Since cortisone and A.C.T.H. were made available in this country in 1951, 78 patients have been treated with these drugs at the General Infirmary at Leeds. In no case has the decision to start the treatment rested on conditions other than therapeutic indication, so that our experience, though fairly broadly based, has been gained more from individual needs than from research interest.

In non-rheumatic conditions the results obtained seem valuable enough to allow of an interim report on our conclusions. Patients in this group have been submitted to treatment not only where it was felt that cortisone or A.C.T.H. offered the best hope of improvement, but also in an attempt to elucidate their various and varying effects in disease processes. Due weight has been afforded these aims in the allocation of cortisone or A.C.T.H. for individual patient treatment, applications for the drugs being submitted to the cortisone committee at the infirmary, one of us (S. J. H.) acting as secretary to this panel.

This report summarizes the results and experience gained in the non-rheumatic diseases. Fourteen patients have been observed with disorders of the blood and blood-forming organs; 16 patients have been treated for disease or dysfunction of the endocrine glands; and in a third, miscellaneous, group the effect of treatment has been studied in two patients with cirrhosis and portal hypertension, in two patients presenting a nephrotic syndrome, and in nine patients suffering from asthma.

No attempt has been made to review the literature, since this is thought to fall outside the scope and intention of a report which deals, in the main, with the routine treatment of problems common to a general teaching hospital.

DISEASES OF THE BLOOD

Acute Acquired Haemolytic Anaemia

Four children, whose ages ranged from 6 months to 8 years, were admitted to hospital during a period of 16 days in March, 1952, suffering from acute acquired haemolytic anaemia. Because of the poor response of three of them to blood transfusions a trial was given to the use of A.C.T.H., and the results have been reported elsewhere in greater detail (Rose and Nabarro, 1953).

Clinical Presentation.—All described a short febrile illness characterized by lethargy, irritability, increasing pallor, breathlessness, and haemoglobinuria; two showed moderate icterus, one of these also demonstrating enlargement of the spleen, liver, and lymph nodes. They were acutely ill, and in no case were any specific aetiological factors evident.

Haematology.—The findings in the peripheral blood were of a severe haemolytic process without evidence of leukaemia. The sternal marrow in the two patients on whom this examination was performed showed only normoblastic hyperplasia. The direct Race-Coombs test was positive on admission in two patients and eventually positive in three.

Treatment.—Three of the children required the protection of A.C.T.H. or cortisone. The fourth responded to a single blood transfusion given on the seventh day after admission, and she remained in good health despite persisting hepato-splenomegaly. Of the three treated with hormones, a girl aged 3 who had relapsed rapidly after each of three transfusions responded to a course of A.C.T.H. given over a period of five weeks, begun at an initial dosage of 50 mg. daily intramuscularly and gradually reduced after three weeks. A second child, a boy aged 8, was given A.C.T.H. because of severe relapse after several transfusions. He responded well to a dosage of 100 mg. daily continued for two weeks, gradually reduced in a "steppage" procedure in the next three weeks, but he relapsed when A.C.T.H. was discontinued. After further transfusion, splenectomy was performed without apparent effect. A second course of A.C.T.H. (100-75 mg. daily) was given, to which he again responded. In the seventeenth week after admission cortisone was substituted for A.C.T.H. A final attempt at drug withdrawal resulted in brisk haemolysis and he still required 75 mg. of cortisone daily, nearly 60 weeks after the beginning of his illness and the start of treatment. His general health remained excellent, though "mooning" of the face was clearly evident. In this case the direct Race-Coombs test, previously positive, became negative during the thirteenth week of treatment whilst he was receiving A.C.T.H., though later it reverted with cortisone.

The third patient to come under treatment, a female child of 6 months, was given A.C.T.H. after a preliminary trial of transfusion. Relapse followed withdrawal

of the drug, which had been given at a dosage of 25 mg. daily, and splenectomy was undertaken during a second course of A.C.T.H. Relapse again occurred when the drug was discontinued. A third course of A.C.T.H., later changed to cortisone, was continued in gradually diminishing dosage for a further period of 14 weeks, and no ill effects have attended its final withdrawal, 28 weeks after the onset. The direct Race-Coombs test, positive at the outset, is now only weakly so.

Comment.—In this small group, one child responded after one transfusion, and another after transfusion and A.C.T.H. The other two were given intensive hormone therapy, and both were submitted to splenectomy. The relatively large requirements of A.C.T.H. made it difficult to achieve haematological response and clinical control without the production of side-effects. Undue gain in weight, mooning of the face, and glycosuria were recorded, but without biochemical or electrocardiographic evidence of electrolyte disturbance. Splenectomy proved of little benefit in the two children who relapsed after withdrawal of the drug, the operation being undertaken because of the large requirements of A.C.T.H. and the long duration of the illness. Of these two children, one appeared to recover after splenectomy performed under the protection of a second course of A.C.T.H., but relapsed on withdrawal of the drug, subsequently responding to intramuscular cortisone. The other child was operated on during a relapse, but failed to improve, the haemolytic process being ultimately controlled with cortisone. Rose and Nabarro conclude that the underlying abnormal antibody reaction can be controlled by sufficiently large doses of hormone, yet cortisone and A.C.T.H. cannot be said to displace transfusion and splenectomy in the treatment of the individual patient, both remaining as important therapeutic adjuvants.

Aplastic and Hypoplastic Anaemia

Two patients with marrow aplasia have received A.C.T.H. A man aged 27 with Hodgkin's disease, confirmed by gland biopsy, was given a long period of treatment with oral nitrogen mustard (R48), for the supply of which we are indebted to Professor Haddow. After nine months a persistent anaemia required frequent correction by blood transfusion. It seemed likely that treatment had conditioned marrow aplasia, for the anaemia was associated with thrombocytopenia and profound neutropenia. Marrow puncture gave no diagnostic information. Accordingly a trial of A.C.T.H. was made: the dosage was 100 mg. daily, reduced after eight days to 75 mg. daily. The drug was continued for 20 days (total 1.7 g.). The blood count at the start of treatment showed: Hb, 72%; W.B.C., 900 per c.mm. (60% neutrophils); and platelets, 40,000 per c.mm. No improvement occurred in the peripheral blood as a result of treatment. In the ensuing months the interval between transfusions has lengthened and the white-cell and platelet count has gradually returned to normal.

A retired policeman aged 64 had been anaemic for three years. Marrow examination at the onset in 1949 demonstrated notable reduction in the formation of erythrocytes, though the marrow was not aplastic. The diagnosis of hypersplenism was considered, but splenectomy in 1950 failed to establish a clinical cure, and since operation he had been kept alive by blood transfusions. A course of A.C.T.H., 100 mg. daily for eight days, was without effect on the anaemia and no reticulocytosis was observed. No decrease in the frequency of subsequent transfusions followed this course of treatment, which was held responsible for the recognition, three months later, of diabetes mellitus, requiring insulin. He died six months later at home, and no post-mortem examination was possible.

Comment.—In the first patient the restoration of a normal blood count was seemingly uninfluenced by A.C.T.H., the subsequent haematological improvement being more in keeping with the experience of Matthews (1950) though occurring rather less promptly, which probably reflected on the large amount of R48 previously given. In the year of observation following the course of A.C.T.H. there has been no progression of the Hodgkin's disease, which appears entirely quiescent. In the case of idiopathic aplastic anaemia A.C.T.H. had no effect on the blood condition, diabetes mellitus developing three months later as a complication of treatment.

Agranulocytosis

A patient with agranulocytosis consequent on thiouracil treatment of thyrotoxicosis was admitted as an emergency. A blood count showed 1,200 leucocytes per c.mm., with 4% neutrophils; and marrow examination demonstrated severe hypoplasia of the myeloid series. A.C.T.H., 25 mg. six-hourly, produced prompt symptomatic and haematological improvement, with myeloid hyperplasia evident at a second marrow examination on the fourth day of treatment, the peripheral blood at this time showing 70% of polymorphs in a total white-cell count of 2,900 per c.mm. Restoration to normality was complete by the seventh day, and there seemed little doubt that A.C.T.H. was the agent responsible for the swift reversal of this profound neutropenia.

A housewife aged 57 had been found to be granulocytopenic two years previously. Apart from a course of sulphonamides, given prior to recognition of the condition, no cause was evident. Treatment with haematins had been without effect and she was subject to recurrent coliform urinary infections. The total white-cell count averaged 2,000 per c.mm., with neutrophils 10-20%. Marrow examination demonstrated a failure of maturation of the cells of the myeloid series in a quiescent marrow. Seven intravenous infusions of A.C.T.H., each of 20 mg. in 1 litre of normal saline, were given on alternate days without significant change in the peripheral white-cell count, and a seven-day course of A.C.T.H. by intramuscular injection (total 900 mg.) was similarly ineffective. Her progress has been followed for 18 months. Her health remains good, though still liable to interruption by urinary tract infection, and on one occasion by a large gluteal abscess of spontaneous origin from which *Bact. coli* was cultured. The added complication of a mild diabetes mellitus, recognized six months after the course of A.C.T.H., has been well controlled by dietary restriction of carbohydrates.

The third patient in this group, a man aged 51, first came under treatment for a left-upper-lobe pneumonia which gradually resolved with antibiotic therapy. Granulocytopenia was observed at this time, the bone marrow showing granulocytopenia to be arrested at the stage of transition from myeloblasts to myelocytes, the more mature forms showing heavy toxic stippling. The erythroid elements were hyperplastic in response to a moderately severe anaemia. The anaemia was corrected by blood transfusion, and the patient returned to work. His condition slowly deteriorated, with irregular pyrexia and progressive fall in the neutrophils to 7% of a leucocyte count of 2,400 per c.mm. A.C.T.H., 100 mg. daily for 16 days, caused some improvement, the white-cell count after treatment being 3,300 per c.mm., with 64% neutrophils. The diagnosis in this case remained obscure, the haematological findings being compatible with a chronic agranulocytosis or progressive marrow aplasia. Further investigation was prevented by the development of psychotic traits, the patient taking his own discharge and dying a month later at home. The possibility of tuberculosis was suggested by a chest x-ray examination within a month of death, which showed a diffuse mottling throughout the lung fields.

Comment.—Of three patients with agranulocytosis, an excellent response to A.C.T.H. occurred in the one in whom thiouracil was the agent responsible for the acute development of serious neutropenia. A.C.T.H. was entirely

without effect in a second case of agranulocytosis of idiopathic origin and two years' duration, and led to the later development of diabetes. In a third patient, A.C.T.H. produced a temporary improvement in the white-cell count where the cause of the granulocytopenia remained obscure.

Thrombocytopenic Purpura

Cortisone has been used in two cases. A man aged 65, with a lifelong bleeding tendency and several previous admissions for thrombocytopenia, was readmitted because of persistent epistaxis, with a platelet count of 100,000 per c.mm. and a bleeding-time of 12 minutes. Cortisone, 100 mg. daily intramuscularly, was given for five days without significant haematological response, though the bleeding stopped on the second day of treatment.

The second patient, a woman aged 39, developed thrombocytopenic purpura after a course of sodium aurothiomalate

FIG. 1.—Effect of A.C.T.H. in a patient with subacute myelogenous leukaemia. Arrows indicate blood transfusions.

given for disseminated lupus erythematosus. The platelet count averaged 80,000 per c.mm., sternal marrow biopsy showing no evidence of aplasia or leukaemia, the megakaryocytes being normal in number and form. The spleen was not palpable. Splenectomy was done without persisting effect on the platelet count and bleeding continued, requiring frequent transfusion. Treatment with A.C.T.H., 100 mg. daily for three days followed by 50 mg. daily for two weeks, coincided with clinical improvement, and bleeding ceased shortly after the drug was discontinued, the platelet count showing little significant change. Since this time two further episodes of bleeding and purpura have necessitated her readmission, but her general condition has steadily improved and she is now well. The lupus erythematosus is quiescent.

Comment.—In both patients clinical improvement coincided with the administration of cortisone or A.C.T.H., unaccompanied by significant haematological response.

Leukaemia

Three patients with leukaemia have been treated with A.C.T.H. The first of these, a woman aged 42, presented in an acute termination of a myeloid leukaemia with the unusual feature of extensive glandular enlargement. Three weeks previously she had completed a course of deep x-ray therapy. Blood examination showed 51% neutrophils, 22% metamyelocytes, and 27% myelocytes in a total white-cell count of 48,000 per c.mm. A.C.T.H. was given at a dosage of 100 mg. daily for seven days, without clinical improvement or haematological response, the peripheral blood demonstrating an increasing number of less-differentiated cells in a higher total count. Her death from cerebral haemorrhage followed shortly on the withdrawal of A.C.T.H.

Our second patient, a man aged 30, had subacute myeloid leukaemia and the clinical appearance of so-called "pseudo-

scurvy." A course of R48 was discontinued on the development of skin purpura and A.C.T.H. introduced in an attempt to influence the extreme dysphagia occasioned by infiltration and oedema of the oropharynx. Symptomatic relief was rapid and striking, regression of swelling and clearing of ulceration from the mouth being associated with control of fever and a sensation of well-being that bordered on the euphoric. The total white-cell count initially increased, but later it progressively and rapidly declined to leucopenic levels, averaging 1,500-2,500 per c.mm., with neutrophils about 40-60% and lymphocytes 60-40%; immature white cells disappeared from the peripheral blood (Fig. 1). The dosage of A.C.T.H. was gradually reduced, but attempts to discontinue it entirely were met by a prompt return of fever with local and general deterioration. It appeared probable that A.C.T.H. was the agent responsible for the temporary control of the leukaemic process, though the concomitant employment of chloramphenicol may well

have contributed to marrow depression—an effect reported in this country by Hawkins and Lederer (1952) and by Wolman (1952). In the fifteenth week of treatment with A.C.T.H., and some nine days after chloramphenicol had been discontinued, the peripheral blood demonstrated a return of leukaemic features, with the re-appearance of primitive white cells. Thereafter deterioration was rapid, jaundice preceding death.

The third patient, a boy aged 16 with acute myeloid leukaemia, received five daily transfusions each of 25 mg. of A.C.T.H. in 1 litre of normal saline. The total white-cell count fell from 140,000 to 13,000 per c.mm. in this period, but the proportion of primitive cells remained unchanged. The later administration of folic acid antagonists clouded estimation of the therapeutic effect, but no remission followed, and the boy has since died.

Comment.—We have had no experience of the effect of cortisone and A.C.T.H. in the acute leukaemias of childhood, in which favourable results have been reported. In this small group of older patients with myeloid leukaemias the discouraging response to treatment has been in keeping with that generally recorded.

ENDOCRINE DISEASES

Exophthalmic Ophthalmoplegia

Our original report (Chandler and Hartfall, 1952) concerned the treatment with cortisone and A.C.T.H. of five patients (Cases 1-5) with this condition. Since then four more patients have been treated, without dietary regulation of sodium.

Case 6.—A woman aged 70 developed thyrotoxicosis in January, 1951. Treatment with thiouracil led to general improvement, but proptosis and chemosis became more pronounced, though unaccompanied by ophthalmoplegia. She was admitted in March, 1952, and given A.C.T.H., 100 mg. daily for 21 days, without change in the ocular condi-

tion, either subjective or objective. Her thyrotoxicosis showed no signs of settling and she was given a treatment dose of 1³¹ in June, 1952. Control of thyrotoxicosis has been associated with a slow improvement in the eye signs.

Case 7.—A woman aged 25 underwent partial thyroidectomy for primary thyrotoxicosis in April, 1951. There was some post-operative increase in exophthalmos, and on admission in May, 1952, the exophthalmometer readings were R. 23 mm., L. 22½ mm. Gross nystagmus, hysterical in pattern, prevented measurement of duction movements. There was no diplopia. She gave the impression of considerable anxiety without evidence of thyrotoxicosis (B.M.R. +20%). Treatment with cortisone by mouth, 25 mg. six-hourly, was started on May 30 and continued to June 19. There was some slight subjective improvement and a minimal decrease in proptosis (R. 21 mm., L. 22½ mm. on June 19). The dosage was reduced to 50 mg. daily on July 2 and then to 25 mg. daily on July 7, and was finally discontinued after another three weeks. No further change was observed, the readings of exophthalmos in November being R. 21 mm. and L. 22 mm. The patient claims continued symptomatic relief.

Case 8.—This patient was a woman aged 50. The onset of bilateral proptosis four years previously antedated by nearly two years the clinical recognition of thyrotoxicosis. Thiouracil treatment was instituted in January, 1951, but was discontinued after five months because of leucopenia. Since this date there has been little change, either in thyroid status or in the severity of the eye signs. In August exophthalmos measured R. 22½ mm. and L. 23½ mm. There was no oedema either of lids or of conjunctivae, and the ocular movements were full. The patient was euthyroid as judged by B.M.R. and radio-iodine studies. A course of cortisone, 100 mg. daily by mouth to a total of 2 g., was entirely without effect on the eye signs, and a subsequent trial of A.C.T.H. was likewise ineffective.

Case 9.—A man aged 54 was admitted on October 19, 1952, with a short history of progressive exophthalmos, first noted in the left eye four months previously. Diplopia was experienced on upward movement, and, concomitantly with the ocular disturbance, increasing irritability and weight loss suggested a mild thyrotoxicosis, confirmed by B.M.R. (+40%) and radio-iodine studies. Examination revealed rigid proptosis (R. 24 mm., L. 27 mm.), with chemosis and conjunctival prolapse. There was gross limitation of upward movement in both eyes with paresis of left inferior oblique and left superior rectus. A course of A.C.T.H. to a total of 2 g. (100 mg. daily for 20 days) was undertaken. During the period of observation and treatment the ophthalmoplegia and area of diplopia increased, later measurement of proptosis showing R. 26 mm. and L. 28 mm.—a small deterioration.

Comment

In summary, six patients showed no improvement, yet three responded well and one dramatically. This conflict of response is reflected in the publications of other investigators, some of whom (Lederer and Hambresin, 1950; Cole, 1951) reported conspicuously favourable results.

The reasons for this remarkable disparity are not immediately obvious, though some preliminary and necessarily tentative conclusions appear to be justified.

1. Our best results were obtained with A.C.T.H. in patients whose exophthalmos was of recent origin or had suddenly and rapidly progressed. It is possible that the greater effectiveness of A.C.T.H. may be the result of the stimulation of mineral corticoid secretion and consequent local withdrawal of fluid from the orbital tissues (Campbell, 1952). Such an effect could be expected in exophthalmos of recent development only before fibrotic changes have occurred in the ocular muscles and tissues. We have previously had experience of the ability of these steroid hormones to promote a saline diuresis in certain oedematous states (notably the nephrotic syndrome), and our original investigation was framed so as to relate the sodium balance of patients with exophthalmos to the effect of treatment.

2. Those patients in whom exophthalmos and thyrotoxicosis co-exist form a group of particular therapeutic difficulty. Though a

treatment dose of 1³¹ may prove a less drastic insult to the thyroid-pituitary relationship than partial thyroidectomy, yet in our series the control of thyrotoxicosis was the most notable feature of the treatment of two patients (Cases 1 and 5) in whom this coexisted with exophthalmos and ophthalmoplegia. This suppressive effect of the adrenal steroid hormones on thyroid function is in accord with the experience of Hill *et al.* (1950), who obtained good results in three out of six patients with uncomplicated Graves's disease. However, two patients in our series (Cases 6 and 9) showing the combination of thyrotoxicosis and exophthalmic ophthalmoplegia obtained no benefit from A.C.T.H.

3. Our experience with cortisone in patients showing exophthalmos unaccompanied by ocular muscle weakness has been entirely disappointing (Cases 6, 7, and 8), and no benefit from treatment has been observed. These patients showed only an overfilling of the orbit, presumably the effect of excess of fat.

4. Another consideration, that of dietary restriction of sodium which was enforced in our original series (Cases 2-5), cannot be discounted as a factor responsible for clinical improvement, bearing in mind the belief that oedema of the orbital tissues plays a part, at least, in the production of exophthalmos.

Simmonds's Disease

A.C.T.H. has been used in the treatment of three women with panhypopituitarism. On inquiry all gave histories typical of this disorder, dating their illness to a previous childbirth which had been attended by severe post-partum haemorrhage, following which lactation had never been established and the periods had failed to return. They had lost in energy, appetite, and variably in weight, one patient in particular presenting the picture of pituitary cachexia originally described by Simmonds (1914). Her slow deterioration over the years had been interrupted by infrequent attacks of drowsiness and coma. One such attack was observed in hospital, the patient lapsing into semi-coma with markedly cold extremities, immersion in a hot bath producing a striking but temporary improvement.

Clinical examination showed, in each, the changes of severe pituitary insufficiency. One patient was notable for the absence of mental change, preserving a bright though facile cheerfulness, in striking contrast to her physical enfeeblement. Of the others, one was deaf and apathetic, the other confused and hallucinated. The details of investigation before and during treatment are recorded in the accompanying Table. The Thorn test was normal in all, and hypoglycaemic unresponsiveness was observed in the two patients (Cases 2 and 3) in whom this investigation was made.

Treatment was by A.C.T.H. alone, and led to an improvement which was considerable in all, and dramatic in one (Case 2). It was appreciated by the patients, who without exception spoke of a feeling of strength and health, which had been absent for many years. The mental condition returned to normal in the two patients (Cases 1 and 2) in whom the symptoms of confusion and hallucination had predominated. Increase in appetite was universal, though gain in weight was not remarkable, averaging 8 lb. (3.6 kg.). All mentioned their new-found freedom from cold.

Concomitant anaemia, of normochromic type, which existed in Cases 1 and 3, did not respond to A.C.T.H., either alone or in combination with haematinics, and blood transfusion was required in Case 3 to correct the deterioration in this respect, the Hb having fallen to 49%.

Urinary excretion of 17-ketosteroids increased in all patients, particularly during the early weeks of treatment, but this was not maintained and perhaps was related to the reduction in dose of A.C.T.H. Examination of the fluid balance was remarkable for the demonstration, prior to the inception of A.C.T.H. therapy, of the small intake of water on which these patients were able to exist, the 24-hour urinary volume averaging 400-600 ml. The low level of sodium, which was a feature of the plasma chemistry of Cases 1 and 2, returned to normal and remained so under the influence of A.C.T.H. Serial E.C.G. recordings showed a parallel improvement. These patients have now returned home. Their maintenance requirements are being met by a single weekly injection of "acthar gel" 40 mg., on which

Effect of A.C.T.H. in Three Patients with Simmonds's Disease

17-Ks = Urinary 17-ketosteroid excretion.

improvement has been steadily sustained: all are leading active useful lives, managing their homes in a way previously impossible of fulfilment.

No toxic effects have been observed in this series, the appearance of oedema of feet and legs during the initial period of treatment responding to moderate salt restriction and the later reduction in A.C.T.H. dosage.

Comment.—The effect of A.C.T.H. in severe pituitary insufficiency has been studied in three patients, with a benefit from treatment so remarkable as to leave no room for doubt. In one patient (Case 2), almost moribund on admission, the effect was life-saving. They are now restored to useful domestic activity, though the glandular deficiency is such that continued maintenance treatment seems necessary.

Adrenal Hyperplasia

Cortisone has been given to four patients. Two were young women showing the syndrome of adrenal virilism, and two were children presenting as pseudo-hermaphrodites.

Adrenal Virilism

A woman aged 22 had noted rapid gain in weight and irregular menstruation for six months. Examination revealed moderate hirsutism, mooning of the face, and gross acne of the chest and back. The blood pressure was normal. The urinary excretion of 17-ketosteroids varied between 28 and 34 mg. per 24 hours, and the test for dehydroisoandrosterone was negative. Perirenal air insufflation and aortograms were thought to exclude an adrenal tumour. Total right adrenalectomy was without benefit or appreciable effect on 17-ketosteroid excretion. Two months later, left hemi-adrenalectomy was carried out under the protection of cortisone, 200 mg. being given on the day before operation, the drug being carried into the immediate post-operative period in gradually diminishing dosage. There resulted a very definite improvement in hirsuties, and the urinary excretion of 17-ketosteroids declined to an average of 6 mg. per 24 hours. Within two months, however, symptoms returned in their old severity, 17-ketosteroid excretion increasing to 15 mg. per 24 hours, and a third operation of left subtotal adrenalectomy was undertaken, the adrenal remnant being some one and half times the size of the normal gland. Five-sixths of this was removed, again under the cover of cortisone, which was given at a dosage of 50 mg. daily for two days before and for seven days after operation. The adrenal tissue removed at these successive procedures showed no histological abnormality. The further progress of this patient has been reasonably satisfactory, though a tendency to hirsutism remains.

The second patient, a woman aged 25, had been raised as a boy until the age of 9, when a large clitoris was removed. The mother noted hirsuties at this time. Menstruation later occurred only under the influence of oestrogens. She presented with typical virilism, a strong beard requiring shaving twice daily. There was no evidence in

the skin or face of basophilism, and the B.P. was 190/120. Urinary excretion of 17-ketosteroids was 26.5 mg. per 24 hours. An aortogram demonstrated enlargement of both adrenal glands without evidence of tumour. Excretion of 17-ketosteroids increased to a maximum of 108 mg. per 24 hours during a period of in-patient observation. Total right adrenalectomy was followed by a course of cortisone, 50 mg. daily for 34 days, during which 17-ketosteroid excretion fell to normal, the hirsuties greatly improving. Left subtotal adrenalectomy was done five months later under the protection of a second course of cortisone, but within two months of this operation a mild Addisonian syndrome developed, with weakness, vomiting, and pigmentation. She improved with deoxycortone acetate and salt therapy, cortisone being withheld as her condition suggested functional activity of the adrenal remnant. The histological appearances were those of simple cortical hyperplasia.

Comment.—Surgical removal of hyperplastic adrenal tissue and cortisone therapy have effected a small improvement in two patients with virilism; in neither did the results appear commensurate with the risks involved, though the time of observation had admittedly been short.

Pseudo-hermaphroditism

An infant of 3 weeks presented with persistent vomiting and perineal hypospadias. The diagnosis of female pseudo-hermaphroditism was confirmed by a raised urinary 17-ketosteroid excretion of 8.2 mg. per 24 hours (normal less than 1 mg.) and the infant's inability to retain salt. Despite vomiting, the urinary excretion of salt averaged 2 g. daily on an intake of less than 0.5 g. a day. The blood sodium was 228 mg. per 100 ml., chloride 430 mg. per 100 ml., and potassium 25 mg. per 100 ml. The infant was given extra saline equivalent to 2-3 g. of salt a day, with cortisone 5 mg. intramuscularly daily. The 24-hour excretion of 17-ketosteroids fell rapidly to an average of 1-1.5 mg., but the child remained ill and miserable, passing loose offensive stools; analysis of a 24-hour specimen showing 47% of total fatty matter with trypsin present down to a dilution of 1:100. A loose cough was uninfluenced by a course of aureomycin. After four weeks, deoxycortone acetate, 2 mg. daily, was introduced and cortisone continued at a dosage of 5 mg. intramuscularly twice weekly, with some clinical improvement and restoration of the blood sodium and chloride levels to normal. The improvement was short-lived, the child dying from bronchopneumonia in the eighteenth week. At necropsy the suprarenal glands were greatly enlarged (each weighing 10.4 g.) and showed a pale hyperplastic cortex. Histological examination revealed fibrocystic disease of the pancreas.

The second patient, first seen aged 3 years 3 months, had hitherto been reared as a boy. He was of slender build with girlish facies, showing a perineal hypospadias flanked on either side by gonadal sacs containing no testes. Over these sacs and the top of the phallus there was a quantity of black hair, suggesting a masculinizing process in a female.

This was confirmed by hormone estimations on the urine: 17-ketosteroids, 16.6 mg. per 24 hours; dehydroisoandrosterone, negative; follicle-stimulating hormone, 17 units. These results suggested bilateral diffuse hypertrophy of the adrenal cortex, though the amount of follicle-stimulating hormone, not usually present at this age, raised the possibility of primary pituitary dysfunction. The patient's bone age was between 5 and 6 years. Laparotomy a year later demonstrated female internal organs, biopsy from the right ovary showing normal ovarian tissue.

Cortisone therapy was started in July, 1952, the child being then almost 5 years old. The dosage was 50 mg. daily for three weeks, reduced to 25 mg. daily for a further four weeks, thereafter continued at 75 mg. and 100 mg. twice weekly. The 24-hour excretion of 17-ketosteroids, which had averaged 18-19 mg. per 24 hours prior to cortisone therapy, was controlled in the succeeding months at 4-6 mg. per 24 hours. Little objective change has so far occurred, but the child is well and happy, conforming easily to feminine outlook.

MISCELLANEOUS CONDITIONS

Cirrhosis with Portal Hypertension

Our experience of the treatment of this syndrome with A.C.T.H. has been limited to two patients in whom hepatic fibrosis had occasioned portal hypertension with frequent episodes of gastro-intestinal bleeding. Previous reports (Bongiovanni and Eisenmenger, 1951) of the effect of A.C.T.H. in cirrhotic subjects have stressed the risk to those patients whose liver function is seriously impaired. In others, certain benefit seems to have attended treatment, though evidence of the specific nature of the response is lacking.

A man aged 35 developed cirrhosis consequent on homologous serum jaundice. Three attacks of haematemesis at six-monthly intervals brought him under our observation, when, in addition to the finding of splenomegaly, extensive oesophageal varices were visible on barium examination and confirmed at oesophagoscopy. Measurement of oesophageal varix pressure (Mr. Allison) showed an excess over systemic venous pressure of 140 mm. H₂O. A course of A.C.T.H. was given over 39 days of study (total 2.5 g.). Day-to-day variation in dosage was determined by the patient's response, particularly in relation to fluid and salt retention and also by the levels of blood sugar. Fluid retention was easily induced—far more readily than has been our experience in other conditions with similar dosage.

