloramphenicol. Our experience with aureomycin and terramycin, to which *H. influenzae* is also very sensitive, is so far too limited to justify any report.

Summary

Of 36 cases of bronchiectasis in children a pure or almost pure infection by *H. influenzae* was present in 35.

Chloramphenicol, to which this organism is highly sensitive, invariably produced a remission while being given in adequate doses. After cessation of treatment, severe cases reverted to their original condition, but some milder ones appeared to have received more lasting benefit.

One patient died of aplastic anaemia, an occurrence which led to the abandonment of the treatment.

We are indebted to Miss Pamela M. Waterworth for skilled laboratory assistance, and to Miss Gosling and her staff at the Meath School of Recovery for collecting and personally conveying to London many specimens of sputum.

obtained that chloramphenicol was more effective than the rest. To confirm this impression capsulated and non-capsulated strains of *H. influenzae* isolated from pathological conditions during the period January 1, 1951, to October 30, 1952, and a number of strains of both varieties from similar routine material kindly forwarded by Dr. K. B. Rogers, of the Children's Hospital, Birmingham, were tested by the standard method described below, and the results analysed. The data were collected as strains became available.

Technique.—As soon as possible after isolation the strains were inoculated into Levinthal broth and incubated overnight. Four drops of a 1 in 1,000 nutrient-broth dilution of this culture were spread uniformly over the whole surface of each of three heated horse-blood (chocolate) agar plates. With a sterile cork-borer a number of holes were punched at regular intervals in the medium around the edge of the plates. The holes were filled to within about 1 mm. of the rim with the dilutions of the antibiotic drugs. Penicillin was tested by itself on the first plate; streptomycin was paired with aureomycin on the second, and chloramphenicol with terramycin on the third plate. The standard dilutions of antibiotics employed were 1 µg., 2 µg., 5 µg., and 10 µg., except for penicillin. Of the last-named drug 1, 2, 5, and 10 Oxford units (corresponding to 0.61, 1.22, 3.05, and 6.1 µg.) were used. After overnight incubation the plates were read and the results recorded.

Definitions.—Some investigators have based their readings on partial, others on complete inhibition (Jackson and Finland, 1951). Results of the two methods arrive at different values. To facilitate comparison with the findings of other workers the results for both methods of reading are given in Tables IV and V. In this investigation the term "partial inhibition" is not based on any measurements of the width of inhibition zones but indicates a marked zone of inhibition of growth around the punch-holes with slight growth still occurring inside the zones and right up to the edge of the punch-holes. The term "complete inhibition" indicates complete absence of growth within the whole or part of the inhibition zone.

Results

A total of 34 capsulated and 50 non-capsulated strains of *H. influenzae* were investigated. All these strains were isolated from cases in which *H. influenzae* was present as the only or predominant bacterium and in which it appeared that the

clinical conditions were related to or aggravated by this organism. Tables II and III give details of the sites from which the strains were isolated and the number of strains isolated from these sites. As was to be expected, the majority of capsulated *H. influenzae* strains were obtained from the cerebrospinal fluid of cases of meningitis in children, and all 21 strains from this site were of type b (Pittman). The possible sources of non-capsulated strains are fairly well represented by the 50 strains investigated. All strains may thus be regarded as unselected.

A more exacting test is the *in-vitro* determination of the concentration of any given antibiotic required to inhibit a micro-organism completely. Table IV shows that in such a test 1 unit per ml. of chloramphenicol inhibits completely one-quarter of the capsulated and two-fifths of the non-capsulated *H. influenzae* strains, while all other antibiotics tested inhibit only 6% or less of all the strains. At a concentration of 2 units per ml. chloramphenicol inhibits one-half of the capsulated and over four-fifths of the non-capsulated strains, while none of the other antibiotics inhibits completely more than roughly one-quarter of the capsulated and one-sixth of the non-capsulated strains. All of the capsulated strains, with one exception, and 100% of the non-capsulated strains are completely inhibited by 5 units per ml. of chloramphenicol, while the most effective of the other antibiotics inhibit only three-quarters of the strains at this concentration. The effective concentrations are naturally lower if partial inhibition is used as the basis to assess antibiotic activity (Table V).

Terramycin and penicillin follow chloramphenicol fairly closely in their *in-vitro* performance against *H. influenzae*, and it would be difficult, on the basis of the figures obtained, to decide which of these two drugs is more active. Streptomycin and aureomycin appear to be roughly equal but less inhibitory than terramycin and penicillin, particularly as judged by the partial inhibition test.

Discussion

The superiority of chloramphenicol in inhibiting *H. influenzae in vitro* in these investigations is somewhat surprising in view of the absence of similar statements in the not inconsiderable literature on the drugs tested, although chloramphenicol and aureomycin have now been in use for five and terramycin for three years. Clinically, however, infections due to Gram-negative organisms have been reported to respond better to chloramphenicol (McCrum et al., 1951). Jackson and Finland (1951) drew attention to the fact that determinations of *in-vitro* sensitivity to antibiotics carried out with diverse methods and in the hands of different investigators cannot easily be compared and that the conclusions reached may differ. Such divergencies in tests on *H. influenzae* are shown in Table I. The argument does not seem entirely valid if used against the results reported in this communication, for the following reasons.

Table I, which summarizes the principal papers on the sensitivity of *H. influenzae* to antibiotics, shows that, with the exception of one (Tunevall), the authors have confined themselves to indicating the upper and lower limits of the minimal inhibiting doses of the antibiotics investigated. In the results here reported the figures have been analysed in such a way as to record the number of strains of *H. influenzae* inhibited at four concentrations of five different antibiotics. This method of tabulating results is better suited to stressing the superiority of one or the other of the drugs investigated. Results similar to the one reported here have been obtained by an independent observer (W. Goldie, personal communication, 1952). However, Tunevall (1952) recorded his findings in a way closely resembling the one used in this communication. In Table I there is a suggestion of a slight superiority of aureomycin over chloramphenicol, although in his conclusions the author regards the two drugs as equally effective. The explanation for the divergence between the two sets of experiments may perhaps be found in the different

techniques used, as Jackson and Finland (1951) suggested. Tunevall incorporated the antibiotics in serial twofold dilutions in a solid medium, which was then inoculated with the strains to be tested, while the present findings are based on the punch-plate technique.

As a rule determinations of sensitivity carried out in fluid media or with the antibiotic incorporated in a solid medium tend to give lower values than those obtained with the punch-plate method. It may be inferred from this fact that the actual inhibitory concentrations of all antibiotics tested in the way here described are lower than appears from the findings recorded. However, the order of effectiveness should not be influenced by lower readings.

Ease of administration favours the so-called broad spectrum antibiotics, but side-effects such as gastro-intestinal irritation may sometimes make their administration difficult if not impossible, quite apart from the uncertainty about the doses given if vomiting occurs. In practice, blood concentrations of penicillin high enough to inhibit most or all *H. influenzae* strains are difficult if not impossible to achieve and to maintain, although such concentrations can be obtained easily in the C.S.F. by intrathecal injection. On the other hand, therapeutically effective blood concentrations of the order of 5 to 10 µg. are the rule with usual oral doses of chloramphenicol, aureomycin, and terramycin, or with intramuscular doses of streptomycin (Zintel et al., 1945; Ehrlich, 1947; Dowling et al., 1948; Glazko et al., 1949; Welch, 1950; Eads et al., 1952). It is evident, therefore, that the quite impressive *in-vitro* performance of penicillin is not likely to be equalled by its performance in clinical infections due to *H. influenzae*, except in some conditions, such as meningitis (Zinnemann, 1946) or empyema, where a high concentration of the drug can be applied locally. This circumstance still further emphasizes the value of chloramphenicol in *H. influenzae* infections, with terramycin as a good second best. Aureomycin is a difficult drug to assess in *in-vitro* experiments, as up to 50% of its activity may be lost during incubation at 37° C. (Chandler and Bliss, 1948). It is possible, therefore, that the *in-vitro* activity of aureomycin against *H. influenzae* is greater than is suggested by the *in-vitro* results given in Tables IV and V. However, observations on patients with chronic infec-

tions due to *H. influenzae* (Allibone, 1953, personal communication) seem to agree well with the *in-vitro* results reported here, the order of *in-vitro* effectiveness being chloramphenicol, terramycin, and aureomycin. It must be stressed, though, that *in-vitro* sensitivities to antibiotics do not necessarily permit conclusions on the effectiveness of these drugs *in vivo* in spite of good agreement in this series.

In view of the greater inhibitory action of chloramphenicol on *H. influenzae* it is unfortunate that this drug is claimed to cause aplastic anaemia and related blood dyscrasias (Volini, et al., 1950; Gill, 1950; Smiley et al., 1952). Sturgeon, 1952; Rheingold et al., 1952; Hawkins and Lederer, 1952; Wolman, 1952; Hargraves et al., 1952). Probably no great harm will be done if chloramphenicol is used for one short course of a few days' duration. Repeated or prolonged administration seems to be the common feature of most of the cases of blood dyscrasias reported hitherto, though a few cases have been described with granulocytopenia following one short course of the drug (Gill, 1950; Volini et al., 1950). Hargraves et al. (1952) attribute the deaths from aplastic anaemia of two of the cases reported by them to comparatively small doses of chloramphenicol, but there is an element of doubt in the history of administration of the drug.

Thus it would appear that the antibiotic having the best *in-vitro* and *in-vivo* inhibitory action against *H. influenzae* may have limitations in practical application. More evidence for or against the prolonged or intermittent administration of chloramphenicol is required to assess its value in the therapy of chronic infections due to *H. influenzae*.

Summary

The *in-vitro* antibiotic action of penicillin, streptomycin, aureomycin, chloramphenicol, and terramycin on 34 capsulated and 50 non-capsulated *H. influenzae* strains has been tested at four concentrations. The punch-plate method was used for these sensitivity tests.

Chloramphenicol is the only one of the antibiotics tested which is capable of inhibiting 100% of the strains investigated at the comparatively low concentrations

TABLE IV: COMPLETE INHIBITION.—*In-vitro* Sensitivity of *H. influenzae* Strains to Antibiotics. Punch-plate Method on Heated Blood (Chocolate) Agar Plates; Units/ml.=Oxford Units in the Case of Penicillin and µg. in the Case of All Other Antibiotics

Terramycin	0	1 (3.0%)	23 (72.7%)	7 (21.3%)		1 (2%)	3 (8%)	33 (74%)	12 (100%)	

Figures in parentheses indicate number of strains not inhibited by 10 units/ml. Plain figures indicate absolute number of strains inhibited by a particular concentration of a particular antibiotic; percentage figures indicate proportion of all strains inhibited by a particular concentration of antibiotic drug.

TABLE V: PARTIAL INHIBITION.—*In-vitro* Sensitivity of *H. influenzae* Strains to Antibiotics. Punch-plate Method on Heated Blood (Chocolate) Agar Plates; Units/ml.=Oxford Units in the Case of Penicillin and µg. in the Case of All Other Antibiotics

Antibiotic Drug	Capsulated Strains					Non-capsulated Strains				
	No. and Percentage of Strains Inhibited by Units/ml.				Total No. of Strains Tested	No. and Percentage of Strains Inhibited by Units/ml.				Total No. of Strains Tested
	1	2	5	10		1	2	5	10	
Penicillin	8 (3) (23.5%)	15 (76.5%)	8 (100%)	—	34	5 (1) (3) (10%)	21 (8) (54%)	13 (1) (96%)	1 (100%)	50
Streptomycin	3 (1) (8.8%)	14 (3) (50.0%)	10 (1) (78.4%)	2 (97.0%)		5 (3) (1) (10%)	21 (5) (58%)	9 (1) (86%)	3 (94%)	
Aureomycin	4 (1) (11.8%)	9 (41.2%)	13 (79.4%)	5 (94.1%)	33	3 (2) (6%)	17 (40%)	24 (88%)	5 (98%)	
Chloramphenicol	17 (8) (50.0%)	15 (1) (94.1%)	1 (100%)	—		41 (1) (20) (82%)	8 (100%)	—	—	
Terramycin	2 (1) (6.1%)	18 (4) (60.6%)	7 (93.9%)	2 (100%)		4 (1) (8%)	31 (2) (70%)	12 (98%)	1 (100%)	

Figures in parentheses = number of strains partially not inhibited at given but completely inhibited at next higher concentration. Figures in square brackets = number of strains not tested at < 1 unit/ml. Plain figures indicate absolute number of strains inhibited by a particular concentration of a particular antibiotic; percentage figures indicate proportion of all strains inhibited by a particular concentration of antibiotic.

obtained with the usually recommended therapeutic doses. Terramycin comes next in order of effectiveness, followed by streptomycin and aureomycin. Penicillin *in vitro* is as effective as chloramphenicol and terramycin, or even better, on a weight-for-weight basis, but blood concentrations within the effective range are difficult to obtain and maintain.

Deterioration of aureomycin at 37° C. may be responsible for the comparatively low rating of the drug, but clinical impressions in chronic *H. influenzae* infections also suggest the superiority of chloramphenicol.

I am indebted to the Medical Research Council for a grant in aid of expenses.

The Home Office has recently issued the report of the Commissioners of Prisons for 1952 (Cmd. 8948). It deals with the administration of prisons; statistics of the prison population; the treatment, training, and after-care of prisoners; Borstal training; detention centres; and the health of prisoners. In spite of the serious overcrowding in the prisons, there was no epidemic of infectious disease last year, and even the usual outbreaks of influenza in the early months were conspicuously absent at most establishments. Indeed, the director of medical services notes, as an interesting observation, that during past influenza epidemics, where three men have shared a cell and one has developed the disease, the infection not infrequently has spread to men in neighbouring cells, while others in the original cell may escape it altogether. However, the potential risk to health consequent on overcrowding is constantly in the minds of the prison medical officers. In August, 1952, the first detention centre for boys of 14 to 17 years was opened, and the medical officer reports that the training there has had a beneficial effect on the physique and health of the boys admitted. The idea of the centre is to provide an alternative to prison for young offenders who do not need prolonged Borstal training yet are unlikely to respond to probation.

THE PROGNOSIS AND ROLE OF SURGERY IN SPONTANEOUS INTRACRANIAL HAEMORRHAGE

BY

JACK M. SMALL, M.B., F.R.C.S.

Consultant Adviser in Neurology to the Birmingham Regional Hospital Board; Surgeon to the Department of Neurosurgery, The United Birmingham Hospitals

J. MacD. HOLMES, M.D., F.R.C.P.

Stafford, Regional Neurologist

AND

R. CAMPBELL CONNOLLY, F.R.C.S.

Consultant to the Birmingham Regional Neurosurgical Hospital; Honorary Neurosurgeon, The United Birmingham Hospitals

A balanced understanding of the diagnosis and treatment at present available for spontaneous intracranial haemorrhage is extremely important, and this paper presents on the one hand our experience and on the other our considered opinion regarding the treatment of this condition. The term "spontaneous intracranial haemorrhage" is used rather than "subarachnoid haemorrhage," as the major portion of the bleeding may be at any site from the subdural space to the ventricle. Apoplexy in the elderly arteriosclerotic, so classical in its clinical manifestations, is not included.

Prognosis

The prognosis in cases treated conservatively has been reviewed many times in the past few years, and there is no doubt that the initial mortality rate is about 50%, rising with recurrent episodes and in older patients. In our assessment our first consideration was a series of 100 consecutive cases managed conservatively by one of us from 1936 until 1951. Conservative care means rest in bed for at least one month, care of the bowels, sedation, and the judicious use of lumbar puncture. In these 100 cases, 53 female and 47 male, there were 43 deaths during the initial period in hospital. Although these 43 deaths occurred at any time up to six weeks after the onset of haemorrhage, one third (14 cases) occurred in the first 24 hours and another third (15 cases) in the second week. Excluding the first day there were only eight deaths in the first week, and six patients died in the second to sixth weeks. Fairly clear evidence of recurrent bleeding was present in half the patients dying during the first and second weeks and in all those dying after the close of the second week. All the 57 survivors have been traced. Eight of them have died from recurrence of intracranial haemorrhage and two others of intercurrent disease. Twenty of them have been left with some permanent neurological disability, although only seven are completely disabled by hemiplegia or intellectual loss. Of the eight late deaths from recurrence only two have been in the disabled group; the other six have occurred in those who had made a complete recovery from the initial haemorrhage. The deaths have occurred after an interval of time up to 12 years from the initial episode. Four died of a single recurrence, but four others of a second, third, or fourth haemorrhage. Before considering the way in which surgical investigation and treatment may improve both the mortality and

the disability rate, we must seek a fairly clear picture of the varying clinical syndromes and pathological findings.

During the first few hours following a haemorrhage, it is clear that certain patients are dying. These are deeply unconscious, with gross changes in the vital signs. Many have a rapidly increasing pulse and respiration rate, and excessive bronchial secretion; often decerebrate rigidity, with the arms and legs held in marked extension and varying areas of the body covered with goose-skin and beads of sweat. They show no response other than a generalized increased rigidity to stimulation. All others must be judged upon the changing signs that occur in the hours immediately after the catastrophe; some are unconscious to varying degree and others never unconscious at all. Headache and neurological disturbance, such as hemiparesis, visual field defects, cranial nerve palsies, or dysphasia, may be present. It is in these hours immediately after the haemorrhage that an assessment of the patient is most important and illuminating. There are those who regain consciousness quickly, who have no evidence of gross neurological disturbance, or rapidly improve. Others are still semiconscious but their condition has remained unchanged over the passage of time, and these are the ones who may recover also. Others, however, begin to show progression of neurological disturbance characterized by increasing drowsiness or coma and pupillary change. It is this group which is developing increasing intracranial pressure and a tentorial pressure cone, the medial portion of the temporal lobe being pushed down between the midbrain and the margin of the tentorium, causing the posterior cerebral artery to press upon the third nerve and bring about the pupillary dilatation and non-reaction to light, as well as disturbing the blood supply and function of the midbrain. Unless urgent surgical treatment is undertaken haemorrhagic infarction of the midbrain will occur with all the signs of impending and inevitable death.

As the hours pass into days so more and more of the patients fall into their obvious categories. We are left with those obviously recovering, those developing evidence of slowly increasing intracranial pressure, and those with varying degrees of unconsciousness or akinetic mutism and disturbance of autonomic signs other than of these patients gross neurological signs other than disturbance of consciousness may be present, but it is when we look to the pathological state that varieties of signs and symptoms fall into their proper perspective and the correct investigation and treatment become clear. It must be understood that at any time there may be a recurrence of haemorrhage of variable severity.

Diagnosis and Diagnostic Procedures

There are certain features in the history and clinical signs which are important, particularly dramatic onset, which in difficult cases may be the only lead to the diagnosis. In those cases in which the bleeding has involved the subarachnoid space there is usually neck-stiffness and a positive Kernig's sign, but the absence of these signs in the early stage does not exclude the presence of a great amount of blood in the subarachnoid space, especially when there is deep unconsciousness. Auscultation of the head, normally so unrewarding, may elicit the presence of a systolic bruit from an angioma. Varieties of neurological signs, and particularly ocular pareses, may be present in many cases, and in some a typical subhyaloid haemorrhage will be observed in the ocular fundus. Ocular pareses when present as isolated signs are likely to be due to an aneurysm in close relation to the nerves, rather than

due to a tentorial pressure cone resulting from an intracranial haematoma, and are therefore valuable localizing signs.

In the early stages, particularly if there has been only a mild or premonitory leak of blood into the subarachnoid space, a variety of lower spinal nerve pains may occur; in one of our patients a diagnosis of appendicitis had been made from the lower abdominal pain, rigidity, and vomiting, whilst another developed an obvious crop of herpetic vesicles around the trunk. The patients in whom a haemorrhage occurs almost exclusively into the substance of the brain may have a sudden onset but a rather slower evolution of a syndrome typified by fairly gross neurological disability and increasing headache, somewhat similar to cerebral abscess. Some cases even more insidious in their progression develop signs of considerably increased intracranial tension with papilloedema and drowsiness, resembling a rapidly developing cerebral tumour syndrome.

Lumbar puncture confirms the diagnosis by the finding of blood or xanthochromic fluid. Where the haemorrhage has been essentially intracerebral, blood is usually absent from the cerebrospinal fluid, but it is surprising how rapidly the fluid may alter, showing a rise in leucocytes and protein content. There are cases of intracerebral haemorrhage which may show a relatively normal cerebrospinal fluid at any early stage, whilst a few days later it may be frankly blood-stained although the patient's clinical condition has remained unchanged or has even improved. This is due to the intracerebral clot discharging itself into some part of the cerebrospinal fluid pathways. In an absolutely uncomplicated subarachnoid haemorrhage the cerebrospinal fluid will have returned to normal in about three weeks. Intracranial tension is usually much raised in cases of intracranial haemorrhage, but in intracerebral clot formation, particularly in the elderly, the pressure may be low, as it is in some cases of chronic subdural haematoma. Although in our experience diagnostic lumbar puncture has never been detrimental, it should be performed with caution, particularly in those cases showing evidence of an early tentorial pressure cone.

Angiography

The essence of investigation of spontaneous intracranial haemorrhage is angiography, and until this has been performed, in the majority of cases, the site and the cause of the haemorrhage are both unknown, and definitive surgical treatment cannot be contemplated. We believe, at this stage in our knowledge, that angiography should be performed on all cases of intracranial haemorrhage unless they have considerable arterial hypertension, which we have regarded as a contraindication. This view may be fallacious, as four of these patients have all died of subsequent haemorrhage within a few months.

The need for angiography at present is to obtain further knowledge, particularly of prognosis as well as the planning of treatment. Our usual practice is to perform angiography by the percutaneous insertion of a needle into the common carotid artery under local analgesia, but in a restless or non-cooperative patient general anaesthesia may be necessary. From 10 to 15 ml. of 35% diodone is injected, which gives a clear radiographic picture of the blood vessels. This must be performed on both sides in all cases, with compression of the opposite carotid artery to prove the adequacy of the collateral circulation through the circle of Willis.

Having made such a demand for angiography, it is only right that its possible dangers should be carefully considered. In only one case in which angiography has been performed for the diagnosis of spontaneous intracranial haemorrhage has there been any detrimental result, and this was a mild decrease in the conscious level of a patient who died several weeks later with infarction in the region of the hypothalamus and the anterior portion of the corpus callosum, the angiographic pictures having been thought to be quite normal. In 200 consecutive carotid angiographies performed for a variety of reasons, there has been one death, due to a thrombosis of the internal carotid artery

which was the site of a previous partial occlusion. Seven other patients, all suffering from organic brain disease, have shown some transient increase of physical signs following the investigation. Air studies of the ventricles are necessary only in confirming the presence of an intracranial clot, though ventriculography at a later stage may show a cyst which was a previous clot cavity in communication with the ventricle. The method should be by ventriculography rather than air encephalography, so that the intracranial pressures are disturbed as little as possible to avoid a recurrence of bleeding. An electroencephalogram is a useful adjunct to other investigations in cases of intracranial clot, and also in proving the tolerance of carotid artery occlusion.

Some Outstanding Facts

Using these methods of investigation in 50 consecutive cases referred to us for a variety of reasons and at variable lengths of time after the initial haemorrhage, certain outstanding facts emerge from their comparison with the 100 cases previously referred to in this paper. The first point is that the causes of haemorrhage demonstrated in the living differ from those found in the dead. In all reviews of the natural history of spontaneous intracranial haemorrhage based upon necropsy findings, aneurysm is the greatest cause, but angiographic investigations in the living show a much higher incidence of angioma. Even after severe haemorrhages, and in some cases where large intracerebral clots exist, no cause can be demonstrated either on angiographic investigation or at operation. This is not surprising, since haemorrhage can occur from minute angioma of capillary type, and this has been the cause of large intracerebral haemorrhages in two of our cases.

It is also true that aneurysms which are not visible on angiography, because of their small size or the almost complete occlusion of their cavity by clot, may be the cause of severe haemorrhage. In this respect one patient of ours, having a left-sided aneurysm which had given rise to bleeding and a right-sided hemiparesis, died in hospital as a result of haemorrhage from an aneurysm of the right internal carotid bifurcation which could not be seen on angiography four days previously. At necropsy this aneurysm was found to be completely full of clot, and a slit in the arterial wall beside the aneurysm had caused this torrential haemorrhage. The usual finding, however, will either be a typical small aneurysm, an angioma, or, more rarely, a very large saccular aneurysm which may have reached most remarkable dimensions. It is in these large aneurysms that relatively small haemorrhages seem to occur into the aneurysmal wall, producing cranial nerve paralysis by direct involvement of the nerves and large amounts of clot within the sac.

The following table of figures compares the post-mortem findings in the deaths occurring in the 100 cases treated conservatively with the angiographic and operative findings in those treated surgically, and demonstrates the different aetiological factors in the living and the dead.

Cases of Spontaneous Intracranial Haemorrhage

	100 Cases Treated Conservatively (43% Initial Mortality)	50 Cases Investigated and Treated Surgically (12% Immediate Mortality)	
		Living	Dead
Findings at 35 Necropsies			
Aneurysms	29 (85%)	29 (58%)	5 (10%)
Angioma	2 (6%)	8 (16%)	0 (0%)
No cause found	4 (11%)	11 (22%)	1 (2%)

Angiography may demonstrate the cause of the haemorrhage and also show distortion of the cerebral vessels indicative of intracranial clots.

In several cases we have been surprised to find at operation that upward displacement of the middle cerebral vessels shown on angiography, and suggesting a clot in the temporal lobe, has proved to be due to long-continued local oedema. The findings on investigation may demonstrate the basic pathology, but the vascular anomalies alone cannot always explain neurological disturbances of widespread nature which may occur. Although the angiographic

picture of the major arterial tree may appear complete, terminal branches may be affected by either thrombosis or spasm leading to these additional gross and widespread signs. In 3 of the 50 cases surgically investigated no obvious abnormality was found on angiography or ventriculography apart from ventricular dilatation of unknown cause. These patients have all demonstrated a condition of prolonged akinetic mutism and varying autonomic disturbances, and have eventually died. In the two cases in which post-mortem examinations were performed there were small areas of infarction in the medial surfaces of the frontal lobes and hypothalamus, with a tiny aneurysm of the anterior cerebral artery.

Treatment

With all the results of investigations at our disposal four distinct lines of treatment become obvious: non-intervention, to allow natural recovery; evacuation of large intracranial clots; proximal ligation of vessels; and direct attacks upon aneurysm or angioma. Sympathetic interruption is still open to question, but we believe, from the extreme narrowness of vessels often seen on angiography in these cases, that spasm is likely to be present. The aim must be to save the patient's life, make his future more secure, and improve his chances of recovery from severe neurological disability, but in so doing never exposing him to a greater risk. Our investigations have shown such a diversity of gross vascular anomalies, with amazing recovery by natural means alone, that we are sure no one should be exposed to a great risk for an uncertain purpose. Many of these natural recoveries have been so good that they would have delighted the heart of any surgeon who had operated and thought his act responsible for the recovery.

Evacuation of intracranial clots usually means the evacuation of intracerebral ones; the majority of the clot, however, may be in the subdural space, particularly in children. The removal of these clots is not technically difficult; in the acute case it is life-saving, and in the more chronic one it reduces the likelihood of severe persistent disability. These intracerebral clots have certain interesting features: in any particular area the enlargement of clot from the haemorrhage is always along certain apparent well-defined tracks, with the ventricular wall forming the inner boundary. In the very chronic cases the clot is still solid, with a reactive glial wall forming around it, stained yellowish-brown from blood-pigment absorption. Within such a clot cavity will lie the cause of the haemorrhage, and in our experience this is always in one of the walls and not in the centre of the cavity. It is through such clot cavities that aneurysms and angioma may easily be exposed and local treatment decided upon. In the 35 post-mortem examinations from the 100 cases treated conservatively, 34% had large intracerebral clot formations, and there is no doubt that these clots were the cause of fatality in most of these cases. In the 50 cases surgically managed, 16, or 32%, have had intracerebral clots. All those from whom clots were evacuated survived, but mistaken surgical judgment in three cases resulted in death of the patient with large cerebral clots existing. Cases with oedema simulating clot benefit a great deal from decompression; therefore the distinction is less important than would be theoretically apparent.

We believe that, whenever possible, proximal arterial occlusion should be the first consideration in any case, and that in many it will remain the ideal or only method applicable. Proof of tolerance of carotid occlusion must always be sought by angiography and trial compression before it is utilized as a permanent treatment. The form of proximal arterial occlusion is best considered according to the type of lesion and its situation. Let us first consider varieties of intracranial aneurysm in this respect. For those upon the internal carotid artery or at its bifurcation there is no doubt that ligation of the common carotid artery, followed at an interval by that of the internal itself, is of great value in reducing the intra-arterial pressure at the site of the aneurysm and leading to thrombosis of the aneurysmal cavity. We hope shortly to show by recordings

of the intra-arterial pressure above the point of arterial occlusion that adequacy of anastomotic circulation can be assessed accurately, and certainty or uncertainty of tolerance predicted. For aneurysms upon the anterior cerebral artery, proximal ligation of the anterior cerebral artery itself just beyond its origin is advised. This also applies to the posterior cerebral artery. For the posterior communicating artery temporary carotid ligation should be employed, with direct attack upon the aneurysm itself in chosen cases. This also applies to aneurysms of the middle cerebral artery, though we are still uncertain of the best treatment of aneurysms affecting this essential vessel.

The angioma of large size, particularly when they are basal or medial in position or bilateral in extent, are often amenable only to treatment by arterial interruption. Here, as in the case of aneurysms, each and every case must be judged on its own merits, its individual anatomy, and its tolerance to arterial interruption. In this respect individual anatomy often causes great surprise: in one of our cases having a large bilateral angioma in the medial surfaces of the frontal lobes angiography showed that the blood supply to the angioma passed through the internal carotid arteries, and that the normal circulation of the brain was via the external carotid and vertebral arteries. This patient tolerated ligation of both internal carotid arteries, but digital compression of both common carotid arteries immediately proved them to be well named as the arteries of sleep, for the patient immediately became unconscious, only to recover within seconds of release of the compression.

It is important to appreciate the individuality of the cerebral circulation and the need for careful proof of tolerance of its interruption. In particular, ligation should not be performed whilst the collateral circulation may be in jeopardy from high intracranial pressure due to intracranial clots, which must be removed by operation before arterial interruption is undertaken. In this respect sympathetic interruption and carbon dioxide inhalation to produce vasodilatation of the cerebral vessels may be useful to improve the cerebral collateral circulation.

The exposure of aneurysms is usually not in itself technically difficult, although it may prove an anxiety to the surgeon and his assistants. The fear of torrential haemorrhage always exists, even though this can be controlled to a large extent by hypotensive drugs and arterial compression. There is really no part of the circle of Willis above the tentorium which cannot be exposed surgically, but, when an aneurysm is found, often only one side of it can be seen so that a number of vessels taking origin from the aneurysmal wall may remain unseen. Carotid interruption will reduce the pressure in aneurysms even of the posterior communicating artery; at operation we have seen fairly large vigorously pulsating aneurysms of this artery cease pulsating, both visually and to a palpating finger, when the carotid artery has been occluded in the neck. If at this stage the aneurysmal wall is opened, blood flows from the aneurysm in a steady stream, which undoubtedly represents the diastolic pressure. The aneurysmal cavity can now be packed with muscle, bleeding controlled, and the cavity completely obliterated. We believe that packing of the aneurysm in appropriate cases is the best treatment, and, failing this, wrapping of the aneurysm in muscle or gauze. The wrapping of an aneurysm is possible only when it is completely exposed, and we have found it to be of considerable value with the small dangerous aneurysms of the middle cerebral artery. Clipping the neck of an aneurysm has not been possible in our hands, and we doubt if by this method the danger area of the aneurysm—namely, the neck and its junction with its parent artery—is rendered safe. It is unfortunate that obliteration of the aneurysmal cavity is no proof that there will not be a torrential haemorrhage from rupture of the artery close to the neck of the aneurysm, which itself is full of organized laminated clot. We must therefore follow up with great care our cases, treated surgically, to see if their future is better than that of those treated conservatively.

The removal of a cerebral angioma may be very simple, particularly if it is a small one lying within the wall of a

clot cavity or cyst cavity resulting from a previous haemorrhage. On the other hand, a large ramifying angioma may be extremely difficult to remove and the patient's life jeopardized by the attempt. We must remember, therefore, that the natural history of the angioma is not so menacing to the patient's life as that of aneurysms. These angioma must be very carefully assessed and the patient's disability considered before removal is decided upon. Certainly it has not been our experience that epileptic attacks can be diminished by the removal of these vascular anomalies.

Surgical treatment as outlined above will undoubtedly reduce the number of deaths due to intracranial haemorrhage of varying cause and severity, particularly those deaths occurring several days after the initial haemorrhage. It is unlikely that the mortality rate over the first 24 hours will be altered very much. It will be remembered that 34% of the cases examined at necropsy in the conservatively treated group had large intracerebral clot formations, and it is true to say that a large percentage of this group could have been saved by surgery. Well-planned proximal ligation will reduce the pressure within the aneurysm and its parent vessels and probably reduce the incidence of recurrent haemorrhage. The incidence of recurrent haemorrhage will also be reduced in those cases in which aneurysms or angioma are completely removed.

The reduction in the mortality rate inevitably increases the number of patients surviving with a disability, and, whereas in the conservatively treated group 35% of the survivors had residual defects, 52% of the survivors in the surgical group were left with some form of neurological disability. In only 12%, however, was this severe enough to prevent gainful employment, and it was in these six patients that the three late deaths occurred. Disabilities among the survivors from spontaneous intracranial haemorrhages make the need for physiotherapy, speech therapy, and nursing care greater. The provision of facilities for investigation, treatment, and aftercare of these patients is an increasing problem in the neurosurgical departments of the country.

Conclusion

Spontaneous intracranial haemorrhage is a dangerous and treacherous occurrence. The initial catastrophe may be overwhelming, and death may take place in a few minutes or hours; but, should a victim of such a haemorrhage survive beyond this, other dangers no less severe lie before him. Provided the first 24 hours are passed few deaths occur in the first week, whilst in the second week the number of deaths equals that of the first 24 hours, unless surgical investigation and treatment are undertaken. These later deaths are due mainly to large intracranial clots or recurrent haemorrhages. The surgical aim, therefore, should be to investigate these patients in the first week after the initial haemorrhage, so that intracranial clots may be removed or other operative procedures performed to prevent recurrence of haemorrhage. Investigation of spontaneous intracranial haemorrhage is of great importance, for there is no doubt that surgical intervention can improve the individual patient's expectancy of life and reduce his neurological disabilities.

Summary

One hundred cases of spontaneous intracranial haemorrhage treated conservatively have been analysed and compared with 50 cases investigated by angiography and treated surgically. It has been shown from these figures that angiography should be done in the first week following the haemorrhage, so that removal of intracranial clots and the treatment of vascular anomalies by proximal ligation or direct attack may be undertaken in order to prevent recurrence of haemorrhage. It has been stressed that caution is needed not only in treatment but in assessing its curative value. There is no doubt that great help can be given to individual patients and the mortality rate considerably decreased.

REVIEW OF MENTAL ILLNESS IN THE OLDER AGE GROUP

BY

E. ELIZABETH ROBERTSON, M.B., M.R.C.P.Ed.
D.P.M.

Assistant Physician, Royal Edinburgh Hospital for Mental
and Nervous Disorders; Lecturer in Psychiatry,
University of Edinburgh

AND

N. L. MASON BROWNE, M.B., Ch.B.

Assistant Physician, Royal Edinburgh Hospital for Mental
and Nervous Disorders

This review of 198 female patients admitted at the age of 60 or over to one particular section of the Royal Edinburgh Hospital for Nervous and Mental Disorders is designed to call attention to the wide variety of clinical syndromes found in this age group. The choice of the age of 60 as a base-line is deliberate, and is a tacit recognition of the conventional tendency to attribute any gross deviation in thought and conduct observed in patients over 60 to a greater or less degree of "senile" pathological change in the cerebral vessels or brain parenchyma. It may be remarked at the outset that our findings do not corroborate this popular assumption. Many other types of toxic-infective, neoplastic, or degenerative cerebral disease may be the underlying cause. Moreover, while it is wise to look first of all for an organic lesion to explain mental symptoms at this period, it is also true that the so-called "functional" psychoses—notably depression—may erupt for the first time in the individual's life cycle after the age of 60. All these alternatives add to the difficulty of diagnosis, but they also imply that prognosis and reaction to treatment may be better than is usually thought.

In the past ten years many excellent papers have appeared on this subject of mental illness in the older section of the population. The majority of these, however, deal with the statistical implications of the rise in mental morbidity in this group. Only a minority are devoted to clinical aspects. This discrepancy has been emphasized by Professor Aubrey Lewis (1946), who states: "The clinical is probably now the most neglected field in the study of the psychiatry of ageing. . . . I would therefore plead for a greater interest in the straightforward clinical aspects of mental disorder as seen in the aged." Even in the few clinical studies published, clinico-pathological confirmation is sometimes lacking, yet it is precisely in mental illness in the elderly, which is often too readily ascribed to senile degenerative processes, that necropsy studies are most valuable.

Clinical Material

The 198 patients reviewed represent all the female patients of the age of 60 or over admitted to one section of the hospital during the six-year period January 1, 1946, to December 31, 1951. Each patient was studied by one of a group of six physicians, and all were under the observation of one of us (E. E. R.) throughout their stay in hospital in the period under review. The number of admissions of the over-60 group during this period was 244, and the number of individual patients 198. The discrepancy between the two figures illustrates the well-known tendency for affective psychoses to recur; for, apart from a few patients with "arteriosclerotic episodes," nearly every patient with two

or more periods in hospital suffered from recurrent manic or depressive episodes. The social background of the patients can be summarized by the statement that they represented a cross-section of all social grades with the exception of the very wealthy.

At the end of the five-year period 81 (41%) had been discharged, 38 (19%) were still in hospital, and 79 (39%) had died. (These figures refer to individual patients.) Thirty-four necropsies were performed, representing 43% of all deaths. This is not as high a necropsy percentage as we could have wished, but every doubtful case was included. This may be illustrated by reference to group II, which included the supposedly rare organic states, such as Alzheimer's disease, Pick's disease, cerebral tumour, etc. In this group necropsy was carried out in every case of death. In addition 14 necropsy reports on patients admitted at the age of 60 or over during an earlier period, but dying in the period under review, were scrutinized for comparison. Of the 14 patients, 10 suffered from an organic cerebral disease and four from a depressive psychosis.

The diagnostic classification of the 198 patients is summarized in the accompanying Table.

	Total	Age on Admission		Deaths During Period	% Necropsies to Deaths
		60-69	70+		
A. Unequivocally organic psychoses (total, 92):					
Group I: Cerebral arteriosclerosis and senile dementia	68	9	59	47	30%
Group II: Organic cerebral disease not included in group I:					
(a) Alzheimer's disease 10	24	24	—	11	100%
(b) Pick's disease 2					
(c) Cerebral tumour 3					
(d) Amyotrophic lateral sclerosis with mental symptoms 1					
(e) Syphilis 3					
(f) Drug intoxications 3	7	5	2	6	
(g) CO poisoning—cerebral lesion 1					
(h) Myxoedema 1					
B. "Functional" Psychoses (total, 96)					
Group III: Affective states:					
(a) Uncomplicated:	58	51	7	4	
Depression 54					
Mania 4	7	5	2	6	
(b) Depression secondary to physical disease:					
(i) Extrapyramidal disease 3					
(ii) Cardiac disease 2					
(iii) Aortitis 1					
(iv) Carcinoma 1					
Group IV: Paraphrenia and schizophrenia	65	56	9	10	40%
Group V: Psychopathic states	23	15	8	6	33%
C. Group VI: Mixed organic and affective symptomatology (total, 10)	8	8	—	—	
	10	7	3	5	66%

A. Organic Psychoses.—Slightly less than half the total number of patients reviewed (92 out of 198, or 46.5%) suffered from organic psychoses—that is, they displayed intellectual and emotional disturbances of the type found in association with pathologically verifiable lesions within the brain (groups I and II).

B. Functional Psychoses.—The number of patients diagnosed as suffering from one or other of the so-called "functional" psychoses (affective states, schizophrenia, psychopathic states) was roughly similar, being 96 out of the total 198, or 48.4% (groups III, IV, and V). Here the mental disturbance was confined to the emotional sphere and intellectual defects were absent. (We are aware that this differentiation between organic and "functional" psychoses on a

basis of presence or absence of intellectual defects is an over-simplification. The aggregation of mental symptoms seen in frontal lobe tumour or as a sequel to some cases of encephalitis, for instance, may include no intellectual defects measurable as such, yet they none the less warrant the designation of organic psychoses. But, accepting this dichotomy between "emotional" and "intellectual" as artificial, it is nevertheless a useful abbreviation for present purposes, and avoids the necessity for summarizing the other manifold criteria of differentiation between the organic and "functional" psychoses.)

C. In 10 of the 198 patients, or 5%, difficulty was experienced in deciding whether the patient was suffering from a pure affective state—the predominant affect in all 10 was depression—or whether senile organic change coincided. They are accordingly classified under the designation "mixed symptomatology" (group VI).

Age Incidence

Illustrated in Fig. 1 are the relative proportions in each diagnostic group, and also the age incidence. It will be noted that by far the greater number of patients diagnosed

FIG. 1.—Diagnostic groups.

as suffering from cerebral arteriosclerosis and senile dementia (group I) were aged 70 and upwards at the time of admission; only 9 of the 68 were aged 60 to 69. An almost exact reversal of this ratio is found in the second largest numerical group of affective states (groups III, a and b), where 56 were aged 60 to 69, and only 9 were aged 70 or upwards at the time of admission. Patients suffering from organic cerebral disease other than cerebral arteriosclerosis and senile dementia (group II) were all aged 60 to 69 on admission. The smaller groups IV, V, and VI show a similar preponderance. This suggests that mental symptoms occurring in patients between the ages of 60 and 69 give rise to infinitely more varied diagnostic possibilities than those occurring in later decades.