FIG. 2.—Effect of A.C.T.H. on a patient with hepatic cirrhosis and portal hypertension. Note initial rapid increase in weight, with equalization of portal and systemic venous pressures at a time of maximum fluid retention, and improvement in the levels and ratio of plasma proteins.

The details of treatment and investigation are shown in Fig. 2. Serial estimations of plasma chemistry showed a progressive and sustained improvement in liver function with final return to normality. Direct measurement of portal hypertension gave equivocal results. By the fifth week of treatment the pressures in the portal and systemic systems were equal, but this second measurement coincided in time with the period of maximum fluid retention and systemic venous pressure was notably raised. Six months later, measurement showed that the difference in pressure between the two systems was as before treatment. Treatment occasioned some improvement in general health, and in the eight months since A.C.T.H. was discontinued the improvement, both clinical and biochemical, has persisted without recurrence of bleeding.

A man aged 36 had survived numerous attacks of haematemesis and melaena as well as the operations of splenectomy and oesophageal devascularization, both without benefit. This patient suffered a recurrence of bleeding whilst under treatment, and has recently reported a further attack of melaena. A.C.T.H. has contributed nothing to this man's rehabilitation.

Comment.—This small experience suggests that A.C.T.H. has no certain place in the present admittedly unsatisfactory attack on the problem of portal hypertension, though it may remain a valuable therapeutic adjuvant in the treatment of cirrhosis.

Nephrotic Syndrome

We have had experience of the paradoxical diuretic power of these drugs in two patients whose presentation conformed to that described by Ellis (1942) as type II nephritis.

A woman aged 48 developed the characteristic triad of oedema, albuminuria, and hypoproteinaemia following on the employment of sodium aurothiomalate for a polyarthritis of rheumatoid type. Yet the time interval of nearly 12 months was such that the aetiological role of gold was of questionable significance. This patient received cortisone at a dosage of 100 mg. intramuscularly daily for six weeks (total 4.3 g.) and by the fourth week of treatment had lost 20 lb. (9.1 kg.) and was clear of oedema. Proteinuria declined from 7.8 g. per litre to an average of 1.2 g. per litre, yet no change in the level and ratio of plasma proteins accompanied this clinical improvement. She slowly relapsed after cortisone had been discontinued, oedema reaccumulating, uninfluenced by a 10-day course of A.C.T.H. (1.1 g.) and a final short course of cortisone, though she never became so waterlogged as on admission. Renal function was unchanged as judged by clearance tests, and the patient was normotensive throughout.

Our second patient, a girl of 15 years, came under observation in March, 1951, when for two months she had noticed swelling of the feet and legs, unaccompanied by haematuria. She was found to have gross albuminuria and a B.P. of 180/120. Since this time, oedema had fluctuated but never remitted. Renal function was adequate: the plasma chemistry demonstrated reversal of the albumin/globulin ratio. In March, 1952, no improvement having followed the adoption of orthodox dietary measures, A.C.T.H. was started at a dosage of 25 mg. intramuscularly six-hourly and continued for 17 days (total 1.7 g.), the patient being placed on a diet providing a constant daily intake of sodium. During the administration of A.C.T.H. she gained weight steadily, oedema sensibly increasing in a period of negative sodium balance (Fig. 3). Cessation of A.C.T.H. was followed by a profound saline diuresis over 10 days, when the patient lost 15 lb. (6.8 kg.) in weight, oedema clearing entirely. Albuminuria

diminished slightly and the level of blood cholesterol fell from 350 to 170 mg. per 100 ml. This patient's progress has been observed for 12 months, and neither increase in weight nor return of oedema has occurred. Hypertension remains unaltered, and renal function is adequate. No significant change was noted in the level of plasma proteins during the time of in-patient observation, but in the succeeding months the trend of the plasma chemistry has shown an encouraging progress to normality.

Comment.—Two patients with a nephrotic syndrome have been treated with cortisone and A.C.T.H. The first patient went into remission whilst under treatment with cortisone, decrease in albuminuria and diuresis occurring simultaneously. Partial relapse followed the withdrawal of cortisone. In a second patient, treated with A.C.T.H., the diuresis was observed immediately after withdrawal of the drug and continued for 10 days. In this case the remission induced by treatment has lasted for 12 months. It seems clear from these observations that A.C.T.H. and cortisone are capable of exerting profound effects on electrolyte metabolism. More doubtful, however, is the possibility that the underlying disease process has been radically altered. This favourable response to cortisone and A.C.T.H. compares with other clinical reports of the effect of induced malaria (Gairdner, 1952), and the natural remissions sometimes observed following measles, for these may well represent the common results of adrenal activation by stress. Whatever the precise mechanism, these effects of the adrenal steroids in nephrotic disease provide interesting problems in fundamental physiology.

Asthma

The dramatic relief afforded to patients with bronchial asthma, and particularly those in status asthmaticus, by cortisone and A.C.T.H. is generally known. We have had the opportunity of observing their effects in nine patients, all of them subjects of severe chronic asthma, for whom emergency hospital admission had been requested after the usual remedies had failed.

Three women in their fifties obtained rapid relief from a single intravenous infusion of normal saline to which 20 mg. of A.C.T.H. had been added. These drips were allowed to run for 12 hours, when symptomatic benefit was such that treatment could confidently be continued by more orthodox means.

A woman aged 45, admitted desperately ill in intractable status asthmaticus, did not respond to A.C.T.H. by intravenous infusion and died on the second day. Post-mortem examination demonstrated almost solid plugging of the air passages by thick mucoid material, a mechanical obstruction to respiration which only bronchoscopic aspiration might have relieved.

Two patients have been treated with cortisone by inhalation, 5 mg. of the standard preparation being made up into 2 ml. with normal saline and administered at two-hourly intervals. The response of both lacked the dramatic quality attending the use of intravenous A.C.T.H., but was judged by the patients themselves to provide more rapid and lasting improvement than they had obtained in previous attacks of similar severity.

Two patients have received cortisone by intramuscular injection. A housewife aged 59 derived no benefit from 100 mg. of drug given daily for five days. The other, a woman of 25 in status asthmaticus, made an excellent response to 50 mg. given thrice weekly for five doses, treatment being continued at 50 mg. twice weekly for a further fortnight. The remission in this patient lasted until her return home one week later.

Though not directly touching on the therapy of the asthmatic attack, cortisone has been used in a case of allergic asthma in which orthodox desensitization had been abandoned because of the production of severe asthma. It was found possible to complete desensitization under the protection of cortisone, 25 mg. twice weekly, and since its completion the patient, a man aged 40, has remained free of attacks.

Comment.—We have confirmed the beneficial effects of cortisone and A.C.T.H. in seven of nine patients with severe bronchial asthma. The intravenous infusion of A.C.T.H. in normal saline seems to offer the best prospect of rapid symptomatic relief, and, together with the topical administration of cortisone by inhalation, allows of considerable economy in prescribing. The remissions induced by these forms of treatment average one to two months, probably differing little from the duration of freedom afforded by the more usual forms of treatment.

Summary

The effect of cortisone and A.C.T.H. in non-rheumatic diseases has been studied in 43 patients.

Fourteen patients with disorders of the blood have been observed. A favourable response occurred in three children with acute acquired haemolytic anaemia, and in thrombocytopenic purpura apparent clinical benefit resulted in the two patients treated. No effects were produced in aplastic anaemia, though one patient with acute agranulocytosis from thiouracil made a good response. The effect of A.C.T.H. in leukaemia was at best temporary. This small experience suggests that, apart from acquired haemolytic anaemia and some cases of purpura, cortisone and A.C.T.H. have little place in the treatment of blood disorders.

Sixteen patients with disorders of endocrine function have been studied. Of nine patients with exophthalmic ophthalmoplegia, only three responded well, the best results being obtained with A.C.T.H. in those examples of recent onset or rapid progression. Three patients with Simmonds's disease have made a dramatic and sustained improvement on A.C.T.H. Two patients showing the virilizing effects of adrenal hyperplasia have been

FIG. 3.—Effect of A.C.T.H. in a patient with nephrotic syndrome. Black areas, positive sodium balance; hatched areas, negative sodium balance. Note rapid loss of weight and saline diuresis when A.C.T.H. was discontinued. The levels and ratio of plasma proteins show no persisting improvement.

treated by adrenalectomy and cortisone: in neither did the results obtained appear to justify the risks involved. 17-ketosteroid excretion was controlled in two pseudo-hermaphrodites by the use of cortisone.

The beneficial effect of cortisone and A.C.T.H. in asthma has been confirmed. The use of A.C.T.H. by intravenous drip and of cortisone by inhalation usually brought prompt improvement and was an important economy in prescribing. In two patients with nephrosis a considerable diuresis attended treatment, and in one of them the remission obtained has lasted more than a year. There is no evidence that A.C.T.H. influences portal hypertension accompanying cirrhosis, though apparent clinical benefit occurred in one patient.

We are grateful to the physicians and surgeons of the General Infirmary at Leeds and the Hospital Cortisone Committee, who have allowed us to publish details of patients under their care. We are indebted to the Medical Research Council for the cortisone used in the treatment of exophthalmic ophthalmoplegia and to Armour Laboratories for a supply of acthar gel.

DEVELOPMENTAL DYSARTHRIA

BY

MURIEL MORLEY, B.Sc., F.C.S.T.

DONALD COURT, M.D., M.R.C.P.

AND

HENRY MILLER, M.D., F.R.C.P., D.P.M.

(From the Children's Department, Royal Victoria Infirmary, Newcastle-upon-Tyne, and the Department of Child Health, Durham University)

In 1950 we advocated a simple classification of speech disorders in childhood (Miller and Morley, 1950). This had grown naturally from our work and was conceived within the framework of accepted neurological terminology. The five broad categories of deafness, defective articulation or dysarthria, retarded development of language or dysphasia, dyslalia, and stammering, with their main subdivisions, are presented again, as follows:

Disorders from Deafness

1. Congenital nerve deafness:
 - (a) Severe for all frequencies.
 - (b) Partial, or high-frequency deafness.
2. Acquired nerve deafness.

Dysarthria

1. Due to local anatomical lesions of the speech organs.
2. Dysarthria with neurological signs of cerebral disease or maldevelopment.
3. Dysarthria unassociated with abnormal neurological signs elsewhere.

Dysphasia

1. Mainly expressive dysphasia.
2. Mainly receptive dysphasia:
 - (a) Dyslexia.
 - (b) ? Congenital auditory imperception.
3. Delayed development of speech or global dysphasia.

Dyslalia

Transient defects of consonant substitution and omission.
Stammering.

Continuing experience has confirmed the value of this classification in assessing the prognosis and designing the treatment of the individual child. In the past two years we have given particular attention to the problem of dysarthria, which is, to us, slow and clumsy articulation arising from dysfunction of the muscles used in speech. The association with cerebral palsy in all its forms is well known. A group of children, however, presented with dysarthria as the only disorder without detectable neurological abnormality in any other part of the body. It is this isolated form of dysarthria which is the subject of this paper. The literature on the subject is scanty, but suggests that the condition is uncommon. As we have studied 18 affected children over a period of four years we realize that it occurs more often than we suspected, and should be more widely recognized. We shall first describe four children whose cases illustrate the clinical patterns we have seen, and then consider the nature of the condition and its differentiation from other forms of defective articulation.

Clinical Patterns in Developmental Dysarthria

Case 1: Dysarthria with Clumsy Movements of Lips, Tongue, and Palate.—This boy is now 7 years 9 months old. He is the second child in the family, was born before the arrival of the nurse, and weighed 12 lb. 10 oz. (5.7 kg.). He breathed and cried immediately after birth, was successfully breast-fed for seven months, and was walking on his first birthday. Words were first used between 12 and 18 months and sentences from 2 years onwards. On his first visit at the age of 5 his mother complained that "he dribbled when he was excited, sucked instead of chewing his food, and could not talk properly." Though rather nervous, he co-operated well and his I.Q. on the Drever Collins scale was 111. No abnormality could be found in the nervous system except that speech was slow and clumsy, the tongue bunched and writhed on lateral movement, and the palate moved to the right. During speech the lips, tongue, and soft palate moved in an awkward and uncoordinated fashion. Two years after the beginning of treatment he could repeat all consonant sounds except "s," and speech was intelligible when spoken slowly, though some final consonants were still omitted. Although it may be some years before he speaks easily, and still longer before speech is satisfactory under stress, it seems likely that this boy will eventually achieve normal speech.

Case 2: Dysarthria with Clumsy Movement of the Soft Palate.—This 15-year-old girl is the second of four children. There is a history of language delay in her father until the age of 7 and of an unspecified speech difficulty in a cousin persisting into adult life. She was born normally and weighed 11 lb. 4 oz. (5.1 kg.). Her mother does not remember the child's early years very clearly, but she did not take the breast or bottle well and was slow in gaining weight. She was walking just before her first birthday. She was almost completely silent until 2, and then words came slowly. When first seen at 11 years she was a pleasant sensible girl with no evident disease of the nervous system apart from a tight soft palate which bunched up in the centre but did not contract at the sides. There was no sign of a submucous cleft. Speech was nasal in character. Consonants were weak or were omitted, and attempts to co-ordinate the use of vowels and consonants produced a

severe dysphonia. She ceased to attend for treatment, and four years later there had been little improvement in articulation. At 15 her reading age was 12 years 8 months and the palatal movements were unchanged. During a further course of treatment a transient dysphonia recurred, but four months later she had made considerable progress, and speech was normal except for an occasional audible nasopharyngeal leak, due to incoordination, when hurried. Her I.Q. on the Wechsler-Bellevue scale was 96, and her school report speaks of a "co-operative well-behaved girl, who, without outstanding qualities, had reached a fairly good standard of general attainment."

Case 3: Dysarthria with Clumsy Movements of the Tongue.—This boy, now aged 6 years 9 months, is a second child. Birth was normal and he weighed 10 lb. (4.5 kg.). There was no difficulty with feeding or swallowing, and he walked at the age of 14 months. His father had had a speech difficulty which persisted into school life. This boy began to use words at a year, and sentences followed very soon after. When first seen at the age of 5½ he was a well-developed boy of high intelligence, with an I.Q. by the Alexander performance test of 150. The nervous system was normal apart from a thick and clumsy tongue with poor lateral movement. Speech, however, was unintelligible. Sixteen months later speech was much improved, especially in formal rhymes and repetition, but was still clumsy when he attempted spontaneous conversation. The abnormal appearance and behaviour of the tongue was unchanged. We have regarded this boy as a case of dysarthria uncomplicated by dysphasia, in whom treatment has been facilitated by high intelligence.

Case 4: Dysarthria Without Apparent Clumsiness of Lips, Tongue, or Palate.—This boy is now 9 years old. The fourth child, he was born prematurely and weighed only 3 lb. (1.36 kg.). His behaviour during the first few weeks is not fully known, but at one stage "he was not expected to live." He did not dribble excessively and there was no apparent difficulty in swallowing. He was walking at the age of 15 months, and has always been a good runner. He did not begin to use words in any quantity until 2. When first seen at 6 he was a friendly active boy with no abnormality in the nervous system apart from defective speech. This was fluent, but intelligible only to his parents. The tongue, lips, and palate were normal in appearance and movement. Although at first he was thought to be an example of simple dyslalia, the failure to respond quickly to treatment suggested a more complex disorder of speech. He had difficulty in imitating and using consonant sounds, and was helped considerably by watching the therapist's articulation. When imitation of consonants was possible in isolation and in single words, he had exceptional difficulty in incorporating consonants correctly in speech. Two and a half years later his articulation was still defective, and, with increasing awareness of this, he had become more cautious, often repeating words silently before speaking. His I.Q. on the Wechsler-Bellevue scale was 113.

General Features of Developmental Dysarthria

Of the 18 children with this condition 12 were boys and 6 were girls. They have been observed for periods varying from 1 to 6 years, and their present ages range from 6 to 17. They come from all social classes and cover the full range of normal intelligence. The four children described earlier in this paper illustrate the clinical variations we have seen, and we shall now comment briefly on some common or frequently associated features.

Family Tendency.—There was an impressive history of speech defect in parents, siblings, or close relations in 10 of our families. Although we were unable to interview all the affected members personally, it was clear from the accounts given by the parents that the difficulty had been considerable and had continued in some instances into adult life.

Birth Injury.—In only three cases was birth injury suspected from the history, and in none was the evidence convincing. That this is unlikely to play an important part is borne out by the position of the affected children in the family. Only one was first-born, eleven were second, and six were third or later births.

Prematurity.—One of the 18 children was born prematurely—an incidence of prematurity similar to that for Newcastle-upon-Tyne in recent years (F. J. W. Miller, 1948).

Emotional Disturbance.—The majority of these children developed normally and happily in spite of their handicap. In two there were intermittent emotional difficulties which were not apparently related to their speech, while in a third, growing awareness of his defective articulation produced a reticence and hesitation which was absent in the earlier years. We have no grounds for believing that psychogenic factors play any important part in this group of disorders.

Appearance and Movements of the Lips, Tongue, and Palate.—Abnormal appearance and abnormal voluntary movements of the lips, tongue, or palate were present in 12 of the 18 children, and were the only abnormal physical signs apart from defective speech. The tongue is often thick and firm, with slow clumsy movements from side to side and difficulty or inability in pointing or turning it upwards over the lip. The upper lip also may give the impression of being tight and inflexible during speech, and the soft palate may show poor voluntary movement or fail to produce effective closure of the nasopharynx.

In the remaining six children, otherwise clinically similar, movements of the lips, tongue, and palate appeared normal on voluntary movements carried out at the examiner's request, but clumsy and awkward when the children attempted the more complex and rapid movements of articulation. We have regarded such cases as possible examples of "dyspraxic dysarthria" or "articulatory dyspraxia."

Associated Disorders of Language.—In nine of the children there was also delay in the development of language. The extent of this difficulty varied considerably. In one child the delayed appearance of words was followed by a limited vocabulary, dyslexia, and dysgraphia throughout school life. In three others, although there was no delay in starting to talk, dyslexia was still present at 9 and 12 years of age. In the remaining five children, words and sentences appeared later than the normal time, but three of these had a generous vocabulary by the age of 6. Dysphasia is a common associate of dysarthria in evident cerebral palsy: if these cases of isolated dysarthria are, as we believe, due to a structural brain defect, the frequency of associated dysphasia is not surprising.

Prognosis.—The less severely affected child, particularly when endowed with high intelligence, can make good progress and achieve almost normal speech by the age of 7 or soon after. The commoner experience is for progress in developmental dysarthria, even with faithful treatment, to be slow, and for the defect to reappear whenever there is emotional stress or excitement. In some children traces of the defect will linger on into the late teens, and in one family not included in the present account four members are still unintelligible at the ages of 54, 61, 69, and 72 years.

Aetiology

There are many features which suggest that these cases are developmental in origin, and we are certain that they are structurally and not psychogenically determined. The family history of speech disorders, the frequency of abnormal movements of the lips, tongue, and palate, the close similarity of these isolated dysarthrias to the dysarthria of cerebral palsy, and the steady but slow improvement in response to time and training are factors which speak strongly in favour of an organic basis.

The natural history of this condition is that of a defect of maturation. The disability shows neither the intermittency and tendency to recurrence of the emotionally determined speech difficulty such as stammering nor the rapid response to treatment with which we are familiar in those cases of temporary consonant substitution to which we have limited our use of the term "dyslalia." In our view the lesion in developmental dysarthria is analogous to that of spastic diplegia in nature if not in situation. The site of the lesion is problematical. It is certainly suprabulbar, and would seem to depend on a focal cerebral dysgenesis essentially similar to but more limited in extent than that with which we are familiar in spastic diplegia. It is for these reasons that we have adopted the term "developmental dysarthria," first suggested to us by Dr. C. Worster Drought (personal communication, 1952), to describe these cases and as the title of the present paper.

Diagnosis

Developmental dysarthria must be separated on the one hand from the dysarthria of cerebral palsy, and on the other from severe dyslalia. Where the dysarthria is part of a persisting minimal spastic diplegia recognition requires nothing more than careful physical examination. The differentiation of developmental dysarthria from the group of articulatory defects for which we reserve the term "dyslalia" is, however, not always easy and may be impossible without testing the response to treatment; but in most instances the distinction can be made on the basis of a careful history and examination.

In developmental dysarthria speech is slow and clumsy and, in severe examples, punctuated by explosive words and phrases. The child is unable to imitate speech quickly and easily, and the chief defect of pronunciation is omission with or without substitution of consonants. Many such children show the characteristic appearances and defective movements of tongue and palate already described and identical with those seen in cerebral palsy. In some children, however, the movements are apparently normal except when the muscles are used in articulation. The specific clumsiness evident under such circumstances appears to depend on a disturbance of function, an articulatory dyspraxia, arising at a higher level of the nervous system than is involved in cases where neuromuscular function is visibly abnormal. In a considerable proportion of dysarthric children there is also a history of slow development of language and a poor vocabulary with persisting difficulty in reading.

In the child with severe dyslalia, on the other hand, language develops at the normal time and speech is fluent even if unintelligible. There is no abnormality in the movements of the lips, tongue, or palate, and the defect of pronunciation is largely one of multiple consonant substitutions. The most striking difference between the two conditions lies in the response to treatment. Whereas in dysarthria recovery is slow, in dyslalia normal speech should be reached within three to twelve months from the start of consistent treatment. That these two broad groups of articulatory defects exist is obvious in everyday experience, and, whereas developmental dysarthria is structurally determined, dyslalia would appear to be a functional disorder of speech which responds quickly to guidance and treatment.

Summary

Within the general context of dysarthria in childhood we wish to draw attention to a group of children in whom dysarthria is unassociated with any neuromuscular abnormality elsewhere. The clinical features suggest that this is a structurally determined condition, for which the term "developmental dysarthria" would be fitting.

We have seen a smaller number of children also covered by this term in whom we suspect that the defect is essentially an articulatory dyspraxia.

The condition may or may not be associated with delayed development of language and difficulty in reading.

The outlook varies with the severity of the defect and the intelligence of the child: response to consistent treatment is usually slow, and occasionally the difficulty persists into adult life.

We value the opportunity which our colleagues have given us to study these children, and would like to express our thanks to Sir James Spence for his encouragement and advice. We are also grateful to Mr. R. F. Garside, of the department of psychological medicine, who assessed the children's mental development.

ESTIMATION OF INTRINSIC FACTOR OF CASTLE BY USE OF RADIOACTIVE VITAMIN B₁₂

BY

SHEILA T. CALLENDER, M.D., M.R.C.P.

ADAM TURNBULL, B.M., M.R.C.P.

AND

GYOICHI WAKISAKA,* M.D. Kyoto

(From the Nuffield Department of Clinical Medicine,
Radcliffe Infirmary, Oxford)

Pernicious anaemia is attributed to the failure of absorption of vitamin B₁₂ in the absence of the secretion by the stomach of the substance known as intrinsic factor (Castle, 1951). The preparation of pure vitamin B₁₂ labelled with radioactive cobalt (Co⁶⁰) (Chaiet, Rosenblum, and Woodbury, 1950) presented a method of assessing the absorption of orally administered vitamin B₁₂ and thus of detecting intrinsic factor activity. Heine and his colleagues (1952) estimated the radioactivity appearing in the faeces after an oral dose of 0.5 µg. of radioactive vitamin B₁₂. They found that between 72 and 96% of the radioactivity in this test dose was recovered from the faeces of four patients with pernicious anaemia unless a source of intrinsic factor was given simultaneously, when the recovery was less than 30%. In two normal subjects on three occasions they recovered no radioactivity, but on one occasion in one subject, when he was convalescing from pneumonia, 42% was recovered. A. D. Welch (1952, personal communication) indicated the difficulties encountered in these early experiments owing to the low specific activity (60 µc./mg.) of the radioactive vitamin B₁₂ used.

Using radioactive vitamin B₁₂ of higher specific activity (245 µc./mg.), Meyer (1953) recovered from the faeces between 89 and 99% of a 1-µg. test dose in four patients with pernicious anaemia and between 15 and 59% in seven control subjects. Significant reduction in the recovery of radioactivity, however, did not occur consistently when a source of intrinsic factor was given with the radioactive vitamin B₁₂.

The preparation by Lester Smith (1952) of radioactive vitamin B₁₂ of high specific activity (420 µc./mg.) has enabled us to extend these experiments.

*In receipt of a British Council Scholarship.

Method

Vitamin B₁₂ labelled with radioactive cobalt (Co⁶⁰) was given to a group of control patients with normal haematological findings and to patients with pernicious anaemia, and the radioactivity appearing in the faeces was measured.

A standard dose of 0.5 µg. of radioactive vitamin B₁₂ containing approximately 0.2 µc. of radioactivity was given by mouth in about 100 ml. of water. No food was allowed after 10 p.m. on the previous evening and for two hours before the dose was given; apart from this the patient took a normal diet. The stools were passed direct into glass containers and were collected until at least one contained less than 1% of the radioactivity of the test dose. No aperients were allowed for 24 hours before or after the test dose. Repeated tests were made on most of the patients in order to diminish the possibility of error due to incomplete collection of the stools. If this was suspected the test was discounted.

Each stool specimen was transferred quantitatively to a domestic electric mixer with enough water to allow the faeces to be blended to a uniform homogeneous suspension, which was then transferred quantitatively to a beaker and weighed. After further mixing an aliquot was transferred to a stoppered glass bottle and set aside for estimation of the contained radioactivity.

The radioactivity of the specimens was estimated by means of a scintillation counter comprising a crystal of sodium iodide 2½ in. (6.3 cm.) in diameter and a photomultiplier and scaling unit supplied by A.E.R.E., Harwell. Each specimen was weighed out into a 30 by 50 mm. glass weighing bottle,

which was stood on a thin brass tray over the crystal. The tray had raised edges, which ensured that each bottle was held in the same place.

Counting was carried out with a photomultiplier voltage of 2 kV and a discriminator bias of 12 volts. Under these conditions background counts of between 120 and 160 a minute were obtained, the efficiency of the counter for Co⁶⁰ being approximately 8%. It was found that the empty weighing-bottles gave counts of 10 to 30 a minute above background, and so each bottle was first counted empty to obtain the true background.

Then 50 g. of each of the faecal suspensions was weighed out in duplicate and the radioactivity counted. Since the specific gravity of the stools is approximately one, differences in volume were negligible. The counts obtained with the specimens were compared with that of 50 ml. of a standard solution containing one-tenth of a test dose. Each specimen was counted in duplicate for five minutes and an average taken of the two results. If, however, these differed by more than 2% (when expressed as a percentage of the total dose administered) further aliquots were counted.

Results

Normals

Radioactive vitamin B₁₂ was given to 10 patients who were in hospital for various complaints but who were considered to be haematologically normal, except for patient No. 7, who had a moderate hypochromic anaemia (haemoglobin 9.8 g.%) following the nailing of a fractured femoral neck and who was receiving ferrous sulphate. These patients were mostly in the same age group as our patients with pernicious anaemia. Their diagnoses and the results obtained with radioactive vitamin B₁₂ are shown in Table I and Fig. 1.

These results show that in the normal patient between 20 and 40% of the radioactivity in a test dose of 0.5 µg. of radioactive vitamin B₁₂ usually appears in the faeces. In the third test on patient No. 2 the recovery was 60%. He was at the time suffering from an upper respiratory infection. Recoveries of between 45 and 60% have also been

Pernicious Anaemia

Radioactive vitamin B₁₂ was given to 13 patients who had had classical pernicious anaemia for various periods. All except patients Nos. 4 and 20 were in good remission under treatment with vitamin B₁₂ ("cytamen"). Nos. 4 and 20 have both responded excellently to injections of vitamin B₁₂ started after their first test with radioactive vitamin B₁₂ had been completed.

The results obtained are shown in Table II and Fig. 2. In these patients between 76 and 101% of the radioactivity in the test dose was recovered from the faeces. Fig. 3 summarizes the results obtained in the normal patients and those with pernicious anaemia.

It might be argued that the apparent failure of absorption of the radioactive vitamin B₁₂ in these treated patients with pernicious anaemia was due to their tissues being saturated with vitamin B₁₂. The test was therefore repeated, giving a source of intrinsic factor together with the vitamin B₁₂. Patients Nos. 20, 22, and 23 received radioactive vitamin B₁₂ mixed with 100 ml. of pooled neutralized normal human gastric juice. Nos. 13 and 21 received as their source of intrinsic factor watery extracts of gastric mucosa. Nos. 30, 31, and 32 were given radioactive vitamin B₁₂ with 10 mg. of an ammonium-sulphate-precipitated fraction of hog stomach mucosa ("fraction B") prepared by the method of Prusoff *et al.* (1950).

The results of these experiments are shown in Table III and Fig. 4. It will be seen that the amount of radioactivity recovered from the faeces was diminished whenever a source of intrinsic factor was given, although it seems that the various preparations differed in potency.

Discussion

Our results confirm those of Heinle and his colleagues (1952) in that we find that there is a gross difference between the percentage of radioactivity of 0.5 μ g. of labelled

vitamin B₁₂ recovered from the faeces in normal subjects and in patients with pernicious anaemia. However, the addition of preparations containing intrinsic factor to the test dose reduced the faecal recovery of radioactivity considerably less than in their experiments. This difference is probably in part due to the greater accuracy resulting from the use of radioactive vitamin B₁₂ of higher specific activity, and in part to variations in potency of the sources of intrinsic factor.