A. Organic Psychoses (92 Cases)

Group I: Senile Dementia and Cerebral Arteriosclerosis (68 Cases)

Sixty-eight patients—approximately one-third of the total patients reviewed—suffered from cerebral degenerative processes classically associated with old age, and of these only 9 were under 70. Senile dementia (in which degeneration occurs primarily in the parenchyma of the brain) and cerebral arteriosclerosis have been bracketed together, since, despite the dicta of some writers, they are not always easy to differentiate on clinical grounds alone. The slow but relentless mental deterioration, global memory defect, and absence of focal neurological signs seen in senile dementia have been contrasted with the fluctuating course, greater retention of personality, and frequency of focal signs regarded as characteristic of cerebral arteriosclerosis. Admittedly, the typical case of either is easily recognized. For instance, using the accepted criteria of diagnosis of cerebral arteriosclerosis, we readily concluded, on clinical examination alone, that 8 of the 9 cases in the 60 to 69 age group and 15 of the 59 aged 70 or over were suffering from cerebral arteriosclerosis and not senile dementia. But cerebrovascular disease does not invariably present with the triad of signs popularly ascribed to it. When vascular changes occur primarily in the smaller cerebral arteries—a condition which by reason of its specific pathology warrants the separate title of *arteriolosclerosis*, the clinical picture closely simulates that seen in senile dementia. And even *atherosclerosis*, or disease of the larger arteries, particularly when it occurs after the age of 70 and is "decreased" in type—that is, unaccompanied by peripheral hypertension—may follow a steady unremitting course, more reminiscent of senile dementia than "classical" arteriosclerosis. Another obvious difficulty is that these pathological conditions may appear in combination. In 24 consecutive necropsies the lesion was found to be sufficiently discrete to merit subdivision in 16, which were made up as follows: atherosclerosis 8, arteriolosclerosis 3, and senile dementia 5; while the remaining 8 cases showed varying combinations of parenchymatous and vascular disease. We stress these points deliberately because we have observed that writers demarcate these conditions on clinical grounds alone, and on this dubious basis draw conclusions on their relative frequency. Although we believe that there are many subtle differences in the mental picture to act as pointers in the differentiation of these senile pathological processes, and that it is an obligatory clinical exercise to attempt such differentiation, we are convinced that separation into two arbitrary categories should not be made unless all the cases considered have been submitted to necropsy.

Group II: Organic Psychoses other than Senile Dementia and Cerebral Arteriosclerosis (24 Cases)

In this group the underlying cerebral lesion was the result of a variety of causes, including infection, intoxications, and tumour, such as may occur at any period of life, or degenerative processes of the Pick or Alzheimer type, the aetiology of which is as yet unknown, but which characteristically appear between the ages of 40 and 60—that is, in the "presenile" rather than the senile period. The various syndromes are included in the Table and are illustrated in Fig. 2. This group of patients, all of whom were aged 60 to 69 at the time of admission, numbered 24. This figure should be set beside the number of patients admitted in the same age decade with cerebral arteriosclerosis or senile dementia, who totalled only 9. The nature of our material precludes the drawing of too narrow conclusions from these figures, since it is probable that patients with mild or transient defects based on cerebral arteriosclerosis, for instance, may never be admitted to a mental hospital. Nevertheless, they emphasize that many aetiological factors require consideration before a final diagnosis is made on an organic mental picture occurring between the ages 60 to 69.

Infections and intoxications do not on the whole give rise to difficulty in diagnosis, since the history is usually sugges-

tive and the bacteriological findings are often conclusive. But it is rare to find the presenile degenerative states and cerebral tumour diagnosed before admission—they are most commonly presumed to be cases of cerebral arteriosclerosis or senile dementia. The failure to recognize tumour rests in part on the tendency to regard headache, vomiting, and papilloedema as early and invariable symptoms, whereas in patients of this age group they are either late in developing or may never appear at all. But a more frequent cause of non-recognition is the tendency to mistake or disregard

FIG. 2.—Analysis of organic psychoses.

focal signs in the psychic sphere. An aphasic defect in the form of difficulty in naming objects, for instance, may be put down to generalized memory loss. A more severe sensory aphasia may be interpreted as apathy and indifference, or even deafness.

Alzheimer's and Pick's Diseases.—These presenile degenerative diseases accounted for the admission of 12 of the 198 patients reviewed, or approximately 6%. Since they are reported to occur more often in women than in men, a comparable group of male patients might not be expected to show quite the same high incidence. In 10 of the 12 patients, symptoms had appeared before the age of 60. There was reason to believe that the same was true of the remaining two, but their histories could not be adequately ascertained. Necropsy was carried out on all patients who died (Alzheimer's disease, 5; Pick's disease, 1) and the diagnosis confirmed. A long history of steady intellectual decline beginning before the age of 60 should give rise to the suspicion of the existence of one of these presenile degenerative disorders. A remarkable finding in this group is the lengthy duration of the illness before referral for medical opinion—relatives accepting the manifold disabilities of the patient without query. Aphasic and apractic defects are invariably present, and the degree of intellectual deterioration is much more profound than that found in any patient of equivalent age with cerebral arteriosclerosis—unless the latter is accompanied by a severe degree of peripheral hypertension. We believe that Alzheimer's disease and Pick's disease are less rare than is supposed. It is not submitted, of course, that their recognition results in any practical therapeutic advantage to the patient. Nevertheless, at some future date their aetiological elucidation may throw light on general problems of ageing, and, at the present

time, statistical surveys of the older hospital patient which neglect the separate diagnosis and classification of this group result in an erroneous interpretation of the frequency of the true senile degenerative states.

B. "Functional" Psychoses (96 Cases)

Incidence of Earlier Mental Illness.—One feature in particular distinguishes the functional psychoses from organic cerebral disease, and that is the frequent finding of earlier mental illness in the former. Such earlier mental illness may have been episodic, as in the affective states, or continuous, as in the majority of cases of schizophrenic or paraphrenic disorder. Or again, as in the psychopathic states, the patient may have shown lifelong aberrations of conduct—such aberrations only on occasion reaching sufficient magnitude to require admission to a mental hospital. In all these cases age may be of little or no importance in aetiology.

Group III: Affective States

Affective psychoses occurring at the age under review customarily take the form of depression—manic reactions are infrequent. This high incidence of depression found in later life has long been recognized by mental hospital physicians. Clouston (1904), in an analysis of cases of "senile insanity," stresses the frequent occurrence of "simple melancholia," adding, "its only special senile character being that it occurred in old people." This phrase admirably describes the cases considered in group III of this series. These also showed the incidental features associated with depression whatever the age of onset, as follows:

1. **High Incidence of Previous Affective Illness.**—All four patients with a manic reaction and 27 of the 54 patients with uncomplicated depression had a history of one or more attacks of a similar illness before the age of 60. All had been capable of normal work in the interval. The remaining 27 of the 54 patients with depression—that is, 50%—had no previous history, and this was also true of no fewer than six of the seven patients who became pathologically depressed in the course of a severe systemic illness.

2. **High Incidence of Attempted Suicide.**—A determined suicidal attempt had been made immediately before admission by 15 of the total group of 65 patients, or 23%. (The methods utilized were: coal-gas poisoning, 6; corrosive poisoning, 2; barbiturate poisoning, 1; cut throat, 2; severed arm vessels, 1; jumping from window, 3.)

3. **Relatively Good Prognosis.**—By December 31, 1951, three of the four patients with a manic reaction had been discharged recovered. Of the 54 patients with uncomplicated depression, 34 (63%) had been discharged recovered. Of these 34 recoveries, however, six had been admitted on two or more occasions during the six-year period with recurrent depressions, and the prognosis in regard to the future of these six was doubtful. This leaves a corrected sustained recovery rate of 28 out of 54 cases of depression, or 52%. Twenty of the 54 did not recover, and, of these, four had been discharged, twelve were in hospital and four had died by the end of the period. Electric convulsion therapy was given to 32 of these 54 patients aged 60 or over. A surprisingly large number recovered in the first month following admission without the aid of E.C.T. A similar observation has been made by Karagulla (1950) in a study carried out in this hospital on a large series of depressions in all age groups. Of the seven patients (group III, b) whose depression occurred on a background of severe physical illness, six died as a result of the underlying illness and one was discharged.

4. **Absence of Gross Histopathological Findings in the Brains of Patients Dying During a Depressive Illness.**—The absence of intellectual defects in the clinical picture of these senile depressive states was reflected in a similar absence of gross cerebral pathological change in those cases submitted to post-mortem examination. The histopathological findings in eight cases (four belonging to this series and four relating to similar patients admitted before 1946 but dying in the period under review) in no way differed from those reported in patients dying at the same age period with other than mental disease. Slight gyral atrophy, slight patchy atheroma, or a minor degree of arteriosclerosis unaccompanied by gliosis or cellular loss were usual findings. Two cases showed no pathological abnormalities.

Relationship of Depressive Psychosis to Ageing.—The finding that 50% of all patients with depression had no history of a similar illness in earlier life—and the additional

finding that in the 50% previously affected long periods of normal functioning had intervened between their former illness and present breakdown, would suggest that the ageing process plays some contributory part in the causation of such depressive illnesses. In this respect depression differs from the other functional psychoses responsible for the admissions of patients in this age group (see below).

Group IV: Schizophrenia and Paraphrenia (23 Cases)

In this group a history of earlier mental illness was obtained in no fewer than 20 of the 23 patients, and in these cases the description given was rarely one of episodic breakdown with intervals of normal functioning as in the foregoing cases of recurring depressions, but took the form of a long-standing socially incapacitating mental illness. In 15 of these 20 the lengthy duration of the illness was confirmed by hospital case records, in 5 by evidence of relatives. Illnesses of 20 to 30 years' duration were common. One patient had first been admitted to this hospital 42 years previously, had been removed a year later, and had lived the life of a recluse under the care of her relatives until her second admission at the age of 68. It was more common to find that these patients had a history of frequent long sojourns in hospital, yet their records also illustrated that a florid schizophrenic thought disorder was not incompatible with equally long periods spent outwith hospital supervision. These are, of course, commonplace facts of mental hospital experience. They are reiterated here in order to stress that admission to hospital with a schizophrenic or paraphrenic illness after the age of 60 does not necessarily imply that the patient first developed symptoms at this age. In only 3 of the 23 patients in this group was the illness of seemingly recent onset. It is appreciated that paranoid symptoms as distinct from paraphrenia are common in this age group. They may occur in depression or in association with organic cerebral disease. But the "systematized delusional insanity" of the older writers would appear from these figures to begin only infrequently after the age of 60.

Group V: Psychopathic States and Epilepsy

These eight patients had shown lifelong aberrations of conduct: in five these aberrations had been so severe as to lead to frequent earlier admissions to a mental hospital. In three the conduct disorder had displayed itself in chronic alcoholism; one suffered from epilepsy, with concomitant emotional disturbance; while the remaining four had displayed antisocial conduct throughout life. This number does not truly indicate the proportion of such patients admitted at the age of 60 or over. Two of the cases of drug intoxications in group II were drug addicts with psychopathic character anomalies. One of the cases of cerebral arteriosclerosis in group I had a long history of behaviour disorder, including chronic alcoholism, and had been admitted at an earlier age with a Korsakoff's psychosis. The necropsy findings in this case revealed, in addition to vascular softening, an extreme reduction in size of both mamillary bodies—an observation of interest in view of the earlier Korsakoff's psychosis. Nevertheless, if a few such cases with psychopathic character anomalies are added, the total number is still small. This corroborates the accepted hypothesis that age, by diminishing the aggressive urges, ameliorates to some extent the condition of this unfortunate group (Henderson, 1939).

Group VI: Mixed Affective and Organic Symptomatology (10 Cases)

The predominant affect in all these 10 patients was depression—four had made determined suicidal attempts before admission—yet they also showed features suggestive of organic cerebral disease. Only two recovered. Their recovery was rapid; electric convulsion therapy was not given, and afterwards they showed no intellectual defects other than those explicable in terms of normal senility—both were over 70.

The remaining eight formed a homogeneous group, alike in clinical symptomatology and the intractable and distress-

ing nature of the illness. All displayed extreme agitation, perseveration in speech and action, and, finally, profound deterioration in personal habits. Of these eight patients five received one or more courses of convulsion therapy, and prefrontal leucotomy was later performed on one of these five. At the end of the period reviewed, three were still in hospital unchanged and five had died. Necropsy was carried out in three of the five deaths. In the first, macroscopic and microscopical examination of the brain was negative; gyral atrophy and a mild cortical arteriosclerosis were demonstrated in the second; while in the third a somewhat more severe arteriosclerosis with slight nerve-cell loss was reported. All three patients were aged 65 to 69 at the time of death. While it would be tempting to postulate of the eight cases showing this malignant syndrome that senile cerebral changes may aggravate and perpetuate a depressive illness, no conclusions can be drawn from these equivocal findings in a small number of necropsies. It may be that, despite the seeming organic nature of part of their symptomatology, these patients actually suffered from a true depression and that the necropsy findings are fortuitous. We feel, however, that their separation from the other cases of depression in this series is justified both by reason of the particular clinical picture shown and because they emphasize the existence of a group of resistant depressions not susceptible to amelioration by physical methods of treatment.

Summary

A review is made of a group of 198 female patients admitted to a mental hospital at the age of 60 and over. Attention is drawn to the diversity of clinical syndromes found.

Approximately one-third of the total suffered from the cerebral degenerative processes commonly associated with old age—namely, cerebral arteriosclerosis and senile dementia. These two conditions are bracketed together, since necropsy studies indicated that they could not always be differentiated on clinical findings alone. One-eighth of the patients suffered from other types of cerebral disease, and this demonstrates that organic dementia occurring in later life should not be too readily ascribed to cerebral arteriosclerosis or senile dementia.

Approximately another third of the total were admitted with a diagnosis of depression. Half of these patients had a history of previous depressive episodes, while half developed a depression for the first time after the age of 60. This suggests that age has some importance as a contributory factor. Two smaller groups of patients were diagnosed as suffering from schizophrenic-paraphrenic psychoses and psychopathic states. The history in almost all these cases revealed that the psychosis or personality anomaly had been manifest long before the age of 60.

All these findings denote that *en bloc* statistics of mental hospital admission can give only inadequate information on the mental sequelae of ageing.

Our thanks are due first of all to Professor Sir David K. Henderson, not merely for permission to publish these cases, but for his teaching, with its emphasis on the importance of exact diagnosis in the organic psychoses. We are indebted to Professor A. M. Drennan and his associates in the neuropathology department, Edinburgh University, for the detailed pathological reports. It is a pleasure to acknowledge the help of former assistant physicians—notably Drs. S. Karagulla, B. Magill, B. Allen, and J. H. Brown—whose careful case histories revived our memory of the individual patients. The diagrams were drawn by Mrs. N. L. Mason Browne.

EFFECTS OF TESTOSTERONE IMPLANTS IN MEN WITH DEFECTIVE SPERMATOGENESIS

BY

G. I. M. SWYER, D.M., D.Phil., M.R.C.P.

Consultant Endocrinologist, Department of Obstetrics,
University College Hospital, London

The causes of defective spermatogenesis in men are largely unknown, and it will generally be agreed that the methods of treatment, correspondingly empirical, are for the most part ineffective. It has seemed justifiable to try any form of treatment which might help at least some men, and, provided sufficiently accurate data are collected, there is no doubt that trials of this kind are fully warranted. Too often, of course, treatment has been given because a single seminal specimen failed to reach acceptable standards; conclusions drawn from such instances are usually misleading. Consequently, lack of adequately controlled observations in most of the literature dealing with this subject has led to a widespread therapeutic nihilism and its attendant apathy. The prevalence of seminal deficiencies, and our ignorance of how to deal with them, demand, of course, a very different attitude.

There is little doubt that testosterone plays a part in spermatogenesis, though its exact role is still uncertain. There is equal certainty that large doses of testosterone will inhibit spermatogenesis, through its action in depressing the production of pituitary gonadotrophin. Heckel *et al.* (1951, 1952), as is now well known, maintain that on cessation of high-dosage testosterone administration the sperm count rises, not only to its pre-treatment level, but, by reason of a rebound effect, to far higher levels. Other workers have been less impressed by this rebound phenomenon, which is certainly missing from many cases treated according to the method of Heckel. It has seemed possible, on the other hand, that continuous low-dosage testosterone administration might actually stimulate spermatogenesis, or improve sperm motility when this is the deficient characteristic. In order to examine this possibility implants of testosterone have been given to a number of men with various kinds of seminal deficiencies. Implantation was chosen as the route of therapy since it is convenient—a single implant remaining effective for some six months—and affords a slow continuous administration of the steroid.

Material and Methods

The men treated in this series were patients attending the Fertility Clinics at University College Hospital and at the Hospital for Women, Soho Square. Seminal analyses on masturbation specimens were made by a standardized technique, which was the same at both hospitals. They involved determination of volume, density, total percentage of abnormal forms and motility indices according to the method of Emmens (1947) at two or more times. The general plan adopted was to obtain three seminal specimens, each preceded by a three-day (at U.C.H.) or five-day (at Soho) period of abstinence (the difference in period of abstinence seems to be immaterial) before treatment; to administer either two or three 100-mg. pellets of testosterone by subcutaneous implantation at the upper outer aspect of the thigh, just below the iliac crest; and to analyse three further seminal specimens, collected one, two, and three months after implantation. Naturally this plan miscarried on several occasions.

In all, 83 implantations were made in 72 men. Of these, 16 men failed to furnish any post-treatment specimens and so must be discarded. There thus remain for analysis 56 men who received 67 implants. Twenty-eight implantations were of two 100-mg. pellets and 39 were of three 100-mg. pellets of testosterone.

Results

General Effects on Seminal Fluid.—In the first place, the mean figures before treatment for each individual for volume, motility, density, and morphology were compared with the corresponding mean figures after treatment. On this basis, it appears that some degree of general improvement in the seminal fluid was found in 28 individuals, of whom 12 had received 200 mg. and 16 had had 300 mg. of testosterone. In 22 men the findings appeared to be unchanged; while in the remaining six men the post-treatment specimens were definitely worse. In this last group, one man had had 200 mg. and five men 300 mg. of testosterone.

The next step in the analysis was to compare the mean figures for all volumes, motilities, densities, and morphologies before treatment with the corresponding figures after treatment. In dealing with motility it was necessary to find a suitable expression for the comparison of different specimens, the motilities for which might have been recorded at different times after production. For this purpose the "five-hour motility" figure has been used. To calculate this, the motility scores, which range from 4 (maximum) to 0, were plotted against the age of the specimen at the time of scoring, a straight line being drawn through the points. The score at five hours was thus interpolated, and was then expressed as a percentage of the maximum figure 4. Thus, if the interpolated motility index at five hours was found to be 3, the "five-hour motility" would be $\frac{3 \times 100}{4} = 75$.

The overall results are given separately for 200-mg. and 300-mg. implants in Table I. From this it is clear that, in general, both doses had similar effects; that little change in volume was observed; that motility appeared to be improved and density increased; and that the percentage of abnormal forms was slightly increased.

TABLE I.—Mean Values and Standard Errors

		Dose of Testosterone	
		2 × 100 mg.	3 × 100 mg.
Volume (ml.)	Before implantation	3.49 ± 0.24	3.42 ± 0.16
	After	3.81 ± 0.23	3.21 ± 0.15
5-hour motility*	Before	34.89 ± 4.28	20.55 ± 2.57
	After	47.27 ± 4.77	35.73 ± 3.43
Density (millions per ml.)	Before	32.08 ± 9.20	26.62 ± 2.04
	After	37.31 ± 7.56	40.94 ± 2.39

	After	43.66 ± 2.09	35.55 ± 1.07

* For explanation see text.

Motility.—Inspection of the data for individual men showed clearly that where the initial motility was of an extremely low order—the mean five-hour motility figure being 5 or less—implantation was followed by no improvement whatever. Since extreme asthenospermia is thus not susceptible to this treatment, it seemed reasonable to exclude such cases and to compare the pre- and post-treatment data for the remainder. This is done in Table II, from which it appears that comparable improvement is found in both the 200-mg. and the 300-mg. series. Reference to Table III, which combines the results for 200-mg. and

TABLE II.—Effect on Motility, Excluding Cases of Extreme Asthenospermia before Treatment. Mean Values and Standard Errors

% abnormal spermatozoa	Before	35.44 ± 1.66	155	1.139	0.05
	After	37.79 ± 0.88	177		

* Highly significant. † Significant.

Density.—The combined mean densities before and after treatment with 200 and 300 mg. are shown in Table III. The difference is significant, though not highly so ($t=2.035$, $n=313$, $0.01 < P < 0.05$). However, when the differences between the mean pre- and post-treatment figures are examined for 200 mg. and 300 mg. separately (Table IV)

TABLE IV.—Effect on Density of 200 mg. and of 300 mg. of Testosterone

		Mean and S.E.	n	t	P
2 × 100 mg.	Before implantation	32.08 ± 9.20	62	0.434	0.05
	After	37.31 ± 7.56	55		
3 × 100 mg.	Before	26.62 ± 2.04	109	3.780	<0.01*
	After	40.94 ± 3.39	87		

* Highly significant.

it becomes apparent that, while for the former the difference is not significant ($t=0.434$, $n=117$, $P>0.05$), for the latter it is highly significant ($t=3.780$, $n=196$, $P<0.01$). One may conclude, therefore, that an implant of 300 mg. is superior to one of 200 mg. in its effect on sperm density.

Volume and Morphology.—It is clear, from Table III, that implantation was without significant effects on the volume of the ejaculate or on the proportion of total spermatozoal abnormalities.

Pregnancies.—The wives of 20 men became pregnant on 22 occasions, all within six months of implantation. Five of these pregnancies ended with an abortion, the incidence thus being 22.75%. This compares with an abortion incidence of 19.1% in a series of 220 pregnancies in women who attended the Fertility Clinic at University College Hospital; an incidence which, it has been shown, is probably not in excess of the general spontaneous abortion rate (Swyer, 1953). Comparison of the mean pre- and post-treatment figures for the individuals whose wives conceived showed an apparent improvement after treatment in 17 cases, no change in 4, and deterioration in 1. These results suggest that conception may indeed have been assisted by the treatment given.

Complications of Treatment.—Testosterone implantation is an innocuous, simple, out-patient procedure which entails no discomfort and does not prevent the man continuing with his work. No patients had any complaints as a result of the implantations, but extrusion of a pellet was encountered on three occasions. This incident is of no serious consequence, and merely requires the application of a dry sterile dressing until the wound has healed.

Discussion

While the statistical analysis of the results of treatment with testosterone implants strongly suggests that motility and density are, in general, improved, inspection of the individual data has made it quite clear that by no means every patient benefited. There can be no doubt that the patients in this series must have presented a very heterogeneous collection of lesions, and it is entirely probable

that testicular biopsies before treatment would have shown the unlikelihood of improvement—from any treatment—in many cases. Extreme oligospermia (mean density before treatment 5 millions per ml. or less) and extreme asthenospermia (mean five-hour motility before treatment less than 5) invariably remain unaffected by testosterone implantation. Clearly, the more the series is weighted with unsusceptible cases the less obvious will be the results of treatment; just as if, for example, in attempting to demonstrate the efficiency of penicillin in combating infections the series of cases studied contained a high proportion in which the tubercle bacillus was the infective agent.

Assuming, as appears to be justifiable, that the kind of treatment used here is effective in some cases of defective spermatogenesis, it becomes desirable to determine, so far as possible, which patients are most likely to benefit. It is difficult to lay down hard-and-fast rules, but the following impressions may offer some guidance. As mentioned above, men with extreme oligospermia and extreme asthenospermia (regardless of sperm density) are unsuitable for testosterone implantation. Moderate oligospermia (15–20 millions per ml.) with fair or good sperm activity was improved in 12 cases, remained unchanged in 3, and deteriorated in 3. Poor motility (five-hour motility 15–30) with fair or good density was improved in 14 cases, remained unchanged in 3, but deteriorated in 3 others. These two, then, would seem to be the principal varieties of seminal deficiency for which this treatment might prove of value.

It is suggested as a practical basis that three pre-treatment specimens should be examined, to obtain a fair estimate of the general characteristics of the seminal fluid, and that monthly specimens should be tested for three months after implantation. If these show improvement, but no conception occurs within six months, a further specimen should be examined. If this shows deterioration, a second implantation might be desirable. Obviously, the examination of specimens after implantation is of as much importance to the patient as of interest to the physician, since the decision to use further implants will be governed by the response, if any, to the first one.

In our present state of ignorance, no useful purpose is served by speculating on the *modus operandi* of testosterone in this treatment.

Summary

The effect of implanting two and three 100-mg. pellets of testosterone subcutaneously has been studied in 56 men presenting seminal deficiencies of one kind or another. These men received a total of 67 implants—28 of 200 mg. and 39 of 300 mg. The seminal fluid appeared to improve in 28 individuals (12 received 200 mg., 16 received 300 mg.); to be unchanged in 22 men; and to deteriorate in 6 others (1 received 200 mg., 5 received 300 mg.). No significant overall effects on volume and seminal morphology were seen, but there was a highly significant overall increase in motility with both doses of testosterone and in density with 300-mg. implants. Extreme asthenospermia and extreme oligospermia were invariably unaffected by the treatment.

The wives of 20 of the men became pregnant on 22 occasions, all within six months of implantation; 5 pregnancies ended in abortion (22.75%), the remainder going to term.

It is suggested that moderate depression of sperm density (15–20 millions per ml.) or poor motility (other than extreme asthenospermia) with fair or good density offers the best chances of improvement after testosterone implantation.

From Crumpsall Hospital, Manchester

It has been known for many years that there is a tendency to loss of height in late middle and old age (Roberts, 1878). Powys (1901) showed that this loss averages 0.33 in. (0.8 cm.) in every 10 years; the standard deviation of height increases with age, indicating that the rate of decline varies with the individual concerned. Progressive wasting of tissue and the develop-

FIG. 1.—An extreme example of the deformity produced by descent of the thoracic cage into the cavity of the false pelvis.

ment of senile kyphosis of the spine have been regarded as the main factors involved. As a result of these changes there is an approximation of thoracic cage and pelvis (Brown and Smith, 1945), and in some individuals the costal margin may sink into the cavity of the false pelvis. An extreme example of this deformity is shown in Fig. 1. The subcostal and supra-iliac lines, traversing the lowest points of the thoracic cage and the highest points of the iliac crest respectively, were originally employed in abdominal topography as the upper and lower boundaries of the umbilical and lumbar regions. Cunningham (1893) showed that these boundaries were unsatisfactory because the distance between them was so variable that in certain individuals the regions so delineated were extremely narrow or even absent. The more widely separated transpyloric and intertubercular lines have now replaced the older boundaries (Gray's Anatomy, 1949), but are more difficult to define in routine clinical examination. The approximation of ribs and pelvis in elderly patients results in increased abdominal protuberance and may make detailed palpation of the lumbar regions very difficult. It has even been known to cause acute intestinal obstruction as a result of incarceration of gut between the ribs and the walls of the false pelvis (E. C. Hutchinson, personal communication, 1952).

Previous workers have considered that the main aetiological factor is an increased obliquity of the ribs due to senile kyphosis and muscular weakness, but few accurate observations have been made. The present paper records the results of an investigation of the extent, causation, and possible clinical significance of this anatomical change in the aged.

Methods

Observations were made on 340 subjects (152 male and 188 female). Only adults were studied, and almost all were chronic cases in hospital, with an average length of stay of 2.5 years. This makes the results inapplicable to the general population, the changes due to ageing being probably more extreme in these subjects than in the average. All adult age groups were included, but there were a great many elderly subjects, resulting in a high average age of 68 years. In all cases accurate measurements of the height of the patient and the distance between the subcostal and supra-iliac lines were made. The latter measurement is here termed the "pelvi-costal distance," and the ratio of this to the height of the patient the "pelvi-costal ratio." The convention was adopted of recording these values as negative in the individuals in whom the subcostal line was lower than the supra-iliac line, this extreme deformity being found in only four patients.

As the investigation was designed to study the causation and significance of a low, zero, or negative pelvi-costal ratio, all individuals with a value of this ratio below 1% were subjected to full radiological examination of the lumbar and dorsal spine. This sample consisted of 22 males and 32 females, and, as expected, contained a disproportionate number of elderly patients, the average age being 74. A group for comparison was taken from the remaining 286 patients. This group was selected to contain exactly the same number of males and females as the previous group and to have precisely the same age distribution, the method of random numbers being employed in choosing between suitable individuals. It follows, therefore, that the two groups were exactly comparable except that the former consisted only of individuals with an abnormally low pelvi-costal ratio and the latter with an average ratio for the age group concerned. These two groups will subsequently be referred to as the "cases" and the "controls."

The following measurements were considered to be possible factors in the production of an abnormally low pelvi-costal ratio, and were obtained directly from the x-ray plates: (a) the angle between the lower ribs and the anterior border of the lower dorsal spine; (b) the degree of lumbar lordosis expressed as an angular measurement; (c) the length of the lumbar spine; (d) the proportion of the lumbar spine occupied by the intervertebral disks; and (e) the degree of spinal osteoporosis.

The last factor is very difficult to express in a quantitative manner, as has been well discussed by Lachmann and Whelan (1936). It was thought impossible to assess the degree of osteoporosis directly from the radiological density of the vertebral bodies, since this is partly dependent on factors which are difficult to control, particularly the exact photographic exposure and the radiological density of soft tissue superimposed on the vertebral shadow. The effect of osteoporosis on the shape of the vertebral body—that is, the production of biconcave or "fish-" vertebrae—was therefore chosen as the index of its degree. The most accurately centred lumbar and dorsal vertebrae were chosen in the lateral films, and the heights of the anterior and posterior borders and the minimum height near the centre of the vertebra were measured. The amount of biconcavity was expressed as the ratio of the minimum height to the average of the anterior and posterior heights, this ratio diminishing with increasing osteoporosis. An assessment of a single accurately centred vertebra was necessary, since parallax effects make similar measurements erroneous in other vertebrae. In practice there was no difficulty in

Nov. 14, 1953

deciding which vertebrae were the best-centred, and, with the particular radiological technique employed, these were the eighth or ninth dorsal and the third or fourth lumbar vertebrae in the two lateral films used.

Finally, the length of stay in hospital was recorded as an estimate of the degree of immobilization. Although the great majority of the patients were not confined to bed, their activity in hospital was much less than would be likely in similar individuals in their own homes. Standard statistical methods (Snedecor, 1946) were employed in the analysis of the results.

Results

A preliminary inspection of the means of the pelvi-costal ratios of patients classified in decennial age groups (Table I) showed that there was a sudden decrease in the seventh decade. In order to decide whether the decrease of this

TABLE I

Age Group	Males		Females	
	No. of Patients	Mean Value of Pelvi-costal Ratio	No. of Patients	Mean Value of Pelvi-costal Ratio
<41	13	1.9%	7	2.4%
41-50	10	1.9%	22	2.5%
51-60	18	2.2%	24	2.6%
61-70	33	1.7%	32	1.8%
71-80	49	1.6%	52	1.8%
81-90	28	1.6%	49	1.7%
>90	1	—	2	1.7%
Total	152	1.75%	188	2.0%

TABLE II

Sex	Age Group	Mean Value of Pelvi-costal Ratio	Difference	Degrees of Freedom	t Value	P
Males	Below 65	2.04%	0.43	51	3.2	<0.01
	Above 65	1.61%		99		
Females	Below 65	2.47%	0.76	64	4.5	<0.001
	Above 65	1.71%		122		

ratio with age was statistically significant, patients below the age of 65 were compared with those above this age (Table II). It will be seen that the difference between these two age groups is highly significant in both sexes. The results are summarized in the distribution curves in Fig. 2. The distribution in females has a larger mean and scatter and is more skewed than in males owing to the comparatively large number of individuals with a high ratio in the former sex. This may possibly be connected with the greater lumbar lordosis of the female, but there were too few x-ray films taken of individuals with a high pelvi-costal ratio to assess this aspect of the problem. Relevant statistical values of the distribution curves in the two sexes are given in Table III. The curve in males does not differ significantly from a normal distribution, while that for females is clearly skewed, so that the modal value is much less than the mean.

FIG. 2.—Distribution curves of the values of the pelvi-costal ratio in male and female patients. Continuous line=under the age of 65. Broken line=over the age of 65.

TABLE III

Sex	Mean Value of Pelvi-costal Ratio	Standard Deviation	Skewness		
			Statistic g_1	t Value	Probability
Male	1.75%	0.87	0.2	1.0	0.4 > P > 0.3
Female	2.0%	1.17	0.5	2.8	P < 0.01

Although the "t test" is not strictly applicable to such a skewed distribution, it was shown to be valid by repeating the test with derived logarithmic values of the pelvi-costal ratio, which gave a strictly normal distribution. A similar t value and probability was thereby obtained.

In the comparison of radiographs of the cases having an abnormally low pelvi-costal ratio with those of the controls no significant difference was found in the lengths of the lumbar spines, in the amount of lumbar lordosis, or in the thickness of intervertebral disks. There was, however, a clear difference in the obliquity of the ribs in the two groups. In both sexes the ribs of the cases were on an average 7.5 degrees further from the horizontal plane than those of the controls (t value=2.8; P<0.01).

There was a significantly greater degree of osteoporosis as measured by biconcavity of lumbar vertebrae in the cases. A summary of the statistical analysis of this comparison is given in Table IV. The difference was more striking in

TABLE IV

Portion of Spine	Samples of Patients	Mean of Index of Biconcavity %	Difference	t Value	Probability
Dorsal	Cases Controls	79.7 82.2	2.5	1.6	P=0.1
Lumbar	Cases Controls	69.8 76.2			

females, eleven of whom were found to have a degree of lumbar osteoporosis of severity sufficient to give an index of biconcavity of less than 67%. All of these were in the group of cases and none in the controls. A comparison of the measurements of the dorsal vertebrae shows a similar tendency, but the difference is not quite significant at the conventional one-in-twenty degree of probability. There was striking biconcavity of vertebrae in most of the spines, the average ratio of the central height to the mean of the anterior and posterior heights of the lumbar vertebrae examined being 73%. This result is almost certainly inapplicable to a healthy elderly population, being an indication of the tendency of patients with long-term illness to develop osteoporosis as a result of relative immobility. In six of the patients examined by radiology the pathological process had progressed further and caused actual collapse of one or more vertebral bodies, almost invariably in the upper lumbar or lower dorsal regions, this being the usual location for this complication (Fairbank, 1951). Three of these were in the group of cases and three in the controls. In almost all the patients the cause of the "fish-vertebrae" appeared to be uncomplicated senile osteoporosis, but in two patients there was Paget's disease with a superimposed osteoporosis; in a third the characteristic changes of ankylosing spondylitis were found; and in the youngest individual amongst the cases osteomalacia secondary to idiopathic steatorrhoea was shown to be the cause.

Rather paradoxically, no correlation was found between the degree of biconcavity of vertebrae and the age of the patients. This is probably explained by the fact that almost all the patients examined radiologically were over the age of 65 and that a maximum change is reached at an earlier age in long-term invalids than in the healthy population. There was only a slight correlation between length of stay as an in-patient and degree of osteoporosis ($r=+0.20$), and this did not differ significantly from zero correlation. It was, however, realized that length of stay was a very poor

estimate of immobilization; but it was the best available in elderly patients usually incapable of giving a satisfactory account of their activity prior to admission.

Discussion and Summary

The results demonstrate that there is a tendency to approximation of the thoracic cage and pelvis with increasing age. The most important factor involved is an increased obliquity of the ribs, which is, at least in part, secondary to the development of senile kyphosis. Radiological evidence of senile osteoporosis is more likely to be found in individuals in whom this change is greater than the average. The explanation may be that osteoporotic shortening of the spine is a further factor in causing this approximation, but, alternatively, it is possible that the rather asthenic type of elderly individual, in whom obliquity of the ribs is above the average, is constitutionally more liable to develop senile osteoporosis.

Senile osteoporosis of the spine is shown to be very common in elderly chronic invalids; indeed, some degree of osteoporosis is almost universal. As in so many other medical conditions, however, it is impossible to define any sharp boundary between the normal ageing process in the spine and pathological osteoporotic change. There is a gradual and continuous variation between spines which, at one extreme, can be regarded as normal for the age group, and those at the other extreme which show severe unequivocal pathological osteoporosis.

From a practical clinical point of view, it can be stated that there is a fair likelihood that spinal osteoporosis of significant degree will be found in elderly individuals in whom the distance between the subcostal and supracostal lines is less than 1% of the patient's height, corresponding in most cases to a distance of $\frac{1}{2}$ in. (1.3 cm.) or less.

We are indebted to Mr. K. Bray for carrying out the radiography and to Miss Perry for the clinical photograph.

The third annual report of the British Empire Society for the Blind was published last week. Preliminary surveys have shown that more than a million people in the Colonies are blind, millions more have incapacitating eye diseases, and facilities are gravely inadequate. Most probably, according to the report, three-quarters of this blindness is preventable. The report describes the start of a systematic attack on "river blindness" (a variety of filariasis affecting the eyes) in West Africa. The disease is spread by a simuliid fly. At least 100,000 people in the northern Gold Coast are victims of the disease, which in the past has depopulated whole villages. The Society has sent two teams, one medical under Dr. F. Rodger, an ophthalmologist, and the other composed of entomologists, to survey the problem in the Gold Coast, the Cameroons, and Northern Nigeria. One of the objects of the survey is to obtain exact information on the life history of the vector fly. In East Africa, where conditions are rather easier, treatment of the rivers with insecticides has been followed by a notable reduction in river blindness. Trachoma is another very important cause of blindness, and a pilot survey at Aden last year showed that in some villages everyone had it in some form or another.

ACTINOMYCOSIS IN SCOTLAND

BY

I. A. PORTER, M.B., Ch.B.

(From the Departments of Bacteriology, University of Aberdeen and Medical School, King's College, University of Durham)

Since 1891, when Wolff and Israel first isolated the causative organism of actinomycosis, *Actinomyces israeli*, much has been written on many aspects of this disease, but the literature reveals little information regarding its incidence. It is not surprising, therefore, to find in one textbook the statement that it is "not a common disease" (Topley and Wilson, 1946), and in another that it is "not infrequent" (Christian, 1947).

Most people will agree with Cope (1949) that "we must put aside the traditional and popular fairy-tale about infection from grass and straw," since from these sources aerobic actinomycetes only have been isolated. It is now commonly held that the infection is endogenous, arising from the micro-aerophilic actinomycetes found in the human mouth, which resemble closely the pathogenic *Actinomyces israeli*. Associated with the exogenous theory of infection was the suspicion that agricultural workers were more often the victims of this disease than those in non-agricultural occupations. Although our ideas regarding the origin of the infection may have changed, it does not necessarily follow that our views concerning the occupational incidence of the disease must also alter. The question of whether agricultural workers are in fact more prone to actinomycosis than others has not so far been satisfactorily answered. Before it can be it is necessary to relate the number of cases of the disease occurring in agricultural and non-agricultural workers to the total number of individuals at risk in the two groups in the area under consideration. A survey of actinomycosis in the north-east of Scotland in which particular attention was paid to this point has already been recorded (Porter, 1951). In view of the fact that the north-east of Scotland is predominantly agricultural it has seemed desirable to extend this survey to the rest of Scotland, in which there is a large industrial belt in addition to agricultural areas.

Investigation

The extended survey was designed to cover all cases of actinomycosis admitted to hospital for treatment during the thirteen years from 1936 to 1948 in those parts of Scotland not originally reported upon—that is, in the whole of the country excluding the five counties in the north-east. Information was sought from all general hospitals and from x-ray therapy departments. Not all the hospitals were able to provide the desired information, sometimes because of inadequate case records and sometimes on account of the absence of comprehensive filing systems covering the period under review.

It is recognized that a number of patients with actinomycosis in its less acute forms may have been treated at home by their own physicians and received no hospital treatment. Such are not included in the survey, and no systematic search of the records of the out-patient departments of the various hospitals was attempted. A few out-patient cases of the disease which had been referred to x-ray therapy departments for treatment were obtained from the records of these departments, and these have been included.

Any case lacking bacteriological or pathological confirmation of the clinical diagnosis has been excluded; likewise a few cases whose normal residence was not in Scotland

Results

The results of this investigation have been combined with those of the previous survey of the north-east area in order to give an overall survey of actinomycosis in Scotland. Where necessary, figures for each of the surveys are given separately so that they may be compared.

The total number of cases for the whole of Scotland was 186, of which 98 came from the north-east area and the remaining 88 from the rest of Scotland. In view of the fact that at the 1931 Census the population of the five north-east counties (Aberdeen, Kincardine, Banff, Moray, and Nairn) was 444,000, compared with 4,398,000 for the rest of Scotland, it is surprising that the north-east area should account for more than half the total number of cases recorded. Even if allowance is made for the fact that 15.8% of the hospital beds in the rest of Scotland were not covered, there would still appear to be a disproportionately large number of cases from the north-east area.

Location

In a report from the Netherlands, van der Hoeden (1939) stated that actinomycosis was ten times as common in rural districts as it was in large towns. The 186 cases of actinomycosis in this survey were grouped according to whether these patients lived in large towns or not. Thirteen cases had occurred in members of the armed Forces, and, owing to the uncertainty of their location prior to admission to hospital they have been excluded, leaving 173 cases for consideration. The results show that there was no significant difference in the rate of attack between those resident in the large towns and those in the small towns and rural districts in the north-east area. However, when the rest of Scotland is considered it appears that there is a significant difference between the attack rate among residents of large towns and that among residents in smaller towns and rural districts: the disease is more prevalent in the latter group.

Age Incidence and Sex

The ages of 184 of the 186 cases are known, and their distribution in the various age groups is shown in the Chart. The maximum number of cases occurred in the 20-29 age

Chart showing distribution of 184 cases in age groups.

group. The combined number of cases in the 10-19 and 20-29 age groups is 94—just over half the total number. The percentage of the population in each age group is marked on the chart, and it can be seen that in the 10-19 and 20-29 age groups more cases of actinomycosis have occurred than would have been expected from the numbers of the population in these age groups.

Males are more commonly affected than females, as borne out by the fact that of the 186 cases 145 (78%) were males.