It is interesting that even the normal subjects in our series did not absorb completely this small amount of vitamin B₁₂. It must be emphasized that it is the Co⁶⁰ which is being estimated, and that this is not necessarily still in a molecule

FIG. 4.—Effect on recovery of radioactivity from faeces of giving a source of intrinsic factor with an oral dose of 0.5 μ g. of radioactive vitamin B₁₂ in eight patients with pernicious anaemia.

of vitamin B₁₂. Moreover, if some vitamin B₁₂ is destroyed in the gastro-intestinal tract with the liberation of free ions of cobalt, it is possible that some of the latter might be absorbed as such.

Some of our patients with pernicious anaemia seem to have absorbed a fraction of the radioactive vitamin B₁₂, and this may indicate, as Goldhamer (1936) first suggested, that some patients with pernicious anaemia secrete traces of intrinsic factor. The significance of our figures depends chiefly on the accuracy of the stool collections. Experience in this department with radioactive iron (Fe⁵⁹), which was given by mouth and recovered from the red blood corpuscles and from the faeces, supports the view that incompleteness of stool collection is unlikely to account for all the radioactivity which was not recovered.

It appears that this technique offers a simple measure of intrinsic factor activity in the patient, and that it may also be used to assay preparations for their content of intrinsic factor. It has many advantages over the clinical assay, which requires patients with pernicious anaemia in relapse, but it has the disadvantage that it is an indirect test which depends on the absorptive power of the gastro-intestinal tract at the time at which the test dose is given. Preliminary evidence of the effect of infections suggests that the absorption of vitamin B₁₂ is easily interfered with in the normal subject. Further investigation of this point is in progress.

Summary

The absorption of vitamin B₁₂ has been assessed by measuring the radioactivity in the faeces after an oral dose of 0.5 μ g. of vitamin B₁₂ labelled with Co⁶⁰.

In 10 patients with normal haematological findings a mean of 31.0% (standard deviation, 6.9%) of the radioactivity in the test dose was recovered from the faeces. In 13 patients with pernicious anaemia a mean of 88.7% (standard deviation, 6.8%) was recovered.

Sources of intrinsic factor given with radioactive vitamin B₁₂ to patients with pernicious anaemia reduced greatly the percentage of the test dose recovered.

It is a pleasure to express our thanks to Professor L. J. Witts for allowing us to study patients under his care and for his constant help and encouragement; Dr. L. Z. Cosin for allowing us to study patients under his care in the Cowley Road Hospital; Dr. Lester Smith, of Glaxo, Ltd., for supplies of radioactive vitamin B₁₂; Dr. Arnold Welch for the "fraction B"; Dr. W. B. Taylor for the gastric mucosal extracts; Mr. Ray Oliver for advice and assistance in the radioactivity measurements; Dr. John Badenoch for help and advice; and Miss Barbara Hunt for technical assistance. This work was in part supported by a grant to Professor L. J. Witts from the Medical Research Council.

The World Health Organization has recently issued the report of the discussion at the third European Seminar for Sanitary Engineers which was held in London from October 27 to November 1, 1952. The book is entitled *Design and Operation of Septic Tanks*, and among topics discussed are the treatment of small sewage plants, the design of small sewage works, and comparative studies of septic tanks. It is published in the Monograph Series (No. 18), price 7s. 6d., and is obtainable through H.M. Stationery Office, London, or direct from the Sales Section, Palais des Nations, Geneva.

RESEARCHES IN AETIOLOGY OF NON-SPECIFIC URETHRITIS*

BY

R. R. WILLCOX, M.D.
St. Mary's Hospital, London, W.2

General Observations

Non-specific urethritis (N.S.U.) is one of the most perplexing conditions encountered in the British venereal diseases clinic to-day. When complicated by Reiter's syndrome its disabling powers are considerable. In the clinics of England and Wales in 1951 there were 10,794 cases of non-specific urethritis, as compared with 14,975 male cases of gonorrhoea.

Although the condition is usually acquired venereally in the male, it is possible that the female may on occasion be infected non-venereally, which would explain the slight non-venereal bias. Thus in 100 cases of gonorrhoea the last sexual risk had been a casual exposure in 60%, whereas in 100 cases of non-specific urethritis the comparable figure was only 40%. Also, of 640 subjects of non-specific urethritis studied 35.3% were married, whereas of 603 male subjects of gonorrhoea only 25% were married. Persons suffering from non-specific urethritis were of slightly older age groups than those with gonorrhoea, and more likely to be in a "white collar" occupation—both observations perhaps being reflections of the marital status.

Some observers (for example, Coutts of Chile) have suggested that the practice of oral and/or anal coitus may frequently be responsible for the transmission of non-specific urethritis. This would not appear to be the case in Great Britain, for such practices were admitted by only 6% of 50 patients with non-specific urethritis so questioned, as against 9% of 100 other patients attending the venereal diseases clinic during the same period.

The incubation period of non-specific urethritis is often longer than that of gonorrhoea. Of two groups, each of 150 cases, 52% of patients with non-specific urethritis had incubation periods of over seven days, as compared with only 32% (in itself a high figure) in the case of patients with gonorrhoea.

Ignoring established rare causes, the following have variously been regarded as possibly responsible for the bulk of cases: (1) bacteria; (2) pleuropneumonia-like organisms; (3) trichomonads; (4) spirochaetes; and (5) a virus. This study was limited mainly to a consideration of bacterial and viral causes.

Bacterial Urethritis

It has for some time been fashionable to divide non-specific urethritis into bacterial and abacterial urethritis, depending on whether bacteria are seen in the urethral smears. Some 301 urethral cultures were made at King Edward VII Hospital, Windsor (pathologist, E. Sayle), on consecutive patients with non-specific urethritis, before and after treatment with the orally administered antibiotics, and on controls. As a result it is considered that "bacterial urethritis" is not a common entity and that the bacteria found are usually commensals (Table I).

*Being a summary of the report presented to the British Medical Association at the conclusion of the term of office as Insole Research Scholar.

Viral Urethritis

Attempts were made, by different means, to ascertain whether there was any cross-reaction in the skin or blood of patients with non-specific urethritis to antigens of various viruses of the psittacosis/lymphogranuloma venereum/trachoma group. A study was also made of Giemsa-stained urethral scrapings, and animal and egg studies were undertaken.

Skin Tests

In all, some 234 tests were performed—175 for lymphogranuloma venereum, 28 for psittacosis, and 31 for cat-scratch fever. Omitting the later tests, the results of the first tests are shown in Table II.

TABLE II.—*Skin Tests*

	Tested	Negative	Doubtful	Positive	% Positive
Lymphogranuloma venereum (1):					
N.S.U. cases ..	84	63	10	11	13.1
Controls ..	62	53	6	3	4.8
Psittacosis (2):					
N.S.U. cases ..	17	15	2	—	—
Controls ..	11	11	—	—	—
Cat-scratch fever (3):					
N.S.U. cases ..	16	12	2	2	12.5
Controls ..	12	12	—	—	—

Antigens kindly supplied by: (1) E. R. Squibb and Sons, International Corporation, New York ("lygranum") and Virus Reference Laboratory, Colindale; (2) Virus Reference Laboratory, Colindale (courtesy of Dr. A. D. Macrae); and (3) Professor P. Mollaret, Hôpital St. Bernard, Paris, and Virus Reference Laboratory, Colindale (courtesy of Dr. H. J. Bensted).

Thus the skin tests for psittacosis gave negative results. In the series tested, however, some positive readings were obtained with cat-scratch antigen in patients with non-specific urethritis, but not in controls. Also a somewhat higher incidence of positive readings to the skin test for lymphogranuloma venereum was noted in patients with non-specific urethritis than in controls. This aspect of the problem, therefore, would merit further attention.

Serum Tests

A total of 412 complement-fixation tests for lymphogranuloma venereum (L.G.V.), on sera from 275 persons, were made by Dr. A. D. Macrae, of the Virus Reference Laboratory, Colindale. A further 323 complement-fixation tests for enzootic abortion in ewes (E.A.E.), on sera from 250 persons, were performed by Dr. J. T. Stamp, of the Edinburgh and East Scotland College of Agriculture, Edinburgh. The latter veterinary disease is considered to be caused by a virus of the lymphogranuloma venereum/psittacosis/trachoma group.

The results of these tests are being recorded fully elsewhere, but are summarized in Table III.

In view of these findings and the results of serial tests performed on some cases, it was not thought that there was any relationship between the results of either test with non-

TABLE III.—*Serum Tests (First Tests Only)*

specific urethritis sera. There was, however, close agreement between the results of the two tests on 263 parallel specimens of sera (Table IV).

Giemsa-stained Urethral Scrapings

As the so-called virus of non-specific urethritis has not yet been successfully passaged in animals or eggs, the evidence for or against its existence has had to depend upon the presence or absence of inclusion bodies in Giemsa-stained urethral scrapings.

Some 1,463 Giemsa-stained urethral scrapings, taken from patients with non-specific urethritis, their female consorts, or from controls, were examined at the laboratories of the School of Pharmacy, London, under the supervision of Dr. G. M. Findlay until his death in March, 1952, his technician being Miss E. M. Howard. Through the courtesy of Professor G. A. H. Buttle, Miss Howard's services were made available after that date so that the work could be completed.

In order to determine the significance, or otherwise, of the various bodies seen, in due course the findings were classified as blue or red "colonies" (being granular bodies varying from 1.6 μ in diameter) and blue or red granules. The incidence of these various bodies in urethral scrapings was compared in male patients with non-specific urethritis before treatment, after successful treatment with one of the orally administered antibiotics, and after unsuccessful treatment (Table V).

TABLE V.—*Incidence of Various Bodies in Giemsa-stained Urethral Scrapings from Male Patients with Non-specific Urethritis*

	Before Treatment (206 Cases)		After Successful Treatment (182 Scrapings)		After Unsuccessful Treatment (103 Scrapings)	
	No.	%	No.	%	No.	%
Blue colonies ..	71	34.5	18	9.9	23	22.3
Red ..	17	8.3	15	8.2	6	5.8
Blue granules ..	36	17.5	15	8.2	17	16.5
Red ..	38	18.4	42	23.1	24	23.3
Nil ..	78	37.9	115	63.2	50	48.5

The fact that the incidence of red colonies and red granules was unaffected by treatment, successful or unsuccessful, appeared at once to exclude these as possessing no significance. On the other hand, the incidence of both the blue colonies and blue granules fell markedly after successful treatment with the orally administered antibiotics, but remained high when the treatment was unsuccessful. Moreover, at the time of actual re-treatment given to 42 cases the incidence of blue colonies was 30.9% and of blue granules 23.8%.

Summary and Conclusions

When compared with gonorrhoea, non-specific urethritis was apparently more frequently contracted from regular consorts, indicating a possible non-venereal bias in its aetiology.

In the urethritis group more patients were married, they tended to be older in age, and they were more likely to have achieved "white-collar" status than those of the gonorrhoea group.

There was no evidence to suggest that the practice of buccal or anal coitus was commonly responsible for the transmission of non-specific urethritis.

The disease tended to have a longer incubation period than gonorrhoea.

A study of 301 urethral cultures taken from patients with non-specific urethritis before and after treatment, and from controls, suggested that the so-called "bacterial urethritis" was uncommon.

The results of 412 complement-fixation tests for lymphogranuloma venereum and 323 complement-fixation tests for enzootic abortion in ewes showed nothing distinctive between sera from patients with non-specific urethritis and from controls.

A study of 234 skin tests for lymphogranuloma venereum, psittacosis, and cat-scratch fever, on the other hand, showed more positive readings in non-specific urethritis cases than in controls, and this aspect of the problem therefore merits further attention.

From the examination of 1,463 Giemsa-stained urethral scrapings it was considered that the bodies seen were products of inflammation and unconnected with the virus of non-specific urethritis. Thus, if inclusion bodies sometimes seen in these scrapings are responsible for the isolated case, the causative organism cannot be seen in the majority.

Attempts to passage the virus into the lungs of mice (1,735 mice being used in these experiments), mouse-brains, guinea-pigs, and into the conjunctiva, knee-joint, and urethra of baboons were also unsuccessful.

The "virus" of non-specific urethritis has not been isolated, and remains to be discovered.

A group of 80 controls was also studied. These consisted of 12 specimens of non-urethral pus, urethral scrapings from 18 normal males, from 13 patients attending the clinic on account of fear of venereal disease, from 17 patients with syphilis, and from 20 patients with non-syphilitic genital lesions (for example, warts, genital herpes, etc.). In only two (2.5%) were blue colonies, and in only one (1.25%) were blue granules discovered. Up to this point, therefore, the material showed promise so far as correlation between the blue colonies and blue granules and the activity of non-specific urethritis was concerned.

However, it was appreciated that the control scrapings so far studied were in the main taken from dry urethrae, whereas those from non-specific urethritis cases were from wet urethrae. A further control series, this time of 108 cases of gonorrhoea treated at varying periods of time previously with penicillin, was therefore taken. In these, 15 (13.9%) showed blue granules and, as this incidence was almost as high as in the untreated non-specific urethritis cases, these, too, had to be discounted. The incidence of blue colonies, however, was 14.8%, still very substantially below the 34.5% found in the patients with untreated non-specific urethritis.

But when the gonorrhoea cases were arranged according to the length of time which had elapsed from the giving of the penicillin until the taking of the scraping it was noted that at one to three days after injection the incidence of blue colonies was 21.7%. This figure was not far removed from the 27.6% incidence of these bodies two to seven days after the beginning of the treatment of non-specific urethritis with one of the orally administered antibiotics (Table VI).

TABLE VI.—*Incidence of Blue Colonies in Gonorrhoea Cases*

Time Since Treatment	Cases	Blue Colonies	%
Untreated ..	23	2	8.7
1-3 days ..	46	10	21.7
4-7 ..	24	4	16.6
Over 7 days ..	15	—	—
Total ..	108	16	14.8

It would seem that the blue colonies were but products of inflammation, since in both gonorrhoea and non-specific urethritis their incidence decreased as the urethra became drier. That they were seen relatively seldom in the discharges of untreated gonorrhoea was probably connected with the essentially high leucocytic and low epithelial count of the specimens at this stage. It was therefore regretfully concluded that none of the bodies studied in this investigation were involved in the causation of non-specific urethritis.

[A consideration of smears from female cases is omitted from this summary and will appear in the paper being prepared with Miss E. M. Howard.]

Animal Experiments

Attempts to transmit the virus of non-specific urethritis into baboons, guinea-pigs, mice, and eggs were made in the laboratories of the School of Pharmacy.

A sustained attempt to passage the virus into the lungs of mice was a failure. The haemorrhagic lesions which were seen in a number of the 1,735 mice used in these experiments proved not to be related to the disease. Limited attempts at intracerebral inoculation into mice, subcutaneous inoculation into guinea-pigs, and conjunctival instillation, urethral inoculations, and inoculation into the knee-joints of baboons, likewise failed to give any clear-cut evidence of transmission. Attempts to transmit the virus in the chorio-allantoic membranes of eggs also failed: these latter experiments, which involved about 100 eggs, were confused by the presence of other bodies which bore a resemblance to those seen in the urethral scrapings of patients suffering from non-specific urethritis.

The World Health Organization has recently published in pamphlet form a survey of modern legislation relating to nursing. The aim of the survey, it is stated, was to examine the extent to which legislation has established a system of control over the organization and practice of nursing and to indicate the new problems caused by the introduction of the auxiliary and specialized nurse. The survey reviews the laws of 22 countries. It notes the dichotomy of nursing laws: on the one hand, permissive laws which do not restrict the practice of nursing, but which give official recognition in the form of legislation to trained nurses, and thereby differentiate the qualified from the unqualified; and, on the other hand, mandatory laws which safeguard the health of the community by prohibiting the unqualified from practising, and which consequently need to define nursing. There is a general lack of precision in the definition of nursing functions, and the survey remarks that nursing, unlike midwifery and dentistry, defies precise legal definition, and consequently the professional nurse is not always provided with sufficient protection in the exercise of her calling. In recent years the shortage of nurses has become acute all over the world, and is mirrored to-day in the increasing number of laws being enacted in relation to auxiliary nursing staff and male nurses.

A SURVEY OF PATIENTS IN TWELVE MENTAL DEFICIENCY INSTITUTIONS

BY

N. O'CONNOR, M.A., Ph.D.

AND

J. TIZARD, M.A., B.Litt., Ph.D.

Medical Research Council Unit for Research in Occupational Adaptation

During the months of November and December, 1951, and January and February, 1952, we carried out a survey of a 5% sample of patients in mental deficiency institutions in the counties of London, Kent, and Surrey. The survey was concerned primarily with factual information relevant to the patients' occupational potentialities and behaviour, but, in addition, opinions on conduct were obtained. Some of the questions relating to conduct were included at the suggestion of Dr. R. F. Tredgold, regional psychiatrist to the South-East Metropolitan Region, to whom a preliminary draft of the proposed investigation was shown. A clinical classification of the patients, following A. F. Tredgold's (1947) system, which was obtained from medical officers at the time of the investigation will be discussed elsewhere.

A list of questions asked is given in summary form in the Appendix. By no means all the information obtained has been summarized in this paper, and anyone interested in other aspects of the survey is invited to get in touch with us.

Population and Sample

The population from which the 5% sample was drawn consisted of patients in all hospitals in the counties of Kent, London, and Surrey which had been classified by the Board of Control (1946) as certified institutions or institutions approved under Section 37 of the Mental Deficiency Acts. Approximately 100 patients housed in five approved homes in Surrey and Kent were excluded from the survey. The survey covered all other institutions in the selected area.

The size of the sample by hospitals is given in Table I. The population from which the sample was drawn consisted of approximately 11,850 patients, nearly one-quarter of the total number of institutional defectives in England and Wales. It should be noted that only patients certified under the Mental Deficiency Laws were included. In the case of Leavesden Hospital, for example, approximately one-third of the patients were either senile or for other reasons not certified under the Mental Deficiency Acts.

TABLE I.—Hospitals and Institutions Visited, with Size of Sample, by Sex

Hospital	Male	Female	Total
Botleys Park	43	37	80

St. Teresa's Home	—	7	7
Total	301	291	592

Method

The physician or lay superintendent of each hospital was written to for permission to undertake the survey. They

were told the purpose of the investigation and a copy of the questions to be asked was sent to them. Permission was obtained in all cases—indeed, the assistance given us at all hospitals was most generous. In each hospital the sample was selected by drawing every twentieth name from a nominal role of patients on the books, listed alphabetically, the first name to be selected being determined by lot from the first twenty names in the book. Case records and orders were examined. Additional information was obtained by questioning senior members of the nursing staff. The clinical classification was obtained subsequently from the medical staff. Patients between 16 and 29 years of age who were classified as feeble-minded and were not on licence or on leave were tested by the investigators on the progressive matrices test, in groups, but without a time limit. Between one and three days were spent at each hospital. The coded information was punched on Hollerith cards and machine-sorted.

Distribution of Patients by Sex, Age, and Grade

The distribution of patients by age, sex, and grade is given in Table II—43 (8%) were admitted under Sections 8 or 9 of the Mental Deficiency Acts, and 435 under Section 6, or other section. The data in Table II have been arranged so that the number of adults and children appear separately.

Children formed 12.33% of the patients, the majority of them being of low grade. (The Report of the Ministry of Health for the year 1949 gives the proportion of children in institutions in England and Wales as 12%, which agrees with the figure obtained in the survey.) There were 43% more males than females among the children. In Table III

TABLE II.—Distribution of Patients by Sex, Age, and Grade

0—Idiot. 1—Imbecile. 2—Feeble-minded person. T—Total. Age is given as from last birthday. The number of patients aged 15 years is given separately in order that the number of children (aged 0-15) and of adults (age 16+) can be calculated.

TABLE III.—Percentage of All Adult Patients (519) by Age and Grade

Age	Grade			Total
	0	1	2	
16-29	2	15	20	37
30-39	1	8	15	24
40-49	—	8	15	23
50+	—	8	8	16
Total	3	39	58	100

is given the percentage of adult patients by grade and age. The most recent report by the hospital authorities to the Board of Control was consulted in order to determine the grade of each patient.

Of the adults, 58% were classified as feeble-minded. Most of these were under 50 years of age.

Distribution of Patients by Type of Nursing Needed and Behaviour

There were 26 male patients and 28 female patients on resident licence from the institutions (8.6% of male patients and 9.6% of females). In addition 21 patients (16 males and 5 females) were on daily licence. The distribution of patients by sex, grade, and type of nursing needed is shown in Table IV.

TABLE IV.—Number of Patients by Grade and Type of Nursing Needed (on Day of Survey)

	Grade			Total
	0	1	2	
Chronic sick	1	9	11	21
Temporarily in hospital	0	3	4	7
Cot and chair cases	12	10	3	25
Low-grade ambulant	13	74	14	101

On leave	0	0	1	1
Abandoned	0	0	6	6
Resident licence	1	4	49	54
Total	35	247	310	592

Supplementary questions added something to the picture so far as behaviour was concerned. Thus only one male and one female patient had attempted suicide during the previous year; 12 (2%) had been charged with stealing; 55 (9%) had had one or more clashes with staff or patients serious enough to be recorded in case notes; 18 (3%) had absconded. Ten (3.8%) of the female patients had been pregnant or had had V.D. at some time in their lives, and 16 (5.8%) of the male patients had histories of homosexuality, indecent assault, or indecent exposure. Some of the incidents listed as indecent assault in case papers or orders were of a trivial character and had occurred many years previously. Seventy-seven patients (13%) were doubly incontinent, and 27 (5%) enuretic; 68 patients (11.5%) suffered from epilepsy, 17 being severe cases (suffering grand mal attacks once a fortnight or more), 14 moderate, and 37 mild. Numerous other patients were recorded on case sheets as being epileptic, but had had no attacks during the last year or, in some cases, at any time during their stay in hospital.

There were marked differences in the proportion of patients in different hospitals who were in locked wards. No doubt the type of patient was in part responsible for this, but hospital policies appeared also to differ. Of the 538 resident patients, 75 (13%) left the hospital grounds once or more on day parole during the month preceding the date of the survey (29 females, 46 males). During the previous year 76 male patients and 47 female patients (25% and 16% respectively) went on leave. Over two-thirds of these patients were on leave for less than three weeks.

Rewards to Patients

The "wages," or rewards, given to patients varied somewhat from hospital to hospital. For low-grade patients rewards consisted of sweets or cigarettes. High-grade patients

TABLE V.—Cash Value of Rewards of Pocket Money Paid During Week of Survey to Patients Resident in Hospital

usually had rewards paid partly in kind, partly in cash. The figures given in Table V refer to the cash value of the rewards, whether or not the patients received money, tokens to be exchanged at the canteen, or actual goods.

For patients not on either daily or resident licence the rewards represented total earnings. Those on licence, however, earned wages which were often in excess of the amount of pocket money allowed them. (Additional amounts, when deductions have been made for board and lodgings, are credited to patients' accounts.) Hospital policies differed in the extent to which they allowed patients on licence control over their own affairs, and wages earned by patients on licence, as well as the amount of money or goods they were given to spend or use during the week of the survey, also varied greatly. Those employed in factories and as labourers earned higher wages than those engaged in domestic service. Table VI gives the length of time patients had been on licence.

TABLE VI.—Duration of Licence of 54 Patients out of Hospital at Time of Survey

made a practice of sending defectives to factory work. Surprisingly few patients were employed on farms or gardens—possibly the sample of defectives on licence was too small to enable us to generalize about the kind of jobs done by patients on licence.

Intelligence of Patients Classified as Feeble-minded

As mentioned above, patients between 16 and 30 years of age who were resident in hospital and available at the time of the inquiry, and who were classified as feeble-minded, were given the group matrices test, using an untimed procedure. The distribution of raw scores is given in Table VIII. The numbers are small—25 males and 24

TABLE VIII.—Distribution of Matrices Raw Scores* for Sample of 49 Patients Tested

Raw Score*	Males	Females
0-9	2	1
10-19	9	11
20-29	5	6
30-39	8	4
40+	1	2
Total	25	24
X	23.9	21.4
S	10.4	10.0

* For subjects between 20 and 30 years of age a raw score of 23 points is approximately equal to an I.Q. of 74 on a test whose mean is 100; S.D. = 16 points. For an unselected adult population 20-30 years of age the mean raw score on this test = 44 points; S.D. = 10 points.

females—and little reliance could be placed on the findings in the absence of other data. However, the results for male patients agree very closely with those obtained from testing 360 patients at Darenth Park, Harpersbury, and the Manor Hospitals (Tizard and O'Connor, 1952). There is thus a considerable amount of evidence to support the conclusion, at least so far as male patients are concerned, that the mean I.Q. on this test of young adult patients classified as feeble-minded is about 74 or 75 points. The mean for females may be somewhat lower. As has been shown elsewhere (Tizard, 1950) norms for the progressive matrices test agree closely with those obtained from other tests more commonly used with defectives. Hence, if these findings are valid over the country as a whole, more than half of the adults classified as feeble-minded in mental deficiency institutions have I.Q.s of over 70 points.

Summary

A survey, based on case records, was made of a 5% sample of nearly 12,000 patients in twelve mental deficiency hospitals in the Home Counties, representing nearly one-quarter of the total number of mental defectives in institutions in England and Wales.

Over half the patients were found to have been classified as feeble-minded. Less than 5% were idiots and just over 40% imbeciles.

Intelligence quotients, measured by the progressive matrices test, in those feeble-minded patients between 16 and 29 years of age who were available, indicated, in conformity with a previous finding, that the average intelligence quotient of young adult feeble-minded defectives in hospitals near London is above 70.

Half the patients did not need special nursing or supervision; a further 24%, while needing no special nursing, were thought to be in need of close supervision.

One patient in eight was on daily licence or resident licence. Only one hospital sent patients out to factory work. Rewards to patients averaged between 2s. and 3s. for the week of the survey, 56% of the sample receiving less than 2s. and 13% more than 5s.

General behaviour of the resident patients was apparently good. Sexual perversion, pregnancy, or venereal disease was recorded in approximately 5%. Three per cent. of the patients in the sample had absconded at least once during the preceding twelve months.

Our thanks are due to the hospital authorities of the 12 hospitals and institutions visited for their kindness in allowing us to carry out the survey, and for their great assistance to us, usually at considerable inconvenience to themselves. Dr. J. M. Crawford, Dr. L. T. Hilliard, Dr. J. K. Collier Laing, Dr. Vera Norris, and Dr. R. F. Tredgold gave advice on questions to be included and treatment of results. We are indebted to Mr. J. G. F. Singleton for carrying out the Hollerith work.

APPENDIX

Survey of Patients in Institutions in London, Kent, and Surrey. Information Obtained

- Hospital.
- Sex of patients.
- Number.
- Date of order.
- Years in present hospital.
- Section of the Act under which certified.
- Age in years last birthday.
- Grade (taken from last report to Board of Control).
- Last I.Q. on case paper.
- Test used to obtain last I.Q.
- Type of nursing needed as in Table IV of text.
- Occupation.
- Pocket money during previous week.
- Paroles during previous month.
- Number of visits per year.
- Whether or not relatives were living.
- Days' leave during past year.
- Number of times absconded during past year.
- Attempts at suicide during past year.
- Times caught stealing during past year.
- Clashes with patients or staff during past year.
- Homosexual behaviour—any history of.
- Indecent assault—any history of.
- V.D. or pregnancy—any history of.
- Behaviour with patients—rating.
- Behaviour with staff—rating.
- Epilepsy recorded as in text.
- Incontinence.
- Whether or not on daily licence at any time.
- Type of work done.
- Reason for failure in past, if any.
- Resident licence.
- To whom licensed.
- Type of work.
- Failure?
- Duration of licence.
- Wages on licence.
- Matrices raw score.
- Clinical classification.

Professor D. R. MacCalman, Nuffield Professor of Psychiatry at Leeds, was the chairman of a World Health Organization expert committee which has recently considered the mental health aspects of adoption. In its report (*Technical Report Series No. 70, 1953*) the committee stresses that the well-being of the child is the real aim of adoption. The family composed of father, mother, and children constitutes the normal and enduring background for a child's education, and the object of adoption is to create a relationship between adopted child and adopting parents which will resemble this as closely as possible. The child must feel certain that those around him are well disposed towards him so that without too much anxiety or sense of guilt he may be able to give expression to the complicated and often hostile feelings aroused in him by the frustrating realities of ordinary life. In former times, according to the report, the adopting family was judged merely from a standpoint of material welfare, but now there is a tendency to pay far more attention to the capacity of the adoptive family and parents to meet the child's other needs. Parents who think they could find satisfaction only in a very gifted child should be dissuaded from adopting young infants; adoptive parents must be ready to run the same risks as other parents. Other advice included in the report is that the child should be adopted at a very early age; the earlier the child knows about his adoption the better; and it is wrong to adopt a child in order to patch up an unsatisfactory marriage.

URINARY EXCRETION OF ACID PHOSPHATASE

BY

OWEN DANIEL, M.B., B.S., F.R.C.S.

PATRICIA R. N. KIND, B.Sc.

AND

E. J. KING, Ph.D., D.Sc., F.R.I.C.

(Department of Surgery and Department of Chemical Pathology, Postgraduate Medical School, London, W.12)

Marked elevation of serum acid phosphatase due to carcinoma of the prostate is often associated with evidence of impaired renal function, thus suggesting the possibility that the kidneys may excrete this substance, and that serum levels represent the balance between the rate of production and that of excretion of acid phosphatase (Daniel, 1952). It has long been known that urine is rich in acid phosphatase (Demuth, 1925), and Scott and Huggins (1942) have shown that, although most of this is added direct in the form of prostatic secretion, part is excreted by the kidneys.