Anatomical Distribution and Incidence of Trauma

The cervico-facial region is the most commonly affected portion of the body (65%), followed by the abdominal region, which accounted for 19% of the infections. Actinomycosis

of the cervico-facial region had occurred after dental extractions on 22 occasions, and in a further 33 patients in whom carious teeth had been noted. There was a history of injury to the face in 5 cases. In 23 of the abdominal cases there was a history of an associated appendicectomy, and in 2 cases of an appendix abscess. It is commonly agreed that actinomycosis may follow or be associated with appendicitis. Two cases of abdominal actinomycosis followed gastric perforations, and in 3 cases a blow to the chest or abdomen had preceded the onset of the disease.

Occupational Incidence

The occupations of 173 of the 186 cases are known. The occupation which accounted for the largest number of cases was agriculture, which gave a total of 39, two of which were under 16 years of age. Since opinion in the past has been divided on the question of whether agricultural workers are more liable to this disease than those in non-agricultural occupations, it was thought desirable to submit the figures resulting from this survey to statistical analysis. The numbers of those engaged in agriculture and in non-agricultural occupations in Scotland between 1936 and 1948 were obtained through the courtesy of the Ministry of Labour. Only males between the ages of 18 and 64, of which there were 88, were subjected to this analysis. The probability was calculated, and showed that, in Scotland, males between the ages of 18 and 64 engaged in agriculture were more liable to develop actinomycosis than those in non-agricultural occupations. The attack rate for male agricultural and non-agricultural workers in the two areas of Scotland are given in the accompanying Table.

Table Showing Attack Rate of Actinomycosis in Scotland of Male Workers

	North-east Area		Rest of Scotland		Total	
	Cases O.M.	Ratio per 100,000	Cases O.M.	Ratio per 100,000	Cases O.M.	Ratio per 100,000
Agricultural workers	19	146	18	29	37	50
	(13,000)		(62,000)		(75,000)	
Non-agricultural workers	20	33	31	3.3	51	5.2
	(61,000)		(919,000)		(980,000)	

O.M. = Occupied males.

Discussion

Our knowledge of actinomycosis has increased greatly during the last 60 years, but there are still many questions to which answers are required. The theory of endogenous infection is now accepted by most workers in this field. *Actinomyces israeli* has been isolated, in the absence of clinical actinomycosis, from carious cavities, from periodontal abscesses, from dental deposits, and from tonsils. Its existence in the mouth offers a possible explanation of the frequency with which the cervico-facial region and the gastro-intestinal tract are affected. It would appear from investigations concerned with the isolation of micro-aerophilic actinomycetes from the mouth that these organisms have been recovered in only some 5% of instances. Thus Lord and Trevett (1936) isolated four strains of anaerobic actinomycetes from dental scum and carious teeth of 90 patients, while Sullivan and Goldsworthy (1940) isolated five strains of anaerobic actinomycetes from 100 periodontal abscesses and one strain from 24 carious teeth. However, Emmons (1937) isolated micro-aerophilic actinomycetes in 23% of cultures from 100 pairs of tonsils.

No details are given of the sex and age of the patients mentioned in these investigations. In view of the fact that this disease is more common in males and in those in certain age groups, it would be of much interest to know if micro-aerophilic actinomycetes are present more often in male than in female mouths, and in certain age groups more often than in others; also if mouths of agricultural workers and rural residents harbour this organism more commonly

than mouths of non-agricultural workers and residents of the larger towns. Such information might be helpful in revealing factors which have so far not been taken into account in working out the epidemiology of this disease.

Although it has been found that male agricultural workers are more liable to actinomycosis than male workers in non-agricultural occupations it does not mean that we must connect this disease with the aerobic actinomycetes found in grains or grasses or even with the presence of the anaerobic *Actinomyces bovis* of lumpy jaw in cattle. Erikson (1940) made a detailed study of 20 strains of micro-aerophilic actinomycetes, 15 of which were of human origin and 5 of bovine origin. She showed that there were certain morphological, physiological, and serological differences between the human and bovine strains. Slack *et al.* (1951), however, in an examination of 11 human strains and 5 bovine strains isolated from cases of actinomycosis showed that they were serologically related. There is little information available concerning the frequency of actinomycosis in cattle and no evidence as yet to warrant connecting bovine with human cases of the disease. The lack of knowledge of the epidemiology of the disease in cattle would appear to be as great as it is in the case of the human subject.

Summary

A survey of the occurrence of actinomycosis in Scotland during the 13 years from 1936 to 1948 revealed 186 cases. All had bacteriological or pathological confirmation of the clinical diagnosis.

The commonest site of infection was the cervico-facial region, and males were more often affected than females.

Male agricultural workers were found to be more liable to this disease than those in other occupations. There was no significant difference in the attack rate of the residents of the larger towns and rural areas in the north-east of Scotland, but the residents of the larger towns in the rest of Scotland were found to be much less frequently the subjects of this disease than those living in essentially rural areas.

I wish to thank the medical superintendents of the various hospitals in Scotland and their records staff for help in obtaining the information on which this paper is based. For advice and assistance on statistics I am grateful to Mr. H. Campbell, Nuffield Department of Industrial Health, King's College, Newcastle-upon-Tyne.

The City Council of Nottingham has recently published an attractive handbook describing the facilities available in the city for users of the National Health Service. The book opens with a brief summary of the medical services during the last hundred years up till 1948. It then describes in simple terms what maternal and child welfare facilities there are in Nottingham, and gives a detailed account of the work of the health visitors, midwives, district nurses, and home helps. In a chapter entitled "Care Service" the book tells of the services for the prevention of illness, by immunization and vaccination, and the control of the spread of tuberculosis and other infectious diseases. There is also a short description of the sanitary services and of the council's efforts to promote smoke abatement and slum clearance. The handbook concludes with the addresses of hospitals and clinics in and around Nottingham where different kinds of treatment may be obtained.

SPECIFIC BACTERIOLYSIN IN SUBACUTE BACTERIAL ENDOCARDITIS CAUSED BY A HAEMOLYTIC STAPHYLOCOCCUS ALBUS

BY

MARGARET M. O'HARE, F.R.F.P.S., M.R.C.P.
Assistant Physician, Southern General Hospital, Glasgow

AND

JOHN S. STEVENSON, M.D.
Assistant Pathologist, Stobhill General Hospital, Glasgow

This report records a case of subacute bacterial endocarditis (S.B.E.) in which there was serological evidence that the causal organism was a haemolytic coagulase-negative strain of *Staphylococcus albus*. So far as can be ascertained, serological evidence of infection in S.B.E. has not been recorded previously. The particular interest in this case was the presence of a specific bacteriolysin in the serum.

Between 1945 and 1952 British and American literature recorded over 30 cases of S.B.E. due to coagulase-negative white staphylococci, and it has been suggested (Dowling *et al.*, 1952) that this type of endocarditis may be increasing in frequency. Out of a total of 2,100 cases of S.B.E. reported in five reviews (Thayer, 1931; Perry, 1936; White *et al.*, 1945; Priest *et al.*, 1947; Cates and Christie, 1951), *Staph. albus* was the causal organism in 20 instances—that is, about 1%. Individual cases are reported from time to time (for example, Cunliffe *et al.*, 1943; Matthew, 1951; Cobb, 1952), and serve to emphasize the fact that *Staph. albus* should not be regarded invariably as a contaminant when found in the blood cultures from these cases.

Case Report

The patient, a married woman aged 33, had a long "rheumatic" history, having had three attacks of acute rheumatism at 14, 27, and 29 years. Between 1947 and 1950 she was admitted to hospital on four occasions, suffering from various degrees of cardiac failure, with mitral stenosis and fibrillation. In 1947 and 1948 she was in hospital for some weeks; rapid improvement was brought about with rest and digoxin therapy.

On April 13, 1949, she was admitted to hospital for the third time, again with severe fibrillation; as before, this was treated with digoxin. Improvement was rapid, but on May 9 it was found that the spleen was enlarged to one and a half fingerbreadths below the costal margin. A persistent anaemia (Hb, 7 g.), very marked clubbing of the fingers, and prominent nodules over the elbows were also found. It was thought possible that an early subacute bacterial endocarditis was present, despite the fact that the patient was afebrile, and a series of blood cultures gave the following results:—May 10: a few colonies of haemolytic coagulase-negative *Staph. albus*; May 12: no growth; May 16 and 17: a heavy growth of a haemolytic coagulase-negative *Staph. albus*.

In vitro tests showed that the organisms isolated (presumably all the same strain) were sensitive to penicillin 1,000,000 units of penicillin daily was given when the second positive culture was reported—this was continued for five weeks. The patient's condition improved dramatically with penicillin therapy. The haemoglobin rose to 11.9 g., her weight increased, and symptoms of tiredness and malaise disappeared. Nine blood cultures taken between May 25 and July 30 were sterile. She was discharged on August 20.

MEDICAL MEMORANDUM

BRITISH
MEDICAL JOURNAL

1087

Medical Memorandum

Amoeboma of the Caecum

A male clerk aged 34 was admitted to hospital on November 20, 1949, with a three-days history of right-sided abdominal pain.

On examination he had a normal temperature and pulse, there was a tender mass palpable in the right iliac fossa, and the white blood cell count was 11,000. The case was thought to be an appendix abscess, and was treated with antibiotics. As there was no diminution of the mass after twenty days, an exploratory operation was performed.

Operation.—On December 9 a Rutherford Morison incision was made and a firm, rather inflamed mass was found occupying the caecum and ascending colon. This was thought to be a neoplasm or a non-specific granuloma, and the affected bowel was exteriorized after suturing the ileum to the transverse colon preparatory to a double-barrelled colostomy. Three days later the affected loop was removed and the intervening spur was crushed soon after. Within three weeks there was considerable excoriation of skin around the colostomy, and this rapidly developed into spreading infection with sloughing of the abdominal wall, which increased steadily until *Entamoeba histolytica* was identified in the skin edge and appropriate treatment given.

The condition improved gradually and sloughs separated, but a large granulating area resulted with a faecal fistula in the middle of it. Closure was effected after the third attempt some eight and a half months from the original operation. Tantalum mesh proved useful in bridging the gap in the abdominal musculature, and the skin defect was made good by sliding and grafting. Bowel action has been regular and normal ever since, but two small sinuses developed which discharged sero-sanguineous fluid but no faeces. Part of the mesh had been extruded and cut off, but it was thought best not to interfere further.

When last seen the patient was enjoying excellent health and going to business as usual.

COMMENT

This case illustrates the importance of excluding amoebiasis when doubtful masses are found in the bowel, especially in view of the relatively large number of persons who have been abroad in recent years. Amoebic ulceration of the abdominal wall seems to be more frequent in the United States—often coming on after appendicectomy in an infected case (Hunter, 1951). Hawe (1945) writes on the surgical aspects of intestinal amoebiasis, and refers particularly to the need of excluding acute caecal amoebiasis before operation for appendicitis in endemic areas. Donald (1940) describes two cases simulating carcinoma of the rectum. It would seem that the cases most likely to cause confusion in endemic areas are those of acute caecal or appendiceal amoebiasis, while the presence of unusual masses in the rectum or elsewhere in the bowel may call for a search for *E. histolytica* in the stools before proceeding to surgery.

Acknowledgments are due to my colleagues at Ashford Hospital, Middlesex, particularly Dr. K. D. Keele, for advice on treatment, and to Drs. W. J. Hamilton and C. F. Ross for pathological reports.

Bacteriology

When the staphylococcus was first isolated (May 10, 1950) it was thought to be a skin contaminant, as it is generally accepted that most albus strains isolated from blood cultures fall into this category. The striking feature of the organism, however, was the degree of haemolysis produced on blood agar; the zone of clearing round each colony was almost as great as that found with a haemolytic streptococcus. In other respects the organism appeared to be an ordinary albus strain; the coagulase test was negative. When similar organisms were isolated from further blood cultures (May 16 and 17) contamination seemed unlikely, and the patient's serum was investigated for antibody content.

The results of the various tests showed that the serum did not contain any agglutinins but that a bacteriolysin was present. This bacteriolysin was evidently specific for the staphylococcus isolated from the blood cultures (see Table).

Bacteriolytic Effect of the Patient's Serum on a Range of Organisms

Organism	Serum Dilutions—Reciprocals										C
	2	5	8	10	20	40	100	200	500	750	
<i>Staph. albus</i> A	+	+	+	+	+	+	+	+	±	—	—

<i>B. friedländeri</i>	—	—	—	—	—	—	—	—	—	—	—

Staph. albus A, B, and C—the organisms isolated from the three positive blood cultures.

Staph. albus 1, 2, 3, and 4—four strains isolated from other patients' blood cultures and classed as contaminants. All non-haemolytic.

— = Clearing of the suspension. — = No change. ± = Partial clearing.

Similar tests were carried out with sera from 12 other patients, including two known cases of S.B.E. due to *Streptococcus viridans*, with negative results. The bacteriolysin was still present in the patient's serum several weeks later, but the lytic titre had fallen to 1:4 within three months. The haemolytic activity of the organism gradually diminished after several months' storage on Dorset's egg medium, and had almost disappeared when examined three years after isolation.

Comment

The anaemia in this case was no doubt due to the haemolytic activity of the staphylococcus: the occurrence of a haemolytic strain of *Staph. albus* in S.B.E. has been noted previously by Allen and Riecker (1949). The development of specific bacteriolysin does not appear to have been reported in other similar cases, and may be a purely isolated finding. Absence of post-mortem data makes it difficult to assess the effect of the septicaemia on the course of the patient's illness, but the degree of cardiac damage was so great that it is feasible to assume that early death was inevitable, irrespective of the blood infection.

We wish to thank Dr. E. Oastler, in whose wards this case occurred, for permission to make use of clinical notes.

Reviews

WILLIAM CHESELDEN

William Cheselden, 1688-1752. By Sir Zachary Cope, M.D., M.S., F.R.C.S. (Pp. 112; 20 figures. £1.) Edinburgh and London: E. and S. Livingstone. 1953.

Although William Cheselden is still, after 200 years, accounted one of the major glories of St. Thomas's Hospital, this volume, written by a consulting surgeon to St. Mary's Hospital, appears to be the first fully documented life to have been published. The author's 1952 Vicary Lecture is the basis, to which he has added much new material resulting from his original researches.

Little is known of Cheselden's early life. Born in the year of the "Glorious Revolution," he lived through the Augustan period of our history, dying in 1752 acknowledged by all (as the *D.N.B.* states) to be the leading surgeon of his age.

For some years before his election to the staff of St. Thomas's Cheselden had conducted regular anatomy classes, which were so successful as to become a necessity for London medical students to attend. He was the first man in this country who insisted on the importance of a sound knowledge of anatomy for the student, and on dissection rather than books for this knowledge. It was some years later that William Hunter, to whom the credit for this innovation is generally incorrectly given, followed where Cheselden had led. He also incorporated in his lectures all that was known of physiology, and was thus the first to conceive the great importance of the preclinical sciences to the medical student. He wrote a famous textbook of anatomy as a companion to his lectures, and this work achieved such popularity that it maintained its place for more than a century. Later he published his great work on the bones of the body, *Osteographia*, and, being no mean artist, he personally assisted in the drawing and the engraving of the illustrations.

In addition to his pre-eminence as a general surgeon—and his speed and success in cutting for the stone had no equal in pre-anaesthetic days—he was a pioneer in ophthalmology. In this connexion his friend Pope wrote:

I'll do what Mead and Cheselden advise
To keep these limbs and to preserve these eyes.

At the height of his fame he retired suddenly from the staff of St. Thomas's (just before Percivall Pott was appointed to the staff of Bart's), and took the post of resident surgeon to the Royal Hospital, Chelsea, in order to obtain the necessary time to devote to his great project of separating the Barber-Surgeons Company, of which he was a warden, into its constituent halves. This he achieved by Act of Parliament in 1745, thus freeing surgery for future progress. He was elected to be second Master of the new Corporation of Surgeons.

In addition to his professional attainments Cheselden understood something of architecture and was largely responsible for the plans of the new Surgeons' Hall which was to house his Corporation, as well as those of the new Fulham Bridge, of which he had been elected a commissioner.

In his lifetime he was much liked for his good nature and generosity, and although his professional success aroused jealousy and criticism he refused to be drawn into controversy. Socially he was, unlike most surgeons at that time, born armigerous, and throughout his life in London he was the friend and companion of the "master-spirits" of the age of intellect—such men as Pope, Richardson, and Arbuthnot. He was appointed surgeon to Queen Caroline a few months after her accession, and on several occasions refused the honour of a baronetcy. He became a Fellow of the Royal Society in 1712, and with Dr. Mead attended its veteran president, Sir Isaac Newton, in his last illness.

He died while on a visit to Bath. The *Gentleman's Magazine* described his end as follows: "Mr. Cheselden Esq. an eminent anatomist, lithotomist and surgeon to the

Royal Hospital, Chelsea . . . had drunk ale after eating hot buns, upon which being very uneasy he sent for a physician who advised vomiting immediately, which advice, had he taken it, it is tho't, might have saved his life." A sad ending to such a distinguished life.

This book, which is well illustrated, should be read by all surgeons, St. Thomas's men, and others who respect the traditions upon which the art and science of medicine (and surgery) are built.

W. S. C. COPEMAN.

MEDICINE IN GENERAL PRACTICE

Modern Treatment: A Guide for General Practice. By 53 Authors. Edited by Austin Smith, M.D., and Paul L. Wermer, M.D. (Pp. 1,146. 147s.) London: Cassell and Company. 1953.

This impressive volume to which 53 American postgraduate teachers contribute is edited by the editor of the *Journal of the American Medical Association* and the secretary of the Association's Committee on Research. It is much more than a textbook of treatment, since considerable space is devoted in each section to physiology, aetiology, pathology, and symptomatology in order that the subsequent discussion of treatment should be rational and not empirical. The work is really a textbook of medicine with emphasis on treatment. In addition chapters are devoted to the principles of pharmacology, immunology, radiology, laboratory procedures, inhalation therapy, and physical medicine, and to the simple surgical, dermatological, and ophthalmological therapeutic principles with which the general practitioner should be conversant.

It is emphasized throughout that the patient should be treated as a whole man and not as a diseased heart, stomach, or lung, and that therapeutics is much more than the prescription of symptomatic or specific medicines. Indeed, the number of drugs mentioned is remarkably small in a book of this size on treatment. In each discussion attention is focused on what, in the author's judgment, is the most effective treatment, but alternative forms of therapy are also critically considered. That there should, here and there, be recommendations with which the reviewer disagrees is only to be expected, but the standard is everywhere worthy of the distinguished authors. All the sections are up to date, well and interestingly written, scientific and yet full of sound practical common sense. The book is beautifully produced and printed. The trouble is that therapeutics is expanding so rapidly that in a few years the work will in parts be out of date, and under the circumstances seven guineas is a lot of money to pay for it.

D. M. DUNLOP.

TOXIC PESTICIDES

Toxic Hazards of Certain Pesticides to Man: Together with a Select Bibliography on the Toxicology of Pesticides in Man and Mammals. By J. M. Barnes. World Health Organization Monograph Series No. 16. (Pp. 129. 7s. 6d.) Geneva: World Health Organization. 1953.

Although pesticides and fungicides have been in use since 1880, the rapid spread of their application on a vast scale has made necessary the fullest possible knowledge of their potential capacity to injure the health of mankind if their object is to be achieved. This object is twofold—the suppression of insect-borne diseases of man, and the reduction of damage to crops sufficiently to ensure adequate nutrition of the world population.

Dr. J. M. Barnes gives us here a timely and valuable contribution to the subject. The book is intended not only for the users of these substances, but also for medical officers and others responsible for public health.

Some countries have attempted legislative control of the new organic pesticides, but a high degree of legal control is difficult, and reliance must be placed largely on the education and training of those who manufacture and apply these poisons. Dr. Barnes frankly admits that there are still many uncertainties about the exact mode and site of

action and even of the precise chemical structure of some of the pesticides, particularly those belonging to the chlorinated hydrocarbon group, of which D.D.T. is a representative. The action of the organo-phosphorus group, including "parathion," is better understood; they act by inhibiting the enzymes which hydrolyse acetylcholine, while the dinitro-derivatives raise the metabolic rate by disturbing vital enzymes and accelerating oxidative mechanisms.

The description of these and other pesticides, as complete as possible in view of the existing gaps in present knowledge, is accompanied by suggestions for control of potential hazards and recommendations for further research, and is completed by an extensive bibliography drawn chiefly from sources in the library of the World Health Organization.

ETHEL BROWNING.

PSYCHOLOGY OF PHYSICAL ILLNESS

Psychology of Physical Illness: Psychiatry Applied to Medicine, Surgery and the Specialties. Edited by Leopold Bellak, M.D. (Pp. 243. £1 17s. 6d.) New York: Grune and Stratton. London: J. and A. Churchill. 1952.

Apart from the introduction by the editor, this book contains articles on the psychological aspects of general practice, internal medicine, malignancy, general surgery, plastic surgery, gynaecology and obstetrics, genito-urinary diseases, orthopaedics, the ear, nose, and throat, neurology, paediatrics, dermatology, dentistry, and the personality of the physician. Of the authors, some well known in their own fields, nine graduated from American schools, the rest from Vienna, Leyden, Prague, Lausanne, Edinburgh, and Groningen. Of the sixteen co-authors nine are psychoanalysts, and most of the remainder have received psychoanalytic training.

These arid details are provided so that the prospective reader may realize how broad are the fields of subject-matter covered, how widely different the backgrounds of the authors, how monotonously uniform their approach. By far the best are the articles written not by psychiatrists and psychoanalysts but by practical workers in the specialty concerned who have merely turned their attention to its psychological aspects. Thus the article by Dr. Haas on psychiatric implications in gynaecology and obstetrics is outstandingly good, and will certainly interest the general medical reader. In much of the rest of the book there is a deficiency of practical clinical knowledge, an excess of theoretical commonplace. Particularly disappointing is the discussion on the psychiatric aspects of neurologic diseases, which is mainly confined to the emotional meaning of illness to the patient. One might have hoped for some discussion of the varieties of psychological experience associated with lesions of particular parts of the brain—for example, the temporal lobe—or with particular types of disturbance of brain function.

ELIOT SLATER.

BIOCHEMICAL TESTS

Scope and Interpretation of the Commoner Biochemical Tests. (Pp. 120. 10s. 6d.) Johannesburg: South African Institute for Medical Research. 1953.

This book gives a judicious account of most of the common biochemical tests, and the author makes no exaggerated claims. Two general criticisms can be made. In the first place, it is now felt that it is not enough merely to give the extreme range of values found in apparently normal subjects. Either some indication should be given of the probability of values that differ from the mean by various amounts, or, at least, the range found in 80 or 90% of normal subjects should be given. It may be possible that total plasma protein as low as 5.6 g. per 100 ml. (the lower level of normal given in this book) may be found in an occasional healthy individual, but such a value should certainly suggest that something was wrong. The second general criticism is that often the author gives no indication of the levels that may be expected in disease.

Certain mistakes and omissions may be noted. Reduction of serum calcium, other than the moderate reduction due to low serum proteins, is not commoner in nephrosis than in nephritis (p. 3). Cholesterol is said (p. 6) to be 30 mg. lower in plasma than in serum; surely this should be lower in whole blood than in plasma. "Secondary prostatic carcinoma" (pp. 10, 92) should presumably be "prostatic carcinoma with secondaries." Estimations of uric acid in serum are more satisfactory than estimations in whole blood. The reader is given little help in choosing between many liver-function tests. Too little is said about tests of water and salt balance.

J. R. MARRACK.

COMPRESSION ARTHRODESIS

Compression Arthrodesis: Including Central Dislocation as a Principle in Hip Surgery. By John Charnley, F.R.C.S. With a chapter on Mechanics by Professor J. A. L. Matheson, and Histological Observations by Professor S. L. Baker. (Pp. 264; 208 figures. £2 2s.) Edinburgh and London: E. and S. Livingstone. 1953.

Mr. Charnley recently stimulated us with an excellent book on the manipulative treatment of fractures. This new volume is a tribute both to his industry and to his versatility.

Compression arthrodesis of the knee has become the accepted technique in Britain because of its simplicity, its certainty, and the speed of union. The author discusses its application to the other joints commonly arthrodesed, but no other joint lends itself quite so easily to this technique as the knee. Charnley has investigated the result of compression in great detail, and its value in accelerating union of cancellous bone seems undeniable. One is still left in some doubt whether compression has a specific effect in stimulating osteogenesis, or whether the complete absence of a gap between the surfaces allows rapid bone union. Whatever the explanation, there is no doubt that this happens at an astonishing speed. This is a delightful book to read and is coloured by the author's vital and forthright comments.

J. I. P. JAMES.

DATA ON RADIOTHERAPY

Roentgen, Radium and Radioisotope Therapy. By A. G. Delario, M.D. (Pp. 371; 65 illustrations. 55s.) London: Henry Kimpton. 1953.

This book is remarkable as a collection by one man of facts, figures, graphs, and tables published before 1951 relevant to radiotherapy. As a radiotherapist I can appreciate to the full the value of the store of easily accessible and thoroughly practical information which the book contains, since in it the necessary data are available for deciding on physical factors required in the treatment of almost any case of malignant or non-malignant condition by x rays, radium, or radioactive isotopes. While everyone would not agree with all his suggested doses, all would not necessarily disagree. For instance, I should consider 600 r in six doses of 100 r inadequate for ankylosing spondylitis. The danger of this work is that it might lead the inexperienced to proceed with more certainty than is justified if used in clinical work. Knowledge of technical details is no more a substitute for clinical knowledge and experience in radiotherapy than it is in surgery, and any tendency to ignore this axiom must be deplored. Dr. Delario would, I am sure, be the first to agree with this, since the parts of the book not filled with other people's data contain passages giving glimpses of his comprehensive grasp of the subject.

The book makes me anxious to meet its author, to find out what manner of man he is who displays such industrious ability, eclipsing even that of his *Handbook* of 1938. It is more difficult for me to assess its value to biologists than to medical practitioners, but I feel that no one interested in radiotherapy, the action of radiations, or in the use of radio isotopes would be wasting his money if he bought the book as a work of reference in which to find important technical details at a moment's notice.

FRANK ELLIS.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 14 1953

SURGICAL TREATMENT OF MITRAL STENOSIS

A large number of mitral valvotomies have now been performed at many centres both here and abroad, and the operation is firmly established as a successful, and relatively safe, method of treatment. After a few pioneer operations about thirty years ago, including a notable success reported in this *Journal* by Scutlar,¹ little progress was made until 1950, when Baker, Brock, and Campbell² published an account of six successful operations, the first series in this country. A little earlier Bailey, Glover, and O'Neill,³ of Philadelphia, had reported eleven successes. By May, 1952, Baker, Brock, Campbell, and Wood⁴ were able to describe a series of 100 operations: 13 of the patients had died, but 7 of these were in the first 20 to be operated on. Of 50 patients followed for at least eight months, 32 had a good or an excellent result. In the opening pages of this issue Mr. T. Holmes Sellors and Drs. D. Evan Bedford and W. Somerville describe the clinical and surgical features of 150 cases of mitral stenosis treated by operation, with only four operative deaths. Four other patients died subsequently. Of 110 patients followed for more than three months, 81 have had a good result and 9 others have had worth-while relief of disability.

At present all that the surgeon does at operation is to enlarge the narrowed mitral orifice. If he can do this so as to re-create mobile valve flaps, allowing an increased flow without reflux, a good result will follow. The stenosis is largely due to organization of repeated fibrin deposits, especially between the cusps, where commissures are formed.⁵ The operation consists in division of these commissures, and this can usually be accomplished by digital pressure. The type of valve ideal for surgery is the diaphragmatic, for reasons clearly shown by Holmes Sellors and his colleagues. More severe stenosis is accompanied by greater thickening of the valve leaflets and by shortening of the chordae tendineae: valvotomy is the more difficult, a knife must often be used, and normal function cannot be restored. The rigid

fibrous funnel of the grossly damaged valve is not suitable for operation, nor, at the present state of knowledge, is the irregular gaping orifice of the incompetent valve.

In selecting patients for operation the surgeon has also to consider the state of the other valves, of the pulmonary vessels, and of the myocardium, though the importance of myocardial damage has perhaps been exaggerated in the past. A patient suitable for surgery must be suffering from symptoms disabling enough to warrant the risk, and these must be due predominantly to mitral obstruction. Breathlessness on exertion is usually the first symptom. Haemoptysis is common, and it is sometimes sudden and massive (pulmonary apoplexy). More serious symptoms are orthopnoea and paroxysmal pulmonary oedema. Attacks of pulmonary oedema usually occur in patients with regular rhythm and a small heart and are a strong indication for operative treatment.

The physical signs associated with a diaphragmatic valve are a tapping apex beat with a snapping first sound and an opening snap—a sharp click following the second sound. Typically there is a loud rumbling diastolic and presystolic murmur, but this may be faint or even absent. The pulse is small. The heart may be enlarged, and in general the larger the heart the more serious the outlook. With mitral stenosis the right ventricle enlarges, displacing the apex beat to the left. Enlargement of the left ventricle, unless the aortic valve is diseased or there is hypertension, is due to mitral regurgitation and is a contraindication to operation. A great enlargement of the left atrium and systolic expansion seen fluoroscopically, especially in the antero-posterior position, also imply severe regurgitation; a systolic murmur is less important. Many stenosed mitral valves which are suitable for operation allow some regurgitation, which should not then prevent operation. Calcification of the valve suggests advanced disease, but may be present in some cases suitable for valvotomy: though an unfavourable feature, it is not a contraindication.

Attacks of congestive heart failure may indicate myocardial damage or a lesion outside the mitral valve; but if the signs suggest a pliant stenosis and if the failure is not of long duration and can be controlled by medical treatment operation should not be withheld. The presence or absence of auricular fibrillation does not influence the decision for or against surgery, except that it is more common in advanced disease. A history of previous embolism is usually considered an indication for operation because patients who have had one embolus nearly always have others and usually die from this cause

within a few years. An additional risk will be run, since thrombus in the left atrium may be disturbed by the surgeon's manipulations and an operative embolus result. This, however, is not an inevitable complication in such cases. Associated disease of other valves is not a contraindication to operative treatment provided that the disability is principally due to mitral obstruction. Disabling symptoms arising during pregnancy need no longer be considered an indication for termination, since several successful valvotomies have been performed on pregnant women with subsequent normal delivery at term.

When operative treatment has been decided on the patient should be made as fit as possible; preliminary in-patient treatment with digitalis and diuretics may be needed. The method of anaesthesia in these cases requires no special comment, but an intravenous drip of saline with procaine is usually given in the hopes of reducing the likelihood of ventricular fibrillation during operation. A blood transfusion must be ready, but there is usually surprisingly little loss of blood. Most surgeons prefer a lateral or postero-lateral approach through the fifth intercostal space or rib bed. The pericardium is opened and the valve approached by inserting a finger through the left auricular appendage after amputating its tip beyond a clamp. The appendage fits the finger snugly so there is no haemorrhage. Many unsuccessful attempts have been made to devise a method of operation which allows a satisfactory view of the valve, but much can be learnt by palpation. As a rule the commissures can be split by digital pressure: the different patterns of knife available for use when pressure fails suggests that the perfect mitral valvotome has not yet been invented.

The most distressing operative complication is embolism, with an incidence of about 5%. It may occur when no thrombus has been palpated or suspected, and may be due to calcified fragments as well as to clot. The most common site is the brain, and death or permanent hemiplegia may result. Some surgeons believe that compression of the carotid arteries does something to reduce the incidence of this complication. Embolus may also occur in the aorta, and occasionally an aortic embolectomy has been carried out a few hours after a valvotomy. But these complications are the exception, and in most patients recovery is straightforward and improvement immediate and lasting. As yet there is no evidence that recurrence due to re-formation of the commissures takes place. Many patients, completely disabled by distressing dyspnoea, have returned to a normal life and to work. The results obtained by Brock, Holmes Sellors, and other thoracic surgeons

are so promising that operation should be considered for every patient who is severely disabled by mitral disease. The decision whether or not to operate can be made accurately on clinical grounds assisted by routine investigations alone. Provided that mitral obstruction is responsible for the symptoms, a good result can be expected.

H. INFLUENZAE AND ANTIBIOTICS

H. influenzae is perhaps more uniformly susceptible to all the major antibiotics than any other species of micro-organism. In the treatment of the most serious infection caused by it—meningitis in infants—we have witnessed the successive trial of penicillin, streptomycin (with or without sulphadiazine and immune serum), and the newer antibiotics—of which chloramphenicol is the most effective, not only because of its high degree of antibacterial activity but because it reaches the cerebrospinal fluid in higher concentrations than any other of these drugs. Nevertheless there are some minor discrepancies in reports of the sensitivity of this organism to different antibiotics, and some findings were based on the study of only a few strains. A comprehensive study of this kind, embracing 34 serologically identified capsulated strains and 50 non-capsulated, is reported by Dr. K. Zinnemann on page 1069. The "punch" or "cup" plate method was used for these tests, and this is apt to give results somewhat unflattering to the drug tested, since its concentration anywhere in the medium surrounding the cup is inevitably less than that of the solution introduced, and diminishes steeply with distance from the margin. More clear-cut results, with lower minimum inhibitory concentrations, are obtainable by mixing the antibiotic uniformly with the medium: by such a method Finland and Wilcox¹ found all their strains of *H. influenzae* to be inhibited by 0.6–1.0 µg. per ml. of chloramphenicol, whereas some of Zinnemann's required concentrations five times greater. A similar difference is observed with aureomycin, most of Finland and Wilcox's strains being inhibited by from 0.6–2 and all by 4 µg. per ml., while some of Zinnemann's were not inhibited by any concentration tested. Whatever the method used, as Zinnemann points out, the relative activity of different drugs can be satisfactorily assessed, and the order of merit based on these tests is chloramphenicol (most active), terramycin, streptomycin, aureomycin. Penicillin ranks with the most active so far as its perform-

¹ *British Medical Journal*, 1925, 2, 603.² *Ibid.* 1950, 1, 1283.³ *J. thorac. Surg.*, 1950, 19, 16.⁴ *British Medical Journal*, 1952, 1, 1043.⁵ Magarey, F. R., *British Medical Journal*, 1951, 1, 856.¹ *Amer. J. clin. Path.*, 1950, 20, 735.² *J. Amer. med. Ass.*, 1952, 149, 231.³ Lewis, C. N., et al., *Antibiot. and Chemother.*, 1952, 2, 601.⁴ *Acta med. scand.*, 1952, 143, 32.

ance *in vitro* is concerned, but is regarded as therapeutically less useful because the corresponding concentrations are not obtained *in vivo*, at least by any ordinary dosage.

These results may be compared with those given by Dr. A. White Franklin and Professor L. P. Garrod (p. 1067) for strains of *H. influenzae* all derived from the sputum of children with bronchiectasis. Their results were obtained by incorporating the antibiotic in the medium, and there is no significant difference in activity between chloramphenicol, aureomycin, and terramycin, a concentration of 1 µg. per ml. of each of these three antibiotics sufficing to inhibit the growth of all strains (it should be remembered in this connexion that in Zinnemann's tests non-capsulated strains from sources such as this were on the whole more sensitive than capsulated). The variation in sensitivity to penicillin and streptomycin is wider, but the majority were inhibited by 1 and 4 µg. per ml. respectively of these antibiotics. The paper reporting these findings is an account of the results of treating bronchiectasis in children with chloramphenicol. The effect of giving adequate doses was always to suppress the infection, even in severe cases: the sputum became scanty and *H. influenzae* disappeared from it. In some mild cases benefit persisted after treatment was stopped, but in most it continued only during administration of the drug, although a diminished dose sufficed. Treatment for one day in each week was found to be inadequate. This study was brought to an abrupt termination by the death of one of the patients from aplastic anaemia, and it is mentioned that an adult in the same hospital treated with chloramphenicol for *H. influenzae* bronchitis developed the same complication, although he survived it. It may be remembered in this connexion that 2 out of 62 patients treated by Wilson and his colleagues² for bronchiectasis with 1 g. of chloramphenicol twice weekly for 5½ and 7 months developed aplastic anaemia, fatal in one of them. He would be a bold man who chose to conclude that the authors of each of these papers had merely been very unfortunate in having seen two cases each of this complication in a comparatively small series of patients. It would be safer to conclude either that the risk is greater from prolonged treatment, although an American survey³ is said to have elicited no evidence of this, or that some extra risk is involved in the treatment of this particular disease.

If it be agreed that the use of chloramphenicol in the treatment of chronic bronchial infection is unjustified, a powerful therapeutic weapon is lost to us. The high concentrations of this drug in the bronchial secretion, as demonstrated by Franklin and Garrod,

may well account for its apparent superiority to other antibiotics. Similar trials of aureomycin and terramycin should evidently be carried out. According to Mulder and his colleagues,⁴ who describe an extensive study of chronic *H. influenzae* bronchitis (it is not clear whether some of their 125 adult patients also had bronchiectasis), these two drugs suppressed the infection at least temporarily in most of the small number of patients so treated. The authors obtained their best results by giving both penicillin and streptomycin in daily doses of 4 million units and 2 g. respectively: this treatment eliminated the infection in 50 out of 66 patients, but is presumably feasible only in in-patients.

It has often been truthfully said that the great advances in chemotherapy have done much less so far for sufferers from chronic infections than for those whose lives are in immediate danger. There is scope for further study in this difficult field, and it should not too hastily be concluded that any benefit achieved can only be temporary, especially in the young.

MODIFIED LEUCOTOMY

Operations on the brain, intended by means of a circumscribed lesion to influence some of the symptoms of illness, have now been developed in considerable number. Surgeons have developed techniques of undercutting the cortex or severing the central white matter in different regions of the frontal lobes, of operating directly on the thalamus and aspirating the cingulate gyrus. All these are very different from the so-called standard leucotomy operation which was the prevailing practice ten, and even five, years ago. In a recent issue of the *Journal*¹ Dr. William Sargant described from a wide and varied experience the indications for a modified leucotomy operation. The particular modification of leucotomy to which he directed attention is that in which an attempt is made to confine the injury to the medial inferior quadrant of the frontal lobe, anterior to the tip of the lateral ventricle, so as to divide only this portion of the thalamo-frontal radiation. Those who have had experience of this operation, which has been developed particularly by Mr. Harvey Jackson and Mr. Wylie McKissock, are satisfied that the amount of undesirable personality change produced by it is very much less than that caused by the old standard operation, while its beneficial effects are probably at least as good.

Prefrontal leucotomy is essentially a symptomatic method of treatment, and does nothing for the cure of any disease which may underlie the symptoms for whose relief it is given. Therefore it can be and has been applied in a great variety of conditions. The patients most often selected for operation are schizophrenics; but the reason for this is not that these

patients are especially suitable—often they are not—but that their state is often so severe, so chronic and otherwise intractable, that any measure, even a damaging operation on the intact brain, seems justifiable if it can promise fair chances of some relief. The symptoms which can be relieved by leucotomy are pre-eminently those of mental distress—states of tension, anxiety, depression, hypochondriacal preoccupation. The operation is therefore of value in relieving intractable pain, as from carcinoma; the relief most commonly seen is that the patient continues to experience pain but is no longer so distressed by it and can apply himself to occupations and distractions. A small proportion of patients who suffer from tinnitus find the noises in the ears unendurable, and are prevented from sleeping, relaxing, or taking the slightest pleasure in any usual interest. They, too, usually benefit from leucotomy, if the gravity of their state is held to warrant it.

However, as Sargant has pointed out, the bulk of the patients for whom leucotomy comes to be considered are those who suffer from psychiatric disorders. In the past these have properly been exclusively patients suffering from psychoses. With the advent of a modified operation which, so far as present experience goes, seems to leave the personality so largely intact, permits a normal social life, and has very little if any ill effect on religious life and ethical attitudes, the time has come when it is right to consider also those patients whose condition is essentially neurotic in nature. Certainly all other reasonable methods of treatment must have received an adequate trial, and the condition must be not only intractable but having a very damaging effect on the life and happiness of the patient. If this is the case, then chronic anxiety states, chronic hypochondriases with marked symptoms of depression or tension, and chronic depressive reactions may all arise for surgical consideration. It is in only a small proportion of cases of these kinds that the indications will be thought to be adequate; but surgery does hold out hope to some of the worst cases at a price which now seems more reasonable than of old.

As has recently been brought out by Kolb² in a review of the results in about 10,000 cases in the United States, one of the prerequisites for successful surgical treatment of severe psychiatric illnesses is the possibility of adequate aftercare. The attitude of the relatives is of supreme importance. If they are prepared to give the patient a new chance, to make allowance for his remaining deficiencies, and to take some personal responsibility in his rehabilitation, then the chances of a good result are much improved. Operative treatment is only one part, even if it is the most significant one, in the whole plan of treatment in those cases in which it is applied. The doctor must be prepared to maintain his interest in his patients after operation, to continue to help them on their way, as Sargant has emphasized, by all the psychotherapeutic and somatic methods they may require, even after the six to twelve months it takes for operation to show its full effects. The principle of therapeutic persistence is one which, here as elsewhere, brings untold benefit.

PLANTAR WARTS

The literature on the infective wart is peculiarly barren. There are few people on whom the impudent visitor fails to call at some time in life, yet our knowledge of the natural history of the disease, our understanding of its aetiology, and the approach to treatment leave much to be desired. It might be thought that a lesion so common and so accessible, associated as it appears to be with the presence of a virus, and producing a wide variety of intriguing pathological patterns of a neoplastic character might provide an important field of research for the experimental pathologist and the virologist. Yet little is written that could not be contributed by the lay wart charmer. It is doubtful if the legitimate practitioner, even when he enlists the services of his psychiatric colleague, approaches the therapeutic success of this unqualified competitor.

The age incidence of warts, the great modification of them produced by the different textures and other characters of the skin affected, and the variable course of the disease in different individuals, variations which may run parallel with changes in the physical and emotional health of the patient, point to the importance of the soil as well as the seed in this disease. Perhaps the discovery of an effective viricide would simplify treatment and make considerations of soil irrelevant, but that day is not in sight. At present the assessment of most methods of treatment is vitiated by ignorance of the psychological factor, which can so modify the skin as to render it unreceptive to the infective wart.

Plantar warts behave in the same manner as warts at other sites, but call for general consideration. The thickness of horn and the trauma of walking drive the warty growth in towards the dermis instead of allowing it to develop outwards. This outward growth in fact occurs if the patient avoids walking and is rested in bed. The pressure on the dermal papillae, by causing pain, may lead to orthopaedic faults, and for this reason plantar warts demand treatment.