The investigation reported here was undertaken with the object of discovering whether carcinoma of the prostate produced a change in the rate of urinary excretion of the prostatic (formol-stable) acid phosphatase, but the results show that there is no such change even when the serum formol-stable acid phosphatase is raised

and the kidney function normal. A series of estimations was also carried out on female patients with carcinoma of the breast.

Materials and Methods

All estimations carried out were of the prostatic formol-stable acid phosphatase (Abul-Fadi and King, 1948), but for convenience' sake they will be referred to as "acid phosphatase" throughout this paper.

The total daily excretion of urinary acid phosphatase was estimated on one or more occasions on four healthy young adult males, ten patients with benign prostatic hypertrophy, seven patients with carcinoma of the prostate, nine healthy women, and 13 women with carcinoma of the breast, of whom five had bone metastases.

Males who could micturate normally were instructed to void in three parts, and the volume and acid phosphatase content of each specimen were measured separately after each micturition performed during the 24-hour test period. It was assumed that the acid phosphatase in the mid-stream specimen had been excreted by the kidneys, and that the larger amounts found in the first and last parts were derived partly from kidney excretion and partly from prostatic secretion. Patients with catheter bladder drainage passed their urine into bedside bottles, and the volume and acid phosphatase content of this were measured for 24-hour periods. It was assumed that there was no regurgitation of prostatic secretion into the bladder and that all the urinary acid phosphatase was excreted by the

kidneys. The healthy women were instructed to measure the volume of urine passed at each micturition during the test period, and to save a part of each specimen for acid phosphatase estimation. In the case of the other women, complete 24-hour collections of urine were estimated.

Estimation of Urinary Acid Phosphatase

Twenty ml. of each sample of urine was dialysed overnight in parchment shells against cold running tap-water, the volume measured after dialysis, and any change accounted for in the final calculation. The dialysed urine was diluted, usually four times, and the enzyme content estimated by a slightly modified King-Armstrong method. 0.5 ml. of urine was added to a substrate buffer mixture consisting of 1 ml. of 0.02 M disodium phenyl phosphate, 2 ml. sodium citrate/citric acid buffer, pH 4.9, and 1 ml. 5% neutral formalin, and incubated at 37° C. After one hour 1.5 ml. of dilute (1 in 3) Folin and Ciocalteu reagent and 3 ml. of 15% sodium carbonate were added, and after further incubation for 15 minutes at 37° C. the colour was measured in a photoelectric colorimeter with an Ilford 608 red light filter (cf. Delory and Hetherington, 1952).

Results

Four apparently healthy males whose ages ranged from 24 to 35 years excreted in the urines a daily average of 1,462 units of acid phosphatase. Of this amount 1,074 units were calculated, on the basis of mid-stream determination, to have been excreted by the kidneys and the remaining 377 units to have been added in the form of prostatic secretion. The average serum acid phosphatase of this group was 1.2 King-Armstrong units per 100 ml., and the renal clearance of acid phosphatase, as calculated from the formula $\frac{UV}{P}$, was 53 ml. of plasma cleared of phosphatase per minute (Table I, A).

Comparison of the acid phosphatase content of the urines collected in three parts shows that the lowest values were constantly found in the mid-stream specimens (Table II).

and that the last part often contained much more acid phosphatase than either the first or the mid-stream specimen. Urine was withdrawn from the bladder of three of the first group of subjects by means of urethral catheters, and the rate of renal excretion of acid phosphatase found to vary from 0.35 to 2.25 units per minute, as compared with 0.38 to 2.4 units per minute as calculated from mid-stream specimens.

Ten patients with benign prostatic hypertrophy, whose ages ranged from 65 to 85 years, excreted a daily average of 262 units of acid phosphatase from their kidneys. Two of the ten were able to collect their urines by the three-part method, and it was found that their prostates excreted an average of 45 units of acid phosphatase each day (Table I, B). The average serum acid phosphatase of the group was 1.5 units per 100 ml., and the average renal clearance of acid phosphatase 9.3 ml. per minute. Each of the ten patients had normal renal function as shown by blood urea

estimations and intravenous pyelography, and in all of them the nature of the prostatic lesion was confirmed histologically.

Seven patients with carcinoma of the prostate, whose ages ranged from 56 to 90 years, excreted a daily average of 128 units of acid phosphatase from their kidneys (Table I, C). Only one of them could collect his urine by the three-part method, and it was found that his prostate excreted 33 units of acid phosphatase a day into the urethra. The average serum acid phosphatase of this group was 37.5 units per 100 ml., and the mean renal clearance of acid phosphatase 1.3 ml. per minute. The diagnosis of carcinoma of the prostate was based on histological findings in five of the patients and on firm clinical or serological grounds in the other two. Four of the patients had poor renal function as shown by raised blood urea, and their excretion of urinary acid phosphatase averaged 85 units a day as compared with 212 units a day for the three patients who had carcinoma of the prostate and normal renal function. The renal function of two of the patients deteriorated during the course of the investigation, and this deterioration was accompanied by a decrease in the excretion of urinary acid phosphatase. In one (Table I, C; R. E. D.), the serum acid phosphatase increased as the excretion of urinary acid phosphatase decreased; and in the other (Table I, C; H. O. B.) the serum acid phosphatase decreased, probably owing to the regular administration of stilboestrol.

Nine apparently healthy women, whose ages ranged from 23 to 60 years, excreted a daily average of 217 units of urinary acid phosphatase (Table III). Age, within the above limits, did not appear to have any significant effect on the rate of excretion of urinary acid phosphatase. The women with carcinoma of the breast excreted a daily average of 132 units of acid phosphatase (Table III). This was less than that excreted by healthy women. On the other hand, the women who had carcinoma of the breast and bone metastases excreted a daily average of 227 units of acid phosphatase, practically the same as in healthy women. A summary of these results is given in Table IV.

Variation in the Rate of Excretion of Urinary Acid Phosphatase

During the tests on normal men and women a note was kept of the time of each micturition, and the urine of patients with catheter drainage was in many instances collected at six-hourly intervals. Information thus gained shows that the concentration of acid phosphatase excreted by the kidneys was inversely related to the rate of urine formation, and that the rate of excretion of acid phosphatase appears to be independent of the rate of formation of urine.

A slight diurnal variation in the excretion of urinary acid phosphatase was found in all subjects, but this variation did not appear to be cyclical, and in women could not be related to the menstrual cycle.

Discussion

Healthy young adults excrete a considerable amount of acid phosphatase in their urines, and of this between one-third and one-fifth can be attributed to the direct addition of prostatic secretion to the urinary stream. Comparison of the acid phosphatase content of the urines collected in three parts (Table II) suggests that the first part of micturition washes out the prostatic secretion that has accumulated in the urethra, and that straining or some other factor associated with the completion of micturition produces an immediate discharge of more prostatic secretion. The volume of prostatic secretion required to produce these effects is probably small, as the seminal plasma is rich in phosphatase—for example, that of one of the subjects contained 6,000 units of acid phosphatase per ml. The assumption that mid-stream urine is reasonably free of prostatic secretion is supported by the close correspondence between the acid phosphatase content of catheter and mid-stream specimens, although the occasional occurrence of unusually high acid phosphatase levels in mid-stream urine (Table II) can probably be attributed to the added prostatic secretion.

Men in the sixth decade and over, with benign prostatic hypertrophy, excrete approximately one-sixth the urinary acid phosphatase of younger men, and this diminution applies to both the renal and the prostatic excretion of acid phosphatase. The output of acid phosphatase in the urine of old men corresponds closely to that of women aged 20 to 60 years.

Men suffering from carcinoma of the prostate excrete slightly less urinary acid phosphatase than men of a similar age suffering from benign prostatic hypertrophy; and the difference is most pronounced when renal function is poor. There is no evidence that the excretion of urinary acid phosphatase is related in any way to serum acid phosphatase

levels, and it can be concluded that the acid phosphatase put into the serum by carcinoma of the prostate is not eliminated in an active way by the kidneys.

Women suffering from carcinoma of the breast do not appear to excrete an increased amount of acid phosphatase in their urine, even though the plasma level is increased. In the cases of breast carcinoma without bone metastases the average daily excretion is lower than that in healthy women, or women with breast cancer with bone metastases.

No cause has been found for the slight diurnal variation of urinary acid phosphatase observed in all subjects or for the more marked variation in the rate of excretion that takes place throughout the day. The fact that the distribution of the rates of excretion of acid phosphatase by the kidneys of individuals fits the curve of general probability suggests that the rate is determined by many small factors operating at random and that there is no important underlying cause for the change. Calculation of the rate of renal clearance of acid phosphatase does not throw any additional light on the material studied, and merely emphasizes the inability of diseased kidneys to excrete acid phosphatase. The fact that women as well as men excreted a considerable amount of formol-stable acid phosphatase in their urine (217 units per day) shows that there must be some source of such phosphatase other than the prostate.

Summary

The rate of excretion of urinary acid phosphatase has been studied in four healthy young adult males, ten patients with benign prostatic hypertrophy, seven patients with carcinoma of the prostate, nine healthy women, and 13 women with carcinoma of the breast. Young men excrete up to six times more urinary acid phosphatase than elderly men or women of various ages. In both carcinoma of the prostate and carcinoma of the breast there was a decrease in the excretion of urinary acid phosphatase, in spite of a raised serum acid phosphatase.

This work was done in co-operation with the Institute of Urology, and we are grateful to the Institute for supplying part of the clinical material.

The findings of a special survey undertaken after four and a half years' experience of the workings of the National Health Service are included in the annual report for 1952 of the London County Medical Officer and School Medical Officer, Dr. J. A. Scott. These include general comments on administration, co-ordination, and co-operation with other services and separate comments on the individual services. The report also includes a detailed statistical account of the "smog" catastrophe of 1952, which in the space of a week contributed to the year's total death rate an extra 0.5 per thousand population. Further statistics show that cancer is the second leading cause of death among Londoners at 2.30 per thousand and that its incidence is increasing slightly, while cardiac diseases are the first. It is reported that there is a continuing drop in the number of children under 5 years who are being immunized against diphtheria, the total percentage now being only 50. The demands on the Council's Ambulance Service were very great, as were those on the District Nursing Associations, each nurse in the service paying on an average fourteen visits a day. The report also includes a detailed account of the School Health Service. The report is published by the London County Council, and may be purchased (price 2s. 6d., by post 2s. 10d.) from the Information Bureau at County Hall, or from Staples Press, Ltd., Mandeville Place, London, W.1, or direct from any bookseller.

type and distribution of the calcification, there was evidence in 10 cases of only one area of undoubted calcification in the lung fields, and in four of an area of calcification in the lung fields with concomitant calcification at the hilum. In one case there was evidence of calcification at the hilum only; another case showed evidence of three foci in the lung fields with a calcified area at the hilum. In no case was generalized miliary calcification observed in the lung fields.

Correlation of Histoplasmin and Tuberculin Sensitivity with Radiological Findings

Correlation between calcification observed in the x-ray picture and the histoplasmin and tuberculin tests both of prisoners and of miners are shown in the Table. It also

H+—An induration of 5 mm. or over occurring after 72 hours from the time of the histoplasmin test.

shows the final analysis in respect of all persons whose x-ray films were examined. The incidence of calcification amongst the tuberculin-positive and histoplasmin-positive group of subjects was four times that of the tuberculin-positive but histoplasmin-negative group. The same trend can be seen in the case of both miners and prisoners. If the tuberculin-negative subjects are considered the same tendency is observed—that is, a greater percentage of the histoplasmin-positive reactors show radiological evidence of calcification. This is proved by the fact that none of the 19 tuberculin-negative and histoplasmin-negative subjects showed calcification, whereas one of the three tuberculin-negative but histoplasmin-positive subjects did.

It is of interest to note that of the 47 prisoners who were known to have been Mantoux-negative at some time within a period of 14 months of the histoplasmin test three showed calcification at the time of performance of the latter. One of these was completely negative to the histoplasmin test, and his serial x-ray films showed a calcification developing in a primary tuberculous lesion contracted a year before the histoplasmin test. One of the other two subjects showing calcification gave a positive histoplasmin reaction, and the other showed a minimal induration of 3 mm. to this test.

It is not possible to make a comparison of the incidence of calcification observed in prisoners and miners in view of the selection that took place among the miners.

Minimal Histoplasmin Reactions and Calcification.—The significance of a small reaction of under 5 mm. to the histoplasmin test is not known. It may indicate a past infection of histoplasmosis, or it may represent a weak cross-reaction to other fungal antigens. The Table shows that the number of persons having minimal reactions and whose x-ray films were available is very small, but it seems that the incidence of calcification among such people (14.2%) is not as high as among the histoplasmin-positive subjects (34.8%), and only slightly higher than that observed in those 51 unselected histoplasmin-negative miners (9.8%).

Discussion

During the past six to seven years much work has been performed with histoplasmin in various parts of the world, but there have been no recorded investigations on this subject in East Africa. The finding of an overall sensitivity rate of 8.5% among adult male Africans in Kenya suggests that histoplasmosis is endemic in at least parts of Kenya. A certain amount of caution in interpretation, however, is necessary, since it is known that weak reactions to the histoplasmin test may represent cross-reactions to other related fungi, particularly *C. immitis*. For instance, it is believed that such is the interpretation of the rather weak histoplasmin reactions observed in California, a known endemic centre of coccidioidomycosis. This explanation may be applicable to Kenya, particularly in the case of those showing small indurations, and it will be necessary to clear up this point by performing sensitivity tests with coccidioidin and histoplasmin at the same time. Induration to a greater extent than 5 mm. to the histoplasmin test may be caused after infection by other related fungi, but in the present series reactions up to 18 mm. were observed 72 hours after the histoplasmin test, and this should provide fairly sound evidence that the response obtained is specific to histoplasmin. It may, however, be that, apart from histoplasmosis, coccidioidomycosis, or indeed other similar fungal infections, is endemic in Kenya. No cases of histoplasmosis or coccidioidomycosis have yet been recorded in Kenya, but the knowledge that at any rate cases of histoplasmosis are to be expected should cause more interest in the subject and a greater search for cases.

It is difficult to explain the high sensitivity rate found among miners as compared with that of prisoners, and until further tests both with histoplasmin and with coccidioidin are performed speculation would be highly theoretical. The sensitivity rate of 14.6% found among miners is the highest rate so far recorded in Africa.

It is known that false-positive histoplasmin reactions have been caused by contamination of the histoplasmin solution or the syringes or needles with tuberculin, but it has been shown among the miners that it is very unlikely that such reactions due to tuberculin have presented as positive tests to histoplasmin. It is even more unlikely that false reactions due to tuberculin occurred when testing the prisoners, as in these subjects the chances of cross-contamination during testing were eliminated by omitting the simultaneous test with tuberculin.

The radiological appearances of healed lesions resulting from histoplasmosis usually mimic those due to healed tuberculosis (Riddell, 1951). Zwerling and Palmer (1946) stated that the appearance of massive bilateral calcification is in most instances due to histoplasmosis. In only one case in the present series was evidence of bilateral calcification found in the lung fields, and this case had a positive histoplasmin reaction. In all other cases the calcification observed was either a single focus or a dual focus similar to that seen in a healed primary complex. The picture of generalized miliary calcification which is described as occurring in histoplasmosis was not seen.

It was also found that approximately one-third of those persons reacting to histoplasmin had radiological evidence of calcification; this should be compared with about 13% of all tuberculin-positive cases that showed calcification. It

should again be emphasized in this connexion that in assessing evidence of calcification in the x-ray films the interpreters had no knowledge of the individual histoplasmin or tuberculin tests. These findings, although based on relatively small numbers, compare closely with those found by Goddard *et al.* among a large series of student nurses in the United States. In the latter investigation it was found that approximately one-third of the nurses reacting to histoplasmin, or to histoplasmin and tuberculin, had pulmonary calcification, whereas approximately 10% reacting only to tuberculin showed evidence of calcification.

Radiological evidence of pulmonary calcification amongst the natives of Kenya is not therefore necessarily indicative of healed tuberculosis; the evidence indicates that it may be due to a past infection of histoplasmosis. It may also be said that radiological evidence of persistent pulmonary infiltrations, as distinct from calcification, may be due to infection by *H. capsulatum*, as Furcolow *et al.* (1947) have indicated that such infiltrations in children are much more often associated with histoplasmin than with tuberculin sensitivity.

Summary

Intradermal sensitivity tests performed on 768 adult African males show an overall sensitivity rate of 8.5% to 1:100 histoplasmin. A further 4.3% of the subjects showed minimal indurations of under 5 mm. to the histoplasmin test.

It is highly unlikely that these reactions are due to contamination of the histoplasmin solution with tuberculin, but it is possible that some of the smaller reactions are due to cross-reactions with other antigenically related fungi.

X-ray films of 130 of the subjects were examined for calcification under controlled conditions. Calcification was observed in 12.3% of the films.

In the tuberculin-positive subjects the incidence of radiological evidence of calcification among histoplasmin reactors was four times the incidence observed amongst the histoplasmin non-reactors. The same tendency can be seen in the tuberculin-negative group of subjects.

Those with minimal reactions to the histoplasmin test did not show the incidence of calcification that was observed in the histoplasmin-positive group and showed only a slightly higher incidence than that of the histoplasmin-negative group.

The appearance of calcification in an x-ray film of a Kenya African does not necessarily indicate a past tuberculous infection, as it may be due to a past infection with *H. capsulatum*. The diagnosis of histoplasmosis should be considered in the face of a negative tuberculin test associated with a persistent pulmonary infiltration.

I thank Dr. W. S. Haynes for help in interpreting the radiographs and Professor John Crofton for reading the draft and making most helpful suggestions. I also thank Dr. R. W. Riddell for supplying the bulk of the histoplasmin, and Dr. G. C. Dockeray for the remainder. Finally, acknowledgments are due to the Director of Medical Services and the Labour Commissioner, Kenya Colony, for permission to publish this paper.

A CASE OF PULMONARY HAMARTOMA

BY

S. D. STORE, M.D., M.R.C.P.Ed., F.C.P.S.

Lately House-Physician, Brompton Hospital, London

The term "hamartoma"—from a Greek word meaning "to err"—was coined by Albrecht (1904), who defined it as "a tumour-like malformation in which in truth one can demonstrate only an abnormal mixture of the normal developmental components of the organ in which they occur, whether it be with regard to the quantity, to the arrangement, or to the degree of development, or in all three respects." He actually used this term for cavernous malformations of the spleen and liver, and also for the fibromata of the medullary substance of the kidney. Both Goldworthy (1934) and Jaeger (1934) used the word for a similar malformation occurring in relation to bronchi. More than 125 cases have been described up to date.

The tumour varies enormously in size. Usually a globular, solid, firm growth of the diameter of a two-shilling piece, it is of greyish-white colour and has a rough nodular surface. Commonly there is round it a capsule consisting of very loose areolar tissue. Microscopically it has a characteristic picture. The predominant tissue is cartilaginous, and may show calcification or even ossification at times. Such islets of cartilage are separated by varying amounts of mesodermal and epithelial tissues, which include fibrous and adipose tissues, epithelial clefts giving at times the appearance of a gland (the epithelium may be cuboidal, columnar, or transitional), smooth muscle fibres, and blood vessels. Essentially these tumours are benign, although very rarely they may undergo malignant transformation. The case reported by Simon and Ballon (1947) did show malignant changes.

Hamartomas can occur in any part of the lung, more commonly, it is said, in the lower lobes. Most of them are peripheral and subpleural, but a few are hilar in relation to the main bronchi. They are supposed to be more common in males than in females in the ratio of 3 to 1, and can occur at any age. Jones (1949) described one in a newborn baby. However, the majority of them are seen in the middle-age groups of 35 to 50 years, perhaps because of their asymptomatic course. Clinically most of the patients are symptomless and the lesion is usually detected on routine chest radiography. When subpleural there is often pleuritic pain. When the lesion is situated at the hilum symptoms of dyspnoea due to bronchial obstruction and of cough with sputum and fever due to infection behind this obstruction may occur.

Pre-operative diagnosis is rarely possible. A rounded shadow in a chest radiograph with well-defined margins, surrounded by normal-looking lung tissue and some scattered calcium in the shadow, when seen in an asymptomatic person strongly suggest the possibility of a hamartoma. No other investigation is helpful except rarely in the hilar variety, when a bronchoscopic biopsy may prove to be diagnostic. Diagnosis is usually arrived at by thoracotomy, when the tumour alone may be removed or, if necessary, with a part of the lung as well.

Case Report

A man aged 53 first had pains in the left lower chest and upper abdomen in 1949. These were sharp and stabbing in character, and very variable in duration. Thorough investi-

gation showed nothing abnormal. In 1950 a chest radiograph showed a prominent left hilar shadow and thickened pleura at the left base. In January, 1952, these changes were well marked (Figs. 1 and 2), and he was referred to the Brompton Hospital.

In February, when first seen at Brompton, he still complained of these pains in the left lower chest and upper abdomen, and of cough with 2 to 4 oz. (57 to 85 ml.) of purulent sputum daily, loss of weight, and hoarseness of voice of about six months' duration. He was admitted under the care of Sir Geoffrey Marshall on April 7 for further investigation. On examination he was seen to be a man of average physique with a moderate degree of finger-

FIG. 1.—Chest radiograph showing well-marked changes.

FIG. 2.—Lateral view.

clubbing. He had a swinging temperature rising to 101° F. (38.3° C.). A small firm lymph node was palpable above the left clavicle. On the chest a big transverse scar was seen, extending from the mid-clavicular line in the fourth left interspace across the axillary region to the inferior angle of the left scapula on the back. That was the result of drainage of an empyema at the age of 5. He also had physical signs of collapse of the left lower lobe. A provisional clinical diagnosis of bronchial carcinoma was made. The cough, with sputum and rise of temperature, was attributed to infection in the collapsed lobe.

A report by Dr. J. W. Clegg on a bronchial biopsy specimen taken on July 8 stated: "The biopsy is a small bronchial papilloma covered by epithelium showing a transitional metaplasia. Below the epithelium there are a mass of fatty tissue and a few atypical mucin-secreting glands. The appearances strongly suggest a benign hamartoma of the bronchus."

A left lower lobectomy was performed by Sir Clement Price Thomas on July 18. The specimens removed at the operation showed the following features, as reported by Dr. J. W. Clegg: "Two operation specimens were received—a lower lobe and a segment of bronchus 3 cm. long dilated by an endobronchial polypoid tumour measuring 2.5 cm. in diameter. This tumour was found to consist chiefly of fat, but there were also areas of cartilage and small numbers of mucin-secreting glands present (Fig. 3). The surface of the tumour was covered by a transitional type of epithelium. These are the classical features of an endobronchial hamartoma. . . ."

The patient was discharged for convalescence on August 9.

Comment

When this growth occurs in the cancer age group it is almost impossible to distinguish it clinically from bronchial carcinoma, and the diagnosis is usually post-operative. This case, however, illustrates the possibility of arriving at a correct pre-operative diagnosis. Even when, as in this case, the growth is within reach of the bronchoscope it may be difficult to obtain a satisfactory bronchoscopic biopsy. The difficulty may be due to the nature of the tissues in the growth—namely, the adipose and cartilage tissues, on which the biopsy forceps slips off easily.

I am grateful to Sir Geoffrey Marshall for encouragement and most valuable guidance during the preparation of this case record, and to Dr. J. W. Clegg, pathologist to the Brompton Hospital, for the detailed report on the bronchoscopic biopsy and the operation specimens. I wish to thank Sir Clement Price Thomas for permission to report this case, Dr. J. G. Scadding for offering me the help of the Photographic Department of the Institute of the Diseases of the Chest, and Mr. D. F. Kemp for the photographs.

EOSINOPHILS IN THE SPUTUM

BY

JOHN VAUGHN, M.D.

(From the Department of Pathology, Mount Sinai Hospital, Chicago; lately of the East African Medical Survey and Filariasis Research, Mwanza, Tanganyika)

The presence of eosinophil leucocytes in the sputum has been traditionally associated with bronchial asthma. Early writers regarded this finding as diagnostic (Bezançon and Israël de Jong, 1912; Barth, 1921), but nowadays it has a wider significance, being found in chronic bronchitis, whooping-cough, carcinoma of the lung, etc. (Unger, 1945). The sputum eosinophilia of asthmatics was in some measure accounted for when Marchand (1915) found, in necropsies on asthmatic patients, extensive infiltration of the respiratory mucosa by eosinophil leucocytes. This is now an accepted pathological finding, as is also the infiltration by eosinophils of the nasal mucosa and sinus epithelium in other allergic states (Cooke, 1947; Baxter and Rose, 1953). Of the eosinophils in the respiratory mucosa, some were mononuclear cells, and there were many surrounding granules of an eosinophilic character; this appearance led Bezançon and Bernard (1930), Cooke (1932), and others to deduce that the eosinophils had been formed locally in response to an antigen-antibody reaction—the accepted mechanism of allergic bronchial asthma. Earlier, however, Huber and Koessler (1922) had recognized these mononuclear cells and scattered granules as stages in the degeneration of the eosinophil and had maintained the identity of the eosinophil in the lungs with the eosinophil circulating in the blood. Several attempts have been made to relate, numerically, the eosinophils in the blood with those in tissues and fluid discharges, but without much success (Cooke, 1932; Knott and Pearson, 1934; Cowie and Jimenez, 1936).

Eosinophilic infiltration of the pulmonary tissues was recently described in guinea-pigs which had developed eosinophilia following injections of toxic materials (Vaughn, 1953). In these experiments it was found that the eosinophils first increased in the circulating blood, then appeared in the lungs, and finally were found within the respiratory passages. From the chronological sequence it was suggested that the eosinophil leucocyte, formed in the bone marrow, proceeds by way of the blood stream to the lungs, migrates into the pulmonary tissues, whence it passes into the bronchioles and bronchi, and so is discharged from the body.

While working among the natives of Sukumaland, in Tanganyika, it was noticed that many specimens of sputum contained eosinophil leucocytes. The relationship which this finding might bear to the high incidence in the local population of parasitic disease, and, of course, to the eosinophilia of the blood so often an accompaniment to it, was considered and an attempt made to assess this relationship. Consequently the simultaneous examination of blood and sputa from a group of the local African natives was undertaken.

Methods and Results

African natives attending the out-patient department of Mwanza Hospital comprised the test group. These patients were not selected in any way except that in view of the

difficulty of obtaining specimens of sputum from young children such cases were omitted. There were only 10 cases of clinically apparent respiratory disorder in the whole series.

Patients were invited to expectorate into a Petri dish and smears were made of suitable specimens. Those specimens which consisted only of saliva were rejected and the patient was encouraged to try again. The smears were fixed, while still wet, in Schaudinn's fluid and were subsequently stained by haematoxylin and eosin, two such smears from each patient being examined. Differential leucocyte counts were found to be unsatisfactory owing to the uneven, often focal, distribution of the eosinophils. It was felt that a general impression of the contents of the smears as a whole would be of more value, and thus the smears have been reported as containing no eosinophils, scanty eosinophils, small numbers, or moderate to large numbers of eosinophils. Eosinophil counts of the peripheral blood were carried out by the method of Thorn *et al.* (1948).

In all, 205 Africans were examined in this way, and by a simple coding procedure examinations of the blood and sputum were made in complete independence.

In the Table the frequency and density of eosinophils in the sputum are shown in the various groups of Africans examined, the patients being arranged according to the level of eosinophils in the peripheral blood.

Occurrence and Intensity of Sputum Eosinophilia in 205 Africans with Various Levels of Eosinophil Leucocytes in the Peripheral Blood

Eosinophils in Sputum	Eosinophils in Peripheral Blood		
	0-500/c.mm.	501-1,000/c.mm.	Over 1,000/c.mm.
None	40	14	6
Scanty	18	21	3
Small No.	12	28	26
Moderate to large No.	3	12	22
No. of patients	73	75	57

Discussion

Of the patients examined, nearly two-thirds had an eosinophilia of 500 or more eosinophil leucocytes per c.mm. of blood, and the general pattern seems to be that as the degree of eosinophilia increases so does the frequency and density of the eosinophilia of the sputum. About one-fourth of the cases, however, do not follow this trend, some eosinophilic patients showing no sputum eosinophilia and some non-eosinophilic patients having numerous eosinophils in the sputum. To assess the importance of these dissenting results, attention must first be drawn to the technical inaccuracies in estimating the frequency of eosinophils in the smears. Also, in the animal experiments quoted above, eosinophilia of the blood was not synchronous with the appearance of these cells in the bronchioles, there being a time lag of some hours. This time lag was also evident as the eosinophilia subsided. This asynchronism has been observed in asthmatics. Tuft (1949) remarks that eosinophils in the sputum "are especially abundant towards the end of the attack." Generally, however, the trend of the present findings does support the view that eosinophils appear in the sputum, and of course in the tissues of the lungs, as late stages in the course of an eosinophilia.

The failure of former workers to establish such a correlation probably lies in their having investigated cases of allergy, the antigenic stimulus of which may not have been enough to produce an eosinophilia of sufficient intensity or duration to permit the relationship to be observed. In the present study the eosinophilia in almost all cases was a response to parasitic infestation, and it is among such cases that some of the highest eosinophil counts have been encountered (Wintrobe, 1951). In one of the cases included here there was a peak eosinophil count of 18,800 cells per c.mm., and the eosinophilia persisted for 10 days.

In a highly parasitized community such as that here examined, the frequency of eosinophilia, including pulmonary eosinophilia as revealed by the sputum, is not a new finding, for there have been many reports associating eosinophilic infiltration of the lungs with parasitic disease (Söderling, 1939; Wintrobe, 1951). The infiltration syndrome (Loeffler, 1932) should thus be expected in any condition in which there is a substantial increase in the number of circulating eosinophil leucocytes for any length of time—for example, periarthritis nodosa (Middleton and Carter, cited by Tisell, 1941).

As evidence accumulates there seems to be less doubt that the state of eosinophilia, of whatever primary aetiology, embodies an increase in the number of eosinophil leucocytes circulating in the blood, their subsequent migration (? selective segregation) into the tissues of the lungs, and their eventual discharge into the respiratory passages and so out of the body.

Summary

Simultaneous examination of blood and sputum for eosinophils was made in 205 African natives in an area where the incidence of parasitic infestation is high.

The results obtained suggest that there is some association between eosinophilia of the blood and that of the sputum.

This association is discussed in relation to the reports of pulmonary eosinophilic infiltration complicating parasitic disease.

It is suggested that eosinophilia of the sputum and its preceding eosinophilic infiltration of the lungs are integral parts of a general eosinophilia, and that the demonstration of eosinophils in sputum indicates that an eosinophilia is or has recently been in progress.

The annual report of the National Institute for the Blind draws attention to the manifold activities now being undertaken by that organization. Of particular interest is the development of the new solid-dot Braille, which composes dots of plastic ink on paper instead of impressing them, and which will make possible the much cheaper production of books, periodicals, music, etc., for the blind. Moon type is a useful complement to Braille, especially for those who become blind in old age. It was developed by Dr. William Moon (1818-94), who lost the sight of one eye at the age of 4, following an attack of scarlet fever, and became totally blind at the age of 22. Although Moon literature is costly to produce, the Institute has continued to supply it. Nearly 50,000 volumes of literature and 2,000 volumes of music were among the year's output of the Institute during the year. The physiotherapy school continues to make its useful contribution to medicine; an arrangement made with the Whittington Hospital, Highgate, has enabled skilled physiotherapy students of the Institute to give 4,000 treatments a month to out-patients. The Institute has begun a new policy whereby its members may obtain Braille watches, clocks, literature, and other goods at greatly reduced cost.

Medical Memoranda

Prevention of Post-operative Backache in Women

Some women suffer from low backache following prolonged abdominal or vaginal operations. The pains are sometimes so excruciating after awakening from the anaesthetic (and commonly during the first post-operative day) that only morphine brings relief. Some of these patients say that they suffered more from the backache than from the effects of actual operation, and this backache may persist for months after the operation.

This kind of backache is due to the forcible flattening of the lumbar spine curvature while the deeply anaesthetized patient is stretched out on a flat operating table. During vaginal operations in the extreme lithotomy position this flattening of the curvature is aggravated by extreme flexion of the thighs. The pains are caused partly by pulling on the interlumbar and sacro-lumbar ligaments, which sometimes leads to slight dislocation of the intervertebral joints.

In other patients, predisposed to degenerative changes in the intervertebral disks, the widening of the lumbar bodies by the forcible flattening of the curvature leads to some protrusion of a disk or disks, with resultant pressure on the dura mater, causing pains similar to those of the common disk lesions. Cyriax calls this kind of pain "dural pains." Deep anaesthesia leads to relaxing of the lumbar muscles, which facilitates the flattening of the curvature. Since the introduction of the relaxing curare preparations the evidence tends to suggest that this kind of backache has become commoner.

In women operated on in the lithotomy position another factor may add to this flattening of the lumbar curvature. If, after the operation, the legs are not put gently into the normal position, but instead one leg is first stretched while the other is still fixed to the stirrup, undue force is applied to the sacro-iliac joints, causing strain to the ligaments and resulting in mild dislocation of these joints.

The flattening is still further increased by the routine nursing with pillows arranged in such a way that the lumbar region remains unsupported. Nurses have for years been trained to adjust the pillows in this manner; four to six pillows are usually placed under the shoulders and back to keep the patient in a propped-up position, but no attention is paid to the fact that the lumbar region is left entirely unsupported. One can push a hand underneath, as if in a tunnel. Consequently the already flattened curvature resulting from lying on the operating table is still unsupported, and so the back pains are increased.

A fourth contributory factor is a mattress which is too soft in texture; this gives too easily, causing dents and so contributes to the flattening.

Two types of women are prone to such post-operative backache—the very stout and the asthenic flabby type. In the former the lumbar muscles are permanently strained in balancing the heavy abdominal weight. These women always have an increase of the lumbar curvature, and during the operation the already overtired lumbar muscles readily give way. The second type have muscles and ligaments constitutionally weak. The intervertebral ligaments are very loose and the spine curvature relaxes easily.

These unpleasant backaches can be prevented by a very simple procedure: (1) During the operation a cushion, not too soft, should always be placed under the lumbar curvature to prevent flattening of that part of the spine. (2) When the patient is changed from the lithotomy to the normal position both legs should be stretched gently at the same time. (3) Nurses should be taught never to allow the lumbar region to be unsupported while the patient is lying on her back, and especially during the first few days after the operation. An ordinary and not too soft pillow

should always support the lumbar region and should be rearranged several times during the day; and the mattress should not be too soft.

Should backache occur in spite of these precautions, a tight strapping of the lumbo-sacral region usually gives relief in a short time.

It is extraordinary, however, how difficult it has proved to get these simple precautionary measures introduced and carried out by nursing staff. Doubtless this is due to the rigid routine instruction during training; and to get nurses to alter this routine may prove extremely difficult, as I have found. Nevertheless when they have put these measures into practice great suffering has been spared to these patients and their convalescence has been made much easier and swifter.

E. SCHLEYER-SAUNDERS, M.D., F.I.C.S.

Investigations on Long-acting Corticotrophin

Corticotrophin remains in the body for only a short time after administration. Sayers *et al.* (1949) found, in two normal persons, the highest blood concentration at the conclusion of intravenous infusions for a half and one hour respectively, whereas three hours after starting the infusions the corticotrophin level had fallen to the control value.

While the decrease in number of eosinophil leucocytes is accepted as a standard for increased activity of the adrenal glands, it is known that the number of eosinophil

leucocytes in the blood does not decrease after a single intravenous injection of corticotrophin (Renold *et al.*, 1952). One intramuscular injection daily, given on three consecutive days, does not stimulate the adrenal cortex as measured by the excretion of 17-ketosteroids in the urine (Querido *et al.*, 1951). The daily therapeutic dose of corticotrophin must therefore be subdivided. This is inconvenient for the patient as well as for the nursing personnel, and consequently a search has been made for an A.C.T.H. preparation which will be effective when injected only once daily. The preparations described below seem to meet these requirements.

Methods.—Using the method described by Goslings *et al.* (1953), we gave six 3½-I.U. doses of the Organon preparation C/41 daily to two male patients suffering from rheumatoid arthritis. The results were compared with those from one 21-I.U. dose of the Organon long-acting (CLA) preparation of the same batch. In the intervals the patients were given dummy injections. The 17-ketosteroids excreted in the urine in 24 hours were assayed according to the method of Kassenaar *et al.* (1950). Eosinophil leucocyte readings were taken every morning at the same time, before breakfast and previous to the first injection, and the cells were stained according to the method of Zollikofer (1901).

Results.—The eosinophil leucocytes showed a distinct decrease during injection of the normal preparation (C), and also during that of the long-acting preparation (CLA) (Figs. 1 and 2). Both C and CLA had a marked effect on the excretion of 17-ketosteroids in the 24-hour urine. In Case 1 (Fig. 1) these values were of the same order of magnitude; in Case 2 (Fig. 2) the excretion was about 80% more during the CLA-period than during the period in which the normal preparation was given.

DISCUSSION

From the criteria of Goslings *et al.* (1953) it may be concluded that CLA has a satisfactory action. This is in accordance with the clinical results obtained by us, and by others (Solem and Holterman, 1952) with zinc-protamine preparations. It is not intended to discuss the validity or otherwise of the Sayers test for corticotrophic preparations. It is important, however, to remember that this test requires intravenous injections, and that only the immediate effect is measured. The long-acting preparations do not lend themselves to intravenous injection, and their effect is spread out over a longer period. It does not seem correct, therefore, to express the strength of a CLA preparation in Sayers units of the basic material from which these preparations are made. Furthermore, it is possible that in preparing CLA some change in the activity occurs.

In order to obtain reliable data on long-acting preparations for clinical use it seems necessary to compare these preparations with ordinary preparations of the same batch, based on the excretion of 17-ketosteroids in the urine in men.

Reviews

ANOXIA OF THE NEWBORN

Anoxia of the New-Born Infant. Consulting Editors: Dr. K. W. Cross (U.K.), Dr. M. Lelong (France), Dr. C. A. Smith (U.S.A.). Editors for the Council: J. F. Delafreschaye and T. E. Oppe. A Symposium organized by the Council for International Organizations of Medical Sciences. (Pp. 230; illustrated. 27s. 6d.) Oxford: Blackwell Scientific Publications. 1953.

When 17 outstanding authorities combine to discuss their subject informally among themselves their confabulations should make informative reading. This monograph is certainly informative; it is also stimulating and provocative. When obstetricians and paediatricians agree about the care of the newborn, and when, joined by pathologists, anatomists, physiologists, and chemists, they can meet together daily for five days "in a tranquil setting," then indeed are the lions lying down with the lambs.

Anoxia, a term which has now superseded the old "white" and "blue asphyxia"—and very properly so—is the subject of many theories but, in its essentials—prevention, early diagnosis, and treatment—of but few facts. In this symposium the theories are discussed and many are discredited, a number of new facts are brought forward, and alternative theories are proposed in the light of the authors' own research. Such vexed questions as the aetiology of hyaline membrane, the significance of foetal haemoglobin, and the value of combining carbon dioxide with oxygen in treating anoxia are fully considered. Dr. Lind (Stockholm) presents results of angiocardigraphic studies on foetuses and newborn infants, offers an explanation of the effect of anoxia on the functional closure of various foetal blood channels, and confirms the value of gastro-intestinal oxygen therapy.

There are five main sections which follow an introduction by Dr. Lelong (Paris). Each section ends with an account of the discussion engendered by the papers. The first is devoted to clinical aspects, with particular reference to the early diagnosis of foetal anoxia (Dr. Mayer, Paris), the mechanism, prevention, and treatment of anoxia (Dr. Gibberd), and the treatment of respiratory difficulties in premature infants (Dr. Rossier, Paris); the second to pathological findings—a symposium by Dr. Lelong, Dr. Clement Smith, Dr. Agnes Macgregor, and Dr. Ahvenainen (Helsinki); the third and fourth to biological and physiopathological considerations respectively; and the fifth to the place of oxygen in the therapy of premature infants and the treatment of atelectasis. In the final section some of the general conclusions are worthy of note, particularly in relation to anaerobic metabolism, arterial oxygen saturation, and oxygen therapy. It is stressed that the aim of resuscitation in anoxia is to oxygenate the medulla rather than to try to cause total expansion of the lung. Any mechanical device for resuscitation should be safe, simple, and readily applied without complicated apparatus or special skill.

Here indeed is a mental feast for all paediatricians, a book of value to all research workers in the field of neonatal physiology and pathology. It is well produced, with an extensive bibliography and excellent photomicrographs, graphs, and angiographs.

WILFRID GAISFORD.

PNEUMOCONIOSIS ABSTRACTS

Pneumoconiosis Abstracts. Volume I. Reprinted from the *Bulletin of Hygiene*, 1926-1938. (Pp. 347; illustrated. 63s.) London: Sir Isaac Pitman and Sons. 1953.

This book is the first of two volumes in which will be collected all the abstracts relating to pneumoconiosis which were published in the *Bulletin of Hygiene* from 1926 until the end of 1950. The present volume contains those abstracts

published from 1926 to 1938. Dr. E. I. Middleton, who has been responsible for the selection of relevant abstracts and for the preparation of the index, has adopted a broad definition of pneumoconiosis to cover all forms of pulmonary reaction to inhaled dust, without any reference to effect on function, and has taken the word "dust" to include fume in the solid state. The abstracts therefore cover a wide field of interest. They are grouped in sections, whose headings indicate their scope. After a general section on industrial hygiene and the relation of occupational dusts to respiratory disease in general, there are sections on silicosis, asbestosis, pneumoconiosis of coal workers, pneumoconiosis caused by other inorganic dusts and by dusts of vegetable origin, and on respiratory disease caused by fumes. These are followed by a section on methods of dust suppression and of protection of the worker against dust. The next two sections are on the periodical reports of various official bodies relating to pneumoconiosis and on pneumoconiosis legislation. Finally, there are a number of book reviews.

The value of such a compilation depends in great measure upon the accuracy and completeness of the index. In this volume the index covers 21 pages in double column, and has obviously been prepared with scrupulous care; a few random tests of it have proved entirely satisfactory. This volume, together with its companion, is likely to prove indispensable to everyone interested in the problems of industrial pulmonary disease.

J. G. SCADDING.

MEDICAL EDUCATION IN THE U.S.A.

Medical Schools in the United States at Mid-Century. By John E. Detrick, M.D., and Robert C. Berson, M.D. (Pp. 380; £1 16s.) London: McGraw-Hill Book Company. 1953.

Medical schools are an expression of the life of a nation, and therefore reflect its social, economic, and political forces; but the response of medical schools to changes in these forces is not instantaneous, and periods of confusion and stocktaking precede readjustment. In the United States medical schools have been evolving continuously for the past two centuries, the tempo varying with events, and there is no sign of finality. That the second world war has created immense problems is evident from this book, which will take its place in the series of classic reports initiated by Abraham Flexner in 1910.

The authors worked for the "Survey of Medical Education," whose committee includes some of America's leading medical educationists. The book is wider in scope than its title suggests, being in fact a comprehensive review of medical education, both undergraduate and postgraduate; the schools themselves are simply the focal point. As Alan Valentine says in his foreword, the book is the first thorough self-evaluation of American medical schools for many years. The materials were collected by questionnaires and visits to a large and representative proportion of the schools, with the full co-operation of deans, staff, and students. The result is much more readable than might have been expected. The book is concise, well-written, and trenchant, each section having a good summary and a list of recommendations appended; and the occasional platitudes may well bring home important truths to some readers for the first time.

The functions of a medical school are distinguished as education, research, and "service." Finance and administration are discussed at length, the topics including the cost of educating a medical student, the relation between medical school and hospital, the organization of departments in medical schools, medical libraries, teaching staff, and the selection of students. The rest of the book is on the theory and practice of the education of students and doctors, and there are interesting appendices, especially one on what students think.

While many of the problems discussed are peculiar to the United States, arising from a political and financial situation very different from ours, some are met with

everywhere. Among those of interest to us are the problems of medical libraries, the overloaded curriculum, encroachment on the student's leisure and vacations, out-patient teaching, domiciliary teaching, and the functions of housemen. British medical teachers and deans would find this record of American experience directly relevant to their own problems. If any British students read it, they will learn that talking to the blackboard and mumbling into one's beard are not peculiar to British teachers, and that British and American students are alike in desiring closer association with the staff.

PRACTICAL PRESCRIBING

Practical Prescribing: An Introductory Guide for Medical Students. By Alastair G. Macgregor, M.D., B.Sc., M.R.C.P.(Lond.), F.R.F.P.S., and Trevor W. G. Kinnear, M.B.E., M.B., Ch.B., M.R.C.P.(Ed.), M.R.C.P.(Lond.). Foreword by Professor J. H. Gaddum, F.R.S. (Pp. 88. 6s.) Edinburgh and London: E. and S. Livingstone. 1953.

This manual is an introductory guide for medical students. The authors therefore give the bare essentials about dosage, prescription writing, prescribing within the terms of the National Health Service, the law and drugs, and methods of administration of drugs. They make no attempt to present prescribing as an art. Further, we are told that "Signetur" in the form of "Sig." is the only permissible Latin word to appear on a prescription, just as B is the only permissible symbol. We have as an example of a typical prescription "B Ferrous sulphate tablets (B.P.)" with the usual directions in English. So be it! We must move with the times even though we may sigh nostalgically for our basis, adjuvant, corrective, and excipient compounded with a fine knowledge of incompatibility and rendered more efficacious by indecipherable dog Latin. There are surely two strong reasons against the jettisoning of Latin: first, speed is gained by using truncated Latin terms; secondly, such a prescription can be understood and thus dispensed over the greater part of the globe.

On page 37 we read that "the danger of diamorphine addiction is so great that this otherwise useful drug has been omitted from the latest edition of the B.P., 1953." This regrettable and ridiculous action might well have been accorded a paragraph of criticism, otherwise the student may conclude that it meets with general approbation. On the same page it is stated that Indian hemp has no legitimate medicinal use, yet as a euphoriant it is the only drug extensively used in the treatment of the anxious patient with duodenal ulcer.

The authors have presented their subject with praiseworthy clarity.

A. H. DOUTHWAITE.

PSYCHO-ANALYTIC PAPERS

Primary Love and Psycho-Analytic Technique. By Michael Balint, M.D., Ph.D., M.Sc., L.R.C.P., L.R.C.S. International Psycho-Analytical Library. No. 44. (Pp. 288. £1 10s.) London: The Hogarth Press. 1952.

Dr. Balint, one of the most distinguished of Ferenczi's pupils in this country, has taken after his master in three main respects—his interest in psychological parallels to the laws of biogenetics, his theoretical and practical concern with the development of libido-theory, and his tendency to speculative handling of psycho-analytical problems, in particular the rationale of psycho-analytical therapy. The present volume consists of papers delivered between 1930 and 1952 and includes discussion of such subjects as pre-genital organizations, primary love, genital love, love and hate, transference and counter-transference, therapeutic aims and techniques, and the termination of analysis. These subjects the author deals with in an easy speculative manner, the effect of which naturally depends on the degree to which the reader is ready to accept the interpretations so disarmingly presented.

On the matter of biological parallels it cannot be forgotten, however, that psychologists can quote biological and anthropological scripture for their own purposes. And when one examines closely the clinical observations on which Dr. Balint's theories are founded one is occasionally disconcerted to find such statements as "coitus . . . begins as an altruistic act," which is either an instinctual truism, a verbal misunderstanding, or a clinical understatement. Even his technical aphorisms are sometimes naive—as where he says that a priori there is no reason why patients should not be able to produce their symptoms at will after treatment "now that they have become fully conscious of their individual mechanisms of production." Similarly his favourite thesis that in a satisfactorily terminated analysis the patient makes a "new beginning" free from anxiety is either a restatement of the obvious or a professional idealization of the analytical process.

Dr. Balint's most important service is the emphasis he lays on early loving object-relations. Whether or not one agrees with his concept of "primary love" (primitive archaic object-relation), he is undoubtedly correct in his criticisms of some modern tendencies of psycho-analysis whereby constitutional sadistic and masochistic tendencies are unduly stressed.

EDWARD GLOVER.

TEN TEACHERS

Diseases of Women. By Ten Teachers, under the direction of F. W. Roques, M.D., M.Chir., F.R.C.S., F.R.C.O.G. Ninth edition. (Pp. 480; illustrated. 28s.) London: Edward Arnold and Co. 1953.

The production of the new edition of this well-known 34-years-old textbook is under the direction of F. W. Roques, assisted by J. Beattie and J. Wrigley as co-editors. Nearly all the London teaching schools are represented in the list of contributors, which now includes S. Clayton, C. Gwillim, and T. Lewis in the places of F. Cook, Sir William Gilliat, and C. White. The principle of collective responsibility, which has the doubtful merits of eliminating heresy and ensuring that nothing is said which would not bear repetition before the most narrow-minded examiner, has the known disadvantage of resulting in an insipid milk-and-water concoction which hardly dares to express a definite opinion. This disadvantage is now recognized, and a serious attempt has been made to allow each contributor sufficient rope to give the book more courage and character, and to inspire the reader with more confidence. The attempt is by no means unsuccessful. Moreover, attention is paid to the changing outlook on the requirements of the undergraduate in that the section on operative treatment is shortened and simplified, while more emphasis is placed on medical gynaecology. The chapter on neurasthenia and neurosis in relation to pelvic disorders deserves special mention. The illustrations are reasonable in number and generally adequate though individually varying in quality.

The student may wish for more on some of the common practical problems such as vaginal discharges and pruritus vulvae, but it is difficult to see how it could be supplied without increasing the size and price of the book—which would be a pity. As it is, the editors and contributors are to be congratulated on the way in which they have moulded advances in knowledge and modern trends in thought around the age-old essentials of gynaecology, and have still managed to keep it within small compass. For this as well as for other reasons it will undoubtedly find favour among large numbers of present-day students, as did its predecessors with previous generations.

T. N. A. JEFFCOATE.

Therapie der Kinderkrankheiten by Professor J. Siegl (Vienna: Wilhelm Maudrich, 1953. M. 32) is a product of the Vienna school of paediatrics and is volume five of a series on paediatric subjects. After an account of feeding normal infants, it goes on to discuss the treatment of diseases of the newborn, and then other disorders of childhood. An appendix lists certain drugs and prescriptions, and discusses dosage.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 2 1954

CORTISONE AND BLOOD DISEASES

During the last three years A.C.T.H. and cortisone have been increasingly used in the treatment of blood diseases. Since quite large numbers of patients have now been treated,¹⁻³ it should be possible to form some sort of judgment on the value of these drugs. Only in acquired haemolytic anaemia of the auto-antibody type and in idiopathic thrombocytopenic purpura have favourable responses been obtained with any regularity. In other types of haemolytic anaemia, in agranulocytosis, chronic leukaemia, myelosclerosis, reticuloses, and in aplastic anaemia the drugs have given far less benefit, a favourable response being a rare and unpredictable event. The acute leukaemias occupy an intermediate position, for some cases in childhood will respond, even dramatically.

Before the physician undertakes the treatment of blood diseases with these drugs he should have gained experience of their general metabolic effects, for they may have to be given for long periods in large doses—for example, in adults up to 300 mg. a day of cortisone or 200 mg. a day of A.C.T.H. or its equivalent as A.C.T.H. gel in divided intramuscular doses. Most patients with acquired haemolytic anaemia of the auto-antibody type, whether "idiopathic" or secondary to some other disorder, respond favourably to treatment; some may obtain complete clinical and haematological remission. A.C.T.H. or cortisone therapy should therefore be the treatment of choice for acquired haemolytic anaemia, and splenectomy, which results in clinical cure in not more than 50% of cases,⁴ should be kept in reserve. If a patient responds to hormone therapy, it seems reasonable to reduce the dosage to the minimum amount that will prevent his haemoglobin level from falling below 11 g. per 100 ml. (74%). It is doubtful if it is worth trying to obtain normal haemoglobin levels by increasing the dosage to perhaps dangerous levels, for there is no evidence that A.C.T.H. or cortisone can cure the patient's disease. The aim should be to control the rate of haemolysis

in the hope that spontaneous cure will take place. In some cases treatment may have to be prolonged. In our opening pages this week Drs. G. M. Aber and G. N. Chandler and Professor S. J. Hartfall describe the follow-up of a child whose earlier history had been reported by Rose and Nabarro⁵; this patient (who had undergone splenectomy) still needed 75 mg. of cortisone a day 60 weeks after the beginning of therapy for the control of haemolysis.

The place of splenectomy in the treatment of acquired haemolytic anaemia needs to be reconsidered in the light of the favourable results of hormone therapy. Unfortunately there does not seem to be any way of telling beforehand which patients will do well after the operation; in particular, a favourable response to A.C.T.H. or cortisone does not necessarily mean that splenectomy will be successful, nor is the converse true. It is probably wise to postpone splenectomy either until it is clear that the patient will not respond to A.C.T.H. or cortisone in large doses and that his illness shows no signs of abating, or until it is clear that large doses of the hormones are required to control the patient's anaemia and that after months of treatment there are still no signs of a remission. In the latter circumstances, even if clinical cure does not result from operation, it may be possible to keep the patient well on smaller doses of A.C.T.H. and cortisone than previously.

As to idiopathic thrombocytopenic purpura, the situation is analogous to that of acquired haemolytic anaemia; most of the patients are benefited by hormone therapy whether the platelet counts rise or not. In acute cases cortisone or A.C.T.H. should be the treatment of choice, but when the disease is running a chronic course splenectomy will probably have to be undertaken sooner or later. The place of A.C.T.H. and cortisone in the treatment of acute leukaemia is more controversial. It seems that a favourable response may be expected only in acute or subacute lymphatic leukaemia affecting children or adolescents. In adults the chances of a remission are remote, and in children acute and subacute myeloid forms usually fail to react. According to Dameshek⁶ the best results are obtained if A.C.T.H. and small doses of aminopterin are given together. Unfortunately, even if remissions occur, they are always temporary, relapse inevitably taking place sooner or later. Most commonly the remissions last a few weeks; they seldom last more than four months. This raises the question whether treatment is worth while; on this crucial point opinions naturally differ. The simplest solution is to give children and adolescents suffering from acute leukaemia the benefit of A.C.T.H. or cortisone treatment. Unlike

treatment with anti-folic-acid drugs⁷ the consequences of overdosage are not serious and distressing; and, if remission follows, the parents of the patient may find that the respite has given them time to adjust themselves to a tragic situation.

TOO MANY DOCTORS?

The beginning of a new year is apt to prompt speculation on the future, and some thought is needed on what should be done about the ever-growing numbers of the medical profession in Britain. Against the hosts of applicants besieging their deans, the medical schools erect some sort of a barrier, with the result that during the last six years the annual entry of students to the medical schools of the United Kingdom and Eire has been between 2,500 and 2,700. The effect of this on the *Medical Register*, after some names have been removed by death and other causes and a few others added, has been to increase the total of registered medical practitioners by about 1,000 a year over the same period. Doctors seeking permanent positions are finding it more difficult than formerly to get the jobs they want, and the deans of the medical schools have a responsibility in relating supply to demand which they are at present compelled to exercise without sufficient knowledge of the country's needs. While the *Register* is likely to show at least the present rate of annual increase for the next five or six years, by virtue of the numbers of students now in training, the question whether these increments should be allowed to continue, and for how long, is surely an urgent one.

A fair approximation to the number of medical practitioners of all kinds in England and Wales and in Scotland may be obtained from the *Medical Directory*. This shows that in 1953 there was in England and Wales one doctor to every 900 persons and in Scotland one to every 600. These figures are of residents in the countries concerned, and do not attribute to Scotland those many doctors who qualify there but practise elsewhere. Some doctors whose names appear in the *Directory* have retired, and some whose names are not listed in it are yet in practice; the difference between these two numbers is unknown, but it is unlikely to be a large source of error in the final figures. In 1939, according to the same source, there were 37,429 doctors in England and Wales, while in 1952 there were 50,574. This is an increase of about 13,000, or 35%. In Scotland, the numbers rose over the same years from 6,091 to 9,096, an increase of about 3,000, or 50%. The *Medical*

Register tells much the same tale: between 1939 and 1952 the numbers for England, Wales, and Scotland rose from 63,360 to 83,914, an increase of about 20,000, or 33%. If this expansion continues, it will soon be impossible for some medical men to find work in Britain, and the scope for practice abroad is now much less than it was.

A year ago the Council of the B.M.A. accepted a suggestion made by the chairman of the General Medical Services Committee that the Committee should look into this question of supply and demand. A subcommittee was appointed, and it reported to the G.M.S. Committee on December 17.¹ Acknowledging that the task is complex and that national policy must be determined by the country's need for medical men and women, the G.M.S. Committee is recommending the B.M.A. Council to invite the Ministry of Health to co-operate in the setting up of a working party. The task of this new committee would be "to examine on a long-term basis and with the widest possible terms of reference the future number of medical practitioners likely to be required in all branches of the profession and to relate these needs to the intake of students to the teaching schools."

Some much-needed information could be gathered from such an inquiry, though there are two hazards to be avoided. The first is too great a preoccupation with details. Any attempt to lay down precisely how many doctors should fill any particular branch of the profession must be put out of court, for it is impossible to impose on the whole of medicine the sort of staff establishment that suits Government services. The expansion of medical knowledge in the past two or three decades has been reflected in a greatly altered distribution of medical men between the various branches of the profession, and such natural flexibility of response must be preserved. The second danger is delay. The numbers of doctors are increasing so rapidly that, apart from the obvious risks of overcrowding to the profession itself, doubts must arise whether the country ought to be spending its resources on training so many students—not in some years' time but this year and next. Even now deans of medical schools might well warn prospective students that competition for the more attractive posts is much keener than formerly—no bad thing—and also that to find any opening at all may be a competitive affair by the time they have qualified in six years' time. If the last six years may be taken as a guide to the next six years, and medical and general populations of England and Wales² estimated accordingly, the student starting his course this year and qualifying in 1960 will find only 800 people per doctor instead of the present 900.

RETICULOENDOTHELIOSIS IN CHILDREN

The main, and often the only, justification for reporting a single case of an undiagnosed or hitherto undescribed condition is that similar cases may be recorded over the years. Eventually a clinical picture emerges sufficiently well defined to merit a name—usually eponymous, but this may be an advantage when aetiology or pathology is obscure. The syndrome associated with the names of Hand, Schüller, and Christian was evolved from descriptive case reports over a quarter of a century, starting in Philadelphia in 1893 with Hand's original description,¹ being embellished by Schüller's cases in Germany reported in 1915,² and returning to America for Christian's major contribution in 1919.³ At first thought to be localized to the skull and characterized by the triad of proptosis, diabetes insipidus, and radiological changes in the cranium, it is now appreciated that the condition is often more generalized and that the spleen, liver, lymph nodes, skin, lungs, and other parts of the skeleton may be implicated. The disease usually starts during the first decade of life and runs a variable course; but it has been described in adults, with a more favourable prognosis and with spontaneous regression and disappearance of the easily seen bone changes. The characteristic histological finding is localized areas of macrophage infiltration containing multinucleated giant cells loaded with cholesterol. Hence the condition has been termed lipophagic granulomatosis and, because of the associated xanthomata in the skin, was at one time classified with the xanthomatoses.