Whitfield¹ recognized two patterns of plantar wart. The first was dependent on trauma resulting from deformity of the foot or from an irregularity in the sole of the boot, and its cure rested upon correction of this fault. The other type of the simple infective variety was often multiple and particularly affected the site of tread. That moisture favours the growth and exuberance of warts seems evident, and many forms of treatment clearly benefit by their desiccating effect. Branson and Rhea,² from their experience of treating forty-eight soldiers with plantar warts in the American Army, claim success from the injection of 1% procaine into the stratum germinativum exactly under the wart. That last injunction perhaps only emphasizes that once again we are reading the results of treatment by suggestion. The procedure must be a very painful one.

There are two lines of treatment for infective warts, no matter what their site. Plantar warts must undergo radical removal or destruction. This is most satisfac-

torily achieved by curettage under anaesthetic or after freezing by carbon-dioxide snow or liquid nitrogen,³ less satisfactorily by diathermy or a destructive dose of x rays. There has quite rightly been much outcry against the use of x rays, and undoubtedly it is improper to produce radiotherapeutic damage of the foot in the treatment of so benign a lesion as a wart. Even so, if properly conducted, the treatment may be both successful and safe.

Other forms of treatment depend essentially on suggestion, though some combine with it some degree of destruction or desiccation. Perhaps the most useful is Thomson's treatment with 3% formalin.⁴ The wart or warts are placed in contact with the solution in an egg-cup for ten minutes each day for six weeks. Less certain measures are adhesive strapping with or without 25% podophyllin in oil and fractional doses of x rays. Astringent foot baths and powders are of some prophylactic value, especially where there is hyperhidrosis.

SUNLIGHT AND MILK

Milk is often exposed to sunlight for long periods. It may be exposed in the van during delivery and later on the doorstep, particularly at week-ends, when the milk bottle left at the side door is a common sight. This exposure to light affects not only the vitamin content of the milk but also its flavour. Considerable quantities of the riboflavin of milk are inactivated by exposure to ultra-violet light, and as much as 50% of the ascorbic acid may be destroyed if milk is left in bottles exposed to bright sunlight for an hour or so.¹ The change in flavour of milk exposed to light seems to be associated with the presence of sulphur-containing compounds.

According to Patton and Josephson² the objectionable flavour is due to the presence of a compound produced by the photochemical decomposition of the sulphur amino-acid methionine, the reaction being accelerated by riboflavin. These workers suspected the importance of methionine in this connexion when they observed that dilute solutions of methionine itself exposed to sunlight developed a flavour identical with that produced in milk treated in the same way. Further examination of the problem showed that the addition of methionine in amounts as small as 4 mg. per quart (1.1 l.) intensified the flavour in skim-milk exposed to sunlight. The process is undoubtedly photochemical, for it depends on the time of exposure and the wavelength of the light, and is independent of temperature. The readiness with which the flavour developed in skim-milk in comparison with solutions of methionine alone suggested that one of the constituents of milk activated the process. It was suspected that this might be riboflavin, which absorbs light and is a component of an oxidation-reduction enzyme system. Patton and Josephson observed that exposure of a solution containing methionine and riboflavin to light developed the flavour to a much greater degree than one con-

taining methionine alone; riboflavin solution alone developed no flavour. Other sulphur-containing amino-acids, such as cysteine and cystine, were tested, but were not found to be associated with the production of the "light" flavour, which seems to result specifically from the photolysis of methionine in the presence of riboflavin.

Whatever the mechanism of the process, milk should be exposed to sunlight as little as possible if its flavour and vitamins are to be preserved. The use of milk bottles made of dark glass would minimize the effect of light on the milk, and as the breakage rate of bottles is very high the gradual replacement of existing stocks would not take very long.

ELECTRONIC EYES?

Someone recently asked St. Dunstan's whether television could somehow be adapted to help the blind to see. This is a recurring theme with each new invention. When the full story of science's part in the war was published radar was proposed as a substitute for sight, and an article in this *Journal*¹ explained why centimetric radio waves were unsuitable for any form of blind aid, and described some research done at St. Dunstan's and elsewhere on ultrasonic aids which were more promising. It was then pointed out that all instrumental aids faced some general difficulties. They had to be very small and light or no one would wear them for long. They had to be simple to control and maintain. All of them took time to learn to handle, and it was found that where a blind person was prepared to spend the necessary effort on a course of instruction—and, since the majority of the blind are elderly, this is not always the case—the end-results were less good than if the same effort had been expended in developing the other senses. In other words the blind man does better by improving his use of his own body than by calling in any of the tools science can offer.

But can science offer electronic eyes? Dr. E. D. Adrian² has explained in a recent issue of the *St. Dunstan's Review* why this is at present impossible. Sensation of light or movement of a crude kind can be produced by stimulating the surface of the cerebrum directly, but to leave electrodes in contact with the brain surface for more than a short time is risky, while contacts on the scalp outside the skull are obviously too distant for precise localized stimulation. Furthermore, "the visual messages from the eyes do not go straight to the cerebral cortex and to nowhere else; they go through an elaborate nervous apparatus in the retina and in the brain stem, so that what arrives in the cerebral cortex is not just a reproduction of the pattern of light and shade falling on the retina." We do not at present know enough about the retinal events and their relation to the conscious events which constitute vision, but even if we did the pattern of electrical microstimulation required might well prove impossible to produce. Research in other directions will be more profitable.

CLINICAL PATHOLOGY IN GENERAL PRACTICE TAKING SWABS

BY

ROBERT CRUICKSHANK, M.D., F.R.C.P.

Professor of Bacteriology, St. Mary's Hospital Medical School

Use of the cotton-wool swab mounted on a wire or wooden applicator for the collection of material for bacteriological examination from various body surfaces and cavities is some 60 years old. Recommended by Councilman in 1893, it was first used in Britain by Hewlett and Nolan (1896) and by Preston (1896) for the isolation of diphtheria bacilli from the throat of affected patients. It has since been widely utilized for the collection of secretions or discharges from the nose, nasopharynx, larynx, trachea, eye, ear, skin, superficial and deep wounds, rectum, vagina, and cervix. The purpose of this article is to discuss the kind of swabs to be used and the best method of collecting material from the sites mentioned.

The Swab

The swab commonly consists of a small pledget of cotton-wool wrapped tightly and smoothly round the roughened end of a wire or wooden applicator in such a

Fig. 1.—Nasopharyngeal swab for use through the mouth.

way that no part of the end of the applicator is left exposed and there is little risk of the swab being pulled off during the collection of the specimen. This latter requirement is particularly important for nasal, cervical, and rectal swabs. The swab should not be bulky, and for per-rectal use should be small enough to avoid unnecessary irritation to the nasal mucosa when being passed back to the nasopharynx. Although the use of absorbent cotton-wool is usually recommended, it is probably more advantageous for the survival of bacteria on plain swabs to use non-absorbent wool (Rubbo and Benjamin, 1951). As regards the applicator, wire is more flexible than wood, but the metal should not be too pliable, as aluminium tends to be: "nichrome" wire is now widely used, but stainless-steel wire, which can be hooked at the end to retain the swab, is also favoured. The wooden applicator is recommended for use with the serum swab (see below) to avoid the discoloration which may result from the interaction of the serum with a metal, although this

Fig. 2.—Perianal swab for threadworm ova.

risk should not occur with stainless-steel wire. The applicator is usually pushed into or through a cork at the holder end, and the whole swab is assembled in a test-tube container.

Swabs of special design are used for the collection of material from particular sites. West's swab in a bent glass tube for swabbing the nasopharynx is now an anachronism: instead the ordinary throat swab with a flexible wire holder may be bent to an obtuse angle (about 120 degrees) $\frac{1}{2}$ in. (1.3 cm.) from the tip and used with a tongue depressor to avoid mouth contamination. The swab described by Tarr (1946) for post-nasal culture is illustrated in Fig. 1. For pernasal swabs fine nichrome (s.w.g. 25) or stainless-steel wire with a hooked end is recommended (Cockburn and Holt, 1948). In collecting material from the conjunctiva some ophthalmologists prefer to use the wire loop, which is inoculated directly on to the culture medium, but a fine cotton-wool swab may be used instead. For laryngeal swabs the choice lies between nichrome wire (s.w.g. 16) and stainless steel, which is rather more rigid: the applicator is 9 in. (23 cm.) long and bent at an angle of 120 degrees about 2 in. (5 cm.) from the tip, and is placed in a large test-tube container (8 by 1 in.—20 by 2.5 cm.).

For obtaining faecal material with a swab passed into the rectum and for swabbing the vagina or cervix, the ordinary throat swab with a 6 in. (15 cm.) long applicator is best. A special type of perianal swab is used for collection of roundworm ova. It consists of a 2 cm. square of plain transparent non-moisture-proof "cellophane" wrapped about the tip of a small glass rod and held in place with a rubber band. The holder end of the rod is pushed through a cork stopper and the whole swab placed in a test-tube container (Fig. 2).

The Serum Swab and Bacterial Survival

A major concern in the use of the cotton-wool swab is the period of viability of pathogenic bacteria on the swab between collection of the material and its inoculation on to appropriate culture media. Because of the poor viability of certain bacteria like the gonococcus and the meningococcus material suspected of containing these pathogens is best inoculated on to suitable media as soon as the swab is taken; but this procedure has obvious disadvantages, and various substitute methods for allowing an interval of time between collection and inoculation of these poorly viable bacteria have been recommended. For example, Stuart (1946) found that gonococci could survive for 24 hours or longer if the swab on a wooden applicator is immersed in Brewer's medium before transportation to the laboratory: a somewhat similar procedure was recommended by Saint-Martin (1949), who used Hirschberg's medium as the vehicle. Downie (1940) found that meningococci on nasopharyngeal swabs could be cultured 24 hours after swabbing if the swab were immediately placed in contact with blood agar in the bottom of the container, while Aycock and Mueller (1950) recommended immersion of the swab in horse blood for the same purpose.

The problem of bacterial survival is not confined to the *Neisseria*, since slow-drying is known to be lethal to most bacterial species. The matter has been extensively investigated by Rubbo and Benjamin (1951), who, as a result of their comparative findings with many different pathogens, recommend the use of a serum-coated cotton-wool swab. The swabs are prepared by dipping the cotton-wool swab on a wooden applicator into undiluted ox serum for 10-30

seconds, spreading them out on sheets of blotting paper, drying in an incubator at 37° C. for about half an hour, and finally sterilizing in the autoclave at 15 lb. per sq. in. (1 kg. per cm.²) for 20 minutes. The finished product is a compact honey-coloured pledget, 3-5 mm. in diameter, in which the cotton-wool fibres are firmly bound to each other and to the applicator.

Rubbo and Benjamin found that, with the exception of the *Neisseria*, the serum swabs prolonged survival and gave heavier growths (compared with plain swabs) of some 16 different bacterial pathogens. In addition, they showed that moistened plain swabs but not serum swabs accelerated the death rate of Gram-positive bacteria like *Str. pyogenes* and *C. diphtheriae*, whereas the survival of the Gram-negative intestinal pathogens like the typhoid bacillus and Flexner and Sonne dysentery bacilli was prolonged in the absence of moisture. The deleterious effect of moisture and slow drying on the viability of *Str. pyogenes* and *C. diphtheriae* has a direct application to the moist throat swab, which with plain cotton-wool is unlikely to give reliable results if there is a delay of twenty-four hours between collection and inoculation. For example, in an outbreak of scarlet fever 170 miles from Melbourne the Australian workers found that plain and serum swabs cultured on blood agar twenty-four hours after collection gave respectively 23% and 39% positive isolations of *Str. pyogenes*. Variations in atmospheric temperature (15-24° C.) were unimportant, but

FIG. 3.—Throat swab with a clear view of the fauces.

better in discharges collected on linen rather than on cotton-wool (see Mackie and McCartney, 1953). If, then, the serum swab is used, and assuming a moderately heavy coating with the suspected pathogen, bacteriological examination of such material usually yields a valid result when cultured within the following time limits:—(1) organisms viable for less than eight hours: gonococci and meningococci (see alternative methods listed above); (2) organisms viable for eight hours: *H. pertussis*, *C. diphtheriae*, *V. cholerae* (moist swab); (3) organisms viable for twenty-four hours: haemolytic streptococci, pneumococci, *Str. viridans*, and *Cl. welchii*; shigellae and salmonellae on moistened swabs; and (4) organisms viable for forty-eight hours: staphylococci, coliform bacilli, proteus, and pyocyanus.

Throat Swabs

The throat swab is used principally to collect material from the faucial area in patients suffering from acute pharyngitis or tonsillitis or suspected Vincent's angina, and in the detection of contact, convalescent, or chronic carriers of haemolytic streptococci or *C. diphtheriae*. The operator must have a clear view of the whole fauces in a good light and see the swab touching the affected surfaces (Fig. 3). The patient should be sitting up or standing with the head tilted back; with children or nervous patients an assistant should support the back of the head with one hand, to prevent sudden or unexpected movement, and hold the patient's hands with the other. If good natural lighting cannot be obtained a hand torch must be used; some tongue depressors

FIG. 4.—Nasopharyngeal swab passed through the nose.

have an illuminated tip which does equally well. It is wise to use a tongue depressor even with patients whose throats can be clearly seen. It should be placed in one movement firmly on the back of the tongue, after which the swab is inserted and rubbed over the faucial area, gently if the throat is acutely inflamed, more vigorously if searching for carriers. In suspected chronic tonsillar carriers or infections the swabbing may be preceded by pressure with the fingers on the tonsils to squeeze out secretion in the tonsillar crypts. When Vincent's angina or monilia is suspected two swabs should be taken, as one will be required for the preparation of smears for direct microscopical examination, which, however, has little or no value in other acute throat infections. Throat swabs are preferred to throat washings for the isolation of poliomyelitis virus from the oropharynx.

Nasopharyngeal Swabs

Some pathogenic or potentially pathogenic bacteria that colonize the upper respiratory tract are to be found predominantly in the nasopharynx or post-nasal space. These include the meningococcus and pneumococcus, and in whooping cough *H. pertussis* is most conveniently isolated by nasopharyngeal swabbing. This area may be reached with a swab passed through either the mouth or the nose. The peroral swab with its bent tip is passed to the back of the throat—a tongue depressor is essential—and then slipped up behind the uvula to the post-nasal space. In infants it may be very difficult to pass the swab up behind the uvula, and instead the tip may be directed downwards to the posterior pharyngeal wall. The pernasal swab is passed more or less horizontally along the floor of the nasal passage (Fig. 4), with the patient's head held firmly because of the natural

FIG. 5.—Swabbing anterior nares for staphylococcal carriers.

tendency to withdraw. If contamination with bacteria in the anterior nares is to be avoided, a nasal speculum should be used.

Nasal Swabs

Swabs may be taken from two different sites in the nasal cavity as well as from the post-nasal space. A high proportion of the population carry *Staph. aureus* in the nose, and this organism is found particularly in the vestibule or entrance to the nostrils, where it multiplies on the moist invaginated squamous epithelium. In searching for staphylococcal nasal carriers, therefore, it is sufficient to rub a moistened swab round the vestibule of both nostrils (Fig. 5). If, on the other hand, material is to be examined for infection of the nasal mucosa or associated paranasal sinuses, the swab should be rubbed over the turbinates. Similarly in searching for nasal carriers of pathogens like *Str. pyogenes* or *C. diphtheriae* and in obtaining swabs from young children with suspected pneumococcal respiratory infection the swab should be inserted ½-1 in. (1 to 2.5 cm.) into the nasal cavity, again using a speculum if contaminants from the vestibule are to be avoided.

Laryngeal Swabs

The laryngeal swab has only recently come into frequent use for obtaining lung secretions in early suspected cases of pulmonary tuberculosis or in convalescing patients who have become sputum-free. With a little experience, at first using a laryngeal mirror, the doctor will find that for this purpose the laryngeal swab has advantages over stomach washings, in that the patient is more willing to co-operate in having repeat swabs taken. The bacteriologist also prefers it because it is easier to handle. It is, however, essential that the swabs should reach the laboratory within a few hours of being taken.

The patient, sitting up and with his head tilted back, is asked to open his mouth widely. The operator, who should wear a mask, catches the tongue in a gauze swab and pulls it forward so that the patient tends to "gag." The laryngeal swab is dipped in sterile water or saline and then with or without the aid of a mirror is passed down into the larynx, when the patient may be asked to cough but usually does so without being asked. Two successive swabs should be taken, placed in the test-tube container, and transported by messenger to the laboratory as quickly as possible.

Eye Swabs

Swabs may be taken from the conjunctival mucosa when it is inflamed or as a preliminary to operations on the eye to exclude the carriage of pathogenic bacteria. The patient is asked to look up. The lower lid is everted and a fine swab is rubbed gently along the conjunctival surface.

Ear Swabs

Infection of the ear may occur in the external meatus or in the middle ear. In otitis externa a fine swab is rubbed gently over the inflamed area. In suppurative otitis media accumulated discharge must first be cleaned away before the swab is taken, preferably through an aural speculum, so that if possible the bead of pus oozing through the perforated membrane is collected.

Skin Swabs

Swabs may be taken from the intact skin in searching for carriers of pathogenic staphylococci among food-handlers in an outbreak of staphylococcal food-poisoning or among hospital staff and patients in outbreaks of staphylococcal infection—for example, wound infection, pemphigus neonatorum, or lactation mastitis. Moistened swabs should be rubbed over the skin of the fingers, back and front, or an area of about 1 sq. in. (6.5 cm.²) on the back of the wrist may be swabbed.

Rectal Swabs

Swabs may be taken from the rectum for the bacteriological diagnosis of infantile gastro-enteritis, bacillary

dysentery, or enteric fever, but in spite of the advantages of the rectal swab in convenience and hygiene of collection it does not allow the full examination for parasites, etc., that is possible with a specimen of faeces. The rectal swab has been used particularly in swabbing groups of young children in day or residential nurseries during outbreaks of Sonne dysentery to find out quickly the incidence of cases and carriers in the group. Whenever it is used, it is important to ensure that, with the patient lying on his side, the swab is pushed well into the rectum and that it is covered with faecal material when withdrawn. The swab must be cultured within a few hours of collection unless some method for keeping it moist is adopted. It is most convenient for collecting specimens from young children; in children over the age of 3 years the doctor should for psychological reasons explain to the patient what he intends to do. It is unnecessary to use a speculum in collecting specimens from children under 5 years of age, but a specially made glass or rubber speculum may be used in older children and adults.

Perianal Swabs

In suspected cases of threadworm infestation a special swab (see p. 1095) may be used to collect scrapings from the anal region, where the ova are frequently found. The edge of the cellophane swab is scraped through the perianal folds and the swab is then transported in the test-tube container to the laboratory, where the cellophane is removed and the swab placed faeces side down in a drop of N/10 sodium hydroxide.

Vaginal or Cervical Swabs

Vaginal discharge may be derived from inflammation of the vagina itself as in trichomonal infection and the vulvovaginitis of children, or from the cervix or uterus as in gonococcal and puerperal infections. For the bacteriological examination of most of these infections in adult women the practitioner will find it most practicable to take a high vaginal swab with the patient lying on her side. The external labia and perineum should first be cleansed with warm water, swabbing towards the rectum in one movement. A Cusco bivalve speculum or a Sim duckbill speculum is introduced and an ordinary throat swab is passed into the posterior vaginal fornix. A cervical swab can be taken satisfactorily only with the patient in the lithotomy position, when with a Cusco speculum the cervix is exposed and the swab introduced. In cases of suspected trichomonal infection some of the discharge should be collected with a Pasteur pipette, which is then sealed with plasticine so that the fresh specimen can be examined as a wet film under the microscope. But a swab may be used, provided enough of the discharge can be collected to allow preparation of the wet film.

For the vulvovaginitis of childhood the patient should be lying in the dorsal position with the knees drawn up and the thighs separated as far as is possible without hurting the child. Any superficial discharge is removed and the external genitalia are separated with gloved thumb and first finger of the left hand. The swab must be pushed well into the vagina and withdrawn with some discharge on it. The first swab is used to prepare a smear and the second for inoculation on suitable culture media as soon as possible.

Nova et Vetera

THE STUDY OF MEDICINE AT THE
UNIVERSITY OF COPENHAGEN,
1537-1645

Dr. E. Gotfredsen has recently reviewed¹ the medical history of the University of Copenhagen with a happy blend of nostalgic piety and gentle irony. The year 1537 is noteworthy for the re-establishment of the University of Copenhagen by King Christian III after the storms of the Reformation had subsided. Two years later the King undertook to uphold the spirit of the restored university with "good professors" honourably paid. The payment was 140 daler yearly—a rate of pay which Professor Erik Warburg has lately found to be equivalent to that enjoyed by "good professors" at the present time when due allowance is made for the cost of living then and now. A professor of theology received 10 daler more a year, but a professor of law had to be satisfied with only 100 daler yearly, and the stipend of a professor of philosophy was down to 70 daler. But, if numbers count, the faculty of philosophy was better represented with its eight professors than the faculty of medicine with its modest two. Professors of medicine had not only to teach but also to attend the sick at Court and at the university as well as the nobility in the provinces.

The range of subjects which the professors of medicine had to teach the young was quite impressive. Lectures were given on mathematics and astronomy, and enough had to be known of the latter to enable a professor of medicine to edit an almanac every other year. Astrology was also included in the syllabus in so far as it had to be invoked in the drafting of a horoscope, but professors were warned to walk gingerly in this particular field, "as Christians should avoid all superstition." The subjects to be lectured on were strictly defined in advance, and the lectures of physicians and theologians were modelled on much the same lines, with only this difference—that for the physician Hippocrates took the place of Luther and Galen the place of Melanchthon as sources of inspiration.

Professors of medicine began their lectures in Latin at 6 a.m., so they may well be excused for having drifted into rather slovenly ways, just reading from a text faithfully taken down as dictation by students happy to absorb knowledge in so simple a way. But this easy system of conveying knowledge by dictating Latin quotations seems at one time to have incurred royal disfavour, for in 1621 King Christian IV complained that "we have also learnt that many of the professors spend most of their time in dictating what they have culled from various other authors in order to save themselves trouble." The royal rebuke continued: "The university is not specially founded for the maintenance of the professors, but solely to the glory of God and for the promotion of youth. We graciously adjure you to discontinue useless dictation so that you can get through your curriculum in the course of a year."

The lectures on medicine were confined to theory and not supplemented by demonstrations of patients, anatomical preparations, drawings, and the many other devices for relieving the monotony of the spoken word. A student could well become a doctor of medicine without having seen a single patient or learnt how to diagnose a disease. But he had wonderful opportunities to acquire facility in debate when he took part in *disputationes* on set subjects. Four times a year a professor of medicine had to supervise and guide medical students in such debates. In 1617 the subject of debate was: "Is the patient suffering from pleurisy to be bled on the diseased or healthy side at the onset of his illness?" This was a terribly knotty question, for Greek and Arabic authorities disagreed over it. Now, with the omniscience of to-day, it is easy to anticipate the correct answer to this question. Bleeding was to be undertaken on the healthy side at the onset of the pleurisy in order to convey

blood away from the diseased side. "To bleed on this side would merely mean a flux of new blood, a hyperaemia which would aggravate the inflammation."

CLAUDE LILLINGSTON.

A "SMOG" EXHIBITION

This month the Royal Sanitary Institute is staging at its headquarters at 90, Buckingham Palace Road, London, S.W.1, a seasonable exhibition illustrating "smog," its causes and effects, and the way to get rid of it. Large-scale models and diagrams impress the visitor with the results of investigations into atmospheric pollution, the damage it causes to health and property, and the advantages of smokeless fuels. From the experience of London last winter atmospheric pollution is not a diminishing quantity, but it is some satisfaction to know that at any rate its measure is being taken. Special instruments for measuring pollution are now established on 870 sites all over the country, and the amount of grit or deposited matter, of smoke or suspended matter, and of sulphur dioxide is carefully recorded. Local authorities, nationalized industries, and commercial undertakings to the number of 175 are co-operating regularly with the Fuel Research Station of the Department of Scientific and Industrial Research in this enterprise.

The effect of the week of "smog" in London in the early part of last December is driven home pictorially, statistically, and in other ways in this exhibition. The maximum concentration of sulphur dioxide in Westminster and eastwards along the Thames during that week was four or five times the normal, while the number of deaths in London ascribed to bronchitis, pneumonia, and diseases of the heart and circulatory system reached a startling level, more than two and a half times as high as the level of the previous week. Another exhibit shows the effect of atmospheric pollution on livestock. The bones of cattle which had grazed on pasture heavily contaminated with fluorine showed exostoses and other changes. Masonry is liable to attack, and this is well shown by stone from the Houses of Parliament, where the acid-laden smoke has destroyed the beautiful incised decoration. The same is true of metals. The British Iron and Steel Research Association demonstrates the results of tests on copper-steel and zinc at 16 sites in Great Britain, and the difference between the Surrey countryside and places like Sheffield from the point of view of corrosion is well brought out.

Belching Chimneys and Smokeless Zones

The domestic fire is arraigned by the National Smoke Abatement Society as responsible for half the 2,500,000 tons of polluting matter which is sent forth from the chimneys of Great Britain each year. An exhibit of smokeless fuels—anthracite, dry steam coal, gas, and hard cokes—points the way to a remedy, and shows also that hygiene is a paying proposition, for such fuels have a higher standard of heat efficiency. Diagrams also illustrate the creation of smokeless zones in which all pollution is prohibited. These can be of any size from a few acres upwards, including the square mile of the City of London, which it is proposed shall be one of them. Much also can be done in the factory to prevent air pollution, for instance, by the use of efficient dust and fume extractors. Another aid is a new type of fire door, developed at the Fuel Research Station, which is said to eliminate smoke and at the same time to increase thermal efficiency. In the ordinary way a Lancashire boiler will emit as much as 30 lb. of solid matter in an hour, and up to 15% of the heat in the fuel goes to waste.

The exhibition does not include means of individual protection such as have led to recent controversy; the effort is made to indicate causes, and in diagram, poster, and leaflet the solution looks simple. However, if any visitor is inclined to excessive optimism, he may be reminded that the very last patent taken out by James Watt was for the construction of a furnace in such a way as to avoid smoke. That was in 1785. The principle was all right; the difficulty lay in its practical acceptance. That is where the difficulty lies to-day.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Treatment of Tetanus

SIR,—In his article on the treatment of tetanus, Dr. J. H. McIntyre (*Journal*, October 17, p. 866) advocates active immunization of babies against tetanus at the same time as the routine immunization against diphtheria.

Mr. A. T. Glenny and I have investigated the antitoxic responses of young babies to a combined prophylactic containing purified diphtheria and tetanus toxoids and whooping-cough vaccine. We are indebted to Dr. N. R. Butler, of University College Hospital, for the clinical side of the work.

Of a group of 64 babies receiving three injections given at the ages of 6, 12, and 18 weeks, 61 had produced at least 1 unit of tetanus antitoxin per ml. at the age of 6 months, and the remaining three had shown satisfactory responses. All babies born with 0.1 unit per ml. or less of passive maternally conferred diphtheria antitoxin (cord-blood titre) responded actively to the diphtheria toxoid in the prophylactic. In some of those with higher cord-blood titres interference occurred through neutralization by the passive antitoxin, but a delayed response may take place.

Although the majority of babies would be adequately primarily immunized against both diphtheria and tetanus by the course we adopted, I would recommend that the first dose should be delayed until the age of 3-4 months. The dosage of the two toxoids was such as to give good immunity to both components in normal animals, however, not only reduces maternally conferred immunity, but upsets the effectiveness of the diphtheria toxoid but upsets the balance of the prophylactic: as a result additional interference with the diphtheria toxoid may occur because tetanus toxoid is then in excess.¹ By waiting until babies are 3-4 months old before starting immunization, the maternally conferred diphtheria antitoxin would have fallen sufficiently in almost all.

We hope to publish our results fully in the near future.—
I am, etc.,

MOLLIE BARR.

SIR,—I read Dr. J. H. McIntyre's paper on the treatment of tetanus (*Journal*, October 17, p. 866) with interest, and I would like to make some comments on the very important point he raises.

A study of papers published during the past few years on the treatment of tetanus with relaxants shows a higher proportion of recoveries than is usual in any large consecutive series treated by older methods. This might indicate that these new drugs were lowering the mortality, but allowance must be made for selection and the human tendency to publish successes rather than failures. Tetanus is a disease in which a comparatively accurate prognosis can be given 48 hours after the onset if certain observations are made, and provided that a large dose of antitoxin is given. Prognosis depends particularly on the presence or absence of the local tetanus involving either the eyes, face, or limbs; the severity and type of wound; the length of the incubation period; and the length of the period of onset. The incubation period is the time between receipt of the wound and the onset of the first symptom—usually trismus. The period of onset is the time between the onset of the first symptom and the occurrence of the first reflex convulsions.

Prognosis is invariably good when there is local tetanus and usually so if the wound is very slight. If prophylactic antitoxin has been given, and if the incubation period is more than 10 days. It is bad if the wound is severe and

heavily infected and the incubation period is less than five days. The period of onset gives the best indication of the severity of an attack. If this is less than 48 hours the prognosis is bad and the patient is unlikely to recover. If it is more than 48 hours there is a good chance of recovery and this increases with every hour the reflex convulsions are deferred. The above observations usually support each other—that is to say, a patient with a severe wound usually also has a short incubation period and a short period of onset and vice versa—but if there is disagreement the period of onset is the most reliable prognostic indication. As Dr. McIntyre states, both his cases were very severe, with incubation periods of four and six days respectively and a very rapid onset of reflex convulsions giving a period of onset of considerably less than 48 hours in both. Neither had any chance of recovery unless relaxants could have worked a miracle.

By contrast and using the same criteria, some of the cases which have been reported would manifestly have recovered on routine treatment whether relaxants had been used or not. In many the essential data by which prognosis could be assessed is omitted, and so the part played by relaxants in furthering recovery is not as clear as it might be. My own limited experience with mephenesin suggests that, although this relaxant is of considerable value in controlling or lessening the severity of spasms, especially in mild cases, it has little effect in very severe ones like those described by Dr. McIntyre. In one patient with a period of onset of about 48 hours in which the prognosis was borderline recovery occurred. Here mephenesin may have tipped the scales towards recovery, and it is probably in cases of this degree of severity that relaxants may save life.

The purpose of this letter is to urge that when reports of tetanus patients treated with relaxants are published all the above data should be included so that they can be used as a yardstick to assess prognosis and to give a more accurate estimate of the value of any drug used. In the present state of knowledge treatment of tetanus is but symptomatic. Death or survival depends almost entirely on the dose of toxin absorbed before antitoxin is given. It still remains to be seen to what extent relaxants combined with adequate control of respiration, as in anaesthesia, can lower the mortality.—I am, etc.,

LESLIE COLE.

Cambridge.

SIR,—It is obviously right that failures of a new form of treatment should be given as much prominence as are successes, and Dr. J. H. McIntyre (*Journal*, October 17, p. 866) does service in recording two fatal cases of tetanus in which muscle-relaxants were included in the treatment.

It has long been held that, when the incubation period is as short as a week, treatment of this disease is ineffective. I believe that the proper use of the muscle-relaxants may enable us to change our outlook, and I am sorry that Dr. McIntyre should support the fatalistic attitude on the experience of his two cases. These, as he says, do not make impressive reading, but I suggest that the potentialities of the muscle-relaxants were not exploited to the full. The exaggerated motor activity of tetanus can be treated either by drugs which act centrally—the narcotics; or by those which act peripherally—the muscle-relaxants. The narcotics all act on those parts of the central nervous system which are already being attacked by toxin and are therefore harmful. The enormous potential value of the muscle-relaxants lies in the fact that they can defeat spasm without lowering vitality. They are difficult to give properly, because the amount needed to counter spasm may be enough to paralyse breathing; and because the amount needed to achieve the best balance in any patient may vary widely from minute to minute. These two difficulties can be met by the provision of positive pressure assisted ventilation whenever the breathing muscles have to be paralysed and by the use of a muscle-relaxant whose intensity of action can be varied from minute to minute to meet the changing need. Succinylcholine is such a drug; curare, gallamine, and mephenesin are not.

The main cause of death from tetanus is usually respiratory infection but with anoxic episodes, exhaustion, and toxæmia as important contributory causes. This is because the tetanus toxin acts on the medullary nuclei, particularly on the nucleus of the vagus, so that the actions of the larynx and pharynx become disorganized. There is thus difficulty in swallowing, and spill-over from the pharynx into the tracheo-bronchial tree, with resulting respiratory infection. The best safeguard against this is early tracheotomy, and I believe this should be done in all cases of severe tetanus, not only because it lessens the likelihood of infection, but also because it prevents that constant irritation from bronchial secretions which accounts for much of the spasm.

If we adhere to the principles of early tracheotomy, assisted respiration, *continuously controlled relaxation*, and the restriction of central depressants—coupled, of course, with adequate doses of antitoxin—we may be able to save cases which would formerly have been regarded as hopeless. One patient was recently treated on these lines and she recovered.¹ Her illness was less severe than those described by Dr. McIntyre; but the methods used might bring some hope where previously there was none, and this letter is a plea for them to be tried.—I am, etc.,

Bristol.

Heartburn in Pregnancy

SIR,—In your annotation on heartburn in pregnancy (*Journal*, October 17, p. 873) you refer to nine cases of hiatus hernia in pregnancy described by Dutton and Bland and you state that "heartburn in pregnancy may therefore be of some importance."

We have tried for a long time to convince doctors that the subject is indeed of great importance, and in the *Lancet* we went so far as to say that we believed the key to the whole problem of incompetence at the cardia lay in the study of these cases.¹ At present we are reviewing 55 cases of hiatus herniation found in pregnancy two years ago.

We still consider that regurgitation and not herniation is the main factor in the production of symptoms. Further, it seems likely to us that this massive regurgitation of gastric contents, so common in pregnancy, may be a very important factor in the aetiology of early post-anaesthetic chest complications in pregnancy. It certainly produces nocturnal cough in many of these cases and it may be that with the abolition of the cough reflex under anaesthesia aspiration of the regurgitated fluid causes "spill" pneumonia. We are studying this subject, but because of the great frequency of heartburn in pregnancy and the difficulty, therefore, of obtaining figures of statistical significance the problem should be studied by many workers.

It would be a great help if someone would determine the true incidence of heartburn in pregnancy, paying strict attention to the definition of the term. With regard to the observation by Williams² that prostigmin is effective in treatment, we have injected prostigmin during the screening of patients but have failed to demonstrate any change in the appearance of the hernia or the volume or frequency of the reflux. We have not been able to relieve the symptoms by the use of prostigmin.—I am, etc.,

Bickley, Kent.

Venepuncture in Young Children

SIR,—Dr. I. A. B. Cathie, in his article on venepuncture in the "Clinical Pathology in General Practice" series (*Journal*, October 24, p. 930), says, when writing about infants, "From birth to the age of about 3 years visible or palpable veins cannot be expected, and some other approach must be made." I must dissent from this view. I find that in the majority of cases veins are palpable in one or other antecubital fossa, even if not visible, and it is more often than not easy to get blood in quantity using the same

technique as for adults, even in infants 24 hours old. I think it is so generally assumed that venepuncture at this site in infants is difficult that it is not even explored. A palpable vein here saves much time and trouble. I find that a needle and attached rubber tubing is easier to use for this purpose than a syringe. Needless to say, the vein is not visible nor palpable except with pressure from above. It is not necessary to see the vein, but it must be palpable, and usually is.—I am, etc.,

Canterbury.

I. B. MORRIS.

SIR,—Dr. I. A. B. Cathie's advice to general practitioners on the withdrawal of blood from infants and young children (*Journal*, October 24, p. 930) is valuable technical instruction, and it is true that if a slick technique is acquired the whole procedure can be finished before the patient has had time to feel more than a little fear. On the other hand, as he admits, it does not always go easily, and surely the occasions when it is necessary to obtain blood from infants outside a children's ward must be so rare that the general practitioner can hardly hope to become expert unless he has had previous experience.

The venepuncture is thus quite likely to be unsuccessful at the first attempt, as it is even in a children's hospital. But Dr. Cathie has omitted any mention of possible harm from prolonging the procedure, for he says: "The traverse beneath the sternomastoid can then be repeated until the vein is entered," and, "If the attempt at venepuncture is unsuccessful on one side of the neck the same procedure should be carried out on the other," without giving any time limit. The actual pricks may not be very hurtful, but the child is too young to know that no more serious attack is to be made upon him. The fear engendered in the 2-year-old by immobilization in a blanket, the sight of the weapons, and the sometimes grim expression of the operator who wishes it was all over may cause lasting harm to a few children under certain circumstances. At the least, it makes the child afraid of doctors for a time, which is a disadvantage at the next consultation.

Venepuncture of infants and young children is necessary sometimes, and any harm it may do is usually trivial, but I should like to suggest that (a) it is done only when the doctor is quite certain that it is really necessary, (b) that the armamentarium is kept as much as possible out of sight, (c) that if it fails after a reasonable three-minute attempt it is abandoned for the day, and (d) that the doctor himself shows affection for the child afterwards in some way in order to counteract any impression that the thing is a punishment.

Dr. Cathie says towards the end of his paper that "failure to obtain blood can be the most exasperating and humiliating experience." He is referring to the person on the right end of the syringe.—I am, etc.,

London, S.E.1.

D. G. VULLIAMY.

Cortisone and A.C.T.H.

SIR,—As a contribution to the discussion on the value or otherwise of these hormones in the treatment of rheumatoid arthritis, I give my experience of their use in 37 cases, treated in 1949 and 1950, and (apart from two patients aged 74 and 72 respectively, who died in 1951 of cerebral haemorrhage) examined or made contact with in 1953.

Careful selection of patients, to exclude pre- or co-existent tuberculous or focal infection, or poor psychological background, was exercised. All cases were treated in hospital, with the continuous co-operation of a physician colleague, the director of pathology, and the physiotherapy department. In these patients all the usual, and many of the unusual, forms of treatment had been employed, to the limits of polypharmacy, without material benefit. The hormones were supplied by relatives overseas, care being taken to ensure that, so far as possible, maintenance amounts should be available.

The results fall into three groups: (1) *Failures*.—Seven cases, where no response was obtained, or where alleviation was transitory, and not recovered even on larger doses of either hormone. (2) *Moderately Improved*.—Twenty-four cases, patients who have resumed their daily activities, in relative comfort and competence,

of whom eight were formerly bedridden or house-bound. The average maintenance dose is 75 mg. (three tablets) of cortisone, or, in a few cases, 10 units of A.C.T.H. per week. (3) *Complete Relief*.—Six cases; none of these patients has required a maintenance dose in the last two years; in three, no cortisone or A.C.T.H. has been called for in three years, and all live physically active lives.

Laboratory control is a necessary adjunct, especially with regard to the blood picture. It is useless to give either hormone where a significant degree of anaemia or reduction in cell volume exists; but neither the sedimentation rate nor the eosinophil count gives a constant guide to progress. Further, any alteration in the sodium/potassium balance is seen earlier clinically in loss of muscle tone than in the laboratory return. For these reasons daily observation of the patient in hospital is, in my view, essential.

Apart from the failures and the case noted below, side-effects have given no concern. Disturbance of water balance and oedema have been overcome by reduction of the fluid intake, by administration of 5 g. potassium chloride daily taken as table salt, and, if necessary, a brief intermission in administration; obesity, by control of diet; psychological aberrations, by care in selection of patients, eliminating the emotionally insecure.

Cortisone administration is essentially substitution therapy; A.C.T.H. stimulates the activity of the adrenal cortex and is effective only in so far as this has not atrophied and can respond. All six cases in group 3 had a four-day course, 20 units daily of A.C.T.H.; and I have the impression that its use is responsible for their "cure" and for the small maintenance dose of cortisone required in the patients in group 2. With the introduction of long-acting "acthar gel," a daily injection of 10 to 20 units makes treatment much easier, and it should, I believe, be tried.

Two cases call for special mention. One from group 1 had given a response to no therapy during seven years, including cortisone and A.C.T.H. His own doctor tried phenylbutazone ("butazolidin") with dramatic success, so that after five months the circumferential measurement of one knee had been reduced by 4 in. (10 cm.). The other, in group 3, had become acromegalic following a fractured base of skull 20 years previously, and was now the subject of active rheumatoid arthritis of polyarticular type, with massive effusion in both knees. The fact that she had formerly suffered from "nervous breakdown" was not forthcoming. After seven days' treatment by A.C.T.H., preferred on the theory that some degree of pituitary atrophy existed, she spent two nights writing poetry, which, believed by her to be original, was actually a reproduction of portions of the *Oxford Book of English Verse*. After an anxious 48 hours, the psyche returned to normal. Later, small doses of cortisone were substituted for A.C.T.H. and continued for four months, with much success. She has had no hormone—and no return of symptoms—since July, 1949, and has nearly full functional activity.

A number of patients included in this series (having read *The Times* extract (October 2) of the articles in the *Practitioner*)² have asked me to put forward this analysis. The joy of being able to get about and resume some degree of social and economic activity after being house-bound for considerable periods is something that the ordinary uninhibited individual has difficulty in appreciating fully. But I have no clue as to why the failure to respond was complete in the seven cases of group 1.—I am, etc.,

Sunderland.

Treatment of Laryngeal Carcinoma by Radium Insertion

SIR,—I agree with Mr. W. Douglas Harmer (*Journal*, October 3, p. 735) that good results are obtained by radium insertion for laryngeal carcinoma, although I use a different method. In principle the technique is as follows.

The thyroid cartilage opposite to the lesion is drilled at its anterior end and three needles 1 cm. apart are inserted between the cartilage and parallel to the affected cord. Ellis¹ first described this technique for radon, and later I described it for radium,² adding a perspex stabilizer to ensure a parallel arrangement of the needles. The technique of loading a hollow needle-sheath can be altered to suit the size of the larynx and can deal effectively with lesions of the anterior commissure. It is likely that the physical distribution of

dosage is more accurate and homogeneous than that employed by Harmer.

In a small series of cases treated from 1-4 years, all remain well with no evidence of cartilage necrosis. This technique is used in preference to external irradiation, and the amount of upset to the patient is about equal to that of Harmer's method.—I am, etc.,

ANTHONY GREEN.