More recently another syndrome, associated with the names of Letterer⁴ and Siwe,⁵ has been recognized. This condition is characterized by a sudden widespread overgrowth of reticuloendothelial cells in the lymph nodes, spleen, liver, and marrow. The histological picture differs from that in the Hand-Schüller-Christian syndrome, the lesions being more diffuse and both giant cells and lipid scanty. Clinically the Letterer-Siwe syndrome is an acute fulminating illness of infants with fever, necrotic lesions of the mouth and pharynx, otitis, cutaneous haemorrhages, and a rapidly progressive anaemia. The picture is reminiscent of an acute leukaemia, but because of the septicaemia-like course it has been called acute infectious reticulosis, although there is little to indicate an infective aetiology. Some patients show features of both syndromes, with fever, lymphadenopathy, petechiae, anaemia, hepatosplenomegaly, and arthritis, and patients with the Hand-Schüller-Christian syndrome may present in the terminal stages with all the features of the Letterer-Siwe syndrome.

Yet more recently a third condition called eosinophilic granuloma of bone has been described.^{6,7} This usually occurs in late childhood or early adolescence, and is characterized by tumour-like destructive swellings of

bone, often single but sometimes multiple. A low-grade pyrexia and leucocytosis may be associated. The histological evidence suggests that these three conditions are variants of a single disease entity—rapidly fatal in infancy (Letterer-Siwe disease), chronic but liable to acute exacerbations in early childhood (Hand-Schüller-Christian syndrome), and fairly benign in later childhood and early adolescence (eosinophilic granuloma).⁸

The effect of treatment is difficult to assess because of the variable course of the disease. Eosinophilic granuloma and, in its more benign form, Hand-Schüller-Christian syndrome show improvement with x-ray therapy. In the more acute type blood transfusions, x rays, nitrogen mustard, and antifolic acid drugs have been used with more limited success. The Letterer-Siwe syndrome is usually rapidly fatal, although Aranson⁹ reports recovery in one infant after treatment with streptomycin. More recently Bass and her colleagues¹⁰ have described the response of five cases to cortisone and A.C.T.H. One infant with the Letterer-Siwe syndrome showed no improvement, but in four children with the Hand-Schüller-Christian syndrome there was regression of the splenic and lymph-node enlargement, remission of fever, and great improvement in their general condition. In one child whose state was similar to that seen in Letterer-Siwe syndrome A.C.T.H. proved life-saving. This type of response is seen in other conditions, such as acute lymphatic leukaemia, after cortisone or A.C.T.H. therapy, but is unfortunately short-lived. Similarly in the Hand-Schüller-Christian syndrome the improvement was only temporary in one case and the child eventually died. In the others hormonal treatment seemed to tide the children over an acute phase and allowed them to live long enough for a spontaneous remission to be manifest.

POST-OPERATIVE CHOLECYSTITIS

The surgeon often alleges most uncharitably that the worst place for a patient to have his peptic ulcer perforate is in the hospital ward of his physician colleague. However, he is not above criticism himself in overlooking the incidental surgical catastrophes which may infrequently occur in the immediate post-operative period. Of the hazards of the acute peptic ulcer, bleeding or perforating, he is well aware, and acute appendicitis may be obvious enough not to pass for long unrecognized. But there is one post-operative abdominal emergency of which he is likely to be unmindful namely, acute cholecystitis. There is nothing unusual in the clinical features of the disease to mislead him: the site and character of the pain and tenderness follow the usual pattern: it is only the timing which is so unexpected. Subhepatic abscess, subdiaphragmatic pleurisy, or a blown duodenal stump are diagnoses which may first present themselves, but this complication is by no means peculiar to abdominal surgery. In only six of Glenn's seventeen cases of this complication did the cholecystitis follow intraperitoneal operations,¹ and in three of the

six recorded by Sparkman² the abdominal parietes were not involved. A more recent communication³ has listed seventeen cases collected over a period of rather more than twenty years from the records of the hospital of the University of Pennsylvania. There were three deaths in this series and in each of them the diagnosis was established only at necropsy. Perforation of the gall-bladder occurred in four patients.

Perhaps during the period of anaesthesia and of the fast that usually follows the bile becomes stagnant and viscid. When later the gall-bladder is vigorously stimulated in response to the taking of food, obstruction and inflammation ensue, especially in the presence of stones. Certainly in a significantly high proportion of cases the first symptoms occur within 48 hours of the resumption of feeding. There can be no easy way of anticipating this complication. Even the palpation at laparotomy of what seems to be a normal gall-bladder is no guarantee against its later acute inflammation. But clearly surgeons should remember acute cholecystitis as an uncommon, though none the less serious, complication following operations for completely unrelated disease.

DIVERSITY IN DEVELOPMENT

In the half-century that has passed since the discovery of Mendel's work, Mendelian inheritance has been demonstrated so abundantly in living organisms that the chromosomes within the cell nucleus are apt to be regarded as the sole means of inheritance. Yet it has long been known that the chloroplasts of green plants are always derived from pre-existing plastids, and consequently their inheritance does not follow the Mendelian laws. In most flowering plants they are handed down to the next generation only from the female parent. More recently a few instances of such extra-nuclear inheritance have been found in micro-organisms. These are favourable subjects for genetic study, and, as Boris Ephrussi has shown,⁴ two distinct types of cytoplasmic inheritance are now known.

In one type—for example, the plastids of green plants and the "killer" character of *Paramecium*—the characters in question are determined by autonomous particles in the cell cytoplasm, which are irreplaceable if lost; and specific genes in the nucleus are required for the reproduction or for the physiological activity of the cytoplasmic particles. In the second type of cytoplasmic inheritance, shown by antigens in *Paramecium*, the characters in question depend on the action of nuclear genes, whose manifestation is controlled by the cytoplasm, which is itself influenced by the external environment. In other words, a cytoplasmic character permits the expression of one particular gene out of a number present. There is no evidence that in this type of cytoplasmic inheritance discrete extranuclear particles are involved, and it seems more probable that, under the influence of different environmental conditions, such as different temperatures, alternative but interacting reaction chains within the cell give rise to alternative stable cytoplasmic states.

These phenomena are interesting in themselves, but they take on a greater significance when compared with the process of differentiation into organs and tissues that is seen during the development of a living organism. Ever since the establishment of the chromosome theory it has been apparent that differentiation must originate in the cytoplasm. In no other way can differences between different cell-lineages arise, since mitosis distributes an identical set of genes to every cell. However, although genetically alike, the nuclei of different tissues may be functionally different. Indeed, it was long ago suggested that development consists in the orderly activation of different sets of genes in different cell-lineages. This is a remarkable parallel with the inheritance of antigenic types in *Paramecium*, where different cytoplasmic conditions call forth the activity of different nuclear genes. But, even if this is the mechanism of differentiation, there still remains the fundamental question of what initiates the cytoplasmic diversity during development. It is in the attempt to answer this question that profound differences of opinion exist at the present time.

Most geneticists favour the idea that the initial cytoplasmic diversity results from environmental stimuli external to the cell. The cytoplasmic diversity is thought to be similar in origin to the antigenic diversity brought about in *Paramecium* by the action of nuclear genes whose manifestation is controlled by the cytoplasm, this in turn being influenced by external stimuli. This hypothesis enables all cytoplasmic diversity (apart from structures known to be autonomous, such as the plastids) to be attributed to the functioning of different nuclear genes in different environments. But Ephrussi expresses a view which is revolutionary to most geneticists. He suggests that the initial cytoplasmic asymmetry of the egg cell reflects an underlying fundamental asymmetry at the molecular level. Furthermore, he thinks that this is inherent in the cytoplasm in the same way as the autonomous particles responsible for the "killer" character in *Paramecium*. Indeed, he goes so far as to suggest that the most fundamental characters of living organisms are inherited in the cytoplasm, and that the nucleus is concerned chiefly with the more superficial differences between individuals. Ephrussi's book is clearly written and he develops his ideas with great skill. Its appearance is salutary and it will give cause for thought on one of the most fundamental problems of biology.

THE FEEBLE-MINDED

The total number of mental defectives now under institutional care in England and Wales stands at 56,629. This figure includes 5,100 on licence, but excludes 2,385 in accommodation not vested in the Minister.¹ The number of patients awaiting admission in 1952 was estimated at 9,000, and of these 3,527 were considered to be urgent cases. Out of the latter figure some two-thirds were described as "low-grade children." Mental defectives occupy quite a large proportion of the total hospital beds in the country, and the long waiting-list is a serious

problem; indeed, it has been referred to by the Minister as "problem No. 1." For the many medical officers of health and others concerned with making the best use of the beds available it will be some consolation to know that the first new hospital to be built in this country since the war is to be devoted to mental defect. On the other hand, it should be noted that 1,921 existing beds are out of use principally owing to shortage of nurses. In the present difficult circumstances the lack of adequate statistical information about the mental deficiency service is unfortunate, the previous reports of the Board of Control being now replaced, so far as mental deficiency is concerned, by a few lonely paragraphs in the general report from the Ministry of Health. The survey by Drs. N. O'Connor and J. Tizard published elsewhere in this issue is therefore welcome. It provides, together with the other information available, a basis for taking stock of the problem of the institutional defective. It also poses the questions whether we are making the best possible use of the existing hospital facilities, and whether enough thought has been given to the possibility of returning some of the long-stay cases to the community.

To those familiar with the problem it will not come as a surprise to learn that over half the patients in mental deficiency hospitals are classed as feeble-minded or that the average intelligence quotient in young adults confined in these institutions is above 70. The reason usually advanced for the continued detention of these patients is that they constitute a "social problem" group. In fact the survey suggests that social problem cases make up only a small proportion of the total. The spread of the intelligence and character of these individuals who have been classed as mentally defective overlaps very widely with that of the general population. Is the fact that a small proportion of patients certified as mentally defective are "difficult" an adequate reason for detaining for an indefinite period others who might become so? Unfortunately the survey does not provide information about the proportion of the total effort devoted to the care of the mental defective which is spent directly on social rehabilitation, though the figures of patients on licence have an indirect bearing on this. A survey devoted purely to this aspect of the problem would be certain to yield valuable results. Meantime it is already apparent from this survey and from previous work reported by the authors that a high proportion of patients in mental deficiency institutions are potentially employable in building, in factories, or in agriculture. A good case has now been made out for the employment of additional experienced social workers or rehabilitation officers in the mental deficiency hospitals specifically for the purpose of placing these patients in suitable employment.

HEALTH HAZARDS IN THE CHROMATE INDUSTRY

Chrome ulceration of the skin or of the nasal mucous membrane has for many years presented a serious industrial problem in every country where chromates are made or used. One of the earliest reports of skin lesions in the form of large penetrating ulcers of the

hands came from Scotland in 1827, and in 1902 the discovery in England by Sir Thomas Legge of a high incidence of perforated nasal septa among workers in a plant producing bichromate led to the setting up of a special code of regulations for the industry. Conjunctivitis, congestion of the throat, bronchitis, and acute toxic symptoms related to the digestive organs and the kidneys have also been noted as specific effects of exposure to chromates, but it is only rather recently that they have been indicated as a probable cause of lung cancer. The first report came from Germany in 1932 and was soon followed by many more, though neither the complete diagnosis of the neoplasm nor its connexion with chromate exposure was always indisputable.

The steadily growing suspicion of a carcinogenic hazard led the representatives of the chromate industry to request the Public Health Service of the U.S.A. to undertake an extensive inquiry into the problem, and the results have now been published.¹ The extent of the problem there can be judged from a comparison of the incidence of lung cancer in chromate workers with that in the general population, as exemplified in an x-ray survey of over 500,000 persons in Boston in 1949-50. This showed an incidence in the 897 chromate workers 32 times that of the Boston population at the age of 60-69 years, and 325 times as great at 40-49 years.

In Great Britain the problem of chrome ulceration has been met by statutory control, including periodical medical examination of workers in nearly all branches of the chromate industry. Most of the cases notified now are associated with chrome plating; the notifications from chrome tanning, dyeing, and finishing, for which Welfare Orders were made in 1918, have amounted to only two in the past five years. In 1951 there was an increase in all cases of chrome ulceration over those notified in 1950; this was largely accounted for by 80 cases occurring in the manufacture of bichromates.

There is certainly no such prevalence of lung cancer here as that indicated in the U.S.A. investigation. An inquiry in 1951 among 724 workers in the chromate-producing industry of Great Britain revealed only one case, a figure too small for a definite conclusion. It was then pointed out that the British process differs from that of both Germany and the U.S.A. in that the residue from the leaching tanks is not, in Great Britain, dried and crushed and used as a filler but is discarded in a moist condition and carried to dumps outside the factory. The residue, when crushed and recirculated, as is the practice in Germany and America, contains certain acid-soluble, water-insoluble chromium compounds, to which suspicion is directed in the U.S.A. report, though whether they are directly carcinogenic could not be established. The report recommends further research on the effects of all chromium compounds and, in the meantime, periodic x-ray examinations of all workers in the chromate producing industry.

CLINICAL PATHOLOGY IN GENERAL PRACTICE BLOOD GROUPING

BY

A. E. MOURANT, D.M.

Director, Blood Group Reference Laboratory, the Lister Institute, London

Persons whose blood group needs to be known for medical reasons fall into three classes: blood donors, blood transfusion recipients, and pregnant women.

Blood donors are almost exclusively grouped by the National Blood Transfusion Service. Relatively small numbers are grouped by the Greater London Red Cross Blood Transfusion Service and by individual hospitals. It practically never happens that a donor has to be grouped or a sample taken for grouping other than at a large transfusion centre of some sort.

Apart from the most severe obstetrical haemorrhages, and uncontrollable haemorrhages due to accidental trauma, transfusions are never carried out away from hospitals. Such obstetrical and traumatic cases will, in general, be transfused with group O, Rh-negative blood by "flying squads" without preliminary grouping. Hence blood grouping of recipients is always carried out in hospitals or is done for them by the laboratories of the National Blood Transfusion Service. The same applies to the direct matching between the blood of donors and recipients.

The blood grouping of pregnant women is carried out for antenatal clinics by hospital laboratories or by the National Blood Transfusion Service, and the necessary samples are taken at the clinics. When a pregnant woman is not attending a clinic, her own doctor should arrange for the performance of the necessary tests either at the local hospital laboratory (as for other pathological tests) or at the Regional Blood Transfusion Centre. Local arrangements vary, but information about them can be obtained from the regional transfusion director or from the medical officer of health.

Collection of Specimens

For the tests a sample of blood of at least 5 ml., and preferably 10 ml., should be taken with a dry sterile syringe into a dry sterile tube. This relatively large volume is needed in order to supply enough serum for antibody tests. If the necessary syringe and tube are not available it is best to use a Behring venule* prepared without anticoagulant or preservative. It is perhaps worth repeating that to release the vacuum in a venule the needle should be bent further away from the axis of the tube, not brought into line with it. The alternative of a syringe kept in alcohol carries the well-known risk of transmitting homologous serum jaundice, but if it is used it should be rinsed several times in sterile physiological saline.

If a woman is found to have an abnormal antibody in her serum it may be necessary to test specimens from her husband and in some cases from their children. The specimen from the husband should consist of 2 to 5 ml. of whole clotted blood. Specimens from children may have to be obtained by pricking the heel, ear-lobe, or finger with a triangular needle. At least 10 drops of blood should be taken into a small dry sterile tube; some laboratories may, however, ask for such specimens to be taken into 3.2% sodium citrate or other anticoagulant.

Where there is a possibility of haemolytic disease of the newborn, it is necessary to carry out blood grouping and

*See the article by Dr. Martin Hynes on "Dispatch of Specimens," published on October 17, p. 876.

other tests on the blood of newborn infants. For certain of the tests (especially the haemoglobin estimation) a cord-blood sample is essential. As soon as the cord is cut and tied, 5 ml. of blood is taken with a dry syringe (or venule) from the maternal end of the cord and put into a tube containing dry oxalate or heparin. It is important to use a dry tube so as to obtain an accurate result in the important haemoglobin determination. A separate specimen without anticoagulant is needed for serological tests. Capillary blood from the infant is useless for haemoglobin tests if they are to be of prognostic value in haemolytic disease of the newborn. The blood should be taken by piercing the umbilical vein in the tied cord as though it was a subcutaneous vein. Any attempt to obtain blood from the open cut end of the cord is apt to lead to contamination with Wharton's jelly or even with maternal blood.

The ABO Blood Groups

The only tests which are performed on all (or nearly all) blood samples are those for the ABO groups and for the Rh factor or factors.

The ABO groups depend upon the existence on the red-cell surface of two substances or antigens known as A and B. Chemically they are very closely similar polysaccharides of high molecular weight, and the only clearly defined difference between them is that shown in agglutination reactions of the kind described below. All human red cells are classified into four groups—A, B, O, and AB—according to the presence on them of either, neither, or both of these antigens. These are detected by tests carried out with certain human sera containing antibodies in solution. When red cells carrying the antigen A are mixed with a serum containing anti-A, the surface properties of the red cell are altered in such a way that the cells stick to one another or agglutinate into large clumps. Cells carrying the antigen B react similarly with a serum containing anti-B. The antibodies in question are present in normal human sera: each serum contains all those antibodies which will not agglutinate the red cells present in the same blood. Thus anti-A testing serum is derived from group B blood, and anti-B serum from group A blood. The above facts are summarized in the Table.

Name of Blood Group	Antigens on Red Cell	Red Cell Reaction with Anti-A	Red Cell Reaction with Anti-B	Antibodies in Serum
O	—	—	—	Anti-A and Anti-B
A	A	+	—	Anti-B
B	B	—	+	Anti-A
AB	A and B	+	+	—

When any blood is tested it is necessary not only to examine the red cells by means of standardized anti-A and anti-B sera but also to test for the presence of anti-A or anti-B antibodies in the serum by the use of red cells known to be of groups A and B. Tests are in general carried out by mixing small quantities of the appropriate sera and red-cell suspensions in glass tubes. The mixtures are kept at room temperature for two hours before being examined microscopically. A working description of the technique of blood grouping is beyond the scope of this article and is given in the *Medical Research Council War Memorandum No. 9*.

In deciding what blood is suitable for a given recipient, the principal consideration is the absence of reaction between

the red cells of the donor and the serum of the recipient. Since high titres of antibody in the serum of the donor may also on rare occasions cause trouble, it is desirable always to give a recipient blood of his own group. In an emergency, however, group O blood can without great danger be given to anyone.

The Rh Factor

Every person, whatever his or her ABO blood group, is either Rh-positive or Rh-negative—that is, the red cells either contain or do not contain an antigen known as the Rh factor, or, more precisely, as the D antigen. The corresponding antibody, anti-Rh or anti-D, is not normally present in the serum of D-negative persons, but such a person, if transfused with D-positive blood or, in the case of a woman, if she bears a D-positive child, may become immunized by the D factor, so that an anti-D antibody develops in the serum. A subsequent transfusion of D-positive blood will then give rise to haemolysis and to a severe reaction. About 50% of D-negative persons receiving a single transfusion or course of transfusions of D-positive blood will become immunized. Of D-negative women who bear D-positive children, about 1 in 20 becomes immunized. It is thus important that D-negative persons, especially women, should, if transfused, receive only D-negative blood. The serum of D-negative persons who have been immunized to the D antigen will, under suitable conditions, cause *in vitro* agglutination of D-positive red cells. Such pathological sera are used in Rh blood-grouping of transfusion donors and recipients.

It is desirable also that the blood of all pregnant women be tested for Rh as well as for ABO. Two objects are in view: one is to be ready to transfuse should there be severe haemorrhage at the time of parturition; the other is so as to recognize the presence of immunization and so to be prepared for the birth of an infant with haemolytic disease. Every woman who is D-negative should therefore have her serum tested for the presence of anti-D.

Rh-testing procedures are complicated by the fact that the Rh factor is a complex entity, though most of its details have very little direct bearing on clinical medicine. Whatever other antigens may be or may become involved in the situation, however, all transfusion recipients who are negative for the D antigen, and likewise all pregnant women who are D-negative, are liable to develop anti-D. Thus a test of the red cells of all such persons should be made with anti-D serum: for nearly all purposes this single test is the only one that need be performed on the red cells.

The tests on donors are less simple and the extra tests mainly concern two other antigens of the Rh complex, known as C and E. Most D-positive bloods contain either or both of these antigens as well as D, and D-negative persons who develop anti-D are liable to make anti-C or anti-E as well. The transfusion of blood from a donor who is D-negative but C-positive or E-positive will of course be dangerous to such a recipient. Thus it is necessary after selecting D-negative donors with an anti-D serum to eliminate the relatively rare ones who have the C or the E antigen, by further testing with anti-C and anti-E sera. There is another antigen which may give rise to difficulties in the testing of donors, recipients, and mothers. It is known as D^a, and persons who have it are liable to appear D-positive when tested with some sera and D-negative with others. When the possibility of its presence is realized this is easily confirmed or disproved. Persons who are D^a-positive may be treated for clinical purposes as D-positive.

Tests for Rh antibodies in sera are carried out by means of red cells of known Rh groups. The sera of persons who are to be transfused may contain any of the antibodies already mentioned (anti-A, -B, -C, -D, -E), as well as other rarer ones which need not be described here. Even Rh-negative blood may react with some of these. It is therefore necessary before any transfusion to test the compatibility of the red cells of each donor with the serum of the recipient.

The methods of Rh testing and of direct matching are described in "The Rh Blood Groups and their Clinical Effects," by P. L. Mollison, A. E. Mourant, and R. R. Race (*Medical Research Council Memorandum No. 27*).

Planning of Blood Grouping

Only the principles and not the practice of blood grouping (including direct matching) are described in this article. It is of the utmost importance that it should be realized both by those who do blood grouping tests and by those who without adequate training may wish to do them, that, of all pathological tests, blood grouping carries the greatest responsibility: it is the one kind of test in which a single error may lead directly to the death of a patient. Thus no one who has not received a course of training in blood grouping should ever attempt to carry out such a test. Under emergency conditions, when the temptation to do the test will be the greatest, the danger of error will also be greatest. Rather should an irate pathologist be awakened from his bed and compelled to travel many miles to the hospital. Any doctor who is going to be completely isolated from laboratory facilities should obtain training in blood grouping just as he would in emergency surgery.

Instruction of house-officers and others in routine blood grouping and direct-matching techniques can be arranged through any regional transfusion director. While the house-officer untrained in blood grouping must never attempt to carry out the test, it is important that both he and his seniors should have an idea of what is involved in blood grouping and direct matching so that they can collaborate effectively with those who are doing the tests. It is agreed by most pathologists that adequate blood grouping and cross-matching tests require incubation for two hours. Hence, in the case of planned operations which may involve transfusion, a sample of the patient's blood should be sent to the laboratory well in advance of the operation, preferably some days before. Many laboratories have special arrangements for emergency grouping and direct matching by special methods which take about half an hour. Where such provision has been made emergencies are only very rarely so acute as to demand the transfusion of group O, Rh-negative blood into an ungrouped patient. Many so-called emergencies can be foreseen, and it must be realized that with emergency direct matching the possibilities of error, though slight, are appreciably greater than in normal tests.

In certain classes of surgery it is necessary that there should be available for each patient large quantities of blood which may or may not prove to be needed. In some cases the same bottles can be matched direct against the blood of several patients, but to save opening of bottles several times, and also possible confusion between the bottles intended for different patients, it is important that the routine of notification, sampling of patients' bloods, testing, and labelling of bottles should be carefully planned by consultation between the surgeon and the pathologist.

Interpretation of Rh Blood-group Tests

Cards bearing a statement of the ABO and Rh group are given to blood donors, to most pregnant women, and to a few transfused persons. On cards given to Rh-negative (D-negative) persons in the latter two classes there may also be a statement that the serum contains anti-Rh antibodies. A woman who knows that she is Rh-negative is likely to approach her doctor for information and advice about the possible effects on her children. If the husband or prospective husband is known to be Rh-negative as well, complete reassurance can be given. The shortage of testing sera is such that it is only in exceptional cases that a special test of the husband's blood can be justified for this purpose. In an Rh-negative woman who has never had a blood transfusion, the occurrence of clinical haemolytic disease of the newborn affecting a first pregnancy is practically non-existent, though slight immunization of the mother may occur. In the second pregnancies of Rh-negative women married to Rh-positive

husbands about 1 in 20 foetuses will suffer from haemolytic disease. The proportion of affected infants will increase somewhat with successive pregnancies. Once a woman has become immunized to the Rh factor all her subsequent Rh-positive children will suffer from haemolytic disease. If her husband is homozygous Rh-positive—that is, if he has received the Rh or D factor from both of his parents—then all the children will be Rh-positive (and therefore affected by the disease), whereas if the husband is heterozygous Rh-positive (having received the Rh or D factor from one parent only and the Rh-negative or d factor from the other parent) then any subsequent child has equal chances of being Rh-positive and affected or Rh-negative and healthy.

If any child of the couple is known to be Rh-negative this shows the husband to be heterozygous. Tests carried out on the husband's blood alone can never show with complete certainty whether he is homozygous or heterozygous, but they can do so with a high degree of probability. Where, therefore, an Rh-negative woman has become immunized to the Rh factor and there is a desire to increase the family, the Rh genotype of the husband should be determined. The necessary test requires the use of scarce and valuable kinds of antisera and can be carried out only at regional transfusion centres and a few other laboratories.

The above paragraphs have been written as though the Rh or D factor were the only one responsible for haemolytic disease of the newborn. In rare cases other Rh antigens, the A and B antigens, and antigens of other blood-group systems may be responsible. Where such cases are detected the medical officer in charge of the testing laboratory will readily give the necessary advice on such matters as prognosis for future pregnancies.

It is well known that Rh-negative persons should, in general, be transfused only with Rh-negative blood. If they have become immunized to the Rh factor by pregnancy or transfusion, any further transfusion of Rh-positive blood may be fatal. It is unnecessary to alarm such persons regarding their "condition," but they must be warned always to carry their blood-group cards and to proffer these when entering hospital for any reason.

OPHTHALMIC SURGERY IN INDIA SOME ENCOURAGING FEATURES*

BY

J. N. TENNENT, M.B., B.Sc., F.R.F.P.S., D.O.M.S.
Ophthalmic Surgeon, Glasgow Royal Infirmary

A visit to India was organized in 1951 by Dr. R. U. Hingorani, an Indian ophthalmic surgeon practising in London. It was primarily a pleasure trip, a sight-seeing tour, but as the party was composed mainly of medical consultants and their wives, with a core of European ophthalmic surgeons, medical conditions aroused most interest, especially the efforts made to remove that great affliction of India, disease of the eye.

The amount of suffering in India is appalling, most of it preventable. This is not surprising, for there is a great shortage of trained medical personnel. A recent estimate states that there is only one trained doctor for

every 10,000 of the population, as against one for 900 in Great Britain. In addition, the doctors are poorly distributed, being congregated mostly in the towns. Facilities for the application of modern scientific medicine are lacking, and there still exists a good deal of native prejudice. Quacks abound. Some have a useful knowledge of Indian herbs and a skill in their application, passed on from father to son, but many indulge in superstitious practices concerned with the exorcizing of demons or the placating of evil spirits, practices which are often both crude and cruel. A man in any walk of life may pick up something about cataract extraction, set up in practice, and soon acquire a reputation as an eye specialist. Government intervention is not yet considered necessary, but it must come sooner or later.

Living Conditions

Poverty abounds. Most of our party had to revise their conception of the meaning of the word "poverty." In some of the refugee camps human beings were seen with scarcely a roof to cover their head. In the village huts we visited there was sometimes little else than some cooking utensils, a few fowls, and a receptacle to hold the family's supply of rice for the year.

With poverty go overcrowding and malnutrition. In the city of Bombay some 200,000 people sleep on the streets. This is partly a matter of choice owing to the heat, but is also partly due to the fact that many have little more than an accommodation address, a room which 20 or more people use to hold their worldly possessions while they eat and sleep on the streets.

Rice is the staple food; indeed, it is almost the only one, with resulting lack of balance in diet and deficiency disease. The fields given over to the cultivation of rice may provide excellent breeding grounds for mosquitoes and the spread of malaria.

A feature of Indian life that strikes the stranger forcibly is the lack of adequate attention to sanitation. Large cities like Calcutta still have open sewers in the streets, and cows are allowed to wander about unmolested even in the main thoroughfares. Some of the villages we visited were quite unprovided with streets, lighting, and sanitation, so that the spread of epidemics in the time of the monsoons can scarcely be avoided.

Finally, there is still to be found the secluded life of many women living in purdah. This system intensifies the lack of medical attention for women and children, and thus leads to needless suffering. A recent estimate gives the expectation of life for an Indian woman as 27 years as against 67 in Great Britain.

It is not my purpose to dwell on the lethargy, poverty, ignorance, and superstition of India. Rather do I wish to draw attention to some signs of an awakening to the need for action which is going on, particularly among Indian doctors. The Government also is becoming more alive to the need to do something to remove the great scourge of disease from India.

The most serious medical affliction is tuberculosis. Next comes eye disease; and here most authorities agree that at least 90% of it is preventable. I shall refer to one or two encouraging features in the ophthalmological field.

The Gandhi Eye Hospital

The Gandhi Eye Hospital is in Aligarh, a Moslem university town of 140,000 inhabitants, in the State of Uttar Pradesh (formerly United Provinces), 84 miles south-east of Delhi. The hospital has 100 beds, and plans to increase the number to 250. It began in 1928 as the private clinic

*A lecture delivered in the Department of Ophthalmology, University of Glasgow, on May 14, 1952.

of a public-spirited Indian, Dr. Mohanlal, who developed the work on a voluntary basis, and in 1941 handed over the assets to a public trust. Since then the hospital has been rebuilt, partly by voluntary subscription and partly by Government grant, and now stands on a new site covering 16 acres. With only 100 beds, extra accommodation has to be found sometimes for as many as 300 patients; and in winter some 500-600 patients may have to be provided for by means of extra tentage. Winter is the best time for cataract operation. In summer it is too hot, patients are restless, there is a constant battle against flies, and infection is more likely. In summer patients with diseases such as trachoma are more likely to find their way to the operating theatre. The hospital building is new and is provided with much up-to-date and expensive equipment. There are separate departments for refraction, radiotherapy, orthoptics and optical dispensing.

The staff consists of one chief medical officer, four ophthalmic surgeons, three assistant ophthalmic surgeons, two refractionists, one laboratory assistant, and several compounders, theatre assistants, and ward boys. Female nurses are conspicuous by their absence, for nursing is regarded as an unsuitable occupation for a girl of education or social standing.

The following figures show the yearly amount of work carried out:

New patients	..	..	20,000
Total patients	..	..	80,000
Refractions	..	..	5,000
Operations	..	..	6,000

The patients bring their own food and linen, with some-one to look after them. Those who are too poor (10%) get free food. Private patients are provided for; these pay 100 rupees (£7 10s.) for treatment and lodging.

The cataract operations in the height of the season number 60 a day. One surgeon generally operates, with three or four tables. The usual mode of extraction is the intracapsular.

The hospital is intended to be the centre for postgraduate study and for research. The most significant feature of this hospital, however, is its interest in rural work and its use of the mobile eye hospital. To appreciate the significance of this it is necessary to know something about the district in which the hospital is situated.

Uttar Pradesh is one of the most important States of India. It is right at the heart of the country—Hindustan of the old Moslem chronologists. It includes important cities like Agra, Aligarh, Lucknow, Allahabad, and Benares. Together with Delhi on the west and Patna on the east, it represents the area of the dawn of Indian history. There Brahminism took form; Buddha was born, preached, and died; the Mogul Dynasty had its most brilliant period; the Indian Mutiny took place, with the establishment of British dominion; and there also New India has more recently taken shape. The State has an area of over 106,000 square miles and a population of some 60 millions.

Before 1930 the facilities for the treatment of eye disease in this Province were meagre indeed. Eye cases tended to find their way to the district general hospitals, the State being divided into 51 districts. There they were seen by the civil surgeon, and treatment was mostly operative. At Agra and Lucknow there were medical colleges, each with an eye department, and at Allahabad there was a hospital where a limited number of eye patients were treated. In addition, in winter a well-known Indian eye surgeon used to hold eye camps where mass surgery was done. The great majority of eye patients were at the mercy, however, of village quacks or couchers.

Around 1930 in Uttar Pradesh there developed two eye hospitals, one at Aligarh and the other in Khairabad. This latter hospital has also recently been rebuilt, and is now at Sitapur. Both these hospitals set out to do village work, and in 1949 the Government approved of a State-wide scheme with them as base hospitals.

In the area allotted to the Gandhi Eye Hospital it is intended that in, say, 15 years each district will have an eye clinic in charge of a properly trained eye specialist. Meantime, however, a short-term policy provides for four mobile eye hospitals. Each of these will have 100 beds, a field operation theatre, and accommodation in tents for staff and patients. Except in the hill areas, work will be done mainly in winter. The hospital will visit one district for six to eight weeks and remain in one centre for, say, 20 days. There will be a permanent staff, with visits from the surgeon of the Gandhi Eye Hospital, and use will be made of Government medical officers and local eye specialists.

The proposed personnel will still be woefully short for such a vast area, but the step taken is considerable and is in the right direction. It will help to break away from outmoded and pernicious eye camps, which, while popular with the people and the Government, have not been run on scientific lines. It will provide for the treatment of eye disease apart from cataract. It will educate the people regarding the prevention and control of eye disease, develop an eye consciousness in school health administration, and break down much prejudice against scientific treatment.

At present eye disease and consequent blindness in the countryside are said to be increasing day by day, so this scheme is a welcome effort to tackle an enormous and serious problem.

Experience in Bombay Province

A well-known Indian ophthalmic surgeon has classified his colleagues into three groups: (a) mass surgeons, (b) scientific surgeons, and (c) occasional surgeons. That classification implies that mass surgeons are not scientific surgeons, and the statement was no doubt true when it was written. In recent years, however, there has been a growing concern in the highest quarters about mass-operation camps, and steps are being taken in some parts to place these camps on an irreproachable basis.

In Bombay Province, for example, the surgeons have become concerned about the advent of outsiders with a medical training, but no training in ophthalmic surgery, who stay for three or four days and conduct a large number of operations for cataract. The cases are then left in the hands of compounders and much sepsis results. In spite of their shortcomings such camps are welcomed by the people, who are often satisfied if they can see even a little again.

The ophthalmic surgeons in Bombay approached the Government to see what could be done, and at once received the challenge, "What can you do to help?" The outcome was the establishment of two camps yearly by the surgeons themselves—one in April and one in October—alternating between the northern and southern parts of the province.

A school or military barracks provides a suitable building for the requirements of the camp. When we visited the province in November one such camp had just finished at Pandharpur, and for some details I am indebted to Dr. Pradhan, of Poona, who took part.

The staff of this camp consisted of two senior surgeons, two assistant surgeons, three postgraduate students, and two additional surgeons from the district. One of the senior surgeons of Bombay was in charge.

An attempt was made to get all patients examined first by local Government doctors so that undesirable cases could be weeded out. When the camp began all the staff devoted the whole of the first day to seeing out-patients. Those with less than a certain standard (6/60 Snellen) were generally admitted. On the second day one-half of the staff operated in the forenoon while the other half saw patients; in the afternoon the order was reversed. Operations went on for four days and then stopped.

The patients were given a careful examination, attention being paid to teeth, lacrimal ducts, blood pressure, and urine,

and the usual dark-room investigation was done. On admission the patient was given a brisk purge; until operation the eye was washed and penicillin drops, 2,500 units per ml., were instilled three times daily. 5 ml. of milk was injected intramuscularly—a non-specific protein therapy which increases leucocytosis. On the operating-table penicillin drops were instilled and 50,000 units injected subconjunctivally in 0.5 ml. of solution before or after the operation. Sulphadiazine tablets were also given for four days. Forty-eight hours after the operation the eye was dressed; if it was satisfactory the other eye was left uncovered. The dressing was repeated every second day and dark glasses were given on the eighth day. Intracapsular extraction was generally done for immature and hypermature cataract; for intermediate types the surgeon used his own discretion regarding the best method of procedure.

This project is financed by the Government. Glasses are supplied free, lodging is free, and the patient's rail fare is paid if necessary.

The following is a brief summary of the work done and the results achieved:

Total No. of out-patients	..	..	3,372
" " " in-patients	..	..	845
" " " operations	..	..	1,084
" " " cataract operations	..	..	676

Of the 676 cataract operations, only 40 showed any post-operative complication, and only four eyes were lost—one from sepsis and three from intraocular haemorrhage. Such results would adorn the records of ophthalmic surgery anywhere.

A High Standard

The ophthalmic surgery is of a very high standard in the leading eye hospitals. In Bombay I had more time to see the hospital work than elsewhere, but members of our party had an opportunity of seeing similar work in Calcutta and Patna; and, as is well known, Madras has been an important centre of ophthalmic surgery for many years. The standard of cataract work in the leading eye hospitals in Bombay is very high indeed, and the results of the keratoplasty work are most encouraging. In a land where corneal opacities are so numerous there must be great scope for grafting, and it will expand in the near future if grafting material becomes more readily available. In Bombay research is being pursued with considerable success.

Eye surgery would seem to be handicapped at present by lack of personnel and lack of finance—both dependent, no doubt, on the general economy of the country. Another difficulty, and one which should be easier to overcome, is the apparent scarcity of surgical instruments of high quality. It should not be impossible to produce one or more Indian firms capable of manufacturing and maintaining ophthalmic surgical instruments adequate in quantity and quality.

Finally, it was a pleasure to meet with so many Indian colleagues, to discuss their problems, and to appreciate their work. There is still much to be done, and signs are not wanting that the magnitude of the task is appreciated and that a bright future lies ahead.

PRESENTATION TO PROFESSOR CHARLES SINGER

Professor Charles Singer has for many years been the leading historian in this country both of medicine and its allied sciences and of technology. When, therefore, the project was mooted of presenting him with a volume composed of a series of special contributions written by his friends and admirers, it met with an enthusiastic response. The responsible and difficult task of collecting and editing the contributions was undertaken by Dr. Ashworth Underwood, and to him must also be given the credit for arranging the various essays into groups having a similar theme or dealing with a definite period. The 90 contributors represent many countries, and the work has been published by the

Oxford Press in two excellent volumes, and entitled *Medicine, Science, and History*. It was arranged that specially bound copies of the two volumes should be presented to Professor Singer at Fowey, which is fairly near his home, and on December 19 the presentation took place at the end of a luncheon which was given in his honour. Among those present were his talented wife, Mrs. Dorothea Singer, Professor Gordon Childe, Professor K. J. Franklin, Dr. F. A. Freeth, Mr. Affleck Greeves, Dr. C. T. Andrews, Mr. Douglas McKie, Dr. Ashworth Underwood, and Professor Singer's son and daughter. The occasion was to have been presided over by Sir Arthur MacNalty, but in his unavoidable absence Sir Zachary Cope deputized for him. A special menu card had been prepared which included a photograph of Professor Singer and also sketches of the four places

(George W. F. Ellis, Bodmin)

Professor Singer receiving the presentation volumes from Sir Zachary Cope.

with which he had been most closely associated, while the different items on the menu had been given names which recalled many of the subjects on which he had written with authority. Dr. Underwood read out many messages of congratulation sent by friends who had been unable to make the journey to Cornwall. In making the presentation to Professor Singer, the chairman said that it was a unique occasion. Never before had any celebrated medical historian received in person such a noteworthy testimony of the high regard in which he was held by his contemporaries. He recalled that they were both alumni of St. Mary's Hospital medical school and that they had been house officers in the hospital together. In handing to Professor Singer the sumptuous volumes, Sir Zachary remarked that they were accompanied by the great respect, admiration, and affection felt towards him, not only by the whole body of contributors, but by a much wider circle of admirers over the whole civilized world.

Professor Singer, who was much moved by the occasion, said that it was the happiest day in his life. He commented on the factors which enabled him to accomplish what he had done. First the influence of his home, for his father was a great scholar and an erudite man, and from his earliest years he had lived in an atmosphere of learning. Among colleagues who had helped him he specially mentioned the late Professor Arthur Platt. He finally paid a glowing and affectionate tribute to his wife, Mrs. Dorothea Singer, who was not only a distinguished scholar in her own right but had inspired and helped him to an incalculable degree. This unity of endeavour was signally shown in his closing sentence: "We thank you from the bottom of our hearts."

Tributes were afterwards paid to their honoured guest by others who were present. Professor Singer is 77 years old.

Nova et Vetera

BIBLIOGRAPHY OF HARVEY

A Bibliography of the Writings of Dr. William Harvey, 1573-1637. By Geoffrey Keynes, M.A., M.D., D.Litt., F.R.C.S., F.R.C.O.G. Second edition, revised. (Pp. 79; illustrated. £2 10s.) London: Cambridge University Press. 1953.

Within living memory the art of bibliography has been refined far beyond anything previously attained. Certainly its recent practice by those with the suitable cultural and intellectual attainments, and, above all, with that indefinable thing called "judgment," has produced results which would have astonished their predecessors. Exact modern bibliography often enables the student to penetrate beyond the printed page to the very mind of the author treated. Among exponents of this art, Mr. Geoffrey Keynes has long been held in honour for the light that he has thrown on the life and work of such figures as Jane Austen, Donne, Sir Thomas Browne, William Blake, Hazlitt, John Ray, and Isaac Walton. This accomplished man has also applied himself to the work of William Harvey, who is in some ways an ideal subject for bibliography, since not a few of the editions of his several works are so rare that the number of surviving copies is approximately known and each copy located.

In 1928 Mr. Keynes produced a bibliography of Harvey in a very limited edition. It has long been out of print and a desideratum of scholars. This second edition, the scheme of which is faultless, is in even more sumptuous form. It follows the general lines of the first, but includes different illustrations, previously unrecorded editions, and a certain number of new facts. Of these the most interesting concern the printing and printer of the *De motu cordis*. It has always been a puzzle why Harvey should not have issued his great work in London, where there were many excellent printers, but at Frankfort-on-Main, with a young and not very competent printer, William Fitzer. The matter has been elucidated by Dr. Ernst Weil, who published his findings in 1944. They are linked with the life of Dr. Robert Fludd (1574-1637), a most peculiar figure who combined some understanding of the "new philosophy"—which we call "science"—with the wildest mysticism. The late Dr. H. P. Bayon threw some light on the relations of Fludd and Harvey. Mr. Keynes thus summarizes these researches:

"It seems that Fludd from 1617 had his books published by Johann Theodor de Bry of Oppenheim, formerly of Frankfort. In 1619 the firm returned to Frankfort, and in 1626, when de Bry died, the business passed to Fitzer, who then took over the publication of books by Fludd. Harvey had many contacts with Fludd beginning in their student days at Padua in 1602, and is exceedingly likely to have been influenced by him in choosing Fitzer as his publisher. Fitzer's career from 1600 to his death in 1671 has been fully elucidated by Dr. Weil but does not further concern us here. The choice of Frankfort, however, was certainly unfortunate, since its distance from London made communication difficult, and it seems to be unlikely that Harvey ever saw any proof-sheets of his book. Had they come under his eye he would hardly, even in those days of bibliographical insensibility, have passed so many errors in so few pages. It is probable that when the first copies reached him he was displeased, and sent Fitzer a list of errata as soon as he was able. A minority of the surviving copies of the book contain an additional half-sheet of two leaves, the first of which carries a list of 126 corrections. Probably these leaves were added only to the remainder of the edition, after the greater part had been distributed—even so the *errata* list was not long enough; the Latin text edited by Mark Akenside for the College of Physicians in 1766 contains 246 emendations."

Anyone who has tried to read Harvey's handwriting will spare a sigh of sympathy for his printer. It is in the mode to ascribe many qualities to the great father of modern physiology, but the hero-worshipper who will credit him with a clear neat script has yet to emerge.

CHARLES SINGER.

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Whither Anaesthesia?

SIR, At the summer meeting of the Section of Anaesthetics of the British Medical Association at Cardiff the subject of the morning session was "A Return to Simplicity?" and I think that the general feeling was that this discussion was timely, if not overdue. Since that date the tendency has been to greater and greater complication.

From a perusal of papers published in the British and French medical journals and those read at the Royal Society of Medicine it would appear that one line of thought now runs as follows. The over-enthusiastic use of hypotensive techniques to provide a bloodless field for surgeons has forced into prominence accompanying dangers. In order to minimize these, it was suggested that hypothermia would reduce the basal metabolic rate, so that such blood supply as remained would afford adequate oxygenation of vital structures. Unfortunately, hypothermia induced by superficial cooling in patients who are sedated or lightly anaesthetized without complete relaxation results in a violent reaction, including shivering, etc., designed to keep the temperature up and to raise the B.M.R. In order to circumvent nature still further, it appears to be necessary to avoid surface cooling (in adults) and to effect the temperature drop by an extracorporeal arteriovenous shunt passed through a refrigerator. If this complicated technique is to be avoided an intravenous infusion of various "lytic cocktails" can be substituted. These may contain a great variety of drugs (some French workers use twelve), including at least two which have not yet been fully worked out as regards their pharmacological effects. It is hardly surprising that patients take a considerable time to recover from these varied assaults, and an impression is beginning to gain ground that pulmonary complications and paralytic ileus are more frequent than with orthodox techniques.

I would be the last to decry real research into anaesthetic methods capable of coping with, say, intracardiac surgery with a shut-off cardiac inflow, but these complicated techniques are being used on some patients undergoing routine surgery which can be dealt with by well-tried and simple methods. Surely the correct and scientific approach to any problem is to investigate it one step at a time. For example, if it is thought that intravenous chlorpromazine is likely to be a useful drug to diminish the B.M.R., to facilitate cooling, to potentiate anaesthetic drugs, or to minimize post-operative vomiting, then it (and it alone) could be added in a series of patients undergoing routine operations, all other anaesthetic and surgical factors being kept the same, so far as practicable, as with a previous controlled series. If significantly beneficial results follow, the optimum dosage could be worked out and the next step embarked upon. If, on the other hand, complications such as venous thrombosis were noted, they must either be overcome or the decision would have to be taken whether the advantages of the drug outweighed its disadvantages. As matters stand at present, groups of workers all over the country appear to be giving large numbers of drugs of diverse actions in various dosages, and in an infinite variety of permutations and combinations with such other procedures as induced hypothermia and hypotension. The results of small series of cases are then rapidly published in terms which are often obscure. For example, what are the definitions of ganglionic and neuroplegic drugs, and is artificial hibernation an accurate term when the differences between hibernating mammals and non-hibernators are considered? Is it any wonder that the student and, indeed, the experienced anaesthetist is becoming bewildered? I am, etc.,

London, N.6.

C. LANGTON HEWER.

Correspondence

Press Publicity

SIR,—What a silly and sanctimonious little piece was that contributed to your issue of December 19, 1953 (p. 1378), by Miss B. M. Willmott Dobbie. "Journalists, of course, have their living to earn." Surgeons, too, I fancy.

Of course, vulgar reporting of medical matters is to be deplored and is deplored by none more so than by responsible journalists. But part, at least, of the blame must be attributed to such superior persons as your correspondent who fail to co-operate in enabling journalists to present simply and factually the more remarkable achievements and advances in the art and science of medicine.—I am, etc.,

JOHN PRINCE.

London, E.C.4.

Intra-arterial Transfusion

SIR,—It appears to me that the success of intra-arterial transfusion depends upon what is called the hydrostatic paradox, which states that "any quantity of water however small may be made to counterbalance any weight however great." This is brought about by the fact that in a liquid great pressure is transmitted equally in all directions, and consequently the pressure on any given surface is proportional to the area of that surface. From this it follows that, if the pressure in a narrow artery is raised by the injection of fluid under pressure, the pressure in the wide aorta is in proportion to the differences of their sizes. This is considerable, even allowing for the loss of efficiency in the hydrostatic system occasioned by leakage into the arterial tree.

The repercussions of raising the intra-aortic pressure are manifold—perfusion of the coronary arteries, oxygenation of the tissues, take-up of blood from the venous bed, filling and emptying of the right heart, leading to increased efficiency of the cardiovascular system, etc.—and are amply illustrated in the reports of successful intra-arterial transfusion.

I submit, therefore, that, rather than continuous intra-arterial transfusion under pressure, it is more rational to apply intermittent intra-arterial injection until the take-up of blood from the venous bed is established in cases of shock, or from intravenous blood in cases of haemorrhage.—I am, etc.,

J. SHEGOG RUDELL.

Northampton.

SIR,—The observations made by Dr. J. A. G. Horton and his colleagues in their article "Intra-arterial Transfusion" (*Journal*, December 12, 1953, p. 1294) are very instructive.

May I point out in this context in favour of intra-arterial transfusion that the whole principle may be looked upon as a second cardiac system, operating outside the body, feeding the whole arterial system with oxygenated blood directly under pressure when it is utterly impoverished, and thus filling adequately the coronaries and increasing the vis-a-tergo, improving the capillary stasis. In addition, the greatest advantage of this route is that it excludes the pulmonary circuit, which is definitely a retarding factor in the effectiveness of a transfusion through the venous route before the blood reaches the left heart. Thus, the more the patient is shocked, more rational it will be to choose the arterial route for transfusion for its immediate dramatic effect.—I am, etc.,

R. CHAKRABARTY.

Braintree, Essex.

Polycythaemia Vera

SIR,—A patient may be said to have polycythaemia (rubra) if the red cell component of the blood of his whole body is decidedly in excess of the normal. But why should one call it polycythaemia vera (true polycythaemia) as if there were such a condition as false polycythaemia (pseudo-polycythaemia)? How can a polycythaemia be false, unless the patient or someone else has injected into his blood the stream a substance imitating haemoglobin? Of course, the term "polycythaemia vera" was intended to mark a distinction from secondary polycythaemias, reactionary results of high altitudes, or malformations or diseases of the heart or lungs. But all such secondary polycythaemias are as

real polycythaemias as so-called polycythaemia vera. Clearly, by the term "true polycythaemia" (polycythaemia vera) a condition of primary polycythaemia is meant—that is to say, polycythaemia of unknown origin, perhaps of neoplastic (or rather "neoplastic") nature, and not secondary to any known cause. In discussions on the subject I occasionally drew attention to this question, but mostly ignored it, in order not to turn an interesting discussion into one of nomenclature.

In nearly all genuine cases of primary polycythaemia there is an increase in the white cells at the very least in proportion to the increase in the red cells; this is a reason why the word "rubra" may be (as it usually is) omitted.—I am, etc.,

London, N.W.1.

F. PARKES WEBER.

Succinylcholine Chloride for Casualty Anaesthesia

SIR,—I should like to comment on Dr. V. P. Wordsworth's first point in your issue of November 28 (p. 1219). The lower end of the oesophagus is controlled not by an intrinsic but by an extrinsic sphincter mechanism which is composed of three elements, first, the pinch cock action of the right crus of the diaphragm which forms the margins of the oesophageal hiatus, secondly, the sharp backward angulation of the lower end of the oesophagus caused by the contraction of the crura, and, thirdly, the acute angle of entry of the oesophagus into the stomach at the cardia. As the crura contain striated muscle Dr. D. C. Adamson's observation in your issue of October 31 (p. 993) that the cardiac sphincter relaxes during oesophagoscopy when succinylcholine is given would appear to be a correct one and is due to the property of the drug in question.—I am, etc.,

Hull.

W. N. ROLLASON.

The Human Foot

SIR,—It was greatly encouraging to those whose approach to foot problems is not that of the surgeon to see two non-surgical papers on foot disabilities appear side by side in the *Journal* (October 3, pp. 745 and 749). The ensuing correspondence has shown how lively an interest is taken in this subject by readers whose thoughts are not bound by acceptance of clinical entities nor harnessed to therapeutic conditions that should be preventable. But, Sir, having read the two papers and studied the material they offer with some care, I venture to ask how far have we been enlightened? Was this type of study in fact calculated to enlighten at this stage? Do the kind of questions both papers put to themselves—at enormous cost of time and labour—tell us anything that we did not know before?

It would be possible to discuss some of the evidence presented—I refer particularly to Dr. Doris Craigmile's paper (p. 749)—in slightly less serious vein. Reading the mass of assembled figures, I longed for a Mr. Schwartz on Sunday to spill them, big and small, into the air like soap-bubbles, juggle with them or let them fall in cascades of glistening fragility, and then return us to the real problems—to what is in fact a major social problem of this day. Not, however, being a Mr. Schwartz, may I put my queries in the form of a few direct questions?

Did we or did we not already know that foot deformities show an undesirable prevalence in early life? Do we or do we not agree that they take an undesirable toll of the comfort and energies, not to say looks, of the community of most Western populations? Are they not in fact costly? Do we or do we not believe that they are not congenital and, since they are eventually disabling, that it is our duty as a profession to prevent them, when our knowledge is great enough? Do we or do we not accept that certain deformities—differing only in degree, not in kind—are more common in adolescent girls and women than in males of the same age? Did we have to be informed that in old age, in a period of major tissue change and degeneration, symptoms mount, and are likely to mount, in both sexes (pace Dr. Craigmile's old ladies, who lose their bunions at 60) and assume new shapes and guises as a greater fraction of the anatomic complex—osseous, ligamentous, nerve, muscular and vascular tissues—is involved?

None of these things, I submit, requires laborious exposition, or analysis, at this stage. The relation between height, weight, and alterations in foot size (D. Hewitt *et al.*, p. 745) is far better

tackled, I would suggest, by insisting on the need for foot measurements every time new shoes are bought (at any age) than by demonstrating what is rational and manifest. Educate the public and the public will, in general, respond.

We, on the contrary, should get on with the problem of the proper protection of the child from early youth into the more mature periods of life, in which new and un-understood factors are unlikely to erupt unbidden, but in which old stresses will begin to show cumulative effects until eventually, in old age, the declension of the entire being causes a calling-in of mortgages, an auditing of all the outstanding accounts of preceding years, that may transmute the clinical characters of what started as a local traumatic lesion. In general, foot deformities are traumatic lesions. Let us deal with the trauma.

If the two studies have provided no major enlightenment, do any points emerge on which further questions arise? I found the following: (a) Some negative evidence in the matter of heel heights and disability—a point still fully open to discussion. (b) Some negative evidence on the inadmissibility of varus metatarsus I as a factor contributing to deformity, the chief point being its apparent tendency to "recede," in both sexes, between the ages of 5 and 15 years. Was this information confirmed by x-ray examination? (c) A failure to observe annual, as opposed to month by month, fluctuations of growth in the feet of the two sexes that might have contributed positive evidence of the effects of specific periods of growth: in particular, a failure to check the effects, if any, of the peculiar spurt of growth manifested by children's feet in the sixth year of life. (d) Some negative evidence, worth clarifying further, on the effects of specific periods of growth on foot deformity—i.e., the considerable increase in cramping of the toes observed by Dr. Craigmille in girls coincidentally with the "third springing-up period" (11-12 years) which comes two years earlier in girls than in boys. (e) A considerably higher rate of valgus ankles in boys than in girls, declining steadily in boys during the school-age period. Could this derive from the later ossification of the secondary epiphyses of the os calcis in boys—at 8 years as opposed to 6 in girls? Does this symptom, very prevalent in both sexes in pre-school life, hinge partly on the presence or absence of the tubercles, of which the posterior medial is the largest, that develop on the lower surface of the os calcis, enabling it to maintain its even keel? How far is the whole symptom of valgus ankles in early youth linked, *inter alia*, with the practice of having a flat, upper heel surface in the shoe, which does not correspond with the inclined plane of the lower surface of the os calcis, minus its tubercles? (f) Some very interesting observations on pes cavus in males at all ages. Has this symptom (I use the word advisedly) ever been related to nervous tensions? Has anyone ever examined statistically the frequency of pes cavus in mental patients of both sexes?

Some bubbles after all sustained their flight! But I revert to my thesis that the work of the future lies with the feet of the children, and with a study of physiology rather than pathology.—I am, etc.,

MARGARET EMSLIE.

London, W.1.

REFERENCE

¹ Harris, H. A. (1947). In *Child Health and Development*, edited by R. W. B. Ellis. Churchill, London.

SIR.—For many years I have been conducting experiments on wear and shrinkage of men's socks, as it had become apparent that many minor disorders of the forefoot were directly attributable to the compression of the toes by hosiery. Among the types tested were the oily woollen fishing socks which are readily available in towns on the West Coast of Scotland, and, although these socks were satisfactory from the aspect of wear and minimum shrinkage, they are rough in texture and quite unsuitable for town wear, although they are remarkably satisfactory for long-distance driving provided there is adequate room in the shoes to accommodate their bulk.

The most unsatisfactory types under test were all-wool hand-knitted socks, which show quite remarkable shrinkages (up to 30%) although they are washed with great care, while the manufactured socks stamped "guaranteed unshrinkable" give some loss of length and girth. Wool and rayon, and wool and nylon reinforced, socks had little or no advantage over the pure wool or wool and cotton mixtures; cotton socks rapidly became harsh and uncomfortable in wear.

On May 13, 1952, I purchased three pairs of 100% spun nylon socks, and one pair was retained as a control while

the other two pairs were worn on alternate days until the end of June, 1953. Each sock was worn and washed 200 times and each was subjected at various times to soaking or boiling in 20% "lysol," 5% "dettol," as well as soaking and boiling in almost every available proprietary washing powder and detergent. The texture of the material has remained very good for 18 months; there has been no breakdown in texture, no holes have appeared, and the length and girth of the test socks still remain identical with the unwashed control socks.

I was surprised to find that the socks were as cool as the same weight of cashmere sock in the summer, and at least as warm as the same weight of woollen socks in the winter, and I was not conscious of cold feet even while driving an unheated 1939-model car. A very notable feature was the quite extraordinary amount of dust or grime in the washing water at each washing. It appears that dirt is much more easily removed from nylon material than from wool, and I feel that these socks would be useful for patients suffering from hyperhidrosis and bromidrosis in particular, and from other skin conditions where cleanliness of the skin of the feet is essential. Several of the commercial washing powders will remove ointment bases from the nylon.