The Broken Acrylic Head

SIR,—I was interested in Mr. K. H. Pridie's letter (*Journal*, October 24, p. 939), as I have also been trying to overcome the faults that he mentions in the standard type of acrylic femoral head and have designed a prosthesis which appears to be rather similar to the one he illustrates. The usual pattern has a further disadvantage in that it transmits the weight to the narrow rim of the neck of the femur, which affords so small an area that bone absorption from excessive pressure must be expected, and indeed does occur.

The stem of the prosthesis shown consists of two flat plates joined together by a cross-member giving an H-shaped section which provides a maximum area for bone contact. The lower and inner plate lies on the calcar femorale, transmitting the weight directly to it along the normal lines of weight transmission, while the upper and outer plate affords counter-pressure against the outer cortex of the femur. The plate forming the base of the neck of the prosthesis also transmits weight to the upper cut surface of the calcar femorale. To reduce weight the rest of the neck and the interior of the hollow metal head is filled with resin. Thus the prosthesis is married to the femur along the normal lines of stress and transmits the weight over a large area. Moreover, being tapered, it will reseal itself if any bone absorption should occur. A possible disadvantage is that its point of junction with the femur is further away from the centre of movement and must therefore be subject to greater stress. Only time will show whether this factor outweighs other advantages of this type of prosthesis.—I am, etc.,

T. T. STAMM.

Mammary Abscess

SIR,—Following my recent plea (*Journal*, July 11, p. 98) for an investigation into the epidemiology of staphylococcal infections in maternity hospitals by means of bacteriophage typing, my attention has been drawn to the work of Dr. J. C. Colbeck,¹ who has done precisely this. His work appears to have attracted little attention in this country, although it was published in 1949, and its practical application is obvious.

Dr. Colbeck has shown that the infant may acquire in the nursery a pathogenic strain as early as 24 hours after birth or much later depending on its contacts. Undoubtedly the common source is another infant whose nasopharynx harbours the particular strain. Thereafter the feeding infant infects directly the mother's nipple. This explains perfectly

the apparent anomalies and provides the solution not only to mastitis in the mother but to staphylococcal ophthalmia and pemphigus in the infant. Its lesson is perhaps applicable to other problems such as neonatal dysentery. If for no other reason, hospital nurseries should be abolished and the infant should at all times remain in the same cubicle as the mother. In the interests of child psychology, etc., the principle of the child being with the mother is observed in some hospitals, but it is almost certain that the infants are collected together at times for certain purposes, which defeats the whole object so far as infection is concerned. May I commend Dr. Colbeck's paper to those administering our maternity hospitals?—I am, etc.,

Kirkcaldy.

Liver Biopsy

SIR,—Your annotation (*Journal*, October 17, p. 874) gave an admirable account of the present attitude towards liver biopsy, but one or two comments could be a little misleading. The mortality of liver biopsy is commonly supposed to be high (one frequently hears figures of 1–5% being used as arguments against using this investigation), and your reference to Davis,¹ who in 1946 discussed 4 deaths in 483 biopsies by various people, might foster this misconception. A more recent analysis of over 10,000 biopsies performed with modern techniques revealed a mortality of 0.12% and a significant morbidity of 0.32%.²

The statement that the abdominal route is "clearly safer in that the needle can more freely enter the liver" is possibly true, but one may add that with this route the needle can also more freely enter the gall-bladder, the stomach, and the colon. Most operators have now abandoned the dangerous subcostal route in favour of the intercostal approach except occasionally in gross hepatomegaly.

The description of biopsy material as 2–3 mm. in diameter would be unfortunate if it encouraged anyone to experiment with such large needles. I think you will find that needles with internal bores greater than 2.0 mm. are no longer used. The popular (but inefficient) Vim-Silverman needle has a bore of only 0.9 mm., although its outer needle is much larger. To use a bore greater than 2.0 mm. is to court disaster. Liver biopsy is rather more valuable in focal disorders of the liver than you suggest. In metastatic and granulomatous disease of the liver, an adequate specimen is diagnostic in 70–90%, depending on the technique employed. Provided a negative biopsy is not regarded as proof of normality of the whole liver, no error or confusion should arise. In addition to the value of liver biopsy in diagnosis, one may point out that it may be employed with great advantage and negligible risk in the management of a sarcoidosis, hepatic tuberculosis, chronic brucellosis, fatty metamorphosis of the liver, and the protracted case of viral hepatitis.—I am, etc.,

London, E.C.1.

Treatment of Malaria

SIR,—It has been suggested by Dr. R. Y. Taylor in a letter from Kenya (*Journal*, August 1, p. 285) that general practitioners in the Tropics could usefully make their records available to research workers and others. This almost echoes a similar request of mine.¹ I feel, therefore, that I should offer an account of nearly thirty years' experience of malaria treatment, in the hope that others also will contribute to help to clear up the confusion which undoubtedly exists and was referred to recently by my old friend Sir Philip Manson-Bahr (August 1, p. 284).

Thirty years ago there was one treatment for malaria: quinine, with its different salts—sulphate, hydrochloride, and hydrobromide. The last was thought to produce less tinnitus, but was seldom effective. Quinine remains the quickest drug to bring down temperature, but it is far from

being the safest. Since the war not a single case of blackwater has shown up here, and this is probably owing to the fact that quinine is now used only in an emergency. During the Japanese occupation our fever hospital saw several cases of blackwater precipitated by alkaloids other than quinine. Just before the war three blackwater cases gave a history of having followed the use of "atebrin." On analysis, samples bought from the native shops where these tablets were said to come from were found to contain a yellow powder and 1½ gr. (0.1 g.) quinine. The maker's name overlapped the tablet, and both the size and colour differed from the original.

Almost everybody has now given up using quinine except in emergency, when it is given slowly by injection intramuscularly. Anyone who favours quinine injections should try giving themselves one. I did it about 25 years ago as an emergency, and have not had one since: only a painful memory remains and a nodule. Quinine treatment in those days meant a course of 10 gr. (0.65 g.) thrice daily for one month, followed by 10 gr. twice daily for another month, and finishing with a daily dose of 10 gr. during the third month. It was normally given in capsule; the acid mixture frequently produced gastric irritation. An Italian patient preferred to drink bottles of quinine, iron, and arsenic, without any apparent ill effect. Several of the older planters spoke of taking as much as 90 gr. (6 g.) a day, and others took a drachm (4 g.) whenever they felt a rigor coming on. But most of these heroes knew nothing of bloodslides and parasites, and many died from blackwater.

If a patient relapsed on quinine sulphate, he was then given a course of the hydrochloride, or another quinine salt like quinidine sulphate. Intravenous N.A.B. was very effective for relapses. Pamaquin ("plasmoquine") came to our aid about the year I came to Malaya, and I remember being presented with a bill for extractions and a denture, said by my patient to be necessary as the result of pamaquin poisoning. This was soon followed by "quino-plasmoquine," one of the best pre-war treatments for relapsing malaria, but few of my patients could stand the full course of four or five tablets daily for a month, as originally recommended by the makers. A modified course, however, gave very satisfactory results in both vivax and falciparum malaria. Quartin is very rarely seen out here.

Then came mepacrine, originally called atebrin, and we used it with great care and in moderation, for it was known to produce yellowing of the skin, which, although not important, was not appreciated by the patients. But we soon found that in a few rare cases it produced mental excitement, sometimes requiring psychiatric treatment. Why it now can be used apparently harmlessly for such conditions as lamblia in very much larger doses is difficult to appreciate. Malaria subjects who appeared to be unaffected by continuous quinine often did well on mepacrine, but it was disappointing as a prophylactic in small doses.

Then the Japanese invasion came, and all the progress in malaria relapsed to where it had been more than twenty years previously, and like those of most others my records, which included over 100,000 spleen palpations, disappeared into oblivion. But the war brought a big improvement in malaria treatment, and since then for some unknown reason, a subject of many medical discussions, malaria in Malaya has been no longer the very serious problem it used to be. Larvae surveys usually produce only few finds, whereas thirty years ago they were prolific.

Since the war mepacrine and proguanil have been used as a treatment for both vivax and falciparum infections. Three mepacrine tablets (100 mg. each) are given daily for three days, followed by three proguanil tablets daily for three days. To complete the course, I usually give a daily tablet of proguanil for one week. I cannot give any accurate relapse rate figures for this treatment, but am satisfied that it is not high.

Of the chloroquine products, I favour camoquin because it is easy to take (three tablets) and has a very low relapse rate. "Resochin" and "nivaquine" have given similar results, as one would expect from their similar formulae. Pyrimethamine ("daraprim") has proved rather disappointing. I do not wish to infer that the other chloroquines are not any good; they may be better. I mention those giving satisfaction out here, which I have used in my practice.—I am, etc.,

Johore Bahru, Malaya.

NORMAN DUGDALE.

Control of Tachycardia by Quinine

SIR,—Like Dr. P. R. Boucher (*Journal*, September 26, p. 727), I have had paroxysmal tachycardia from drinking coffee, but also, like Dr. H. L. Maclure (*Journal*, August 29, p. 511), I have successfully treated a case with quinine.

A woman of 77, who had had much malaria and dysentery in India but remained strong in body and spirit, came under my care three years ago with a history of frequent and severe bouts of paroxysmal tachycardia, sometimes lasting all day, for two years. Cardiologists had investigated her heart and found it normal. She had had "all sorts of x-rays." She stated that quinine and digitalis were poison to her, and resented having been instructed, when these drugs failed, to take phenobarbitone and pull herself together. The patient stated that an attack was often preceded by a feeling of distension below the left costal margin. A barium meal showed a single diverticulum at the splenic flexure. Having seen the patient in a number of attacks, and confirmed that simple measures were ineffective and that various forms of digitalis by mouth, digoxin intravenously, and quinine by mouth would all terminate an attack, but only by producing violent and alarming vomiting, I tried carbachol, and this usually terminated an attack, at the cost of tolerable diarrhoea instead of intolerable vomiting. Efforts were now made to prevent distension of the diverticulum by means of a low-residue diet, the regular administration of liquid paraffin and "laka-diastase," and courses of phthalylsulphathiazole. There was a reduction in the frequency of the attacks, but it was only when the patient took quinine hydrochloride 5 gr. (0.32 g.) three times a day that they became really infrequent, occurring at intervals of months instead of days. The lady is now 80 and her failing memory and pride cause her to prove the efficacy of these measures, because her attacks now occur when the medicines have not been taken for a few days.

I have not tried to terminate an attack by the injection of quinine bihydrochloride.—I am, etc.,

DAVID MILWARD.

SIR,—The reaction of Dr. P. R. Boucher (*Journal*, September 26, p. 727) to Dr. H. L. Maclure's letter (*Journal*, August 29, p. 511) has stimulated me to draw the attention of your readers to the fact that quinine, not quinidine, was originally used in various abnormalities of the cardiac rhythm. In 1912 Wenckebach¹ discovered—more or less accidentally—the beneficial effect of quinine in some types of irregular action of the heart. His disciple Frey also studied this phenomenon, and he, together with Wenckebach, showed² that quinidine—the dextrorotatory isomer of quinine—acts almost twice as potently as does quinine. Since then quinidine has come to the fore in cardiology, but quinine is still used in some cardiac patients, often in combination with other drugs.

It is therefore quite possible that the paroxysmal tachycardia which Dr. Maclure describes in his patient was indeed controlled by the daily prophylactic use of quinine, but surely it is not necessary to assume that the use of proguanil was in one way or another connected with the patient's tachycardia, as Dr. Boucher has suggested.—I am, etc.,

Amsterdam.

Histoplasmosis in Great Britain

SIR,—In a paper under this title, Dr. S. Locket and his colleagues (*Journal*, October 17, p. 857) reject as "very doubtful" a case of histoplasmosis from Africa, reported in England by me.¹ May I point out that this was a proved case of histoplasmosis, the diagnosis being based on the identification of the causative fungus in culture isolated from the lesion, and on the histopathology of the lesion.

This strain of *Histoplasma*, in its normal mycelial form, presented the specific morphological characters of *Histoplasma capsulatum*, but in the yeast phase, both in parasitic life and in culture, large forms developed which, although occasionally to be

found in *H. capsulatum*, were much more marked and more constant in this tropical African strain. After prolonged study of the fungus in culture and in experimental disease I concluded that it could be distinguished from *H. capsulatum*, of which it was a stable variety, probably peculiar to tropical Africa. This opinion was borne out by the discovery and study of other cases of this form of histoplasmosis in various parts of tropical Africa. Recently Vanbreuseghem² accorded this variety specific rank under the name *Histoplasma duboisii*. The original strain isolated by me in 1943 is still available.

Including the case of histoplasmosis described by Locket and his colleagues, but not the one referred to at the conclusion of their paper, five well-authenticated cases of histoplasmosis have been identified in Great Britain since 1941. In all five cases there was a history of residence abroad in a warm climate; in three the disease was unquestionably contracted abroad; and in the other two there was no evidence that the infection was incurred in Great Britain. In fact the results of epidemiological surveys with the histoplasmin skin sensitivity test have failed to indicate the existence of endemic histoplasmosis in Great Britain.—I am, etc.,

A Human Blood-group Chimera

SIR,—I have read with the very greatest interest the report in the *Journal* of July 11 (p. 81) of a human blood-group chimera by Mr. I. Dunsford and others, together with your annotation (p. 89) on the subject. You mention a number of implications of this observation, but there is another to which I wish to draw attention.

It has been shown by Medawar and his colleagues¹ that skin homografts interchanged between non-identical twins in cattle may survive permanently, and I would venture to predict that if the twin of the blood-group chimera, reported by Dunsford, were still alive and skin homografts were made from one twin to the other these would probably survive permanently. It is clearly impossible to test this particular hypothesis, but it would be of great interest and importance to undertake reciprocal skin homografts if further blood-group chimeras are found. We are looking out for suitable cases here, but as the phenomenon is apparently a rare one I am writing to you in the hope that if the opportunity to perform an experiment of this kind arises elsewhere it should not be neglected.—I am, etc.,

A Danger of Succinylcholine Chloride

SIR,—At the close of an emergency operation performed at another hospital, under succinylcholine chloride ("sco-line") drip with gas-oxygen anaesthesia, administered by one of us (J.W.M.) the drip was turned off by the anaesthetist but had not yet been disconnected when a surgical colleague restarted it, ignorant of the fact that the bottle contained 0.1% succinylcholine chloride.

In the hope of preventing an occurrence of this type of accident (which in the above case did not prove fatal) discussions with colleagues, the theatre sister, and the pharmacist have resulted in the adoption of the following safety precautions. The use, for succinylcholine chloride drip solutions, of transfusion bottles different in size and label from those normally used for ordinary intravenous saline therapy. Immediately the succinylcholine has been added to the bottle by the anaesthetist, a special stick-on "caution label" is applied to the bottle by him. This label is 3 in. by 2 in. (7.5 cm. by 5 cm.), red-edged, printed in bold red lettering on a white background, and worded as follows: "Caution. Succinylcholine muscle-relaxant has been added to this bottle."—We are, etc.,

London, E.11.

Heparin in Intravenous Infusion

SIR,—I would like to support Mr. H. F. Smith's suggestion (*Journal*, September 5, p. 569). I have followed a similar course for a number of years with advantage and without mishap. I have been in the habit of adding 0.5 ml. of the 1,000 units per ml. strength to each pint (0.57 l.), making 500 units per pint (0.57 l.). Run in at the usual rate of 40 to 60 drops per minute, or 0.57 l. in three to four hours, the clotting time was unaffected in 10 cases investigated. One got the impression that the life of drips, especially the more sticky ones of blood and glucose, was appreciably prolonged. To confirm this, heparin was added to alternate infusions required in a general surgical ward. Infusions which stopped before the fluid therapy was completed were compared in the two series, others being ignored. In a total of over 70 infusions the superiority of the heparin-treated fluids was not so marked as one had expected. Unfortunately, I have not the figures to hand, and in any case I understand they were of little significance statistically.

I would like to add a note of warning. I make a point of adding the heparin myself or entrusting it to a reliable assistant. At the same time a label is stuck on the bottle stating that 500 units of heparin has been added. This is to avoid further doses being added by people who know "he likes heparin in his drips."

I have seen a dose of 100,000 units of heparin—that is, ten times the standard dose—given intravenously, by mistake, at the end of an operation for ligation of the femoral vein because of recurrent emboli. There was no doubt about the massive haematoma that developed in the wound. However, after evacuation of the blood clot there was minimal bleeding and the wound healed well after secondary suture. No doubt as the haematoma increased in size the pressure on it increased, which tended to stop further bleeding; in any case, the action of heparin given intravenously only lasts for three to four hours, the clotting time of the blood then returning to normal. Though this set of circumstances may not hold in all cases, I feel that perhaps the dangers of bleeding after the use of heparin have been over-emphasized.—I am, etc.,

Nairobi.

ANDREW HICKS.

Any Complaints?

SIR,—While endorsing wholeheartedly your leading article (*Journal*, August 29, p. 479) that medical students, and in particular those least likely to end up in general practice, should receive first-hand instruction in the conditions of it, may I protest against your suggestion that they should learn "what patients first complain of"? I believe that patients do not complain of their symptoms until we as a profession teach them to do so. They may complain of their neighbours' wireless, but they simply "have" a rash or a pain until we suggest the term complaint, with its innuendo of responsibility lying either with the doctor or more broadly with the Health Service and the community at large. Thus we sow the seed which may blossom as neurosis and bear the fruit of litigation.

Certainly our clear duty is to relieve our patient's symptoms, and, if possible, help him so to alter his external and internal milieu that his disease or injury may cure itself; but seldom shall we help him by accepting, or suggesting to him that we accept, the responsibility for it. Well equipped as we may be to kill micro-organisms and set fractures, a large part of our function is to help our patient to tolerate his disease so long as it may last. "This is your pain"; "This is your skin's reaction to its environment"; "This I can offer to help your body to recover." "What have you come to see me about?" may be bad grammar (though not worse than, "What are you complaining of?"), but at least it is good medicine and can be followed by a discussion of symptoms as a matter of mutual interest and concern free from the emotional tone of plaintiff and defendant.—I am, etc.,

Bradfield, Berks.

G. A. BECK.

Cancer and the Public

SIR,—I beg the favour of your pages to answer the multiple criticisms of my letter (*Journal*, October 3, p. 779).

Dr. Sidney Russ (*Journal*, October 17, p. 883) is not a "doctor" but a distinguished physicist, yet he exhibits a strange inconsistency when, as such, he insists on using wrongly the word "cure"—the obvious cancer may be surgically removed but the pabulum on which it grows remains, as do often the malignant cells which have been disseminated throughout the body. These by their growth may become manifest in a few weeks, a few months, or years, and we have no means of preventing it and often no means of detecting it until the end is near. He must know that some of these "5-year cures" merely continue with a disease a rather pitiable existence, at least as pitiable as those who have had no "cure" but continue to live for 7–10 years. All I ask to be told is the truth, not what is considered by some to be expedient, since it has but a temporary basis and permits and encourages a tremendous amount of useless expensive repetition. Dr. E. D. Y. Grasby (*Journal*, October 17, p. 883) can rest assured that I would quietly take all those measures which good medicine dictates, for I am at least as keen on a cure for cancer as any propaganda enthusiast is, but I believe that knowledge is so widespread that the patient is at least as safe for guidance in treatment in the hands of a sound practitioner, since he is not so obsessed or blinded by scientific aids on which the specialist solely relies.

Dr. Grasby states, "It is to allay such fears [of cancer] that education may be of service," but in a later paragraph to combat my statement that "the major manifestations of syphilis have been abolished even though secrecy and not propaganda has dominated treatment," he states: "Surely neurosyphilis may be completely incurable even with the most violent treatment." Most doctors would agree that if the public were told this it would hinder and not help to induce patients to come for treatment; though my statement, which is true, would. Propaganda for cancer has always increased the fear of it—it has led many healthy people to seek "check-ups"—but it will never induce the doctor who is a sufferer or a layman who has seen some of the results of treatment to divulge that which he knows is feeding "on the pith of life."

Let me reassure "A Grateful Patient" (p. 883) that I am fully alive, as are all general practitioners, to the benefits available from surgery where the cancer is occluding a vital tubular structure—the sooner a necessary plumber's job is done the better—and to comfort him further by telling him that I have a patient alive more than 20 years after resection of such a lesion of the colon. But that patient, like him, had complained of signs and symptoms which indicated the possible site of the lesion and she had the desirable surgery.

Are we to understand from Dr. John McFarland (*Journal*, October 24, p. 936) that the ignorance of the general practitioner was responsible for the patient's death? Let me comfort him and Sidney Russ with the words of a dying surgeon, Mr. Percy Furnivall: "The surgical part of my case was trivial and painless. I would not wish my worst enemy the prolonged hell I have been through with radium neuritis and myalgia for over six months. . . . For an old man with an early growth to have an adequate surgical operation only would be well worth the possible extra risk of recurrence," and his obituary notice¹ ran: "He formed the opinion that the treatment he had undergone had increased his suffering and made his passing more difficult, and he wished in his love for humanity to save others from a like fate."

The personal experiences of William Gosse² are of a similar nature, and they still continue.—I am, etc.,

Birmingham, 15.

Orthopaedic Care in Poliomyelitis

SIR,—It is always regrettable when senior members of our profession resort to bickering in public, and the present controversy between orthopaedic surgeons and Dr. Ritchie Russell is no more seemly a passage of arms than was to be expected. In the Leeds region for the past six years poliomyelitis has been treated by the combined and harmonious efforts of a consultant in infectious diseases, a neurologist, a research anaesthetist, and an orthopaedic surgeon in a team whose members have not yet had occasion to be jealous of each other's contribution. It would seem that a similar pattern of working in the treatment of poliomyelitis would be to the benefit of the country at large.—We are, etc.,

HUGH GARLAND.

JOHN M. P. CLARK.

Leeds.

POINTS FROM LETTERS

Sweating in Shock

Dr. J. S. H. WHITEHEAD (London, S.E.22) writes: The fact that sweating occurs under certain conditions in anaesthetized persons was said by your expert ("Any Questions?" *Journal*, August 29, p. 520) to be "teleologically unfortunate." Dr. Ronald Woolmer (*Journal*, October 10, p. 832) took exception to this on the ground that it was merely ignorance of the whole truth that made it appear so. Surely the term "teleologically unfortunate" is self-contradictory, for according to Webster's dictionary teleology is the theory that the phenomena of organic life are explicable only by purposeful causes.

The Couvade

Dr. THEODORE LOUCAIDES (Nicosia, Cyprus) writes: With reference to the correspondence published about the custom of the couvade (*Journal*, August 23, 1952, p. 454, September 6, 1952, p. 555, and September 20, 1952, p. 667), I suggest that the following may be the origin of the hitherto unexplained custom. According to Plutarch (*Theseus*, 20), Theseus on his way back to Athens from Crete was blown by the winds to Amathus (now Limassol, Cyprus), where he was obliged to leave Ariadne (the daughter of Minos) because she could not continue her voyage to Athens (she was pregnant and suffering excessively from seasickness). At Amathus Ariadne could not bear being abandoned by Theseus, and she fell into marasmus and died during labour. She was buried at Amathus in the forest of Ariadne-Aphrodite. When Theseus returned to Amathus to fetch Ariadne he was informed of the unhappy event, and before leaving Cyprus he erected two statues and inaugurated a feast in honour of Ariadne. He left money to the Amathusians so that they might celebrate the feast annually. As a result of this feast Ariadne came to be worshipped at Amathus as a goddess of midwifery, and women honoured her statues representing a woman holding a baby in her arms. The feast was held during Gorpheos month (latter half of August and first half of September), and during it a man lay down and cried and acted as a woman in labour.

Acute Inversion of the Uterus

Dr. B. BHATTACHARYA (Darlington) writes: I read with interest Dr. J. F. Enright's report of a case of acute inversion of the uterus (*Journal*, September 26, p. 714). I have made a study of this subject based on nine such cases, and I entirely agree with Dr. Enright that quick and gentle reposition of the inverted uterus is the secret of success. In my opinion this should be done as soon as possible after the occurrence.

Cancer and the Public

Mr. A. P. BERTWISTLE (Birmingham, 28) writes: With reference to Dr. J. F. Brailsford's letter (*Journal*, October 3, p. 779), I believe that cancer propaganda among laymen would do more good than harm if expressed in an optimistic vein, and this is justified by the results of surgery, aided by modern radiology, antibiotics, and anaesthetics. I think we have come to the stage when we can say that all skin cancers, and most lip, tongue, uterine body and neck, and rectum cancers if taken early are curable by surgery and radiotherapy. I understand early malignant disease of the lip is treated as an out-patient operation in the U.S.A. How can a doctor tell a patient that he or she should have come earlier, when they know nothing of early symptoms? There is considerable propaganda regarding venereal disease—vide the walls of public conveniences. Why should not cancer propaganda be more widespread in an effort to help humanity?

Obituary

E. CHRISTINE PILLMAN WILLIAMS,
M.B.E., M.B., B.S.

Dr. Christine Pillman Williams died at her home in London on October 28 at the age of 64. She was the daughter of Mr. J. C. Pillman, a member of the Baltic Exchange, and was born on December 6, 1886, one of six children. Two of her brothers were famous players of Rugby football, and it was a special pleasure to Dr. Williams that her own four sons were all keen players.

Emma Christine Pillman went up to Girton College, Cambridge, in 1906, and took the natural sciences tripos in 1910. She qualified M.R.C.S., L.R.C.P. from the Royal Free Hospital in 1914, and obtained the London degrees of M.B., B.S. in 1916. After holding house appointments at the Royal Free Hospital until 1916, she worked at the Ministry of Munitions as chief medical officer at a shell-filling station; her war service there was recognized by the award of the M.B.E. in 1918. From 1919 to 1921 she was a member of the B.M.A.'s Ministry of Health Committee as the nominee of the Medical Women's Federation.

In 1919—the year in which she married Dr. Ulysses Williams, radiologist to the Royal Free Hospital—she returned to hospital to undertake research in the maternity wards with a Medical Research Council studentship. During her three-year tenure of this award she began, in collaboration with Dr. Lucy Wills, her work in the pathology department, which she continued on a voluntary basis until, in 1929, she was appointed lecturer in chemical pathology and chemical pathologist to the Royal Free Hospital. When war broke out again in 1939, the department of pathology was moved to the Three Counties Emergency Hospital at Arlesey, Bedfordshire, and Dr. Williams undertook full-time work there at the request of the Ministry of Health. She returned to London at the end of the war and took up her duties at the Royal Free Hospital again, being granted recognition as a teacher of the University of London in 1945, and appointed senior lecturer in charge of the department of chemical pathology in 1947. She was due to retire next year after 33 devoted years of work for her medical school and hospital. Her colleagues mourn her loss as a pathologist and as a very dear friend to many of them, and their sympathy goes out to her husband and family.

R. A. W. writes: Dr. Pillman Williams's long association with the Royal Free Hospital was temporarily interrupted on the outbreak of war in 1939, when the department of pathology was evacuated to Arlesey; she went with the first load of equipment and did not return to Gray's Inn Road until six years had passed. In the early months at Arlesey, when improvisation with makeshift apparatus was the rule, her cheerful acceptance of all difficulties and her help and encouragement in establishing teaching and hospital routine in the new and strange surroundings were invaluable.

Dr. Williams made a home for herself and her family on the outskirts of Letchworth, and there members of the staff and students were always sure of the warmest welcomes. She was soon engaged in committee and subcommittee work, in addition to her routine and teaching duties, and her advice on dietary subjects was in demand from other hospitals near by as well as from her own. Dr. Williams gave unswerving loyalty to the Three Counties Emergency Hospital, as she had always done to the Royal Free, and as she was to do again in the years that followed 1945. Nothing could daunt her indomitable spirit. To see, as we did in the severe winters of 1940 and 1941, her Balaclava helmet bobbing above the great snowdrifts as she ploughed her way to work each morning was a sight to cheer the faint-hearted. The emergency hospital in the country owes to Dr. Williams, as it does to her clinical colleague, Mrs. Chodak Gregory, a deep debt of gratitude for their faithful service to all its interests.

In reorganizing the department of chemical pathology at the Royal Free Hospital after the war Dr. Williams worked unrelentingly and did not spare herself, and she had the happiness of seeing it grow in stature and importance before her last illness took her from it. Her colleagues will miss her sorely. No one could have been kinder or more loyal. No one ever sought her help in vain.

D. C. H. writes: I first met Christine Pillman Williams in 1918, when she was in medical charge of the women in a munitions factory, which she invited me to visit with her. There she was tackling the problems of T.N.T. and allied poisonings and was winning the ready co-operation of all who worked under her by her sympathetic and understanding approach. A year or two later I was in daily contact with her at the Royal Free Hospital, where our association continued till 1937. Dr. Williams excelled as a clinical pathologist, and her help in the diagnosis of a difficult case was invaluable, for she viewed the problem as a whole and kept the clinical probabilities always in mind when advising on laboratory investigations. Anyone who had the privilege of working with her, whether as junior resident or one of the senior staff, owes her a debt of gratitude for the help she gave so readily from her funds of knowledge and experience.

Quite early in her career Dr. Williams became interested in the disorders of pregnancy and did valuable work on the biochemical changes associated with these disorders and with their dietetic treatment, and later we worked together on the dietetic treatment of rheumatoid arthritis. The effects of various diet treatments were studied from the clinical aspect with the concurrent biochemical changes, other therapeutic treatments being excluded. Some extremely interesting results were obtained and cinematograph records of clinical progress were made. The work, however, was interrupted by the outbreak of war in 1939. A modified form of Bircher-Benner diet was used in a number of cases, Dr. Williams being responsible not only for the drawing up of the diet sheets but for the close supervision of the preparation of the food in palatable form in the diet kitchen. Her biochemical research work covered many fields, but was always directed to clinical problems, to which she made many valuable contributions. Her loss will be mourned by all who knew and loved her.

N. S. FRASER, O.B.E., M.D.

The medical profession in Newfoundland has lost a prominent member by the death of Dr. N. S. Fraser at St. John's on October 6 in his ninetieth year.

Nutting Stuart Fraser was born in 1864, the youngest son of the late James Oliphant Fraser, one-time Member of the House of Assembly and a former Postmaster-General for Newfoundland, and grandson of the Rev. Donald Allan Fraser, pioneer kirk minister of the County of Pictou, Nova Scotia. After receiving his early education at the Protestant Academy in St. John's he attended Queen's University at Kingston, Ontario,

and matriculated with first-class honours in Latin and Greek. Later he entered Edinburgh University to study medicine, and graduated M.B., C.M. in 1886, in the same year passing the examination for the M.R.C.S. in London.

After graduation he held residential appointments at the Simpson Maternity Hospital and the Royal Sick Children's Hospital, Edinburgh, and then in 1887 returned to St. John's, Newfoundland, entering practice as a junior partner with the late Dr. Thomas Howley. From that time until his death he lived a life of devoted and unselfish service. In 1893 the Government of Newfoundland appointed him to the first medical board formed under the Medical Act, and he maintained his membership of the board for 60 years, being its president for the past 25 years.

In 1936 Dr. Fraser celebrated his fiftieth year in practice in a remarkable way. He wrote a thesis on some original studies, and was awarded his M.D. for this work by the University of Edinburgh. All through his professional career he kept his knowledge up to date, and as recently as September this year he took an active part in the discussions of the Newfoundland Medical Association and gave the members a short address on pancreatitis. He was a pioneer in many medical activities, including the use of x rays, and he established and maintained for many years the only children's hospital, as well as conducting a large general practice. He was a consultant on the staff of the general hospital, and for some years was port doctor and health officer for the port of St. John's. During the influenza epidemic of 1918 he was recalled to the health department, and by his strong action in closing all places of entertainment and banning mass meetings he did much to stop the spread of the infection. At the same time he organized a volunteer nursing service and temporary hospitals. In 1945 he was appointed O.B.E. for his medical work in St. John's.

Dr. Fraser was prominent in church circles and a faithful member of St. Andrew's Church as the senior elder and superintendent of the Sunday school. Numerous contributions on current topics and historical subjects were published over his initials in the local daily paper. He leaves four sons, one of whom, Dr. Nutting Stuart Fraser, is a consultant anaesthetist in Edinburgh, and another, Dr. J. Oliphant Fraser, is in general practice in St. John's.

Dr. C. E. MORRIS, a past president of the Chester and North Wales Medical Society, died at his home in Holywell, North Wales, on October 7, at the age of 81. A popular figure in the town since 1898, he had completed 50 years in practice before he retired a few years ago. Charles Edward Morris was born at Rhosllanerchrugog, near Wrexham, on May 31, 1872, and from Ruabon Grammar School he went on to study medicine at University College, Liverpool, and later at St. Mungo's College, Glasgow. He qualified in 1895 and then held a post as house-surgeon to Sir Robert Jones at the Royal Southern Hospital, Liverpool, an appointment which encouraged his keen interest in orthopaedic surgery. In 1898 he became resident surgeon at the Flintshire Dispensary, and after holding that appointment for some years he went into partnership with the late Dr. Owen Jones, of Holywell. During his professional life he was closely associated with the hospital at Holywell and often operated there. One of his main interests was obstetrics, and he was very accomplished in this work. He was surgeon to many of the industrial concerns in the area, and was often called to attend injured colliers at the coal-face. In the medico-political world he took a very prominent part. He

was secretary of the Denbigh and Flint Division of the B.M.A. from 1913 to 1917, chairman of the Division in 1924-5, president of the North Wales Branch in 1931-2, and he represented his constituency at ten Annual Representative Meetings between 1919 and 1935. He was also a former member of the Welsh Committee of the B.M.A. A member of the old Flintshire Insurance Committee for many years, he was also secretary of the local panel committee, and became a member of the Denbighshire and Flintshire Executive Council at its inception. In 1912 he saw the inauguration of the National Health Insurance scheme, of which he was a whole-hearted supporter, as he was of the National Health Service Act of 1948. His non-professional interests were many, and in particular he was a loyal member of his Church, serving on the representative body of the Church in Wales. A keen archaeologist, he was a member of the board of governors of the National Museum of Wales. At one time he was a member of the senate of University College, Bangor. Another of his interests was Freemasonry, in which he held several important offices. Dr. Morris will be greatly missed by his patients and colleagues; his kindly nature, his humility, and his versatility were only a few of his many virtues. He leaves a daughter and four sons, the eldest of whom, Dr. J. E. Ll. Morris, remains in practice at Holywell.—D. B. E.

Dr. S. B. HERD writes: When Dr. C. E. Morris, of Holywell, passed quietly on, there was extinguished a flame that had illumined with a bright steady light the medical, religious, and scientific life of Flintshire and regions further afield for many years. Charles Morris was not merely a fine general practitioner and no mean surgeon, as his long and devoted service to the Holywell Cottage Hospital showed, but a humanitarian in the very deepest and best sense of that word. He devoted his energies to the service of the people in the district, who loved him for his kindness and sympathy, as well as they admired and trusted him for his skill. He was for many years an active member of the North of England Obstetrical and Gynaecological Society, travelling long distances to attend meetings, and was always held in respect and admiration. Many will remember how he would sometimes break his usual modest silence and give a discussion with the fruits of his long clinical experience. He found time, too, for archaeological and other non-medical interests, and his perennial energy even in his later years was the envy of his juniors. Behind his jizzical and habitually semi-humorous expression there was a tranquillity and steadfastness, a serenity and quiet confidence, on which he drew to meet the trials of bereavement and illness. To those around him he was able to pass his serenity and faith.

Mr. ROBERT JAKES, who died in Worthing Hospital on September 20 at the age of 91, was, before his retirement 20 years ago, a consultant ophthalmic surgeon in Plymouth and a member of the honorary staff of the Royal Eye Infirmary. Born at Antrim, Northern Ireland, on February 28, 1862, he was educated privately and later came a medical student at King's College Hospital. He qualified in 1900 and obtained the diploma of F.R.C.S. three years later. After holding resident appointments at King's and at the Royal Eye Hospital, Southwark, he settled in practice at Plymouth as an ophthalmic surgeon. In his younger days Mr. Jakes took an active interest in medico-political affairs and was chairman of the Plymouth Division of the British Medical Association from 1911 to the end of the first world war and vice-chairman for four years thereafter. He was president of the South-western Branch of the Association in 1923-4 and a past president of the Plymouth Medical Society. A scholarly man with advanced political views, he foresaw much of the trend of medical practice as it is to-day. In 1909, for instance, he published a paper titled "Nationalization of Medicine." Colleagues of his will recall to mind his kind, whimsical disposition and his command of language as a public speaker. His death was regretted by many old friends in Plymouth.

We announce with much regret the sudden death on November 6 of Dr. JOSEPH BRAMHALL ELLISON at the age of 55. Educated at Rugby School, he saw service in the 1914-18 war in the Royal Engineers: he suffered severe shock as the result of being "buried alive" for several hours. Ellison went to Clare College, Cambridge, after the war, and thereafter to St. George's Hospital. He qualified M.R.C.S., L.R.C.P. in 1924, and took his Cambridge M.B., B.Ch. in 1925 and the M.D. in 1930, the same year in which he acquired the D.P.H. At St. George's, in the year of his qualification, he was awarded the Certificate of Honour and the Brackenbury Prize in Medicine. He was house-surgeon at St. George's and at Addenbrooke's and house-physician at the Queen's Hospital for Children. Not long after these appointments he entered the Fever Hospital Service of the Metropolitan Asylums Board, later taken over by the L.C.C. For the past twenty-five years he had worked at the same hospital—the Grove Hospital, Tooting—content to remain there in a relatively junior position. Ellison's friends and colleagues had little doubt of the brilliance of his mind and of his potentiality for achieving a more outstanding position in medicine than he did. His many gifts and a wide range of non-medical interests probably made it difficult for him to pursue with concentration any one course in life. He had a remarkable knowledge and appreciation of art, literature, and music, and he would take more pride in a poem he had written than in a paper published in one of the medical journals. At one time he embarked on the hazardous venture of promoting a film. Ellison was a stimulating and witty conversationalist, and no one could know him without feeling enriched by the experience. The guiding motive of his professional life was his unflinching affection for the sick children under his care in the fever wards of the Grove. He would prefer to spend his Christmas in the hospital so that he could entertain the children and make them laugh, and there must be in the neighbourhood of Tooting many hundreds of children who, with their parents, recall with deep affection his vivid and cheerful personality; they owe much to him. Ellison was a valued occasional contributor to the *B.M.J.*, and his knowledge of French and German was turned to good account in the work he did for *Abstracts of World Medicine*. His friends mourn the passing of a brilliant and lovable person whose character was marked with that eccentricity of personal idiom that is peculiarly English.

Universities and Colleges

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of the Council of the College held on July 25 the following officers were re-elected: *President*, Mr. Arthur A. Gemmell; *Vice-presidents*, Professor G. I. Strachan, Mr. A. J. McNair; *Honorary Treasurer*, Mr. A. C. H. Bell; *Honorary Secretary*, Mr. H. G. E. Arthure; *Honorary Librarian*, Mr. A. J. McNair; *Honorary Curator of the Museum*, Mr. A. W. Bourne; *Honorary Treasurer, Canadian Regional Council*, Mr. W. R. Foote. The following officers were elected: *Honorary Treasurer, Australian Regional Council*, Mr. J. N. Chesterman; *Honorary Treasurer, New Zealand Regional Council*, Mr. J. E. Giesen.

The Bernhard Baron Research Scholarship has been awarded to Mr. Stanley Albert Way for research on problems connected with the early diagnosis of cancer in women.

The following candidate was admitted to the Membership: D. S. Burris.

The following candidates were elected to the Membership: L. J. Abramowitz, S. Alankaram, W. J. R. Anderson, G. S. Andrew, A. K. Bose, J. C. Brace, E. R. Broadberry, T. J. Buckley, S. Burke, R. K. Burt, J. G. Cameron, R. S. Casement, Po Wong Christina Chow, Maureen D. Connolly, R. L. Edwards, M. B. Flanagan, F. M. C. Forster, Kathleen M. Frith, M. C. G. Grant, P. B. Guastalla, R. H. J. Hamlin, J. W. S. Harris, C. A. Jones, R. Ll. Jones, I. R. Macdonald, Betty Mallace, G. A. Manly, D. N. Menzies, M. C. Michelow, J. Natrass, H. H. Neifeld, F. N. Neser, J. P. O'Dwyer, D. R. Patnaik, Clara Phillips, B. G. Pickles, W. Rotheram, J. S. Scott, J. M. Stewart, R. A. Struthers, Valerie M. Thompson, C. J. Thornberry, H. Ulman, C. G. Wilson.

Medical Notes in Parliament

SOCIAL SERVICE LEGISLATION IN NEW SESSION

The Queen's Speech opening the new session of Parliament on November 3, stating the Government's intentions to strengthen the national economy and thereby to safeguard the high standards of the social services, attracted diverse comment in the subsequent debates. The Speech also promised legislation to consolidate and extend the law on the safety, health, and welfare of miners and quarrymen, to provide benefit for certain further cases of disablement from industrial diseases, to amend and consolidate the law relating to food and drugs, and to restrict night working in the baking industry.

The EARL OF ROTHES, who moved the Address in the House of Lords in reply to the Queen's Speech, spoke as a governor of a London teaching hospital in expressing some disquiet about the rising cost of the Health Service. He said it had been thought that the high initial cost would tend to stabilize itself, because a better service would mean better health and a consequent reduction in demand. In practice the reverse seemed to be happening—both demand and cost had increased. It was unthinkable to try to stop the advance of medical science, so it would seem that the country must face a rising cost year by year.

Prevention of Tuberculosis

Miss EDITH PITT, an industrial welfare officer elected in July for the Edgbaston division of Birmingham, who seconded the address in the Commons, directed attention to the treatment and prevention of tuberculosis. The stage had been reached when there was an opportunity to eradicate it entirely. The number of ascertained cases awaiting hospital treatment remained the immediate problem. More beds were needed, more nurses, and improved surgical facilities. It would help to make the most effective use of existing beds if some kind of hostel or intermediate accommodation could be provided for those who only needed limited supervision and perhaps some nursing. A recent survey in the Midlands showed that between 15 and 20% of the beds occupied came within this group.

Mental Health

Mr. MALCOLM MCCORQUODALE hoped that the Royal Commission on the lunacy laws would consider closely whether there should not be a much greater separation between the problem of mental health and that of the mental defective. He would like to see mental hospitals, where the treatment was medical, and mentally ill patients remain under the Health Service; and colonies for defectives, whose treatment was a matter of care and education, returned to the local education authorities. He hoped also that the commission would not flinch from considering whether special medical treatment should be given to patients who had no control over their sexual appetites, and who were kept in institutions although in all other respects they could find a satisfactory place in society.

Mr. JAMES SIMMONS, who has worn an artificial limb since 1917, pleaded for some special consideration for the 24,000 men still surviving who had one or more limbs amputated in the first world war. They were an ageing group—the average age was 62—and they had special problems arising from the "wear and tear" from artificial limbs that should be compensated. A few years ago the Rock Carling committee was set up to inquire into the effect of amputation on the heart and lungs. Since that inquiry some limbless men—himself among them—had been personally examined. He hoped the Government would hasten the findings of the Rock Carling committee and announce their intentions for the limbless veterans.

"Smog" Masks and Research

Mr. SOMERVILLE HASTINGS asked the Minister of Health what research had been made to determine how much of

the sulphur oxides and other gaseous contents of fog were removed from inspired air by the use of a dry gauze mask.

Mr. IAIN MACLEOD, replying on November 3, stated that there has been extensive research on protection from the toxic solid and gaseous contents of air in different conditions. Respirators to achieve this had been known for many years; they were of rather elaborate canister types, something like those used in the Forces. But the real problem of the "smog" was that of persons—and particularly old persons—suffering from weaknesses of the lungs or heart, as last winter showed, and further research was needed to determine what respirators could be safely worn by such people for long periods. This was going on actively among the out-patients of a large hospital. As to surgical gauze masks and chiffon scarves, he was advised that they would be of little or no value in absorbing the toxic gases, although, like any other comparable form of improvised protection, they would impede some of the solid particles.

EARL JOWITT in the House of Lords on November 4 urged the development of smokeless fuel and the extension of the smokeless zones.

LORD WOOLTON, replying for the Government, said an interim report was due soon from the committee appointed by the Minister of Fuel and Power.

Nerve Gases

Mr. IAN WINTERBOTTOM asked on November 9 if an antidote to nerve gases had been discovered, and referred to the recent death of a volunteer during experiments. Mr. DUNCAN SANDYS, Minister of Supply, replied that no complete antidote had yet been discovered. Mr. WINTERBOTTOM asked if the Minister could explain how the categorical statement that an antidote had been found had made its way into the American press by way of the *British Medical Journal* (August 9, 1952, p. 334, article from Chemical Defence Advisory Board). Mr. SANDYS replied that what he said was that no complete antidote had been found; a partial antidote had been found, but it was not regarded as wholly satisfactory.

Prospects for Registrars

The House of Commons had a short discussion on November 6 on the employment prospects of hospital registrars.

Mr. HORACE KING, who initiated it, recalled that in 1951, when it was discovered that there were more registrars than the Health Service could absorb, the decision was made to cut the intake of registrars to the approximate number of consultant posts likely to become vacant from year to year. His concern was with the men who already, in good faith, had taken posts as registrars and now found it difficult to obtain posts of any kind.

This problem confronted a group of 300 or 400 senior registrars. He described cases in the Southampton area to illustrate the difficulty the registrar had in trying to get into general practice: a surgeon-registrar who in desperation had taken a post in Australia; another registrar who did not even get on the short list for a vacant post in general practice; and a third who had hoped to become a consultant in general medicine but who had now switched over to pathology and taken a registrar's post.

He quoted also from a letter in the *Supplement* of October 3 (p. 161), "a bitter but revealing letter," he called it, "from a doctor who gave tragic pictures of the fate of three registrars," and from an annotation (*Journal*, p. 773), which said, "There is more than a grain of truth in the jocular remark . . . that to the applicant for a general-practice vacancy the possession of a car is more important than the possession of M.R.C.O.G., F.R.C.S., or—most dangerous encumbrance—M.R.C.P." It was a parlous state of affairs, Mr. King went on, when a medical journal could poke cynical fun at academic medical qualifications. It was bad for the health of the medical profession and of the Health Service. He did not blame the Minister. Vacancies were filled in the first place by a joint committee consisting of members of the health executive and the local medical committee; the former might be laymen, the latter were

entirely members of the medical profession. The short list went to the Medical Practices Committee, a national body consisting entirely of doctors, which finally made the appointment. So if a wrong was being done by the Health Service to registrars it was being done by members of the medical profession. The B.M.A. might be a very old trade union, but it was not as loyal to all its members as some others. The solution of the problem of registrars' entry lay largely in the hands of the profession, which dominated the committee which—independent of control—filled partnership and assistant posts as they became vacant. He urged that the Minister should use what influence he could by direct instruction, by exhortations to the medical practices committee and the local joint committees and to the B.M.A., and by direct action, if necessary, to see that the older registrars got a square deal.

Dr. BARNET STROSS said that many senior registrars found difficulty in obtaining consultant posts because of the reluctance of established consultants to allow them into the field at all. Since the emergence of the Health Service, and payment for all work, consultants' incomes had increased, sometimes in a spectacular fashion. But despite this there had been a decided reluctance by established consultants, particularly in the countryside, to allow any new men to come into this sphere of work.

Miss PAT HORNSBY-SMITH, Parliamentary Secretary to the Ministry of Health, said the fact that more men went into the senior registrar grade than it was possible to absorb into consultant posts in hospitals had been the subject of negotiations with the profession, and it had now been agreed that there should be an intake of approximately 270 new senior registrars each year. The number in the early years of training was now closely in line with this plan. But the number in the later stages of training was still in excess of the vacancies available. It was not the case, as Mr. King had said, that consultants were staying on longer.

The largest problem was in the category of registrars. It was never thought that all those who took registrar posts could possibly become specialists. The development of medical treatment and of the hospital service generally had called for many more registrars, and there was a grave shortage of this classification in some areas. This problem was under close examination by the profession and the Ministry, and it was clear that the remedies must include an increase in full-time and part-time registrars.

The main complaint of Mr. King was that there was discrimination against these registrars when they attempted to get into general practice. She thought too much emphasis had been put on the advertised vacancy relating to single-handed practices. It was not surprising that preference was often given in these cases to the man who had had general-practitioner experience. The wider field was unquestionably more in partnership than in advertised vacancies. There was far greater scope for a registrar to obtain an appointment in partnership, because it was unrealistic to think that the Medical Practices Committee, assessing the ability of a doctor to take over practice single-handed, and start in a new designated area, would overlook the doctor who already had general-practice experience. Generally speaking, a registrar had the highest qualifications in other ways, but his first steps in general practice would be far more advisably taken in a partnership. Having obtained that experience, he would, with his additional qualifications, be a very strong candidate for a single practice.

Dr. STROSS said he accepted this, but was any method available by which registrars looking for posts of this kind might know where they could apply?

Miss HORNSBY-SMITH replied that it was up to the partnerships to advertise, but she would examine the extent to which, by consultation with executive councils, they might know of vacancies that were imminent. She also pointed out that competition was particularly strong in the South of England, where there had been as many as 70 applications for single-practice vacancies. In the industrial North and in Wales there had been difficulty in getting one application for a designated area.

She disagreed with Mr. King's strictures on the medical profession. It had a dominating position on executive councils and on the Medical Practices Committee. One or two letters in the *British Medical Journal* had protested against the present method, but if it were reversed there would be enough letters to fill the entire journal from people who opposed the idea that anybody other than members of the profession were qualified to judge the suitability of those who wished to take up practice. In making their selections the Medical Practices Committee and the executive councils were doing a very good job.

Medico-Legal

VIOLINIST AWARDED DAMAGES

Damages of £1,240, with costs, were awarded by Mr. Justice Havers in the Queen's Bench Division last week to Miss Julie Saumarez, aged 43, of London, who sued the Medway and Gravesend Hospital Management Committee, alleging that negligent treatment of injuries to her left hand had ruined her career as a professional violinist.

Her case was that in a fall in July, 1949, she sustained a fracture of the base of the proximal phalanx of the left thumb and a chip fracture of the base of the distal phalanx of the middle finger of the left hand. On July 15, 1949, and on several occasions thereafter, until October, 1949, she attended the Sheppey General Hospital, Kent, for treatment, the doctor treating her being Dr. J. R. Theobalds. She was satisfactorily treated for the thumb fracture, but she alleged that Dr. Theobalds failed to discover or diagnose the chip fracture to the finger. Although she complained several times about the finger, and told him that an x-ray examination at the London Hospital had revealed a chip fracture, further examination was refused. As a result the bone had set in a crooked position, making it impossible for her to play the violin properly and thus ruining her career as a professional violinist.

The hospital management committee, denying negligence, contended that examination and treatment of Miss Saumarez's injured hand were properly carried out. They denied that she ever made any complaint about an injury to her finger. They did not admit that plaintiff had sustained any injury to her finger at all, and denied that she had suffered the damage alleged.

In evidence, Miss Saumarez said that when she first went to Sheppey General Hospital she did not know the nature of her injuries. Later she complained to Dr. Theobalds several times about pain in her middle finger. She said she told Dr. Theobalds she had been to the London Hospital and had been told that she had a chip fracture of the middle finger. He told her the x-ray plates at Sheppey showed no such injury.

Mr. R. Y. Paton, surgeon, called for the plaintiff, said that when he examined her in 1951 the distal phalanx of her left middle finger had a marked deviation. He considered the accident in 1949 was the most likely explanation of the deformity. The injury could have been remedied if discovered within three weeks.

Dr. Theobalds said in evidence that when the plaintiff first came to him a thorough clinical examination revealed injury to the thumb only. He had the thumb x-rayed, and treated it. On subsequent occasions he examined only the thumb specifically, but he would have noticed any obvious injury to the finger. On no occasion did Miss Saumarez complain about her finger or say anything about an x-ray examination at the London Hospital.

Called for the defence, Mr. O. J. Vaughan-Jackson, surgeon, said he examined plaintiff's hand in 1951 and found no injury to the middle finger, although there was a deflection of the distal phalanx. He was uncertain whether this had been caused by the phalanx. He was uncertain whether the deflection should have been examined, or whether it was a pre-existing abnormality. Cross-examination, he agreed that the deflection should have been obvious on examination unless masked by swelling. He also agreed that either a deflection or a swelling ought to have been investigated further, although an x-ray examination might not have been necessary.

The Judgment

In his reserved judgment Mr. Justice Havers said it was not disputed that plaintiff now had a fairly obvious deflec-

tion of the distal phalanx of the left middle finger. The dispute was whether it was congenital or due to the accident. Another matter not disputed was that Miss Saumarez had her left hand x-rayed at the London Hospital on August 30, 1949. Here the dispute was why she went there, what the x-ray film showed, and whether she told Dr. Theobalds about it.

His lordship found that Miss Saumarez did suffer a chip fracture of the distal phalanx of the left middle finger in the fall in July, 1949, and that she complained about it to Dr. Theobalds. He accepted plaintiff's evidence that the reason why she went to the London Hospital for an x-ray examination was because she was worried about the condition of her finger.

He found that the injury was such that Dr. Theobalds should have discovered it on his first examination, or later. If he had discovered it, his duty would have been to make a further clinical and x-ray examination. It was even more incumbent upon him to make further inquiries if, as his lordship found, Miss Saumarez complained of injury to the finger. For these reasons his lordship held that Dr. Theobalds was lacking in that standard of care which he owed to a patient. The medical evidence was that, if properly treated, there was a good chance of such an injury being completely cured.

On the question of damages, the judge said he was driven to the conclusion that Miss Saumarez's career as a soloist or as a leader or deputy leader of an orchestra had come to an end before the accident. He thought the damage to her career as a result of the negligence of Dr. Theobalds was very slight. He assessed general damages at £900 and special damages at £340, and entered judgment, with costs, for the plaintiff for £1,240.

Vital Statistics

Week Ending October 31

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,226, whooping-cough 2,067, diphtheria 18, measles 842, dysentery 394, paratyphoid fever 8, and typhoid fever 4.

Poliomyelitis notifications (uncorrected) were as follows: paralytic, 88 (89); non-paralytic, 34 (46); total, 122 (135). This is a decrease of 13 compared with the previous week, the figures for which are in parentheses.

Infectious Diseases

Infectious diseases were more prevalent in England and Wales during the week ending October 24. Rises in the number of notifications included 207 for scarlet fever, from 1,062 to 1,269; 119 for measles, from 742 to 861; 94 for whooping-cough, from 2,096 to 2,190; and 78 for dysentery, from 232 to 310.

Only small rises were recorded in the local returns of scarlet fever; the largest was 35 in Yorkshire West Riding, from 155 to 190. The increase in the incidence of measles was due to the experience of the northern section of the country; in the southern section a small decrease was reported. The largest increase in measles was 67 in Lancashire, from 183 to 250. 29 cases of diphtheria were notified during the week, 9 more than in the preceding week. The largest rise was from 0 to 7 in Staffordshire. The chief centres of diphtheria were Lancashire, Liverpool C.B. 6; Staffordshire, Brownhills U.D. 4; Berkshire, Abingdon R.D. 3. Only small fluctuations were recorded in the local trends of whooping-cough. 9 of the 17 cases of paratyphoid fever were notified in Surrey, Merton and Morden U.D.

135 cases of acute poliomyelitis were notified during the week. These were 8 more for paralytic and 1 more for non-paralytic cases than in the preceding week. The largest returns were Yorkshire West Riding (Spenborough U.D. 3), Lancashire 13 (Liverpool C.B. 3, Preston C.B. 3), Nottinghamshire 10 (Nottingham C.B. 5), London 9, Warwickshire

9 (Birmingham C.B. 5), Southampton 7, Glamorganshire 7, and Kent 7 (Deal M.B. 4).

The chief centres of dysentery were London 66 (Islington 16, Chelsea 13), Yorkshire West Riding 40 (Bradford C.B. 14, Sheffield C.B. 11), Lancashire 37 (Royton U.D. 10), Yorkshire North Riding 28 (Middlesbrough C.B. 28), Kent 23 (Royal Tunbridge Wells M.B. 19), Gloucestershire 18 (Gloucester C.B. 9, Bristol C.B. 7), Northumberland 15 (Gosforth U.D. 6), and Middlesex 15 (Edmonton M.B. 7).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus -----, the figures for 1953 thus -----. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Medical News

B.C.G. for School-leavers.—The Ministry of Health and the Department of Health for Scotland have written to tell local authorities that approval will be given to schemes for offering B.C.G. vaccination to children before they leave school. This is on the understanding that such schemes do not prejudice existing arrangements for the vaccination of tuberculosis contacts. Most children will be vaccinated in their 13th year, so that they can be followed up afterwards for a year at school. Children of 15 years and over are to be excluded so as not to interfere with the Medical Research Council's current trial of B.C.G. in school-leavers. The Ministry of Health states that there is as yet no scientific evidence of the true value of B.C.G. vaccination, and recognizes that some authorities may prefer to wait until the results of the M.R.C. trial are available in three years' time before themselves launching new vaccination schemes.

A New Journal.—*Radiation Research*, a journal devoted to all phases of radiation research, is to commence publication in February, 1954. Its object is to promote the integration of physics, chemistry, biology, and medical research, in so far as they are concerned with the effects of radiation on matter. The term "radiation" is interpreted broadly to include ionizing, ultra-violet, infra-red, and visible radiation. The journal will appear bi-monthly under the editorship of Dr. Titus C. Evans, University of Iowa, and be the official organ of the Radiation Research Society. The publishers are the Academic Press, 125, East 23rd Street, New York, 10.

Copley Medal.—Professor A. J. Kluyver, professor of microbiology at the Technical University, Delft, has been awarded the Copley medal of the Royal Society for his fundamental contributions to that science.

Nichols Fellowship.—The Council of the Royal Society of Medicine invites applications for a grant of £225 per annum for research in the fields of obstetrics and gynaecology. The award will be made for a period of one year in the first instance, but may be extended for a second year. Further details may be obtained from the Secretary, Royal Society of Medicine, 1, Wimpole Street, London, W.1. Applications must be received by May 15, 1954.

Leukaemia Award.—The Robert Roesler de Villiers Award was conferred on Dr. Ludwik Gross at the New York Academy of Medicine last month for his contributions to the knowledge of the nature and cause of leukaemia.

British Cardiac Society.—The autumn meeting of the British Cardiac Society was held in London on October 30 under the chairmanship of Sir John Parkinson. Both the morning and afternoon sessions were devoted to short communications arranged by Dr. Samuel Oram, the secretary of the society. They included papers on sodium chloride and cardiac muscle, pulmonary distensibility and respiratory work in mitral stenosis, cardiac output during exercise studied by the Fick method (illustrated by a film), pulmonary venous drainage into the right heart via a persistent left superior vena cava entering the left innominate vein, and the ballistogram in coronary artery disease. A dinner was held at Simpson's Restaurant.

Conference of Army Pathologists.—The 7th annual conference of Army pathologists was held at the Royal Army Medical College, Millbank, on October 22 and 23. The first morning was devoted to technical demonstrations arranged by the professor of pathology at the College, and in the afternoon there was an administrative meeting in the War Office. On the second day there were lectures by civilian guest lecturers. The annual dinner was held at the Junior United Services Club.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending October 24 (No. 42) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
§ Includes puerperal pyrexia.

White. — On October 7, 1953, at 31, Union Street, Oldham, Lancs, Adam Crawford White, M.D., aged 84.

Henderson and Haggard also classify hydrogen sulphide as an irritant gas, especially at the low concentrations which may be expected to be produced by industrial effluents.

The gas may be detected by smell at about 3 p.p.m., but detection by odour should not be relied upon, as the olfactory nerve endings are readily paralysed by this gas. 20 p.p.m. should be regarded as the maximum allowable concentration for continuous exposure during the working day, to avoid conjunctival and other irritation. Exposures to 200-300 p.p.m. for up to four hours may produce nausea, belching, cough, headache, and dizziness, as well as irritation of the conjunctivae and blistering of the lips. Concentrations above 600 p.p.m. may produce death after upwards of 15 minutes' exposure and at 1,000 p.p.m. death may be instantaneous (Hamilton and Hardy). Henderson and Haggard write that moderately high concentrations may cause death from cessation of breathing owing to undue reduction of the CO₂ in the blood from overbreathing; very high concentrations cause respiratory paralysis. The hydrogen sulphide is rapidly oxidized in the blood, and once the symptoms of acute intoxication have passed off there should be no systemic sequelae.

Flat Foot

Q.—(1) Is there a hereditary predisposition to flat foot? (2) At what age can the condition first be reliably diagnosed? (3) What prophylactic measures—for example, exercises or alteration to the shoes—are recommended for early cases, and at what age should they be begun?

A.—(1) The evidence for a hereditary predisposition to flat foot is extremely vague. In general terms, it is probably not an inherited condition. However, it would seem likely that certain races are more predisposed than others.

(2) The ordinary child's foot appears flat because the arch is obscured by subcutaneous fat, and it is not until this disappears that an accurate diagnosis can be made. The time of this disappearance varies considerably in individuals, but certainly 18 months to 2 years may be regarded as the earliest age at which the diagnosis of flat foot can be accurately made.

(3) The wearing of good shoes, by which is meant shoes which are broad and well made, would seem to be the only prophylactic measure available. The part played by the muscles in the maintenance of the arch is disputed, but it seems unlikely that the performance of special exercises on a few occasions in a week can have much benefit, as the child is, in any case, actively using all these muscles all day long in his play. Not only is it doubtful whether these methods are of benefit as a prophylactic measure, but the use of exercises and wedges in the treatment of early cases is also of questionable value. The difficulty in flat foot is that there are no objective standards by which we may measure the severity of the condition, or improvement obtained by treatment, and at present a sceptical attitude to these measures is probably justified, but this is a matter of opinion, as there are few ascertained facts.

Clamping the Umbilical Cord

Q.—For some time now I have refrained from clamping or ligating the maternal end of the umbilical cord on the grounds that this aids separation of the placenta. This practice was recently challenged. What is your expert's view? Of course, I ligate the maternal end of the cord when dealing with a multiple pregnancy.

A.—This is an idea which most obstetricians have heard of from one of their earlier teachers, but it is rarely mentioned in modern textbooks. An exception is Stoeckel's *Lehrbuch der Geburtshilfe* (1930 and 1941 editions). In the past, however, it was a popular subject of dispute. In early times it was probably the general practice not to tie the maternal end of the cord, but during the seventeenth and eighteenth centuries certain European obstetricians advocated clamping it—some because they found that the turgid placenta after delivery was easier to demonstrate to students, some because they considered that the practice stimulated the

uterus to expel the placenta more expeditiously. Smellie preferred to leave the cord untied, believing that its smaller bulk could pass more easily through the cervix, but he mentions the contrary arguments (vol. 1, p. 230, of the New Sydenham Society Edition of Smellie's *Treatise on the Theory and Practice of Midwifery*). The matter was never proved one way or the other and gradually ceased to attract interest, as it became clear that it had no practical importance. During more recent years a closely related subject which has received attention is the suggestion that overdistension of the placenta with saline injected through the cord (Mojon-Gabastou's method) facilitates separation and delivery of the "retained" placenta—again an idea which is not universally accepted.

In the routine management of labour the baby should not be separated from its mother until the cord has ceased pulsating, and in these circumstances the maternal end of the cord bleeds very little even if left untied. Moreover, by the time pulsation has ceased the placenta should already have separated. The conclusion, therefore, is that so far as the progress of the third stage is concerned it makes no difference whether the maternal end of the cord is tied or not. Clamping it merely prevents a little unnecessary soiling of the bed linen.

Ringworm of the Feet as an Industrial Injury

Q.—Ringworm of the feet is fairly common among miners, particularly where pit-head baths are used. Should such cases be regarded as of industrial origin—for example, as a compensatable variety of dermatitis?

A.—To obtain benefit under the Industrial Injuries Act an occupational dermatitis must be "produced by dust, liquid, or vapour." This designation is usually regarded as not covering infective conditions. In certain cases, however, where bathing after work is considered to be essential (for example, in coal-miners) infection from this fungus may be regarded as an "injury by accident" and benefit paid accordingly.

Trypsin Therapy

Q.—What are the indications for trypsin therapy? How should it be given?

A.—Trypsin therapy may be indicated when the pancreas has sustained severe damage as in chronic pancreatitis. In these circumstances it is possible that enteric-coated tablets of pancreatin (B.P.) may be beneficial. Recently trypsin has been given by inhalation in cases of bronchiectasis, as the enzyme is able to liquefy viscid secretions, but this application is still experimental and not without danger.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 4499. TELEGRAMS: Attilology, Westcent, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, on receipt of proof. Authors overseas should indicate on MSS. if reprints are required, if proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 4499. TELEGRAMS: Britmedad Westcent, London.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY NOVEMBER 28 1953

CLINICAL TRIALS OF INFLUENZA VACCINE A PROGRESS REPORT TO THE MEDICAL RESEARCH COUNCIL BY ITS COMMITTEE* ON CLINICAL TRIALS OF INFLUENZA VACCINE

In November, 1951, the Medical Research Council set up a Committee on Clinical Trials of Influenza Vaccine. This report deals with the studies made by the Committee in the winters of 1951-2 and 1952-3.

Small-scale Serological Trials in the Winter of 1951-2

The Committee at its first meeting in December, 1951, decided that, as an epidemic of influenza A was unlikely to develop during the winter of 1951-2, small-scale trials should be organized with the following objects:

(i) To assess by serological methods the comparative value as antigens of vaccines prepared from certain selected virus strains. These were chosen as being representative of the influenza A viruses recovered during the epidemic of influenza in 1950-1.

(ii) To determine the occurrence, severity, and duration of local and general reactions to these vaccines.

(iii) To study the reported illnesses occurring in the inoculated persons, together with symptoms and diagnoses.

(iv) To investigate methods of recording observations to ensure that the documentation in large-scale field trials would be as efficient as possible.

These objects were chosen because the experience of previous field trials had indicated the great importance of choice of virus strain in the vaccine, the need to avoid clinical reactions, and the desirability of assessment of the value of the vaccine by a method wholly free from bias. It was considered that, despite the obvious difficulties of clinical diagnosis, an influenza vaccine which gave useful protection should yield a reduction in clinical illness. Therefore, provided that laboratory tests in the country as a whole indicated the widespread prevalence of influenza virus A infection during a certain period of time, the assumption could be made that a high proportion of the illnesses diagnosed as influenza in controls and vaccinated persons during the same time were probably due to influenza A.

In view of the changes in antigenic structure of epidemic strains of influenza A which had attacked this country since 1946 the following vaccines were selected for trial.

Vaccine A: Made from a virus strain isolated in the Liverpool epidemic of 1951 in threefold concentration expressed in terms of the titre of original allantoic fluid.

Vaccine B: As in A, but in tenfold concentration.

Vaccine C: Prepared from a strain of virus isolated in the Swedish outbreak of late 1950 in threefold concentration.

Vaccine D: As in C, but in tenfold concentration.

These vaccines and those referred to below were prepared by Dr. F. Himmelweit at the Wright-Fleming

*Members of the Committee: Professor C. H. Stuart-Harris (chairman), Dr. C. H. Andrewes, Dr. W. H. Bradley, Sir Alexander Fleming, Professor A. Bradford Hill, Dr. F. Himmelweit, Dr. F. O. MacCallum, Dr. J. C. McDonald, Surgeon Captain J. G. Maguire, Major-General A. Sachs, Professor Wilson Smith, Wing Commander G. H. Stuart, Dr. I. N. Sutherland, Brigadier A. E. Richmond (secretary).

Institute of Microbiology, St. Mary's Hospital, London, by adsorbing the virus from formalized (1:10,000 formaldehyde) allantoic fluids on to aluminium phosphate, followed by washing and resuspending of the deposits in neutral phosphate buffer solution to which merthiolate had been added to a final concentration of 1:10,000. The final preparations contained per dose (1 ml.) 10 mg. of aluminium phosphate and in vaccine A 19,200, vaccine B 64,000, vaccine C 12,000, and vaccine D 40,000 haemagglutinating units, as assessed by the "plastic plate" method (W.H.O., 1953) in use at the World Influenza Centre.

For the trial of the vaccines, volunteers were invited from university students, and from hospital nursing staffs in the four metropolitan hospital regions. Some 1,200 volunteers in 11 universities and 30 hospitals thus obtained were at each centre inoculated with the vaccines in serial order, so that approximately equal numbers in each centre received one of the four vaccines. At the time of inoculation each volunteer gave a blood sample for serological examination. A second sample was taken a fortnight later.

The serological investigations were carried out at the World Influenza Centre, Mill Hill, and in the bacteriological departments of Edinburgh and Liverpool Universities, the department of medicine of Sheffield University, and nine selected laboratories of the Public Health Laboratory Service. Haemagglutination inhibition tests were made using formalized egg antigens prepared from viruses homologous with those used in the actual vaccines. The sera were not treated with cholera filtrate before the tests to destroy non-specific inhibitors. A statistical summary of the serological results is shown in Table I.

TABLE I.—Comparison of Increase in Antibodies With the Various Vaccines

Vaccine	No. of Volunteers	Agglutination Inhibiting Antibodies			
		Geometric Mean Titre		Rise in Mean Titre (Ratio 2nd to 1st Serum)	
		1st Serum	2nd Serum		
Liverpool strain	A—threefold B—tenfold	294 294	53.0 38.5	168.1 188.0	3.2 4.9
Swedish strain	C—threefold D—tenfold	294 285	104.7 98.4	300.8 372.9	2.9 3.8

The following conclusions were drawn from these trials: (a) A slightly greater antibody response was produced by the vaccines made from the Liverpool (1951) virus. (b) Any advantage of the tenfold concentration in each case was so slight as not to justify the expense and other disadvantages of its use. (c) There was no appreciable difference in the number and severity of reactions produced by the vaccines under trial. (d) In a population similar to that under trial and at the same season of the year, about one in three might expect to have respiratory illness of some kind in the

eight weeks following inoculation. A large number of such illnesses would be ordinary (afebrile) common colds.

Field Trials in the Winter of 1952-3

As an outbreak of influenza A in the winter of 1952-3 seemed probable it was decided that field trials of a pilot nature should be carried out using a selected and a control vaccine. The arrangements made for these trials were as follows.

General Organization

(i) *The Main Trial.*—The main trial was organized in 128 volunteer centres throughout England and Wales, Scotland, and Northern Ireland. These centres were in industrial communities of various kinds (factories, etc.), universities, hospitals, and the fighting Services (Table II). Industrial concerns tended a little to concentration in the North of England, but other centres were scattered more evenly. In all 12,710 volunteers took part.

(ii) *A Subsidiary Trial in Scottish Villages.*—This was carried out in villages scattered along the route from Stornoway to the Butt of Lewis in the Hebrides, with a later extension to Carloway. Volunteers in alternate villages were inoculated with the influenza vaccine, and those in the other villages with the control vaccine. The original intention was that the inoculations should be carried out by the practitioners in their surgeries and at home visits, but it was found necessary to arrange evening sessions in local schools in addition. The programme of inoculations began in late November and was continued into the latter part of December. Although the response to the call for volunteers was not as good as was hoped, helpful information would have been obtained if influenza had developed, but in fact no influenza occurred.

(iii) *A Special Trial at Vauxhall Motors Ltd., Luton.*—The primary object of this investigation was to gain experience of a trial method in which special means were taken to ensure as accurate a diagnosis of influenza as possible. These comprised an overall supervision by one single observer and a more extensive use of laboratory methods. The 455 volunteers who took part are included in the numbers given in (1) above. Results from the more general point of view are included below with those of the main trial. A detailed report of this investigation is to be published separately.

Vaccines

The trial vaccine (X) was polyvalent with equal proportions of a threefold concentration of F.M.1 originally recovered in 1947 in the U.S.A. and of the egg-adapted Liverpool strain (1951). Each dose of 1 ml. contained 9,600 haemagglutinating units of F.M.1 and 12,000 such units of the Liverpool (1951) strain adsorbed on to 10 mg. of aluminium phosphate.

The control vaccine (Y) was a bacterial "anti-influenza" vaccine of low potency, which contained, per 1 ml., 12.5 million *H. influenzae*, 25 million pneumococci, and 2.5 million streptococci, in addition to 10 mg. of aluminium phosphate and merthiolate to a final concentration of 1:10,000.

TABLE II.—Participants in the Main Trial

Type of Centre	No. of Centres	No. of Volunteers		Total
		Trial Vaccine	Control Vaccine	
Industrial (factory workers, etc.)	36	3,560	3,555	7,115
Hospital (nurses)	59	1,131	1,163	2,294
Universities (students)	13	346	355	701
Services (Army and Royal Air Force personnel)	20	1,303	1,297	2,600
Total	128	6,340	6,370	12,710

Procedure in the Main Trial

Inoculations.—The vaccines were given by deep subcutaneous injection into the left upper arm. Almost all inoculations were given between November 26 and Decem-

ber 5, the few exceptions being completed by December 12. It was hoped that this timing would permit the development of immunization before the expected outbreak of influenza.

Inoculation Registers.—An inoculation register was prepared for each volunteer centre which gave in consecutive order: (a) the code letter and serial number to be allotted to the person inoculated; (b) the vaccine (X or Y) to be used for each person; (c) a blank space for the name and initials of the volunteer. Separate registers were used for males and females. The sequences in which the two vaccines were to be used were based on random sampling numbers and varied in each register, so that, although in each centre approximately equal numbers of volunteers received the trial vaccine and the control, it was not by simple alternation of the two vaccines. It was essential that the vaccine given was strictly in accordance with the registers, and special instructions were issued on this point. It was imperative that those responsible for the subsequent follow-up should not know which vaccine the volunteers had received. All registers were therefore returned to the secretary of the Committee as soon as the inoculations had been completed; no copy of the register was allowed, and no record of the vaccine given was kept on the volunteer's personal record card.

The Follow-up.—Volunteers were questioned about reactions 48 hours after inoculation and then kept under observation until March 31, 1953. A personal record card for each volunteer was kept by the supervising medical officer of each centre. On this form were recorded details of reactions and dates of all absences from work due to illness of two working days or more. For each such absence of an inoculated volunteer in a hospital, university, or Service group the medical officer listed the symptoms complained of and gave his opinion of the diagnosis. In industrial centres each volunteer was given an additional illness record card, which he was asked to present to his general practitioner should he be ill. On it the practitioner was asked to fill in the symptoms and diagnosis of the illness. On completion it could be sent by the practitioner direct to the industrial medical officer concerned or could be handed to the patient for delivery when he returned to work. If this form was not completed by the general practitioner, the industrial medical officer made a retrospective diagnosis by questioning the patient. The personal record card and the illness record card are shown in full in the Appendix. At the end of the trial period the personal record cards were returned for analysis by the Medical Research Council's Statistical Research Unit at the London School of Hygiene and Tropical Medicine, who were also in possession of the inoculation registers.

Reactions to Inoculation.—Local and general reactions were recorded by their severity in four groups: (a) nil; (b) slight and insufficient to interfere with normal activities; (c) moderate and interfering with normal activity; and (d)

TABLE III.—Percentages of Volunteers Experiencing Various Degrees of Reaction

Severity of Reaction	Local Reactions		General Reactions	
	Trial Vaccine	Control Vaccine	Trial Vaccine	Control Vaccine
Nil or slight	97.3%	95.9%	98.2%	97.6%
Moderate	2.6%	3.9%	1.2%	1.9%
Severe	0.1%	0.2%	0.5%	0.5%

severe and causing absence from work. There was considerable variation in the assessment of nil reactions. The proportion of local reactions so described ranged from 2% to 100% of volunteers in the Service group, and from 4% to 85% in industry. Similarly the general reaction rate described as nil varied from 48% to 100% in the Service group and from 65% to 99% in industry. The nil and slight categories have therefore been combined in Table III. Reactions were if anything slightly less severe among those who had been given the trial vaccine than among those given the control. With both vaccines females suffered more than males.

The Influenza Epidemic of the Winter 1952-3

The rise in the number of deaths from influenza in the great towns of England and Wales and the increase in claims upon the Ministry of National Insurance indicated that influenza was prevalent in Britain during the first quarter of 1953. The first laboratory evidence of influenza virus A infection was obtained from single isolations of virus from Kent on December 8, 1952, and from Surrey on December 30, 1952; subsequent tests confirmed that the epidemic which followed was due to the same virus. Weekly totals of positive tests for influenza A in the laboratories of the Public Health Laboratory Service confirm that influenza A was prevalent during the first 10 weeks of 1953. The rise in influenza mortality in 160 great towns in this period indicated the same. Analysis of laboratory results by geographical regions suggests that the peak of the epidemic was reached earlier in the south and east than in the north and west. While the trial was in progress about 5% of all cases of influenza diagnosed serologically by the Public Health Laboratory Service were due to influenza virus B. The strains of influenza virus A recovered during the epidemic and which were examined in detail at the World Influenza Centre, London, were reported as being antigenically related to but not identical with those recovered in 1951 (personal communication from Dr. C. H. Andrewes).

Laboratory confirmation of the presence of influenza among volunteers was not planned, but evidence of influenza virus A infection was in fact obtained from volunteers in four out of eight centres from which material for laboratory examination was collected. Specimens from uninoculated persons were tested and found positive in 8 of a further 12 centres. In addition, at least one case of influenza A was confirmed in 33 of the 41 counties of the United Kingdom in which there were trial centres. It seems probable, therefore, that many of the volunteers would have incurred some exposure to the risk of infection with influenza A between one and three months after inoculation.

Results of the Main Trial

It was unfortunate, so far as this trial was concerned, that the incidence of influenza A was comparatively slight. The disease was also largely confined to Southern England, and in those areas in which it occurred it did not invariably spread. As a result there was no evidence of influenza in volunteers in more than one quarter of the centres, while in the remainder the incidence was low.

A summary of the sickness experience of volunteers is given in Table IV.

TABLE IV.—Absences Due to Illness in Vaccine and Control Groups

Diagnosis	Trial Vaccine (6,340)		Control Vaccine (6,370)		Difference between Percentages and Standard Error of Difference
	No. of Attacks	% Attacked	No. of Attacks	% Attacked	
Influenza	192	3.0	309	4.9	1.9 ± 0.34
Febrile cold	218	3.4	242	3.8	0.4 ± 0.33
Febrile sore throat	86	1.4	86	1.4	0.0 ± 0.20
Other respiratory diseases	131	2.1	145	2.3	0.2 ± 0.26
Non-respiratory diseases	253	4.0	208	3.3	-0.7 ± 0.33
Total	880	13.9	990	15.5	1.6 ± 0.65

It may be seen that the difference between the influenza attack rates in the two groups, 1.9 ± 0.34 , was statistically significant, while the differences in incidence of febrile cold, febrile sore throat, and other respiratory diseases were not significant. The volunteers who received the trial vaccine had more absences due to non-respiratory diseases than those who received the control vaccine. Though the difference is just significant statistically, it may have been due to chance or there may be some other explanation. It is clear, however, that the absence rate due to all causes is still significantly less in the volunteers who received the trial vaccine.

TABLE V.—Influenza Attack Rate by Type of Centre Vaccine and Sex

	Males		Females	
	Trial Vaccine (X)	Control Vaccine (Y)	Trial Vaccine (X)	Control Vaccine (Y)
Industry:				
No. exposed to risk	2,820	2,816	740	739
No. of attacks	94	147	29	53
Percentage attack rate	3.30	5.22	3.92	7.17
Difference (X-Y)	-1.92 ± 0.54			
Services:				
No. exposed to risk	1,169	1,162	134	135
No. of attacks	25	31	2	9
Percentage attack rate	2.14	2.67	1.49	6.67
Difference (X-Y)	-0.53 ± 0.63			
Hospitals:				
No. exposed to risk	100	94	1,031	1,069
No. of attacks	3	8	27	44
Percentage attack rate	3.00	8.51	2.62	4.12
Difference (X-Y)	-5.51 ± 3.32			
Universities:				
No. exposed to risk	249	257	97	98
No. of attacks	7	15	5	2
Percentage attack rate	2.81	5.84	5.15	2.04
Difference (X-Y)	-3.03 ± 1.81			

A more detailed analysis of the absences ascribed to influenza in male and female volunteers in the main trial groups is shown in Table V.

In seven of the eight comparisons the influenza attack rate was lower in the trial vaccine group, though it was only in the industrial group that the difference was statistically significant. In the remaining groups the differences were too small to be significant on the numbers concerned. In the female university students the influenza attack rate was higher in those given the trial vaccine, but the numbers at risk were small and the total absences due to influenza were only 7. Of the cases of influenza in the industrial group, 78.5% were diagnosed by general practitioners whose co-operation in the trial was both essential and unstinted.

Regional Differences.—From the available national records of influenza mortality in the great towns the intensity of the influenza outbreak varied from south to north. It was thought of interest, therefore, to compare the results in the trial from the areas with a high incidence in their large towns with those from areas with medium and with low incidences. Deaths per 100,000 of the large town populations in the first quarter were found, and Wales, the northern region, and the north-west region, with rates of 8.1 or less, were taken as areas of low incidence, and London and the south-eastern counties, the eastern, south-western, and the southern regions, with rates of 16.2 or more, were taken as areas of high incidence. Those with rates between 8.1 and 16.2 were regarded as areas of medium incidence. The results obtained are shown in Table VI. It will be noted

TABLE VI.—Influenza Attack Rates in Different Areas of England and Wales

	Trial Vaccine (X)		Control Vaccine (Y)		(X-Y) Differences
	No. Exposed	% Attacked	No. Exposed	% Attacked	
Areas of low influenza incidence	2,160	2.92	2,194	3.60	-0.68 ± 0.5
Areas of medium influenza incidence	2,992	2.81	2,995	5.08	-2.27 ± 0.5
Areas of high influenza incidence	1,188	3.79	1,181	6.61	-2.82 ± 0.9

that while in each group of areas the influenza attack rate in those receiving the control vaccine exceeded the rate in those given the trial vaccine, the difference grew more pronounced as the incidence of influenza increased (as estimated from mortality data).

Seasonal Differences.—An examination was made of the weekly absence rates on account of influenza, febrile cold, febrile sore throat, and other illnesses, in the trial and control groups from the week ending December 29, 1952, to that ending March 30, 1953. No table is given, as the information added nothing material to that already obtained and the length of time since inoculation did not appear to be a factor determining the differences between the trial and control groups already mentioned.

Discussion

A full recapitulation of the various publications dealing with the results of trials on influenza virus vaccines in man is deemed unnecessary in this report because excellent reviews have appeared recently—for example, Frances (1953). Previous trials of influenza vaccine have ended sometimes with results of an equivocal character either because of the low incidence of influenza experienced both in control groups and in those given vaccine or because of a lack of identity between the virus strains incorporated in the vaccine and the viruses causing the outbreak. This latter reason may have been responsible for the failure of the vaccine to exert protection in the previous large-scale trial in this country in 1947 (Mellanby *et al.*, 1948) and in America in the same year. It will be recalled that these failures followed upon the successful use of vaccine in diminishing the incidence of influenza A in the American trial in 1943 (U.S. Commission on Influenza, 1944). Thus, doubt has existed concerning the value of a vaccine against the strains of influenza virus A which have been encountered in epidemics in all parts of the world since 1947 and whose antigens have deviated widely from those of viruses encountered before 1946. Trials carried out in the U.S.A. recently (Meiklejohn *et al.*, 1952) provided evidence that if the vaccine contains virus strains with antigens resembling the viruses causing the outbreak some protection is conferred by immunization. In these American trials the diagnosis of influenza in controls and immunized men was based upon the serological tests rather than on clinical findings, because of the well-known difficulty of clinical diagnosis, particularly in Service establishments.

The present report indicates that major consideration was given by the Committee to the problem of the particular virus strain to be used in the vaccine and also to the method of assessment of illness in those taking part in field trials. The small-scale trials carried out in the winter of 1951-2 were designed partly to test methods of recording likely to be used in a large-scale trial and partly to give evidence of the relative potency in stimulating antibodies of two antigenically distinct virus A strains similar to strains recovered during the 1950-1 epidemics in Europe (Isaacs, Gledhill, and Andrewes, 1952). The vaccine used in the large-scale trial in the winter of 1952-3 contained two chosen strains—one the Liverpool 1951 strain, and the other a strain originally isolated in 1947 (F.M.1) which had been used in the American trial already mentioned (Meiklejohn *et al.*, 1952).

The vaccines used in both winters were essentially similar to those employed in previous British and American trials but differed in their low content of non-specific protein. The purification was achieved by the use of aluminium phosphate, which adsorbs selectively many influenza viruses from infected allantoic fluids (F. Himmelweit, details to be published elsewhere). Its retention in the final preparation has the added advantage of retarding the rate of absorption of the vaccine from the site of inoculation. The decision to use aluminium-phosphate-adsorbed vaccines was based upon the experience of other workers (Appleby *et al.*, 1951) that a low rate of both local and general reactions could be anticipated with this type of preparation.

The decision to rely upon clinical methods for the diagnosis of illness in inoculated persons during the follow-up period was made after consideration of the practical difficulties which exist in obtaining blood and garglings at a sufficiently early stage of illness in those living at home or in lodgings. Moreover, doubt exists concerning the validity of some of the serological methods commonly used for the diagnosis of influenza in individuals who have previously been immunized with influenza virus antigens. Some evidence in confirmation of this difficulty was obtained in the subsidiary trial carried out at Luton. Thus, although there is undoubted difficulty in arriving at a diagnosis of influenza on purely clinical grounds, this method was chosen as the main method of assessment in the large-scale trial. The alternative diagnoses of "febrile sore throat" and "febrile cold" were suggested for illnesses of the respiratory tract

which might be confused with influenza but which are endemic in the population during the winter season. Illnesses which caused an absence from work of less than two days were excluded from the records in order to avoid inclusion of common colds.

The evidence obtained in the laboratory that influenza virus A was actually causing infection in the groups of persons taking part in the 1952-3 trial, though indirect, was nevertheless regarded as valid. The differences found between the several categories of clinical illness in the two groups of inoculated individuals who took part in this trial were slight, but provided definite evidence of a protective action by the virus vaccine. For, if the latter had been without effect, it is difficult to understand why there should have been a difference in the number of illnesses clinically diagnosed as influenza, particularly when the recorded cases of febrile colds and febrile sore throats were so similar in number in the control and virus vaccine groups. The reduction of influenza attacks in those receiving the virus vaccine is therefore believed to be real. The figures set out in Table VI may indicate that one reason for the relatively slight protective effects was the generally low incidence of influenza in both groups: protection was apparently greater in areas of high influenza mortality than in those where it was low. It is important to stress the fact that the clinical workers and those who recorded the illnesses had no knowledge of the particular type of vaccine received by an individual. The recording of the clinical illness during the follow-up was blindfold. The results obtained are not explicable on the basis of a bias for or against the use of the term influenza for illnesses in individuals in any particular category.

Summary

Small-scale trials in the winter of 1951-2 allowed of the assessment by serological methods of the comparative value as antigens of certain influenza A vaccines.

Large-scale controlled field trials of an influenza A vaccine were carried out in 128 centres in the winter of 1952-3. This vaccine contained equal proportions of a three-fold concentration of F.M.1 (U.S.A. 1947 strain) and of the Liverpool (1951) strain. There were in addition subsidiary trials in villages in the Hebrides and in the Vauxhall works at Luton.

In the main trial there was an attack rate of clinical influenza of 3% in 6,340 volunteers in the trial vaccine group and of 4.9% in the control group of 6,370 volunteers. This is equivalent to a 40% reduction in influenza in the former group as compared with the control. Other acute respiratory conditions occurred equally often in vaccinated and control groups.

Information was also obtained about the extent and degree to which reactions occurred in the inoculated, and about other matters of interest, details of which are reported.

No outbreaks of influenza developed in the Hebrides. No results were therefore forthcoming.

The trial at Luton, of which the main object was to gain experience of special methods of ensuring accurate diagnosis, is to be reported on separately.

Acknowledgments

The Committee wishes to acknowledge the support and co-operation it has received from many sources, and without which little could have been achieved. It is very grateful to all those in industries and in the hospitals, universities, fighting Services, and elsewhere, throughout the United Kingdom who volunteered for inoculation in the earlier serological tests or in the later field trials. It is most grateful to those in the various volunteer centres who so kindly went to much trouble to collect volunteers to make the necessary local arrangements for the trials, and to shoulder the various responsibilities involved in the trials. The help of the Public Health Laboratory Service was invaluable, particularly of

its Central Laboratory at Colindale, and the laboratories at Cambridge, Manchester, Bradford, Nottingham, Newcastle-upon-Tyne, Cardiff, Exeter, Hull, and Winchester. The fullest assistance on the serological side was forthcoming also from the departments of bacteriology at Edinburgh and Liverpool Universities and from the medical department of Sheffield University. The laboratory of the World Influenza Centre at the National Institute for Medical Research at Mill Hill, including especially Dr. A. Isaacs of that laboratory, gave considerable help with the more technical aspects of the problems involved.

The Committee is deeply appreciative of the help afforded by Dr. W. J. Martin, of the M.R.C. Statistical Research Unit at the London School of Hygiene and Tropical Medicine, who spared no effort to assist in the organization of the trials and the analysis of the results.

The Committee would finally express its gratitude to the Wright-Fleming Institute of Microbiology at St. Mary's Hospital, where under the direction of Dr. F. Himmelweit the vaccines for the trials were produced, and where many of the preliminary investigations essential to their large-scale production were carried out.

TRIALS OF INFLUENZA VACCINES

ILLNESS RECORD CARD

The holder of this card (Full name)
has been inoculated in the trials of influenza vaccines now being conducted by a special Committee of the Medical Research Council.

In the event of any illness occurring within three months after inoculation and which confines the holder to bed, he/she has been asked to call in his/her usual medical attendant and to present this card.

The Committee would be very grateful if you, the medical attendant, would give on the back of this card a few particulars of the patient's present illness, paying special attention to the diagnosis.

On completion the card should be placed in the envelope supplied.

On returning to work the patient will report with it to the industrial medical officer who is supervising the trial on behalf of the Committee. If you prefer, the card may be posted to the test centre named on the envelope.

Any further information required can be obtained from this centre.

LABORATORY EVIDENCE OF INFLUENZA IN ENGLAND AND WALES DURING THE WINTER OF 1952-3

A REPORT FROM THE PUBLIC HEALTH LABORATORY SERVICE*

During the winter of 1952-3 an intensive effort was made to confirm the presence of influenza virus infections in as many parts of England and Wales as possible. The aims were to obtain early evidence of the presence and types of infecting viruses as part of the scheme for "Winter Epidemics" described in the Monthly Bulletins of the Ministry of Health and the Public Health Laboratory Service for December, 1951, and November, 1952, and to provide a representative number of virus strains for the antigenic and epidemiological studies of the World Health Organization, World Influenza Centre.

The complement fixation test with influenza A and B "soluble" antigens was used for the serological tests, and only fourfold or greater increases in antibody between suitably spaced pairs of serum specimens were considered significant. Virus isolations were made by amniotic inoculation of fertile hens' eggs.

The specimens were received from many sources, of which the most important were medical officers of health and general-practitioner "spotters," who provided material from cases of uncomplicated influenza under the winter epidemics scheme. Service medical officers provided similar material, and pathologists, Service and civilian, submitted specimens mainly from cases of pneumonia in which a virus aetiology was suspected. In addition, information was exchanged with Captain J. E. Stauch, of the U.S. Air Force Laboratory in London (494th Clinical Laboratory).

Laboratory Evidence

Influenza A.—The first evidence of the presence of influenza A infection was the isolation of virus from the post-mortem specimen of lung obtained from a patient dead with pneumonia in North-west Kent in the second week of December. Shortly afterwards infection with influenza A was confirmed in an outbreak of respiratory disease amongst the residents of a nurses' home in North Surrey. This outbreak began in the second and third weeks of December, and continued till the end of the month. During the last week of December civilian and R.A.F. cases of influenza A were confirmed in Somerset (Taunton area), Army cases in Surrey (Camberley), and cases were reported by the U.S.A.F. laboratory from units in Oxfordshire, Gloucestershire, and Bedfordshire. At the end of the first week of January positive tests were obtained from Naval personnel in Devon (Plymouth), from Army personnel in Nottinghamshire (Chilwell), from R.A.F. personnel in Buckinghamshire (Halton), and from civilians in Surrey (Epsom), Sussex (Eastbourne), Lancashire (Manchester), and Bedfordshire (Bedford).

During the second week of January further cases were confirmed in the southern areas, and cases were detected in a Service unit in Yorkshire (Middlesbrough), from R.A.F. units in Essex, Norfolk, and Suffolk, and from civilians in

*Serological and virus isolation tests were undertaken at the Virus Reference Laboratory, Colindale (Drs. B. E. Andrews, G. B. Bruce White, and J. C. N. Westwood), and at the Northampton Laboratory (Drs. L. Hoyle and A. J. Beale). Serological tests were undertaken at the following laboratories: Exeter (Drs. B. Moore and E. M. Mackay Scollay), Manchester (Dr. M. O. Adams), Winchester (Dr. R. D. Mackenzie), Cardiff (Dr. A. D. Evans), Nottingham (Dr. G. B. Ludlam), Cambridge (Dr. P. J. Wormald), Hull (Dr. J. McCoy), and Newcastle-upon-Tyne (Dr. C. R. Peck).

Cambridgeshire (Cambridge) and Suffolk (Ipswich). At the end of the second week cases were first reported in Wales (Cardiff).

In the third week of January cases were detected in all parts of the country, and in Tables I and II positive tests obtained between January and June, 1953, are shown classified by the week in which specimens were collected, and the Registrar-General's geographical regions of England and Wales.

Influenza B.—A small number of cases of influenza B were detected. Weekly and regional totals of positive laboratory tests are included in the margins of Tables I and II.

Influenza A

Timing of the Epidemic

The first cases of influenza A were detected in mid-December, but no marked increase in the weekly totals of positive tests was observed till the second week of January. During the remainder of January the number of cases detected rose and the peak of positive serological tests occurred in the week ending January 31. In February the numbers decreased rapidly. A small number of cases were detected in March and only one in April. More than 50% of sera were positive between the weeks ending January 17 and February 7, and so it is concluded that the peak of the

Weekly totals of positive laboratory tests, deaths from influenza pneumonia, and the number of local offices of the Ministry of National Insurance which received excess notifications of sickness (A = Influenza A, positive serological tests; B = Influenza B, virus isolations; C = Influenza pneumonia deaths in 160 great towns; D = Number of Ministry offices which received an excess of sickness notifications (reduced to one-fifth true vertical scale). D = Number of Ministry offices which received an excess of sickness notifications (reduced to half true vertical scale).

influenza A epidemic occurred between these dates and most probably during the last week of January. However, since in some areas specimens were not submitted after the presence of infection had been established it seemed desirable to check this conclusion by other means. The Registrar-General's weekly returns for deaths from influenza pneumonia in the 160 great towns provide an index of the progress of an epidemic (Logan, 1951), and these figures, together with the weekly totals of positive laboratory tests are shown in the Chart. The numbers of sickness benefit claims (from all causes) received at the Ministry of National Insurance and Pensions have also been shown to provide a basis for assessing the progress of an epidemic (Masse, 1951). Figures showing the numbers of local offices of the Ministry which received claims in excess of 225% of the for November, 1952, were available, and these are also shown as weekly totals in the Chart. (It should be noted that

* For cases in December, 1952, see text. † Virus isolated by Dr. J. O'H. Tobin, Department of Bacteriology, University of Manchester.

the vertical scales of the curves in the Chart have been adjusted to emphasize their time relations, and actual numbers, except in the case of laboratory results, cannot be read direct from the printed scale.) Bearing in mind the relatively small number of cases of influenza B detected by laboratory tests, it seems reasonable to conclude that influenza virus A infection was associated with a large proportion of the illnesses and fatal cases of influenza pneumonia which, as shown by the curves of the Chart, occurred in the last week of January and during February. The figures for positive laboratory tests began to rise and reached their peak about one week earlier than those for the excess sickness benefit claims, and about two weeks before those for the pneumonia deaths. These differences in time would be accounted for respectively by the interval between the onset of illness and the presentation of sickness benefit claims at the offices of the Ministry of National Insurance, and by the interval between the onset of influenza and the pneumonia which subsequently led to death. It is assumed that most of the pneumonias were of the post-influenza type rather than the fulminating acute type sometimes observed during an influenza epidemic.

Thus there seems to be substantial agreement between estimation of the time limits for the epidemic arrived at by each of the three methods; and the conclusion reached from the evidence provided by the laboratory findings—namely, that the peak of the epidemic occurred in the last week of January—appears to be reasonably accurate.

One of the aims of this investigation was the early detection of influenza, and since the first cases were confirmed four to six weeks before the disease became widespread this object appears to have been satisfactorily achieved.

Geographical Spread of Infection

Influenza virus A infections were first detected in South-east England in mid-December, in the South around the

New Year, and in the South-west and Midlands towards the end of the first week of January; whilst in Wales, East Anglia, and the North cases were not confirmed till the second week of January. These observations and the figures quoted in Tables I and II suggest that the epidemic spread northwards from the South-east and South of England. This hypothesis is in general supported by an (unpublished) regional analysis of the numbers of local offices of the Ministry of National Insurance and Pensions which received excess claims for sickness benefit.

The material varied widely between areas, and in some areas lack of evidence for influenza may have been due to failure to submit specimens for examination. For example, several instances occurred where no material had been submitted from an area and positive results were obtained only after urgent requests for material had been made to the authorities concerned; and, in retrospect, it appeared likely that infection had been present in the area for many days. In some areas, also, the first specimens were not received till after the peak of sickness notifications to National Insurance offices. Clinical criteria for the diagnosis of influenza appear to vary between regions, and introduce a further source of error. It was noticed that material sent in response to a request from one authority tended to be collected immediately after the date when a notice on the subject was received by local medical officers, and also that this notice often reached the doctors in the South earlier than those in the North, so that analysis of material from this source may not have given a reliable estimate of the rate of spread of infection through the country. The proportions of material received from Service, civilian practitioners, and hospital sources varied widely between regions, again making it difficult to compare results. Therefore, whilst the figures suggest the direction and rate of spread of the epidemic, they do not provide evidence from which hard-and-fast conclusions can be drawn.

Influenza B

The total of cases of influenza B detected was small, and the figures shown in Tables I and II do not suggest that infection was widespread in any particular part of the country. Evidence of infection was obtained mainly from the South; no cases were detected in the Northern and North Midland areas, but this may be due to the relatively small numbers of specimens from these areas.

The most striking features shown by the figures are the absence of any peak and the observation of positive results throughout a period of almost eight months. Whereas in the case of influenza A there was a sharp peak, and although a much greater number of cases were detected, all the positive results occurred in a period of four months. It is interesting to notice also that cases of influenza B have been detected in three of the last four years.

Virus Isolations

Distribution and Antigenic Groups of the Virus Strains Isolated

Most of the above discussion is based on serological results. In all, 106 strains of influenza virus A were isolated, and the figures arranged by weeks and regions in Table II give a similar picture to those for sera in Table I. The aim was to provide a representative selection of strains from the various regions and at different stages of the epidemic. Several strains were obtained in each of the Registrar-General's regions, and the 106 isolations represent 62 different localities. The interval between first and last strains isolated was 13 weeks, and in most regions four or five weeks elapsed between the first and last isolations, so that it may be fairly claimed that the aims mentioned above were achieved.

In 1951 two antigenic groups of influenza A were present in the country, and exact information regarding their distribution was rather scanty. During the past winter, virus isolations were undertaken on a relatively large scale so that in the event of more than one antigenic group being present adequate material would be available for epidemiological studies. Strains of influenza viruses sent from the Public Health Laboratory Service laboratories to the World Influenza Centre have all, with one exception, been closely related to, but not identical with, the Scandinavian group strains isolated in England in 1951. The exception was one of several strains isolated from patients in the Ipswich (Suffolk) area, and was related to the Liverpool group strains, which were also present in England in 1951. A second strain of this group was isolated at the World Influenza Centre, London, from a member of their staff.

Strains of the 1953 Scandinavian group were also found this year in Japan, the U.S.A., and Western Europe, and Liverpool group strains were isolated in Paris, Switzerland, and Portugal.

Included in the figures for virus isolations were 28 specimens of lung obtained *post mortem*. Two strains each of influenza A and B were recovered from these specimens, and it is interesting to note that both the A strains were from patients in the London area who had died suddenly during the fogs of December and January respectively. Twelve other specimens of lung from patients in the same area whose death was also believed to be associated with fog were negative in virus isolation tests.

Summary

The laboratory evidence for influenza virus infections in England and Wales during the winter of 1952-3 is presented and analysed according to regions and the date of collection of specimens.

The first cases of influenza A were detected in mid-December, and the disease became epidemic at the end of January—that is, four to six weeks after the first evidence of infection was obtained.

In the country as a whole there was close agreement between estimates of the time limits of the epidemic derived from the laboratory results, the Registrar-General's weekly returns for deaths from influenzal pneumonia, and increased claims for sickness benefit received by local offices of the Ministry of National Insurance and Pensions.

The evidence suggests that the influenza A epidemic spread northwards from the south-east and south.

A few cases of influenza B infection were detected during most weeks between mid-January and mid-May, and occasional cases were detected up till August.

106 strains of influenza virus A were isolated, and these were well distributed with regard to time and place.

Information regarding the antigenic groups of influenza virus A was kindly supplied by Dr. A. Isaacs, of the World Influenza Centre, London. Figures for deaths from influenzal pneumonia are quoted from the Registrar-General's weekly returns, published in the *British Medical Journal*. The figures for local offices of the Ministry of National Insurance and Pensions were calculated from data made available by and quoted with the kind permission of Dr. A. Massey, Chief Medical Officer of the Ministry of National Insurance and Pensions.

CENTENARY OF HYPODERMIC INJECTION

BY

G. A. MOGEY, M.B., B.Ch.

Department of Pharmacology, University of Leeds

Hypodermic, or subcutaneous, injection of drugs being now so catholic, it is surprising to find that of all the common current methods of exhibition this is one of the most recently introduced. Inhalation, rectal administration, and even intravenous infusion were in use when Dr. Alexander Wood, of Edinburgh, gave the first subcutaneous injection, in the modern sense, one hundred years ago. As the present year is the centenary of that injection it may be of timely interest to recall the origins of the method and something of its author.

The modern hollow hypodermic needle and its companion, the syringe, have evolved from earlier and cruder predecessors made when man first began to inject drugs intravenously and to practise blood transfusion. So perhaps the common origin of these procedures is the best point to begin a consideration of the development of hypodermic injection.

The First Blood Transfusion

Although the ancient Egyptians may have practised it the first really successful blood transfusion was not performed until the middle of the seventeenth century. The story of the rejuvenation of Aeson by Medea (Ovid 43 B.C.) is interpreted by some as an indication that the notorious sorceress was acquainted with the method and that therefore the early Greeks knew of blood transfusion. However, Ovid's description of the rejuvenation simply establishes Medea as an ear-pharmacologist rather than as the deviser of blood transfusion. It is difficult to be sure whether she should be regarded as the first to inject drugs into the human body, for there were no eye-witnesses—except Liber-

CENTENARY OF HYPODERMIC INJECTION

BRITISH
MEDICAL JOURNAL 1181

of the operation, which is reputed to have been done by cutting Aeson's throat and pouring "the juices," prepared from various plants and animals, into his veins. Again, it is often stated that the first transfusion was carried out on Pope Innocent VIII (1432-92); but, as Keynes (1949) has pointed out, the papal elixir was simply a draught prepared by a Jewish physician from the blood of three boys who were bled to death for the purpose—at least, they died soon after the bleeding.

Precisely when blood transfusion came into existence is still a matter of dispute, but it is certain that transfusion was preceded by infusion. The earliest attempts at intravenous injection were made in England in the middle of the seventeenth century and were soon followed by infusion of blood into animals and then into man.

Intravenous Injection

In 1657 Christopher Wren—while he was Savilian Professor of Astronomy at Oxford and before he became famous as an architect—conducted numerous experiments, with the assistance of Robert Boyle and a Dr.

FIG. 1.—Engraving from page 2 of Major's *Chirurgia Infusoria*. Kiloni, 1667, showing his injection apparatus. (Photograph of engraving kindly supplied by Mr. W. J. Bishop, of the Wellcome Historical Medical Library.)

Wilkins, on the giving of drugs by intravenous injection (Oldenburg, 1665). Bishop Sprat (1702) said of Wren: "He was the first Author of the Noble Anatomical Experiment of Injecting Liquors into the Veins of Animals. . . . By this operation divers Creatures were immediately purg'd, vomited, intoxicated, kill'd, or reviv'd, according to the quality of the liquor injected: Hence arose many new Experiments [*sic*], and chiefly that of Transfusing Blood, which the Society has prosecuted in sundry Instances, that will probably end in extraordinary Success."

Wren appears to have been the first to perform an intravenous injection in man in, it is thought, 1657 (Clarck, 1668). During the injection the victim—a delinquent servant of a foreign ambassador—fainted and the experiment had to be stopped. Boyle (1664) described this experiment in a way which suggested that the foreign ambassador had performed the injection, but Clarck made it quite clear that it was Wren who did it in the house of the Duc de Bourdeaux, the French Ambassador. A few years later, in 1662, J. D. Major also performed some successful intravenous injections in man (Major, 1664).

For these early injections both of blood and of drugs, a quill, later replaced by a silver or gold tube—the "pipe"—was inserted into the vein and the injection made through it, either by using a small bladder—"like

a clyster"—as a pump or by means of a gravity feed. The first injections were chiefly of water, opium, and purging medicines. Intravenous administration of jalap resins, as practised for example by Fabritius (1667), was particularly popular, especially in the treatment of syphilis.

The frequent use of opium led to the early observation that it stupefied dogs and excited cats (Boyle, 1664). But opium and narcotics were by no means the only substances injected intravenously. Fortescue-Brickdale (1904) quoted Purmann (1706) as giving a list of drugs sometimes used. It includes amber, arsenic, cinnamon, oil of sulphur, snail water, spiritus lilior convallarium, spiritus nitrosi vel vitrioli, and spiritus salis ammoniaci.

With only impure drugs and crude apparatus available, the method of intravenous infusion soon fell into disrepute, and for the remainder of the seventeenth century was carried out but sporadically. Very little more was published on the subject until near the end of the eighteenth century, when there was a temporary revival of interest, which continued well into the next century. During this period Magendie was one of those most actively interested: he attempted to treat hydrophobia with injections of opium, or sometimes even warm water (Olmsted, 1944). But little success attended him, and again, except for saline infusion, the practice seems to have been little used until later in the same century, when there was a further revival of interest about 1870. It was not, however, until the irrepressible Ehrlich showed that intravenous administration of his arsenical compounds really was a practical procedure that it became commonplace in therapeutics.

The Work of Pravaz

While the practice of intravenous injection of drugs waxed and waned in the nineteenth century a special type of intravascular administration was described. Its originator was Dr. Charles-Gabriel Pravaz (or Pravas), of the Veterinary College in Lyons, France. His method was presented to the Academy of Sciences in Paris on January 10, 1853, by M. Lallemand, a director of the College. It was published in the correspondence section of the Academy's proceedings under the title "Sur un nouveau moyen d'opérer la coagulation du sang dans les artères, applicable à la guérison des aneurismes." Pravaz injected iron perchloride "au maximum de concentration" into the vessels of sheep and horses through "un trois-quarts très-fin or ou en platine" introduced obliquely by "une espèce de mouvement de vrille." "A ce trois-quarts se trouve ajustée une seringue dont le piston doit être à pas de vis, afin que l'injection s'opère sans secousses et que la quantité de liquide injecté puisse être mesurée avec précision."

Pravaz suggested that the method might be modified to render it suitable for the treatment of aneurysms in human beings, and calculated that the injection could be made, with time allowed for clot formation, in about four to five minutes. As he designed and caused a syringe to be made for this work, the erroneous claim, such as that of Fluck (1953), is sometimes advanced that Pravaz was responsible for introducing hypodermic injections: but of this more anon. (Experiments on the coagulation of the blood had been carried out long before the time of Pravaz. For example, Bishop Sprat, in his *History of the Royal Society of London* (p. 199) says that the Society received a communication telling "of making the blood Florid with Volatil and coagulating with Acid Salts." Presumably he was referring to the work of Fracassati, who, in a communication to the Royal Society in 1667, described such experiments on dogs. Robert Boyle (1667) performed similar investigations on shed blood, and claimed that it was from these experiments that Fracassati got his ideas.)

Shortly before the work of Pravaz, in a period which coincided with the isolation of the first pure alkaloids from some of the crude drugs used earlier for intravenous injection, a new technique of administering medicinal agents had been evolved. In it the drugs were not given direct into the circulation, but were placed beneath the skin, from which site they gradually found their way into the system. And even prior to this, drugs had been administered through the skin, by the application of ointments and liniments to the epidermis, sometimes accompanied by vigorous rubbing. These methods were not very satisfactory, and neither was their extension—the direct application of drugs to the dermis, following the removal of the epidermis by blistering agents or caustics. Another method, more closely resembling the modern subcutaneous one, was described in 1836 by Lafargue in France. He smeared drug, in the form of paste, on the tip of a vaccination lancet, which was then pushed through the skin, where it remained for a short time before withdrawal. However, as the dose was obviously not determinable, and the method laborious and time-consuming, it never became popular.

Rynd's Method

From Dublin, in its heyday as a medical centre while Graves, Stokes, Adams, and Corrigan were leaders of the profession, there came a different approach to the problem of finding a more generally applicable and safer parenteral route of administration than the intravenous. Francis Rynd, surgeon to the Meath Hospital, devised a form of subcutaneous administration of drugs which has a slight claim to be the forerunner of the modern hypodermic method (Rynd, 1845). Under the title "Neuralgia—Introduction of Fluid to the Nerve," he described how, on June 3, 1844, "a solution of fifteen grains of acetate of morphia, dissolved in one drachm of creosote, was introduced to the supra-orbital nerve and along the course of the temporal, malar, and buccal nerves by four punctures of an instrument made for the purpose." He found that the pain of the neuralgia was abolished very rapidly, and that the patient, an elderly lady, had a better sleep the following night than she had had for months.

FIG. 2.—The apparatus used by Rynd (from *Dublin Quart. J. med. Sci.*, 1861, 32, 13).

He also described the case of a man aged 28, who seems to have had sciatica, successfully treated by a similar technique, although the concentration of morphia was reduced by a third. Rynd did not describe the instrument in this paper and quoted no references. It was not until a good deal later that he published an article giving details of his apparatus (Rynd, 1861), which was essentially a trocar and cannula. After insertion through the skin the trocar was made to spring back out of the cannula into the body of the instrument by pressure on the lever at the side (Fig. 2). The drug solution was then poured in through a small hole near the base of the cannula and allowed to gravitate into the subcutaneous tissues.

In 1845 a claim was made by Arthur Guinness that on reading Rynd's article he was reminded that "it had been my intention long since to have sent you an account of some cases treated by me during last summer in a similar manner. . . . I used a common lancet armed with morphia, mixed in a little water, about the consistence of a paste and operated precisely as is done in vaccinating an infant; I did not use creosote with it. . . . In another bad case of neuralgia I determined on using creosote without morphia. . . . It was of decided benefit in my case." This technique described by Guinness was not new, for it had been employed eight years earlier by M. Lafargue, and in any case it was not the ancestor of the present-day practice of hypodermic injection.

Although Rynd's method of administering fluids has been held by some to be the beginning of modern hypodermic injection (Macht, 1916; Pfender, 1911) it is extremely hard to make a really good case for this. Rynd did employ a hollow cannula, which could be regarded as a forerunner of the hollow hypodermic needle, but he depended upon gravity to force the drug solution into the tissues. Further, he was interested only in the local pain-relieving properties of his injections and did not seem to realize that effects remote from the site of injection might be obtained. This is all the more surprising when the doses are known: "The fluid I have found most beneficial is a solution of morphia in creosote [*sic*], ten grains of the former to one drachm of the latter; six drops of this solution contain one grain of morphia, and a grain or two or more may be introduced in cases of sciatica at one operation" (Rynd, 1861). As the syringe is now an essential component of the hypodermic apparatus, Rynd's instrument was most definitely not a direct forerunner of the modern equipment.

Introduction of the Hypodermic Method

It was in 1853 that hypodermic injection as we know it to-day came into being, although the first public pronouncement about the method was postponed until 1855. In 1853 Dr. Alexander Wood, of Edinburgh, instituted the practice of injecting drug solutions through the skin, using a syringe and needle. The idea of subcutaneous administration came to him while considering a development of the special type of injection introduced by Pravaz for the treatment of aneurysm. Thus, subcutaneous injection really grew out of earlier intravascular practice. Wood wrote: "Having occasion, however, about the end of 1853, to endeavour to remove a naevus by injection with the acid solution of perchloride of iron, I procured one of the elegant little syringes, constructed for this purpose by Mr. Ferguson of Giltspur Street, London. While using this instrument for the naevus, it occurred to me that it might supply the means of bringing some narcotic to bear more directly than I had hitherto been able to accomplish on the affected nerve in neuralgia. I resolved to make the attempt, and did not long lack the opportunity."

An elderly lady who had suffered for a long time from cervico-brachial neuralgia—and who, incidentally, could not take opium in any form by mouth without being violently sick—was the patient who afforded Wood his desired chance. "Accordingly, on November 28th, I visited her at 10 p.m. to give the opiate the benefit of the night. . . . I inserted the syringe within the angle formed by the clavicle and acromion, and injected twenty drops of a solution of muriate of morphia, of a strength about double that of the official preparation."

Wood (1855) published this description of the first hypodermic injection in the modern sense under the title "New Method of Treating Neuralgia by the direct application of Opiates to the Painful Points." To the twenty-sixth Annual Meeting of the B.M.A., held in Edinburgh in July 1858, he stated that the solution injected was "made of morphia in sherry wine, because I thought it would not irritate and smart so much as alcohol, and because it would not rust the instrument as a water solution of opium would do" (Wood, 1858). (Incidentally in this address Wood

that his first injection was given in November, 1843, not 1853, and Howard-Jones (1947) doubted that this was a genuine mistake. If accepted it would, of course, give Wood's method priority over that of Rynd.)

Wood injected a solution "of a strength about double that of the official preparation." Whether there was any difference between the official and official preparations is not certain. This was in the days when the colleges issued their own pharmacopoeias, and it is more than likely that Wood used the then current Edinburgh issue of 1841. In it the Morphiae Muriatis Solutio is prepared by dissolving 3 iss muriate of morphia in a mixture of 5 fluid ounces of rectified spirit and 15 ounces of distilled water. It therefore contained 1 gr. (65 mg.) of morphia muriate in 106 minims (6.4 ml.) of solution. So, if Wood injected twenty drops of a solution about double this strength, he gave a dose of about $\frac{2}{3}$ gr. (26 mg.) of morphia hydrochloride.

Although Wood, like Rynd, was interested mainly in the relief of pain in the neighbourhood of the injection, he realized that general effects were important too. His conclusions indicate this quite clearly:

"1st, That narcotics injected into the neighbourhood [*sic*] of the painful point of a nerve affected with neuralgia, will diminish the sensibility of that nerve, and in proportion diminish or remove pain.

"2d, That the effects of narcotics so applied are not confined to their local action, but that they reach the brain through the venous circulation, and there produce their remote effects.

"3d, That in all probability what is true in regard to narcotics would be found to be equally true in regard to other classes of remedies.

"4th, That the small syringe affords a safe, easy, and almost painless method of exhibition.

"5th, That, destitute as we are of any precise experiments as to the applicability of cellular tissue as a medium for the reception of medicinal agents, the experiments made with the syringe show that it seems to offer an excellent surface for the absorbent action of the venous system."

FIG. 3.—Dr. Alexander Wood's syringe (by courtesy of Mr. J. N. J. Hartley, Curator of the Museum of the Royal College of Surgeons of Edinburgh). Since this photograph was taken the syringe has suffered further damage and the barrel is now shorter than shown here.

These passages make it quite obvious that Wood realized the general applicability of his method. But in spite of this he was mostly concerned with injections at the seat of the pain, although he believed that both a local anaesthetic effect and the general narcotic action of morphia were of value in the treatment of neuralgia.

The syringe which Wood used is well known and is preserved in the Museum of the Royal College of Surgeons of Edinburgh. There is no trace of the needle (J. N. J. Hartley, personal communication, 1952).

Wood's Syringe and Method of Injection

Comrie (1927) described Wood's syringe thus: "The syringe is 90 mm. in length, and the barrel, which has been broken towards its base, is 10 mm. in diameter. The piston is wrapped round at its extremity with cotton wick to make the plunger fit the barrel. At its apex the barrel is drawn into a conoidal extremity which fits a metal nose cap. The cap is of curious construction and consists of one inner filler-shaped part which fits closely to the diminishing portion of the glass barrel and ends in a pointed extremity, which is threaded externally, to allow a hypodermic needle to be screwed on. The filler-part is grasped by a metal arrangement, whose apex is tightly applied to it at the screw. It is prolonged upwards by two lateral metal strips, bound

by a circle round the middle of the inner cap, and prolonged upwards further by the two lateral bands, to end in a ring, which does not touch the barrel, and may have been used to steady the syringe and prevent the metal cap being forced off during administration of a hypodermic injection."

It is surprising that Wood did not describe the needle, for it is such an important part of the equipment, and differed from anything before it in being attached to the syringe to form a composite instrument. Far from describing the needle, he wrote, in his 1855 article, about inserting the syringe. However, his biographer, the Rev. Thomas Brown, who married Wood's sister, stated that the design was based on the sting of the bee (Brown, 1886). This information was probably obtained from Wood's description of the type of syringe he was using in 1858, one which had been improved by the addition of graduations to the barrel. "The instrument is of the simplest construction and is a modification of Mr. Ferguson's, already alluded to. It consists of a small glass syringe graduated like a drop measure, and to this is attached a small needle, hollow, and having an aperture near the point like the sting of a wasp" (Wood, 1858). These scant statements appear to be the only information about the actual needle used by Wood. The needle is probably more correctly compared to the sting of a wasp than to that of a bee, because of the barbs on the latter. The photograph of the syringe shows that the nozzle was adapted for the application of some kind of needle which screwed on to the metallic male end of the apparatus.

Wood's method of injection was taken up by others in many countries only after his 1858 paper. At first, however, all adhered to the principle of injecting the pain-relieving drug into or near the site of the pain. The demonstration, that to relieve pain the injection of morphia did not have to be at the sore place, was due to a London surgeon, Charles Hunter. He pointed out that repeated injection into "an unsound or morbidly sensitive part" increased the tendency to sepsis, and was accompanied by great pain during the actual injection (Hunter, 1859). He maintained "that, by the introduction of narcotics into the cellular membrane of the body, we have a mode of attacking and subduing cerebral excitability more rapid, more certain, and more pure in its action, than by stomachic doses of narcotics." Hunter described the needle he used, and gave an illustration of it (Fig. 4). The "pipe," as he called it, was

FIG. 4.—Hunter's needle. (From *Med. Tms Gaz.*, 1859, 19, 354.)

FIG. 5.—The Huber needle. (Reproduced, by permission, from the article by Dr. O. Schwidetzky in *Medical Physics*, vol. 2, edited by Dr. O. Glasser, Year Book Publishers Inc.)

made of silver with a hardened gold point. He had two pipes, the smaller of which was about 1½ in. (3 cm.) long and about 25 or 26 s.w.g. Each pipe was pointed "like a needle," tapering from all angles as does a pencil point, and occupying a place between the usual hypodermic needle of to-day with its bevelled end and the Huber needle (Fig. 5). Hunter went on to use drugs other than morphine and to develop the grandiose idea of a "hypodermic treatment of disease."

Biographical Notes on Dr. Wood

Dr. Alexander Wood, who undoubtedly deserves the credit for the introduction of the hypodermic method, was born at Cupar, Fife, on December 10, 1817. He belonged

*From the
Edinburgh*

FIG. 6.—Dr. Alexander Wood as an elderly man. (From Dr. Alexander Wood, M.D., by Rev. Thos. Brown, Edinburgh, 1886.)

to a family distinguished medically, and his ancestry has been traced to a Dr. Alexander Wood, "who in 1682 married the daughter and heiress of Jasper Johnston of Warriston and Curriehill" (Brown, 1886). The Alexander Wood of hypodermic fame is often called Secundus to distinguish him from his grand-uncle, an earlier Dr. Alexander Wood (1725–1807), familiarly known as Lang Sandy. Educated at adventure schools until 1826, Wood Secundus then went to Edinburgh Academy, opened two years earlier. Entering Edinburgh University in July, 1832, he took the usual

Arts course at the same time as he followed the medical curriculum. One of the great men who had a profound effect on Wood at the university was Dr. (later Sir Robert) Christison. Wood was a member of the Royal Medical Society, which he served as Junior President from 1837 to 1839. He graduated on August 1, 1839. In 1840 he was elected F.R.C.P.Ed., and in 1841 was appointed Lecturer in the Practice of Medicine at the extramural school.

His first published paper was on poisoning with corrosive sublimate (1839); this was followed by others on homoeopathy (1844, 1845), mesmerism (1851), and subcutaneous injection (1855). In 1842 he married an Irish lady, Rebecca Massey, of Tipperary; so far as I have been able to find, they had no children. He took a lively interest in medical politics, and was a representative of Scottish medicine on the General Medical Council in London. Elected sixty-seventh President of the Royal College of Physicians of Edinburgh, he remained in this coveted position from December, 1858, to December, 1861. He was a formidable debater at professional meetings, but was very gentle and kind as a teacher in the Sabbath School. His religious habits are certainly not in keeping with the suggestion that he purposely instituted, or knowingly allowed to continue, the false impression that his first subcutaneous injection was performed in 1843 and not 1853. He died on February 26, 1884.

Terminology

When Wood introduced the method of injecting drugs below the skin he called it the "subcutaneous" route. When Charles Hunter, as already described, extended the applications of the method he introduced the term "hypodermic." Hunter's reason for giving a new name to his method, which really only withdrew the emphasis from the local action, was, no doubt, that he wanted his "remote" injections to be regarded as something completely new and different from the locally acting injections of Wood and Rynd. Wood and Hunter carried out a long correspondence in the *Medical Times* and *Gazette* on the subject of who was the first to recognize the remote effects following an injection (for references, see Howard-Jones, 1947).

The names applied to the injection of fluids under the skin are interesting. Called by Wood "subcutaneous" after the Latin—the word being in use before Wood's time—it was dubbed "upodermic" by Hunter in his first paper on the subject. Upodermic was used because it was of Greek origin and therefore similar to the terms endermic and enepidermic, which were fairly common at that time. In his second paper Hunter used the term "hypodermic," adding a footnote, "In the first part of this paper the word hypodermic was spelt upodermic; but I now spell the word in accordance with common orthography." The most likely reason for Hunter's adoption of the form "upo" is that he did not realize the significance of the rough breathing mark in ὑπό. Perhaps some colleague with a better classical education pointed out the error in time for it to be changed in the second paper.

It is doubtful if Hunter was right in his choice of name, although he was justified because of the existing words from the same root. The name is derived from δερματικός, not δέρμα: the stem is dermat, as in dermatitis and dermatologist. Hence hypodermatic would be more correct than hypodermic. Hypodermic, however, is sanctioned by long usage and has the advantage of being the shorter form.

Early Forms of Hypodermic Syringe

The Ferguson syringe used by Wood is undoubtedly the forerunner of the modern "hypodermic," although there have been some modifications since it was first used for subcutaneous injection. The needle screwed on to Wood's syringe, and the glass piston, wrapped in cotton-wool or gauze to reduce leaks, was operated by a push-pull action. When hypodermic injection became popular on the continent of Europe, the syringes used were at first based on that which Pravaz had employed for injecting clotting agents into aneurysms. These differed from the Ferguson-Wood type, for the syringe was of metal and the piston was operated by a screw mechanism. The mode of use was also different: with the Pravaz type of syringe, which Béhier popularized in France for subcutaneous injections, a trocar and cannula were inserted through the skin; the trocar was withdrawn and the syringe screwed on to the cannula, which remained in position until the injection was completed.

This method was obviously cumbersome and it was impossible to avoid the injection of air. Besides, when injecting aneurysms, clotting was apt to occur when blood and sclerosing fluid met in the cannula and, when this happened, to cause a leak back past the piston. As most syringes were of silver the leak could not be seen; so, to obviate the difficulty thus caused, Lenoir had a glass barrel made for his syringe. He also introduced the use of a fine second cannula. This was attached to the syringe, charged with fluid, and inserted through the wider first cannula, already placed in position in the tissues. Lenoir's work is well reported in the *Association Medical Journal* (Report, 1853), but even when his modifications were adopted for subcutaneous injections the method remained complicated and was totally unlike present-day practice. In Wood's

technique, however, as in the modern hypodermic method, perforation of the skin was effected with the penetrating needle already attached to the syringe.

Advances in Design

The screw piston remained on Continental syringes until H. Wulffing Luer, a Parisian surgical instrument maker, introduced a metal-and-glass instrument which dispensed with the screw piston and adopted the push-pull mechanism of the Wood apparatus. Luer also rejected the screw mount for the needle, and in this respect set the fashion for the hypodermic syringe as we know it to-day. He did not adopt Wood's addition of graduations to the syringe barrel, but marked the piston-rod instead. Although his syringe had a push-pull mechanism there was a movable stop which traversed a thread along the piston shaft. By setting this stop before injection the dose to be delivered was fixed and could not be exceeded without further manipulation. A similar running stop is still to be found on some present-day syringes.

The next advance in syringes came about 1896, when Luer introduced an all-glass model (Schwidetzky, 1952). Schwidetzky also stated that the first of the familiar Record syringes was made in 1906 by the German firm of Dewitt and Hertz. Though the Record mount is probably the most widely used in this country to-day, it seems likely that it will ultimately be replaced by the Luer mount, which is much sturdier. The British Standards Institution has, in its specification BS 1263 of 1946, adopted the Luer mount for all-glass as well as metal-and-glass hypodermic syringes for general use. It is probable, therefore, that the standard for hypodermic needles will, when published, also specify the Luer fitting. It is to be hoped that, when this standard is drawn up, a rational orismological system will be advised and adopted. Such a system would improve upon the present habit of the use of manufacturers' code numbers, which often combine gauge and length of needle: in a pithy form it should give details of length of needle and gauge of cannula, type of point, and size of mount, with, if possible (but not so essential) the wall-thickness of the cannula. (There have, of course, been many other modifications to the hypodermic syringe, such as the use of rubber or leather washers on the piston; hollow pistons to contain needles or drugs; permanently fixed needles protected by covers, which could also be used to prepare injection solutions, and so on. But these are mostly side branches of the genealogical tree of the modern hypodermic syringe, and so have not been described.)

Future Development

It is difficult to foresee the future development of the syringe and needle, quite apart from the many special types which have been developed and which will no doubt be made for particular purposes, but it is interesting to speculate. Is it likely, for example, that the orthodox equipment will be replaced by the "cartridge" syringe, already familiar to dentists and of which only the needle has to be sterilized? Or will there be a return to their wartime popularity of those extremely handy, single-dose, collapsible tubes with covered, sterilized needles already attached? Or will the hypospray technique, described by Figge (1947) and Hingson and Hughes (1947), supplant the older methods? Will the many disadvantages of this new method, such as expense, limited dosage, frequent tissue injury, and complicated maintenance be offset by its simplification of the steps necessary for sterility and its ability to overcome the fear of the needle? Is it likely that Wood's lost needle will be permanently abolished by the wide acceptance of jet injection, which is only radical departure from the method used by Dr. Alexander Wood one hundred years ago?

At any rate, it is certain that, to oust Wood's time-tested simple, accurate, and flexible injection technique from its place of universal popularity, any new method will need to possess merit indeed.

Conclusion

It seems reasonable that, although no one individual was entirely responsible for the introduction of the method of injecting drugs into the subcutaneous tissues, Dr. Alexander Wood should be granted the major share of the credit. There is no doubt that drugs were inserted below the skin before his time, but Wood's method of injecting is the one we use to-day. True, Wood was obsessed with the idea of local action, and credit must go to Charles Hunter for turning the general systemic effects after hypodermic injection to good account. But Hunter used Wood's subcutaneous method and, calling it by its equivalent Greek name, merely extended its applicability.

So Wood, availing himself of an instrument which had been evolved for intravascular administration, performed the first subcutaneous injection shortly after 10 p.m. on November 28, 1853. He introduced the method "quietly and unobtrusively" (except for some bickering with Hunter over the question of who was the first to make use of the remote effects) and "left it to make its own way" (Brown, 1886). He made no fortune from his invention and gained little fame, for, although the method is in daily use by almost every practitioner, how many know the name of the man to whom the medical profession, and indeed mankind in general, is indebted for its introduction?

I am grateful to Dr. E. Ashworth Underwood, of the Wellcome Historical Medical Museum, for drawing my attention to the very complete historical survey of hypodermic medication by Dr. N. Howard-Jones, from which a lot of my information has been obtained. A further interesting and detailed account of the history of injection—intravenous, subcutaneous, and intramuscular—is contained in the centenary number of the *Ciba Zeitschrift* (March, 1946), which is entirely devoted to Die Injektion. I would like to thank Professor W. A. Bain for many stimulating discussions and for editorial criticism, though he has forbidden me to do so. Mr. C. N. England prepared all the photographs except Figs. 1 and 3.

ATTEMPTED SUICIDE IN OLD AGE

BY

I. R. C. BATCHELOR, M.B., M.R.C.P.Ed., D.P.M.
Deputy Physician-Superintendent, Royal Edinburgh Hospital
for Mental and Nervous Disorders; Lecturer in Psychiatry,
University of Edinburgh

AND

MARGARET B. NAPIER, A.M.I.A.
Senior Psychiatric Social Worker, Royal Edinburgh Hospital
for Mental and Nervous Disorders

Suicide and the mental disorders of old people are two of the foremost social and psychiatric problems of today. Though the incidence and types of mental disorder occurring in old people have recently attracted much attention, and the rise of the suicide rate with advancing age has long been recognized, few clinical studies of suicide or suicidal attempts in this age group of the population have been reported. This is the more surprising since, as the proportion of old people in the community rises, the suicide rate may for that reason also rise. It is striking, for example, to find in a recent authoritative study of the mental disorders in later life (Kaplan, 1945) only brief reference to suicide, and no elaboration of its clinical aspects.

Gruhle (1941) is often quoted in an opinion which minimizes the importance of psychoses in the genesis of suicidal acts in this age group and emphasizes, as motives, morbid reactions to physical illness and mental incapacity, idleness, boredom, loneliness, and inadaptability in changed circumstances.

Swinscow (1951) in a valuable statistical investigation has come to the conclusion that "suicide in the last 50 years has increasingly become a disorder of elderly people," and has suggested that, "as the present century has advanced, the old may have found their environment more hostile than the young."

Kiorboe (1951) has made a study of 14 old people who committed and 21 who attempted suicide. His condensed findings cannot be abstracted briefly. All his cases were residents in an institution, and his sample is therefore not representative of the community at risk. His conclusions differ materially from those of this paper—for example, he reported in his group a high incidence of syphilis, and found alcoholism to be an important factor and loneliness rare as a motive for suicide.

Roth and Morrissey (1952), from a study of 150 patients over the age of 60 admitted to a mental hospital and a review of the literature, suggest a special association between old age and depressive illness, and support their opinion of the importance of the affective psychoses in this age group by reference to suicide rates. They report that only 12 of their 150 patients had made attempts at suicide, and that each of these was suffering from an endogenous depression. They are critical of Gruhle's opinions, and state that "it is not argued that social factors play no part, but that it is through their role in the precipitation of depressive psychoses that they contribute to the causation of suicide in the old." It seems possible, however, that the factors noted by Gruhle may act not merely as precipitants of depressive psychoses but more intimately in affecting their course and outcome.

There is obviously a need for further studies. Social and psychiatric data must be accumulated, from a sufficient number of cases, at different centres.

General Characteristics of the Cases

In a series of 200 consecutive cases of attempted suicide admitted to a general hospital in the years 1950-2 and personally observed, 40 (20%) were aged 60 years or over. These 40 cases have been studied in detail. The sample is small, but it is likely that it is reasonably representative of an urban population. The large majority of all suicidal attempts occurring in the city of Edinburgh are admitted to this hospital: suicidal attempts in old people usually demand active surgical and medical treatment, and there is naturally a great reluctance to commit an old person directly, as an emergency, to a mental hospital.

The sex, ages, and marital state of these 40 people are detailed in Table I.

TABLE I

Age Group	Male	Female	Total	Marital State	Male	Female	Total
60-64 years	5	4	9	Single	3	10	13
65-69 "	5	11	16	Married	7	3	10

80-84 "	2	1	3	Divorced	—	—	—
Total ..	16	24	40	Total ..	16	24	40

Family Histories

In 26 (65%) of the cases there was a family history of psychiatric abnormalities, which were manifested in 54 of their relatives; 7 (17%) of the cases gave a family history of suicide, seven of their relatives having attempted suicide, five successfully. In 14 (35%) cases a history of mental illness in first-degree relatives was obtained. In 12 of these 14, affected relatives had suffered from severe depressive breakdowns: in 6 of the 12 the history was indubitably of manic-depressive psychoses.

Previous Personal Histories

One-half of this group of people (male 11, female 9) had experienced a "broken home" in their childhood. This high proportion corresponds to that found in a large series of cases of attempted suicide of various ages (Batchelor and Napier, 1953).

More than one-half of the cases (male 9, female 13) had been mentally ill before the present breakdown. Less than one-quarter (male 6, female 3) had previously received psychiatric treatment. The large majority of the previous illnesses had been depressive in character.

Seven individuals (male 5, female 2) had made a previous suicidal attempt. Three of these attempts occurred in an earlier phase of the present illness.

One-quarter of the group were considered to have adequate personalities. The remaining three-quarters seemed vulnerable. Most common factors were a morbid sensitivity and shy seclusiveness which had developed in some instances into jealousy, suspicion, and ideas of reference; and anxious, timid, obsessional dispositions with a tendency to hypochondriasis. A number showed undue dependency of long standing, and passive homosexual trends. The majority had restricted interests.

The intelligences of the group seemed to parallel those of an average sample of the population of the same age.

The great majority of these people had satisfactory work records; but their limiting personality traits, in the cases where frank failures in social adaptation had not occurred, had led usually to no better than fragile adjustments. Social adaptation had been defective in one-half of all the cases. Most of these people had had few friends: self-centred and prickly, they were disposed to loneliness. Only 7 (male 6, female 1) had a present affiliation to any organized non-religious group. Four of these seven individuals, all men, were members of clubs for old people.

Statistical researches seem to show that religious beliefs play some part in determining the incidence of suicide. Nothing definite in this direction emerged from the present investigation, so the data may be stated briefly. Of the group, 38 were Protestants (one British Israelite and one

Plymouth Brother included); 2 were Roman Catholics. Almost all expressed a belief in a personal God, while none denied His existence. The majority also believed in some sort of immortality or after-life; but 6 individuals (5 men) stated frankly their disbelief. Only 12 of the Protestants (9 women) were church-going; one of the Catholics had lapsed. These older people were on the whole more religious than younger suicidal individuals who were examined. But no evidence was found that their religious beliefs had played any significant part in hindering their suicidal attempts: not one of these people had consulted a minister in his perplexity or was inhibited by fear of punishment beyond the grave.

One-quarter of the group stated that they did not know that attempted suicide was an offence against the law; while only those whose previous attempts had brought them to police notice knew what precise action the law might take. No evidence was found to show that legal sanctions had acted as a deterrent.

Social Data

Table II gives an analysis of the social conditions of the group. One-quarter had suffered a fall in social status over their lives, which could probably be correlated with their personality defects. Only one individual had suffered any great change (decline) in social status over the past twelve months. Only three had experienced a significant change in their living conditions in the past twelve months. Apart from the three living a communal life in lodging-house or hostel, one individual suffered from overcrowding and three others lacked privacy at home.

TABLE II

	Male	Female	Total
(A) Present Social Class:

Living in lodging-house or hostel	2	1	3
" alone	2	4	6

(E) Social Circulation and Mobility.—Of the group 38 were Scottish; 12 were rural bred; the majority had spent many years in Edinburgh. In the past twelve months only 5 had changed the locality they lived in, and all these moves were local ones in the city. As one might expect, social mobility was not high in this group: old people prefer to be stationary.

(F) Group Membership.—Details of religious and other group affiliations have been given under the heading of "Previous Personal Histories."

Psychiatric Diagnoses and Symptoms

Cases of attempted suicide in this age group are more easily classified than those occurring in people in the first half of life. The persons here are usually definitely mentally ill: at least two-thirds are certifiable as insane, and the personalities of the majority are clearly involved to a psychotic extent.

In younger age groups a heterogeneous collection of reaction types is found among cases of attempted suicide; and there is a considerable proportion of persons suffering from psychopathic states and of temperamentally unstable people allied to these in their reactions, whose precise psychiatric classification is difficult and debatable. But, in old people, clear-cut depressive states comprise the setting in which the great majority (80% in this series) of suicidal attempts occur.

About one-half of the cases of depression in this series were first attacks (Table III). Ten patients had suffered from one previous attack of depression, three from two, two from three, one from four, and one from more than four previous attacks. Only one of these 17 patients had previously

TABLE III

attempted suicide. This suggests that the recurrence of a depressive reaction in old age tends to be less well tolerated than earlier attacks: understandably so, since the resilience of the old person is impaired, relapse has added its quota of disappointment, and hope for the future is less native.

Only four individuals (10%) suffered from organic reaction types. In each of them the dementing process had not advanced far. These findings are in accordance with expectation, since retention of affect and volition are prerequisites for the genesis of a suicidal act. The depressive affect was prominent also in each of these four cases: one had had a depressive illness, and another had attempted suicide, some years previously.

The symptoms which precede suicidal attempts in old people are symptoms which frequently precede suicidal attempts at other ages, and are the common features also of depressive states which may not proceed to suicide. Depression and insomnia are almost always present. The depression is usually accompanied by anxiety and agitation; there is usually little or no retardation, and the depression may even be masked by a smiling exterior. Insomnia is usually persistent and accompanied by great concern: "It was the want of sleep that was troubling me"; "I haven't slept for four months"—are typical protestations.

Loss of appetite and hypochondriacal complaints about the alimentary tract are common, and the individual may be exclusively preoccupied with them. Complaints of indigestion, flatulence, and intractable constipation may have more or less justification owing to the decreased physiological efficiency of the old person's body, but they often become morbidly dominating and have delusional force: "It's as if I was going to burst"; "I can't expel anything." Such hypochondriacal delusions may be accompanied by other nihilistic delusions—for example, of poverty. Ideas of reference are not uncommon, and a few cases had unsystematized paranoid delusions.

Feelings of weight upon and tension in the head, and head noises, are commonly the bases of fears of insanity. The patient may complain of a feeling of something about to snap in his head, or the feelings may be expressed in more bizarre terms: "It is as if my brains were turning upside down"; "Whiles you'd think there was cold water in it [head]." Only one individual attempted suicide at the command of auditory hallucinations.

A few patients who were fully orientated complained of being "mixed" or "muddled up." Three others of those suffering from depressions were transiently confused (for a few days) after their suicidal attempts and disorientated in time and place: in at least one of these cases the confusion

had also shortly preceded the suicidal attempt. In none of these cases was there evidence of drug intoxication or vitamin deficiency, nor, either at the time or later, were there symptoms of cerebral arteriosclerosis. None of them had an amnesia for the suicidal act. It seems possible that the intense, agitated preoccupation with the wish for death had caused a temporary clouding of consciousness, with neglect of the material environment. The term "catastrophic reaction" appears particularly applicable. The confusion in these cases cleared, to unmask a profound depression and intact faculties.

Indications that the inner tension was becoming intolerable to the individual were commonly present before the self-injury was inflicted. Twelve patients (6 men and 6 women) made direct suicidal threats in the present illness; 6 other women made suicidal threats by implication.

Physical State

The physical condition was unsatisfactory in 24 (60%) of the cases: 8 individuals were suffering from cardiovascular disease, 5 were disabled by arthritis, 4 had organic diseases of the nervous system, 3 affections of the alimentary system, 2 of the respiratory. One woman was suffering from mild bromide intoxication.

Serious defects in vision and hearing were found in 4 cases. Malnutrition and loss of weight were common; but in no case was malnutrition accompanied by clinical evidence of vitamin deficiency. Fatigue was almost constantly present.

The Suicidal Attempt

Old people seem to show a greater preference for active methods of suicide than do younger people. They can rarely give an adequate reason for their choice: the usual reply to questioning about this is, "I don't know." The figures given below show, however, that more than one-half of this series chose poisoning. In this age group, as in others, availability of method plays some part. It is interesting to note that all of Kjørboe's institutional patients used violent methods in their attempts.

Impulsive suicidal attempts in old people are much less common than in younger age groups. Less than one-quarter of the attempts in this series seemed to have been impulsive. More than one-quarter of them had been contemplated for weeks or months.

Four of the poisonings were multiple; these have been listed under the main toxic agent (Table IV). One man cut both throat and wrist.

TABLE IV

	Male	Female	Total
<i>Passive:</i>			
Poisoning	7	18	25
Barbiturate	4	11	15
Coal gas	1	4	5
Aspirin	1	1	2

Shooting	1	—	1

The attitude of the patients after their suicidal attempts is shown in Table V.

TABLE V

	Male	Female	Total
Suicidal intention admitted immediately	9	16	25
" " " denied; later admitted	4	4	8
" " " denied	3	2	5
Amnesia claimed	—	1	1
Not known	—	1	1

There is rarely any doubt that the suicidal attempt of an old person has been a genuine one. Those who deny their suicidal intentions usually admit to having had feelings of hopelessness. The denial may be paradoxical: one man who had come into hospital asking to be kept safe from his suicidal urges, later, when admitted after taking 100 aspirins, denied his suicidal intentions; a woman said, "I have a confession to make to you, I *didn't* attempt to take my life."

Of the 40 cases, 22 (55%) had to be admitted for further treatment to a mental hospital—almost twice the percentage immediately requiring such treatment in a series of cases of suicidal attempts in adults of all ages.

Precipitating Factors and Motives

The diagnosis of an abnormal type of mental reaction in the individual concerned is not a sufficient explanation of a suicidal attempt. While it is probably true that more suicidal acts in old age can be more nearly explained in terms of mental illness than is the case in younger age groups, the question immediately arises: Why is it the minority of the sufferers from these illnesses who are driven to suicide? There is no mental illness, in any age group, the majority of whose victims make suicidal attempts. A case history may be briefly quoted here.

A retired public servant aged 72, none of whose near relatives had been mentally affected and who had never himself previously had a nervous illness, whose personality had been robust and work record exemplary, was bereaved of his spouse. Shortly afterwards his only son married and brought a young and aggressive wife into the house. In this setting the old man became deeply depressed in his spirits, took alcohol in excess for the first time in his life, committed, while sober, his first police offence by shoplifting, and, when partly under the influence of alcohol, made a determined suicidal attempt. There was no organic mental deterioration.

The depressive reaction in this case apparently released three distinct kinds of abnormal conduct. Even if we suppose it to have been the essential condition for the development of the deviant behaviour, the different deviations cannot conclusively be given the same, even if it is an attractively simple, explanation. We cannot be content with the finding that the depressive psychosis has been the main item in the aetiology of this suicidal act.

In old people as in all other age groups, the aetiology of suicide and suicidal attempts is multiple. So far as we know, there are no aetiological factors, either personal or social, which are peculiar to any one age group. But in the case of old people certain personal factors are more commonly, and others less commonly, encountered than they are at other ages. Among suicidal old people feelings of loneliness and of increasing physical incapacity are very often found: dramatic gestures, demonstrations of omnipotence, and reactions of escape from social embarrassments are uncommon, and intoxication is less often a complication.

Loneliness.—Feelings of loneliness, of being a burden on others, or of being unwanted, found in 23 of the 40 cases, were the commonest psychological precursors of suicidal attempts in this series. Frequently the old person states that it was a feeling of estrangement which most powerfully prompted his act: "I felt as if nobody wanted me"; "I just stay myself, I feel lonely"; "I felt I was keeping my daughter back." The same sentiments are commonly expressed in suicide notes.

Social integration is a concept which is difficult to define, and which cannot be expressed satisfactorily merely by stating the living conditions. It is obvious that an individual who is living alone may not be lonely; while a member of a family group may feel isolated. Social integration exists where there is a reciprocal sympathy between the individual and his social environment: loneliness is a sensitive indicator of its deficiency. The domestic background of the cases of this series in which loneliness seemed an important factor is interesting and, though the numbers which may be quoted are too small to be dependable, they are probably significant. Loneliness was a factor in 10 of 11 of those

living with offspring, in 8 of 8 living alone or in a lodging-house, in 3 of 7 living with a sibling, and 0 out of 9 living with a spouse.

It is recognized that the incidence of suicide in an urban area may be correlated with the percentage of those in the community living alone (Cavan, 1928; Sainsbury, 1951). The above figures may be held to confirm this to some extent; but they also emphasize that the old person may be nominally integrated by being a member of a family group and yet feel socially isolated. There is a suggestion in these figures that to be with coevals is for the old person easier than to have to adjust to the pace of life and interests of younger people. And it was clear that, in certain cases, to the loneliness in some measure inseparable from old age it self there had been added the bitter experience of emotional rejection by the children who resentfully were materially supporting and housing the old person.

Physical Incapacity.—This was a major factor in 18 cases. It was not the degree of disability which seemed usually the important element, but the rapidity of its onset or its unexpected nature. The ageing individual, with limited assets, may have to meet abruptly a new and disturbing situation. A fall, producing only bruises and shock, or increased demands upon energy and resourcefulness owing to the illness of a helpmate, may bring the old person to a sudden realization of his frailty. Forced by ill-health to keep to the house or to take temporarily to bed, he may see in this a threat of permanent invalidism and helplessness, and decide that such a future would be intolerable. Many patients after their suicidal attempts reported such reactions: "I was beginning to feel my age"; "I felt I was done"; "Lying in bed for a fortnight upset things; I was accustomed to a hard life all my days." Physical pain and discomfort strengthened the suicidal urge in 8 cases. Increasing blindness was a leading cause of suicide in one case. Three individuals were severely deaf: though they did not make their deafness a major complaint, it must have contributed to their social isolation.

Fears.—Closely allied to the above and found also in 18 cases, based usually on a misinterpretation of somatic symptoms, are fears of having contracted a fatal physical illness or of becoming insane. The physical illnesses most commonly the foci of phobias were cancer and heart disease; phobias of tuberculosis and of venereal disease were also encountered. Eight patients feared insanity, and in three of these cases the suicidal act was precipitated by arrangements being made for mental hospital admission. Perhaps the most potent fear of all is the dread which is nameless and unfocused, and from which the patient sometimes comes seeking protection saying that he feels that something terrible, he knows not what, is about to happen.

Identification with a Dead Person.—In suicides of all ages, identification with, or the hope of rejoining, a dead person is a prominent motive: it was found in 11 cases in this series—about the same percentage of cases as in a larger group of adults of all ages (Table VI). In younger people the dead individual most commonly identified with is the mother; in old people it is the spouse.

TABLE VI

	Male	Female	Total
Identification with spouse	2	4	6
" " sibling	1	1	2
" " father	1	—	1
" " mother	—	1	1
" " offspring	—	1	1

Financial Anxieties.—These played a part in the suicidal attempts of 6 individuals (3 men and 3 women).

Hate.—Hatred of another person, an important and striking motive in many of the suicidal attempts of younger people, is a less common element in the suicidal attempts of old people—unless one is to presume its presence in all those who are living with relatives and are to some degree estranged from them. At any rate, if it is commonly present

as a motive in old people it is usually less obvious and less intensely focused. Few suicidal attempts in this age group are precipitated by overt quarrels; and spite, revenge, pique, and jealousy are infrequent motives. Homicidal trends were clearly identified in only four cases. One old man confessed to fears that he might harm the married daughter whom he was living with and who was showing him little affection; another warned his wife not to sleep with him, in case he might strangle her. A widowed woman brandished an axe over her only daughter, who was shortly to get married; and a spinster had obsessional thoughts and impulses towards attacking with a knife her younger and more attractive sister.

Guilt.—This factor, often difficult to assess, was infrequently expressed by these suicidal old people in depressive delusions or in self-reproach. It does not appear to be a major factor in the suicidal attempts of the senium.

Alcohol.—Three men were under the influence of alcohol at the time of their suicidal attempt, but not to the degree that they later had an amnesia for the act. Two men and two women habitually took alcohol in excess; two men and one woman had previously been alcoholic.

Other Factors.—Retirement from work contributed directly to the suicidal attempts of two men; but its more indirect and insidious effects are difficult to gauge. Recent moves of home and changed domestic circumstances precipitated the attempts of two women. The death of friends appeared to be the motive in only one case. Disillusionment is hard to judge: it is part of the senescent attitude to life; one would not expect it to be of lethal strength.

One is aware, in listing the various motives, that some of them are superficial and derived from the patients' rationalization, and that the explanations advanced are at best partial. Ultimately these morbid acts are discharged at an unconscious level and are the outcome of a tremendous emotional turmoil, of which we discern only some of the effects. We guess at the strength of the despair, and we assume, though we cannot clearly define, the lessened controls.

Discussion

The state of the old person who attempts suicide reminds us of the vivid words of that Anglo-Saxon elegy, *The Wanderer*:

"He knows who puts it to the test how cruel a comrade is sorrow for him who has few dear protectors; his is the path of exile, in no wise the twisted gold; a chill body, in no wise the riches of the earth; he thinks of retainers in hall and the receiving of treasure, of how in his youth his gold and the friend was kind to him at the feast. The joy has all perished. . . . Then comes darkness, the night shadow casts gloom, sends from the north fierce hailstorms to the terror of men. Everything is full of hardship in the kingdom of earth; the decree of fate changes the world under the heavens. Here possessions are transient, here friends are transient, here man is transient, here woman is transient; all this firm-set earth becomes empty."

In this age group, as in others, while suicide may appear a sufficiently logical reaction to an intolerable situation, it is in very few instances carried out under the direction of reason unperturbed by morbid emotions.

The infirm situation of the old person needs no elaboration here; his vulnerability to disease and death and his relative social inutility are obvious. With a sense of this latter old people may be rather deeply imbued. In certain primitive societies it was conventional, and apparently occasionally obligatory, for old people to commit suicide when on account of their infirmity they had become a burden on the rest of the community. A period of famine was then the usual precipitant of their self-sacrifice. While such crude biological and economic pressures have been more or less lifted from old people in our society, the mechanization, pace, and restless competitiveness of an industrial civilization may equally be inimical to them.

Prone as he is to painful feelings of being a burden to others, it is obviously very necessary for the old person,

particularly if he is no longer economically useful, to feel loved and wanted. There is much concern about the welfare of old people, but the very fact that their position is receiving such detailed scrutiny indicates that their social status is changing. In their ever-increasing numbers old people are becoming a social problem, and the fear is expressed that they may be becoming a social burden. Old people seem more often now to be falling outside family units. The attitude of our society as a whole seems to be ambivalent. There is a tendency, for example, towards segregating old people—a tendency which is not wholly explicable in terms of the housing shortage; and, while the importance to the old person of continued employment for as long as possible is stressed, arbitrary and traditional ages of retirement are maintained and even embodied in new legislation.

Though, judged by crude material standards (such as their financial state or their housing situation), the old people in this series of cases were in general not badly off, there was evidence that they were subject to environmental stresses, particularly to community attitudes expressed in the behaviour towards themselves of their own relatives, which, though more subtle, were not less wounding. Most of these old people were also temperamentally vulnerable. Many gave a family history or previous personal history of nervous or mental illness; many had suffered the disabilities of a broken home in childhood; and most of them had defects of personality which had made them prone to reactions of anxiety and insecurity, and to social isolation with its attendant feelings of loneliness. It seems that when a depressive illness develops in such a predisposed individual—particularly when resistance, already lowered by the effects of old age, is still further impaired by physical ill-health, and there is a lack of love due to the loss of a marital partner or rejection by offspring—a reaction of weariness, loneliness, and despair may be set in motion which tends to eventuate in suicide. This is a generalized statement; but it is doubtful if we have at present enough evidence to be more specific. Each case differs in certain respects; predisposing and precipitating factors vary in the relative intensities of their incidence, and much in every case remains unknown.

It is evident from the above that the known factors which tend to precipitate suicide in old people are the same factors which in general tend to precipitate their mental breakdown. The prophylaxis of suicide in this age group coincides, therefore, with the wider objectives of a programme of mental hygiene, about which fortunately there is now wide theoretical agreement. The promotion of optimum mental health in earlier years; the encouragement of continued occupation for as long as possible and the fostering of other interests; the maintenance of social integration; the avoidance of undue fatigue; the early and adequate treatment of physical illness and the alleviation of fears about it; the prompt diagnosis and treatment of mental illness, and particularly of depressive reactions; the recognition of the warning in the suicidal talk of the old person: all these items and objectives are of the greatest importance, and in their pursuance a great many agencies and individuals have their parts to play. The problem is far wider than merely a medical one. Suicide is a disease of the community, and the community as a whole has to exert many resources in its self-healing.

Summary

In a series of 200 consecutive cases of attempted suicide admitted to a general hospital 40 were aged 60 years or over. Detailed social and psychiatric data about these 40 cases are presented.

A family history of psychiatric abnormality was obtained in 65% and of suicide in 17% of the cases.

One-half of the group came from "broken homes." More than one-half had previously been mentally ill. Previous suicidal attempts had been made by 17%. Three-quarters had vulnerable personalities, which tended to isolate them socially.

Of the suicidal attempts 80% occurred in the setting of a depressive state. Evidence suggested that the recurrence of a depressive illness in old age had been less well tolerated than earlier attacks, and that the suicidal attempt of an old person is almost always a genuine one. Less than one-quarter of the attempts had been impulsive.

Significant physical disease was present in 60% of the cases.

Attention is drawn to the multiplicity of precipitating factors and motives, and stress is laid on the importance of feelings of loneliness and physical incapacity, fear, and identification with a dead person.

Adverse social factors of a material kind were found to be less important than community attitudes, which tend to make the old person feel useless and unwanted.

The importance of the problem of suicide in old people is emphasized, and a relevant mental hygiene programme is outlined.

We are grateful to Professor Sir David K. Henderson for his criticism and advice, and to Dr. J. K. Slater for permission to study these cases in his wards of the Edinburgh Royal Infirmary.

WORK AND AGE: STATISTICAL CONSIDERATIONS*

BY

W. P. D. LOGAN, M.D., Ph.D.

Chief Medical Statistician, General Register Office

I propose to deal with four basic considerations regarding the elderly worker: (1) the relative numbers of old and young people in the population; (2) the proportions of old people still at work; (3) the relative mortality risks to old people in various broad types of employment; and (4) the amount of time lost on account of sickness.

Population

It is no longer news to any audience to announce that the proportion of young people in the population of this country is becoming smaller and that the proportion of elderly people is increasing. This situation, which is occurring in a most Western countries as well as our own, is the result of a prolonged decline in the birth rate from about 1870 until about 10 years ago, accompanied by a reduction in mortality that began a few years earlier and which is still continuing. The outcome has been an age redistribution of the population, and Fig. 1 shows the changes that have occurred during the past 110 years and also what the situation is likely to be in 1991, as estimated on the basis of some simple and reasonable assumptions about trends of births and deaths during the next few decades. The proportion of the population of working ages, taking these as 15 to 64 years, has increased during the past century, and by 1951 there were 67 people of working age to every 33 people outside this age range—that is, two-thirds of the population in 1951 were aged 15–64. Unfortunately, the ratio of persons

WORK AND AGE

BRITISH
MEDICAL JOURNAL 1191

FIG. 1.—Percentage age distribution of the population (male and female) of England and Wales, past, present, and future.

FIG. 2.—Death rates per 1,000 males in age groups, England and Wales, 1841-5 and 1946-51.

of working age to other ages is now just about its maximum, and by 1991 we shall be back to where we were in 1901. There will, however, be one very important change: a hundred years ago there were about eight children to every old person and at present there are about two children to each old person, but by 1991 there are going to be almost as many people aged 65 and over as under 15.

Now, although one of the main factors responsible for these changes has been improving mortality, the degree of improvement has been very different at different ages, as Fig. 2 indicates. During childhood and young adult life death rates have declined by 80% to 90% in the past 100 years, whereas at old ages the decline in mortality has been less than 20%. The effect of this differential improvement can perhaps best be illustrated by means of "expectations of life"—namely, the average number of years that people of a given age will live if subject to given mortality conditions. For a newborn boy in 1841 expectation of life was 40 years (Fig. 3) and by 1950 it had risen to 66 years—that is, an increase of 26 years. For girls the increase was even greater—namely, 29 years. For boys aged 15 years the expectation increased from 43 years in 1841 to 55 years in 1950. I mentioned, however, that improvement in mortality

has been greater at younger than at older ages, and the effect of this is seen in the changing expectation of life of people aged 60. In 1841 this was 14 years both for men and for women, but by 1950 it had increased for men only to 15 years and for women to 18 years. This is rather an important point: although expectation of life at birth has increased 20 or 30 years this does not mean that people approaching retirement nowadays have 20 or 30 more years of life before them than their grandfathers, or perhaps great-grandfathers, had. In fact, they will on average live only a year or two longer.

None the less there has been some increase, and in showing that the changes at older ages in mortality, and therefore in expectation of life, are small compared with younger ages I do not want to give the impression that the age structure of the population over the age of 60 has been quite static, though indeed it was so for a long time. Fig. 4 gives the proportions of men at various ages over 60 years in four different years. In 1841 and 1901, men aged 60–64 outnumbered those over 75 by more than 2 to 1; in 1951 the ratio was 3 to 2; and by 1991, if recent mortality trends continue, there will be as many men alive aged 75 and over as aged 60–64.

FIG. 3.—Expectation of life in England and Wales at various ages and at three periods of time.

FIG. 4.—Percentage age distribution of male population of England and Wales, aged 60 and over.

I turn now to my second topic, the occupational distribution of the elderly population as determined by the 1% sample analysis of the 1951 census returns. Fig. 5 shows the proportions of elderly men describing themselves as occupied or unoccupied. At ages 60-64 87% were still working full-time and 10% were retired. At ages 65-69 the proportions of these two categories were practically equal—48% still working whole-time and 47% retired. In the next age group, 70 and over, 20% were working whole-time, and 70% were retired.

Fig. 6 shows the status distribution of men still occupied at ages 60 and over. At ages 60-64 operatives constituted 78% of the total, and men working on their own account 9%. By ages 70 and over the percentage of operatives had fallen to 64, with a corresponding increase in the categories of employers, managers, and those working on their own account. People in these latter occupations carry on working after many of the men classed as operatives have stopped.

FIG. 5.—Percentage distribution of men aged 60 and over according to whether occupied or retired. Great Britain, 1951 census, 1% sample.

FIG. 6.—Status distribution of occupied men aged 60 and over. Great Britain, 1951 census, 1% sample.

FIG. 7.—Percentage of men aged 70 and over, retired from selected occupations. Great Britain, 1951 census, 1% sample.

Fig. 7 lists a number of large occupational groups and shows the percentage of men aged 70 and over described as retired, expressed as a percentage of the total number of men at these ages in those occupations. The lowest proportion of retirements was for agricultural workers, 59% retired, followed by directors and managers, of whom 63% were retired. Occupations in which high proportions were retired were rail transport workers (96% retired), fishermen (94%), mining and quarrying (92%), and teachers (91%).

Occupational Mortality

Since 1851 it has been the custom of the Registrar-General to calculate occupational mortality rates for years in or around that in which there was a census, and in due course an occupational mortality analysis for years 1949-53 will be made upon the basis of the 1951 census. A preliminary analysis has just been completed for the year 1950, utilizing the census 1% sample occupational data, and Table I shows some of the results that have emerged. For men aged

TABLE I.—Death Rates of men Aged 60-64 in Selected Occupations Per Cent. of Corresponding Rate for All Men. England and Wales, 1950

Social Class	Occupation	Death Rate
II	Farmers	69%
	Hewers and getters	187%
	Other mine-workers	139%
III	Transport workers	108%
	Clerical workers	98%
	Armed forces	171%
IV	Agricultural workers	74%
	Mine-workers	101%
V	Building labourers	70%
	Dock labourers	128%

60-64 mortality was notably low for farmers, for other agricultural workers, and for building labourers, all with death rates less than three-quarters of the average for all men of that age group. Mine-workers in social class III—that is, skilled workers—had an unfavourable mortality experience particularly hewers and getters, and another occupational group with a high death rate at ages 60-64 were men described as members of the armed Forces.

Incapacity Amongst Elderly Men

One of the important factors to be taken into consideration in determining whether an elderly man is still employable is the amount of time he is liable to lose from work on account of sickness. Some information on this question can be obtained from the results of the monthly Survey

conducted in England and Wales from 1944 to 1951. For the purposes of this survey, incapacity was defined as inability on account of sickness to go out to work or, for persons not at work, inability to go out of doors. It is important to note this dual definition of incapacity, because it is a little difficult to interpret the figures for elderly men, many of whom do not go to work and to whom the second half of the incapacity definition applies. Since a retired man may be well enough to go out of doors but might not, had he been still working, been well enough to go to work, the incapacity rates revealed by the survey are not quite comparable from age to age. None the less they are worth looking at and thinking about.

In an average month of 1950 the percentage distributions of men aged 16-64 and men aged 65 and over according to their reported days of incapacity compared as shown in Table II.

Days of Incapacity	Ages 16-64	Ages 65+
0	91.3	89.1
1-3	2.7	1.7
4-10	2.8	3.4
11 and over	3.2	5.8

It is surprising how little difference there is between the two groups; almost 9% of men of working ages had some incapacity in the month, and for elderly men the proportion increased only to 11%. It was mainly in the group with incapacity of more than 10 days that the elderly men were in excess, their proportion (5.8%) being nearly double that for younger men. This predisposition of the elderly group towards more prolonged incapacity resulted in their having a quite definitely higher average incapacity rate than younger men—namely, 1.6 days per man per month, compared with 1.9 day for men aged 16-64. However, it must not be supposed that suddenly at age 65 the incapacity rate jumps from the lower to the higher level. The increase is gradual and continuous from about 35 years of age upwards, and indeed the figures suggest an actual falling off after 65.

Age:	16-	25	35	45	55	65	75+
Days of incapacity per man per month	0.69	0.69	0.79	1.02	1.61	1.57	1.58

By reason of the special definition of incapacity already referred to, applying to people who do not go to work, the flattening off of the rising trend of incapacity rates after age 55 is probably fallacious, and no doubt the curve in fact ceases rising. I do not want to enter into a detailed discussion of these incapacity figures, and I shall merely emphasize the two points which they bring out—namely, that the proportion of elderly men who do not have any incapacity is almost as great as for younger men, and also that there is no evidence of a sudden increase in incapacity amongst the higher age groups, but a gradual increase throughout adult life.

These figures support in a general way the thesis which is being increasingly put forward nowadays, that there is no justification for an arbitrary and rigid retirement policy applied to everyone at, say, age 60 or 65 years, or indeed at any age, on the grounds that beyond that age service will be so punctuated by incapacity as to make it unprofitable for it to continue. Though this is no doubt true for certain occupations that impose a heavy physical or mental burden upon the elderly and impair their health, it is not the case for the majority of occupations, and, provided an elderly man can be relieved of some of the load he has previously carried, there seems every reason for him to keep on working until his own individual state of health renders it expedient that he should stop. The important thing, however, is that he be relieved of his load, and in some cases this may be achieved only by change of occupation. There is indeed much to be said for every man taking stock of his

position when he is approaching the sixties and considering how long he will be physically and mentally able to carry on with his present job, and whether he wants to carry on any longer.

The man who carries on with his customary work after 60 may find himself unable to cope with it a few years later, and he may also find that he has lost the ability and inclination to turn to anything new: but the man who breaks away at 60 and takes on a lighter job, particularly if it is one in which he can find some personal interest, may find that he has embarked upon a second career in which he can continue to give useful and satisfying service for a further 10 years or more. Though we may all have some kind of humanitarian urge to relieve elderly people of the burden of having to keep on working for their living and to allow them the rest that they deserve, it has to be realized that to remove compulsorily from work an elderly man who is fit and eager to carry on doing something is not an act of kindness to that man. The suicide rate is high amongst elderly people. It might not be so high if more of them were given the opportunity of continuing to be useful, productive members of the community.

EXTENDING THE EMPLOYMENT OF OLDER PEOPLE*

BY

A. T. WELFORD, M.A.

(From the Nuffield Research Unit into Problems of Ageing, Psychological Laboratory, Cambridge)

It is perhaps presumptuous for a psychologist, especially an academic psychologist, to speak about the employment of older people, since industry and industrial medicine have had to deal with this problem in a practical way for many years, and have managed to solve it with very fair success in a number of cases. I hasten to say, therefore, that I speak with a very real sense of humility and that my remarks should be taken as suggestions for consideration rather than as confident assertions.

It is well known that the average age of the population has been increasing during recent years. From 1851 to 1921 the proportion of people over 65 was nearly stable at about 10% of those between 20 and 64, but in the 1951 census the proportion had risen to 18%, and it has been estimated that by 1961 it will be 22%, and by 1971, 28%. In other words, whereas up to the years immediately following the first world war there were about 10 people between 20 and 40 for every one over 65, there are now fewer than six, and 20 years hence there will be fewer than four. If present retirement ages continue there is likely to be a serious shortage of labour before long. Realization of this has led to questions being raised in many quarters whether employment and retirement policies for older people, built up in the early years of the century and in the slump conditions of the 'thirties, are adequate for conditions to-day. Even if they are, it is urged that some measures should be taken now to forestall future difficulties.

The problems of employing older people involve several disciplines. Some are medical. Some are economic, concerned with pensions schemes and pay

*Read in opening a discussion in the Section of Occupational Health at the Annual Meeting of the British Medical Association, Cardiff, 1953.

rates related to age. Some are social, such as the effect of the age of retirement upon the age of promotion for younger men. I shall not consider these problems, but will confine myself instead to those which are concerned with some aspect of ability. I do this not only because these are the problems with which I am in closest touch, but because it is likely that many economic and social problems are secondary to them. It is well known that many changes occur with age—eyes and ears become less sensitive, reactions become slower, and ability to learn diminishes. These are facts we cannot escape. It is often believed that we can transfer the implications of these generalizations direct to the problem of employability, but this we can do only in part. Such generalizations are unduly wide, in the sense that they are true only of some people and in some respects. At the same time they are too narrow in that they fail to recognize many other changes which occur. Even when they are true the circumstances may be such that they are unimportant.

One of the commonest policies with regard to the employment of older people is some form of conscious or unconscious selection of a few to stay on while the rest retire. This policy is justifiable in the sense that for almost any job we like to name we can find some older people who can do it well. As we go up the age scale the differences between one individual and another become greater, so that, although the average performance may fall, some individuals will do as well as, or better than, the majority of young men. What is required, however, is a more radical solution than this. We need to specify work which is suitable for the majority of older people, which will enable them to continue at their jobs beyond what is now regarded as the normal retiring age, and in doing so to maintain their efficiency and self-respect, if possible without special allowances.

I will try to summarize the main points about what we know. Some are perhaps obvious, some may be new. As we know little as yet, I make no apology for giving some attention also to the methods of research whereby we can learn more.

Methods of Research

Two points should be stressed at the outset. The first is that our problem is not solely with employment beyond the normal retirement age. Ageing is continuous; by the age of 30 the beginnings of many changes, which become striking in extreme old age, can already be seen. As a result, many of the most important problems of ageing in relation to employment occur in middle age. The second point is that, as in most human affairs, it is that which is unpleasant and distressing to which we are apt to pay greatest attention. Most of the scientific knowledge we possess about ageing is of ways in which capacity and performance get worse as people grow older. There are, however, clearly ways in which age brings improvement, such as steadiness of character, conscientiousness, and patience. Unfortunately these qualities are elusive of precise definition and have so far not proved amenable to scientific study.