Subsequent tests have shown that daily washing of the socks gives the most satisfactory results, as three, four, or five intervals produce a temporary hardening of the foot of the sock, something like the hardness found in cotton material. As I give quite a number of talks on "foot care" to women's institutes each year I have been a little amused to discover that none of the members (among whom there are many ardent knitters) has been able to identify the spun nylon socks, and these women, who are usually knowledgeable about materials, were surprised to find that the socks were not pure wool.—I am, etc.,

London, S.W.1

C. F. KEMP

Hypothermia

SIR. Your leading article on hypothermia (*Journal*, December 5, p. 1256) interested me considerably, for, as I pointed out some years ago,¹ and probably many others have realized it too, there are many points in common between the action of cold and morphine. Both reduce the body temperature, both depress respiration, and, especially, both reduce the demands of the tissues for oxygen—that is, slow metabolism. Morphine, of course, has also marked effects on the central nervous system, but these are, on the whole, entirely beneficial in anaesthesia. It would seem right therefore to point out that in giving morphine before anaesthesia we are, in some degree, actually achieving some of the advantages claimed for hypothermia. The problem is, How far can we go and what can be done to prevent the obvious possible dangers of increasing the dose of morphine?

In the article quoted I mentioned the case of a missionary in India who had tried to put a woman in the bush out of her misery by giving her an overdose of morphine, only to be greeted by her some years later as the man who had saved her life. I recall, too, a girl who was apparently dying of general peritonitis after an operation (this was in 1915) to whom the house-surgeon, confusing liquor morph. with the injectio morph., gave ten times the dose he had intended. He spent a most uncomfortable weekend while the girl slept solidly, but on the Monday his chief was surprised to find her so much better and she eventually recovered. No doubt many other stories of the life-saving power of morphine might be cited, and no less of unexpected fatalities.

If morphine is to be used for these often unconsidered effects I think we must realize certain things. First of all, its benefit is often mainly due to the fact that it diminishes the tissue demands for oxygen, and if after giving it we persist in trying to maintain the body temperature by hot-water bottles, etc., we are inevitably increasing these demands and so undoing the benefit we may otherwise obtain. It is, indeed, questionable how right we are physiologically in trying to keep up the temperature of a patient during operation if he has had morphine previously. It might be safer to let the temperature drop a little, for the traditional prevention of shock after an anaesthetic by keeping the patient warm was established, as I know, before premedication was at all common. Furthermore, later studies—long after my day—of

electrolyte balance, etc., after operation have shown what a baneful effect fluid loss has; and maybe our present technique is unconsciously increasing this.

The next thing is that morphine undoubtedly depresses respiration. Now Barcroft's work,² to which I referred in a letter recently (*Journal*, August 29, p. 510), showed that in the foetus (and the same probably holds throughout life) asphyxia progressively alters the source of the respiratory rhythm from the respiratory centre itself to lower and lower portions of the C.N.S., and that these respond, not to oxygen lack, but to external or internal stimuli. He pointed out that one of these stimuli is certainly muscle tone, and with the increasing use of muscle relaxants it is clear that this source of respiratory stimulus is diminished or abolished. It is therefore of the utmost importance that any patient who has had morphine should be ensured of an abundant supply of oxygen if normal respiration is to be maintained.

The last point I make is that we have now at hand many agents which can, in case of need, counteract some of the dangers of morphine therapy. As you pointed out in an annotation (*Journal*, August 8, p. 329), the newly introduced N-allyl normorphine has in some unknown way the power of rapidly counteracting the depressive effect of morphine on the respiratory centre. Chilling is not, of itself, a cause of infection, for infecting organisms all multiply very much faster at higher temperatures, but penicillin (and possibly other antibiotics) should prevent chest complications, for the shallow respiration of morphine narcosis is not, *per se*, a cause of congestion or atelectasis; in fact cardiac action, and so the circulation, is probably relatively improved rather than diminished by morphine.

This last statement is, I think, substantiated by the life-saving properties of morphine in cases of coronary thrombosis—not that I am here belittling in any way the effect of the anticoagulants. The question does arise, however, whether when we have given morphine to such cases we do the best for them by keeping them warm, or whether they would not really have a better chance of recovery if we allowed their temperatures to fall to, say, 96° or even 95° F. (35.6° or 35° C.), as in fact it naturally does unless we take measures to prevent it. Admittedly all these points are hypothetical, and perhaps highly controversial, but I think they do arise and that modern treatment might possibly be improved if they were answered, or at least were present in the minds of those who undertake to teach it.—I am, etc.,

Winsted, Cheshire.

Infected Urine

SIR.—The article by Mr. Cuthbert Dukes (*Journal*, December 5, p. 1262) on infected urine in the series "Clinical Pathology in General Practice" has been greatly appreciated, but it is felt that it is concerned more with the examination of urine in the laboratory rather than in the surgery or even the clinical sideroom. It is regretted that Mr. Dukes did not deal more fully with the examination of the urine for pus. Usually this is the first, and perhaps the only, test that needs to be done by the general practitioner when faced with a suspected case of renal tract infection. For this purpose, as Mr. Dukes mentions, microscopy is essential, and it is agreed that "the simplest and quickest" way of doing this is by examining a measured quantity of urine, using a counting chamber (an ordinary blood counting chamber may be used if a Fuchs-Rosenthal is not available). Not only is the counting chamber method to be recommended because it is easy to do, but it is also much more useful than the microscopic field counts method, for it avoids its ambiguity and detects small but significant quantities of pus that otherwise would be missed. The interpretation of microscope field counts of pus cells can be very confusing, as the range of normal excretion cannot be determined precisely since the method is so inaccurate and the quantities of urine examined are variable. On the other hand, Mr. Dukes himself has ascertained the limits of normal excretion of pus cells measured in a counting chamber for uncentrifuged urines from adults,¹ and I wish he had emphasized the value of this method.

Recently observations have also been made on children of all ages² using the counting chamber method. Briefly, it appears that in males and catheter specimens from females urines usually contain less than 50 cells per c.mm., between 50 and 100 cells is suspicious, and over 100 abnormal. In females contamination may occur, but over 500 cells per c.mm. indicates probable infection.

Finally, Mr. Dukes has not mentioned the need for repeated urine examination in a suspected case of renal tract infection. Both pyuria and bacilluria may be intermittent. The diagnosis of renal tract infection cannot be ruled out on the evidence of a single specimen of urine which is normal.—I am, etc.,

Durham.

Unwrapping the "Journal"

SIR.—May I recommend to the attention of your correspondents the following method of resection of the wrapper of the *British Medical Journal*?

An ordinary dinner knife is required. With its aid the free ends of the leaves of the *Journal* are located at one end of the package, and the knife is gently inserted so that it lies between the leaves, with its sharp edge pressing against the wrapper. The knife is then pushed, with a saw-like motion, to the other end of the package, cutting the wrapper as it moves. By this method the *Journal* can be shelled out, like a sebaceous cyst, with minimal laceration both of the operator and of the pages. We in this college would not recommend the attempt without the use of what Dr. Lyndhurst Duke (*Journal*, December 12, p. 1326) describes as a special implement, any more than we would recommend an appendicectomy performed with the bare hands.—I am, etc.,

London Hospital Medical College.

STEPHEN BUTTERWORTH.

A Cosmetic Amputation

SIR.—When those who are amongst the acknowledged leaders of our profession express opinions, these opinions are likely to have a wide hearing. It is therefore unfortunate that opinions which may be controversial should be expressed as *ex cathedra*, as they may then be accorded full and indeed overriding authority. It is particularly unfortunate when the vexed questions which arise in assessment of disability for the purposes of insurance are made the subject of opinions expressed in this way. For these reasons I consider Sir Heneage Ogilvie's letter (*Journal*, December 12, 1953, p. 1322) to be regrettable.

My experience of amputation of the index finger or of the little finger is that many patients are more comfortable and are less functionally disabled if the distal part of the metacarpal is removed. It is not my experience that the movement of the adjoining finger is limited if the amputation is performed in this manner, nor that the occurrence of painful neuromata is more common if the associated metacarpal is removed; indeed, I think it is less so. It is a fact that, if the metacarpal is removed, the scar of amputation can be placed dorsally where it is free from the impacts which fall on the palm or upon the terminal projecting stump which must result from disarticulation of the finger without removal of the metacarpal. The only patients who are adversely affected by lack of breadth of the palm are those engaged in the gripping of heavy objects with large handles such as picks, shovels or heavy hammers, and not all of them are. Those who are working with machinery commonly find the metacarpal stump a considerable nuisance, and indeed often return asking to have it trimmed.

I propose to continue to remove the index finger with the removal of the associated distal part of the metacarpal in most patients requiring this amputation.—I am, etc.,

Edinburgh.

IAN LAWSON DICK.

Chronic Gastric Ulcer

SIR,—Your statement in your leading article (*Journal*, October 17, p. 871) that "in ordinary clinical practice the combination of careful radiology, aided when necessary by gastroscopy, can safely distinguish between them [benign gastric ulcer and early, ulcerating gastric cancer]" is a most remarkable one, and seems to me to require examination and comment.

The phrase "in ordinary clinical practice" is not clear to me. Do you mean by "ordinary" a practice in which the bulk of the patients are just average, run-of-the-mill citizens—perhaps with their medical fees prepaid through taxes—or a general practice, as distinct from one limited to gastro-enteric diseases? The inference that you are referring to some sort of *milieu* in which no very great degree of exactness of diagnosis need be aimed at seems virtually inescapable to me. I trust I have not understood you correctly.

I do not understand, certainly, your implication that the comparative unlikelihood of malignant degeneration in a benign gastric ulcer (which is admitted by most workers, I am sure) contravenes in any way the belief of "many workers in the U.S.A." that "a gastric ulcer carries a 10% chance of malignancy." The word "But," initiating this sentence, seems quite gratuitous. The only thing wrong with your statement about the American workers is that the figure given is too low. Lampert, Waugh, and Dockerty¹ found 13% of 550 radiologically and clinically benign gastric ulcers to be malignant histologically. Allen² found 14% to be malignant under the microscope. Smith and Jordan³ at the Lahey Clinic found 21% of apparently benign gastric ulcers were actually early gastric cancer. Banks and Zetzel⁴ found that 8 of 48 cases of chronic and apparently benign gastric ulcer died of carcinoma.

I know of no radiologist, nor any gastroscopist, who believes he can say with assurance of any ulcerating gastric lesion that it is definitely not a carcinoma. As long as any such statement has to be prefaced with "probably," the decision should be left to the pathologist—quite apart from the fact that about one out of four victims of truly benign gastric ulcer receives any lasting benefit from medical treatment.—I am, etc.,

Hawaii.

Hexamethonium in Acute Pancreatitis

SIR,—In view of the interest aroused in the article by Mr. Russell Davis, Mr. F. T. Moore, and Mr. D. Wynn-Williams (*Journal*, December 5, p. 1251), it may be valuable to record our experiences in this subject. In 1949 we concluded that if hexamethonium would abolish the secretion of hydrochloric acid and inhibit gastric motility for three or four hours it would also serve to diminish or even abolish the production of secretin by the duodenal mucosa. If this proved to be the case, it should then be of value in pancreatitis purely from the point of view of resting the gland. With this in mind, we tried to assess its activity in normal individuals. A Rehfuess tube was passed into the second part of the duodenum under the x-ray screen, 100 ml. of 50% glucose was given by mouth, and suction applied for 4 hours. The following day the experiment was repeated with 100 mg. of hexamethonium given intramuscularly at the same time. The pancreatic juice was measured and its tryptic activity and pH were assessed by Dr. MacGowan. The amount of trypsin was considerably reduced in five cases and was

unchanged in one. The changes in pH were not significant, but in all except one case the volume of the pancreatic juice secreted during the four hours was markedly diminished. This crude experiment suggested that hexamethonium exerted an effect on the pancreas, either by the suppression of secretin or possibly by its autonomic ganglionic blocking activity on the pancreas itself.

Between October, 1949, and February, 1952, with the help of our colleagues in the clinical area, we were able to observe and treat 24 cases of acute pancreatitis. (We took as our criteria a serum amylase above 250 units, associated with severe upper abdominal pain of fairly sudden onset, with vomiting. Actually many cases had a serum amylase above a thousand.) Eighteen of the 24 cases were treated with hexamethonium. In all but five cases there was relief of pain, relief of vomiting, and steady clinical improvement under a dose of 25 mg. four-hourly. Three cases died; two of them after 24 hours with an acute haemorrhagic pancreatitis. The other one died on the third day from coronary thrombosis. Hexamethonium had given complete symptomatic relief. In three cases there was no apparent relief of pain but they nevertheless recovered. One case had no relief from his pain, but there was immediate benefit from intramuscular methantheline ("banthine"). In four cases the blood pressure was so low on admission that it was not deemed advisable to give hexamethonium. Three of these cases recovered.

It was apparent from this that, although hexamethonium gave relief from pain, its side-effects, and especially that of further lowering the blood pressure in an already grave condition, did not make it an ideal drug in this disease. We were of the opinion that methantheline or propantheline bromide ("probanthine"), or even atropine, pushed to its limits, give equal relief without the dangerous lowering of blood pressure. We therefore abandoned its use as a routine measure.

It seems to us that the response to hexamethonium in pancreatitis cannot be held to indicate that thrombosis, embolism, or infarction is a primary aetiological factor. We cannot believe that a further lowering of blood pressure of 10 to 20 mm. Hg is likely to benefit thrombosis or infarction. It is more likely that improvement is due to diminished formation of secretin.

Finally, if laparotomy for this condition is recommended in order to assess the degree of destruction of the gland, then the mortality will steadily rise. In our view, the correct treatment according to our present knowledge (or ignorance) of the aetiology consists mainly in very careful gastric aspiration to prevent acid passing into the duodenum together with a full dose of methantheline or atropine, and supportive therapy. Hexamethonium should only be given initially where the blood pressure is not seriously lowered and continued only where dangerous hypopiesis does not develop. We cannot believe that laparotomy could affect the outcome otherwise than adversely. We are, etc.,

FRANK I. TOVEY

Appendix in the Hernial Sac

SIR,—In view of the recent correspondence on inflamed appendices in hernial sacs, it may be of interest to record a case in an obturator hernia which came under my care in Italy during the war.

The patient was in the W.R.N.S., in the early 20s, and complained of moderately severe right-sided lower abdominal pain. On vaginal examination a hard, tender mass could be felt over the right obturator foramen. In view of this, some displacement of the uterus, and a positive Howship-Romberg sign, a provisional diagnosis of obturator hernia was made. At operation the fimbriated end of the right Fallopian tube and about 1 in. (2.5 cm.) of the appendix were found to be adherent in the sac and inflamed, the right ovary lying over and blocking the foramen. The tube and appendix were reduced and separated and the appendix removed, but not the Fallopian tube, and the sac repaired. Convalescence was uninterrupted.

I reported this case to the North of England Obstetrical and Gynaecological Society, and fuller notes can be found in the proceedings for 1946.—I am, etc.,

Manchester.

DUDLEY RACKER

Obituary

THOMAS COCHRANE, M.B., C.M.

Dr. Thomas Cochrane, who died suddenly at Pinner, Middlesex, on December 7, 1953, at the age of 87, graduated in medicine at Glasgow University in 1896. He then went for a short time to do pioneer medical mission work in Mongolia, and in 1901 he was asked to go to Peking to reorganize medical work in that city, where everything had been destroyed during the Boxer troubles of 1900. He was soon asked to fill important posts. For example, he was known to be interested in bacteriological and public health work, and during an outbreak of cholera he inaugurated and conducted the first official public health campaign in China for the Chinese Government, with the support of Prince Su and Sir Robert Hart. He was appointed medical officer to the Imperial

Maritime Customs and adviser to the Chinese Government. He was acting medical officer for some time to the British Legation at Peking and did medical work in most of the legations in the capital besides attending the highest officials in the empire and the court of Peking.

But Cochrane's greatest contribution to China was in connexion with education. He helped to form and was for a time president of the North China Educational Union, out of which grew the present large university scheme in Peking. He founded and was the first principal of the Peking Union Medical College, which in his hands became the most efficient medical college in China and was taken as the model for government institutions. This college has now become one of the great medical colleges of the world and has made contributions of world-wide value—for example, in the discovery of ephedrine and in other directions. He was appointed one of the trustees of this institution on the Rockefeller Board in New York. He was the first foreigner in China to petition the throne in the interests of scientific medical education, and he received the first and only gift ever made by the throne to a foreigner for educational purposes. The large sum of money he received from the Empress Dowager was followed by a grant of land from the Emperor. A committee was formed, composed of the Emperor, a grand councillor, the president of the Board of Finance, and Sir Ernest Satow, the British Minister: the Chinese members of this committee intimated to all the provincial governors the contribution made by the Empress Dowager, and her example was quickly followed. When the college was built a high commissioner was appointed by the throne to declare it open, which he did in the presence of the most brilliant international assembly that China had ever seen, including princes, dukes, grand councillors, presidents of government departments, and representatives of all the foreign powers. The board of education gave the college the unique privilege of recognition, and the government made annual grants towards the current expenses of the institution. Dr. Cochrane

made other contributions to China through his literary activities, which included *Lectures on Osteology* (in Chinese), a translation of Heath's *Practical Anatomy* into Chinese, *A Survey of China*, and *A Survey of Medical Education in China*.

In 1915 Dr. Cochrane returned to England, where his influence and statesmanship in missionary matters were at once in evidence. He and the late Mr. S. J. W. Clark, influenced very largely by the writings of the Rev. Roland Allan, founded the Survey Application Trust, the object of which was to encourage indigenous principles in missionary planning and to emphasize priorities. The trust sponsored the World Dominion movement which has had a profound influence in missionary strategy. He was editor of *World Dominion* (an international review of Christian progress) since its inception in 1923. In 1931 he founded the movement of World Evangelists, of which he was president. He was a recognized authority on religious, social, educational, and medical mission situations throughout the world and the author of many published surveys.

Dr. Cochrane married in 1896, and his wife shared all his early adventures before the Boxer rising in China. His first wife died in 1930; he married again in 1935 and is survived by his widow and three sons, all of whom are in the medical profession.

CYRIL HORSFORD, M.D., F.R.C.S.

Mr. Cyril Horsford, one of the older generation of laryngologists—probably even better known among singers and actors than in his own profession—died in London after a short illness on December 16, 1953, at the age of 77. It was as a consultant particularly helpful in the ailments of the throat and problems of the voice of singers and actors that Cyril Horsford made his reputation, and at the height of his career he was one of the best-known laryngologists in London. He was himself an accomplished musician, and during the opera seasons at Covent Garden his house was a rendezvous of foreign operatic stars, whose carefree and uninhibited singing in Horsford's friendly salon was wont to enliven the early hours of the morning in Harley Street. Many famous singers have expressed their gratitude in no uncertain terms for Horsford's timely help.

Born at St. Kitts, in the West Indies, on January 25, 1876, Cyril Arthur Bennett Horsford was the son of the Hon. S. L. Horsford and was educated at Bedford Modern School and at Edinburgh University. He graduated M.B., Ch.B. in 1898 and proceeded to the M.D., with honours, in 1902, becoming a Fellow of the Royal College of Surgeons of England in the following year. He was appointed a clinical assistant at the Throat Hospital, Golden Square, in 1902, and from 1905 to 1913 he was registrar at the Central London Throat Hospital. Subsequently he received appointments as honorary laryngologist to the Princess Beatrice Hospital, Kensington, and as surgeon in charge of the

[Hay Wrightson, London]

throat and ear department of the St. Pancras Dispensary. During the war of 1914-18 he served for a time in the R.A.M.C. as an aural specialist with the rank of captain. For many years he was honorary laryngologist to the Royal College of Music, the Royal Choral Society, and the Royal Society of Musicians, and was a popular lecturer to non-medical audiences on such subjects as the anatomy and physiology of the larynx.

Cyril Horsford's contributions to medical literature were comparatively few, but they were all helpful and practical. In discussions at meetings of the section of laryngology of the Royal Society of Medicine he was an occasional but always pungent contributor; and he was a loyal and regular attendee at the dinners of the Edinburgh University Club in London, of which he was one of the oldest members. He married Miss Edith Louise Sayers, adopted daughter of the late Miss Lascelles-Jones, and had a son and a daughter, with whom he led a most happy and devoted family life.—R. S. S.

ADAM BARR, M.B., F.R.F.P.S., F.R.C.O.G.

Dr. Adam Barr, senior obstetrician and gynaecologist at Stobhill Hospital, Glasgow, died suddenly on December 11, 1953, while on his way home from hospital. He was 60 years of age.

Adam Barr was born on May 29, 1893, at Rutherglen, a royal burgh on the outskirts of Glasgow, and there he spent the early years of his life. He graduated M.B., Ch.B. at Glasgow University in 1921, his medical course having been interrupted by a period of service as a combatant in the first world war. After graduation he held several house appointments and then spent five years in general practice. But he had always been much interested in obstetrics, and as soon as the opportunity offered joined the staff of the Royal Maternity and Women's Hospital and the Royal Samaritan Hospital in Glasgow. In 1929 he was given charge of the obstetrical and gynaecological units of the Eastern District, Western District, and Stobhill Hospitals, and, while holding these appointments, acted for a time as professor of midwifery in the Anderson College of Medicine. He relinquished this post to become senior assistant to Professor S. J. Cameron at the university and at the Western Infirmary. He was elected F.R.F.P.S. in 1926 and two years later he took the diploma of L.M. of the Royal College of Physicians of Ireland. In 1940 he became a Fellow—he was a founder member—of the Royal College of Obstetricians and Gynaecologists.

More recently he retired from private practice and from his other hospital appointments and devoted himself entirely to his work as senior obstetrician and gynaecologist at Stobhill Hospital. Under his supervision the obstetrical and gynaecological unit there developed into a department of over 200 beds. The university, recognizing its importance, appointed Dr. Barr an honorary lecturer in clinical obstetrics and gynaecology and arranged that he should undertake the teaching of a considerable number of the university students. He also acted as examiner to the university, to the Central Midwives Board, and to other institutions, including the Royal Faculty of Physicians and Surgeons of Glasgow.

Dr. Barr excelled as a clinician, a teacher, and a consultant. As a teacher, he never forgot that the majority of his students would enter general practice, and he made it his business to fit them for their task. His own early

experience and his gift of stating the essentials in plain terms enabled him to do this with outstanding success. For the same reason no postgraduate course was complete without his lecture on midwifery in general practice. He acquired a very large private practice, which with his hospital work kept him so busy that he had little time for research, even if his interests had leaned in that direction. But his main concern was with the purely practical aspects of his specialty, and his published work deals exclusively with practical matters. Perhaps his most outstanding contribution was the development (in conjunction with Dr. Andrew Tindal) of the Barr-Tindal apparatus for the self-administration of gas and oxygen. Other pieces of work included an investigation into the value of serum in the treatment of puerperal sepsis, and the use of "prontosil" in cases of renal infection.

Outside medicine his main pleasures were a love of the countryside and a keen interest in the Church. He was a devout churchman and took an active share in the services and in the social work of the congregation to which he was attached. He was particularly fond of the old Scottish psalm tunes, and when unable through pressure of work to attend a service he used to play over to himself the records of the old psalm tunes as sung by the Glasgow Orpheus Choir. Dr. Barr is survived by his wife, who is also a doctor, and by his only child (a daughter), who is a second-year medical student; to them, and to his other relatives, we extend our deep sympathy.—J. H.

WILFRED SHAW, M.D., F.R.C.S., F.R.C.O.G.

C. R. M. writes: As a house-surgeon many years ago of the late Wilfred Shaw, whose obituary was printed in the *Journal* of December 19, 1953 (p. 1380), I should like to pay a humble tribute to a great man. Although he will always be remembered for his work in science—especially on ovarian tumours—I shall always think of him as a superb clinician, operator, and teacher. He must occasionally, like all of us, have made clinical mistakes, and yet I cannot recollect an occasion when this occurred. The search for truth was the objective from which he never deviated. Ready at all times to consider the opinions of others, he was equally stubborn in defending his own unorthodox views, if he was sure that he was right. His genius for sifting the mass of material in the modern medical press was remarkable, and a day or two spent with him in the operating theatre, out-patients, or on a ward round were worth any postgraduate course or conference.

To his old students, or for that matter any visitor, he was an inspiration and ever ready to help, advise, or listen. I was privileged to see the proofs of his *Operative Gynaecology*, fortunately completed. This magnum opus, not yet published, will undoubtedly be the brightest star among his other well-known publications. The loss of this remarkable man at such an early age is indeed a severe one to British obstetrics and gynaecology.

The Services

Brigadier A. Sachs, C.B.E., Q.H.P., late R.A.M.C., has been appointed D.D.M.S., and has been granted the temporary rank of Major-General.

Captains R. P. Hickey and D. R. Patchett, R.A.M.C., have been awarded the Military Cross in recognition of gallant and distinguished services in Korea.

Surgeon Captain A. A. Pomfret, O.B.E., R.N., has been appointed Honorary Surgeon to the Queen in succession to Surgeon Captain M. Brown, R.N., who has been placed on the Retired List.

Medico-Legal

BELL'S PALSY IN DRAUGHTY OFFICE

A South-western Electricity Board temporary clerk, Mr. N. L. Andrews, aged 53, of Minehead, Somerset, unsuccessfully brought an action for damages against the Board before Mr. Justice Parker at Devon Assizes recently on the grounds that when employed in the Board's office between December, 1951, and March, 1952, he had to sit in draughts which caused him to suffer from Bell's palsy, with a result that he was now prevented from doing any sustained work. His case was that for the rest of his life he would suffer a considerable degree of disability, and the disease was one which could be caused by exposure to draughts.

Since Mr. Andrews had contracted the disease the Board had fitted draught-excluding devices to the windows and doors of the premises.

Dr. P. B. Stirling Cooper, of Minehead, said he believed that Mr. Andrews's complaint was caused by a draught on the side of his face.

Dr. T. Rowland Hill, consultant in neurology, said the form of palsy from which Mr. Andrews suffered was nearly always caused by a draught striking the face. He thought Mr. Andrews was truthful when he said that he could not work for any longer than half an hour without getting a splitting headache. There had been a nervous reaction in Mr. Andrews, although in about 18 months the patient might be able to do a full day's work again.

The defendants contended that, if the plaintiff was right, even people who had got influenza might be taking out writs against the transport authorities for allowing draughts in trains and buses. An employer was bound to take reasonable precautions for the safety of his employees, but precautions against draughts fell into the category of welfare and not safety. It was not certain that Bell's palsy was caused by draughts. From clinical experience it was thought that was probable, but it had not been established.

Judgment

Giving judgment, Mr. Justice Parker said that on March 30, 1952, Mr. Andrews woke up with his jaw distorted, his left eye closed, and the whole of the left side of his face paralysed. The complaint was correctly diagnosed as Bell's palsy.

It was the plaintiff's case that the disease was caused by the negligence of his employers. A plan showed the office in which Mr. Andrews worked for the Board to be a passage in which Mr. Andrews had said that the office was very draughty room. Witnesses had said that the office was very draughty and cold with badly fitting doors, and people who walked through left the doors open. But there had been a good deal of exaggeration in the evidence given on the part of the plaintiff, and he was satisfied that the office was no more draughty than any other office, subject of course to its being a passage room.

The latest theory was that certain people were predisposed to Bell's palsy. On the balance of probabilities he was satisfied that in the Board's office the conditions did predispose that disease in a man already predisposed towards it in the sense that he already had a virus infection of a nerve. There was no question of the employers' having the slightest knowledge or suspicion that the plaintiff was so predisposed to that disease. Eliminating that, one asked oneself what steps a reasonable and prudent employer should take in regard to his office staff in conditions such as those in that case. Conditions in the Board's office were quite comparable with those existing in other offices and were not such as the employers ought reasonably to have foreseen injury to health, although they might well recognize that there was discomfort, as opposed to danger to health. The defendants in that case had not been guilty of any breach of duty and the claim therefore failed.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on October 31 the following medical degrees were conferred:

D.M.—R. G. White, E. O. Field, E. C. Hoff.

The Board of the Faculty of Medicine has awarded medical scholarships to Roland David Stedeford (Worcester College) and Ortwin Answald Alwin Bock (University of Pretoria).

UNIVERSITY OF CAMBRIDGE

In Congregation on November 14 the degree of M.A. was conferred on F. W. Campbell, Ph.D., M.B., Ch.B., University Lecturer in the Department of Physiology, and the degrees of M.B., B.Chir. on R. J. Hutchinson (by proxy).

The following degrees were conferred on October 31:

M.D.—D. H. M. Woollam, T. M. Robinson, R. B. Welbourn. M.A.—C. W. McE. Pratt, M.B., Ch.B., University Demonstrator in Anatomy.

M.B., B.Chir.—Mrs. Stella M. E. Ambache (by proxy).

UNIVERSITY OF ABERDEEN

The following medical degrees were conferred on October 28:

Ch.M.—G. E. Mavor.

M.B., Ch.B.—Frances Allan, J. G. Barnett, G. R. Buchan, Vera C. Coutts, B. B. Dale, N. L. Edmond, J. D. Garden, W. Geddes, J. D. Johnston, D. Macintosh, J. McNab, C. O. Macrae, A. N. Milne, V. J. Murphy, G. G. Rennie, T. F. Rennie, N. F. Stewart, J. V. Watt, Isobel M. Wood.

UNIVERSITY OF LONDON

The Court of the University has re-elected Sir Archibald Gray as deputy chairman, and Dr. C. F. Harris has been elected chairman of the Academic Council.

Dr. P. W. Rowland has been reappointed representative of the University on the governing body of the Colchester Royal Grammar School.

Mr. J. H. Daggart has been recognized as a teacher of ophthalmology of the University at the Institute of Ophthalmology.

The Laura de Saliceto Studentship has been awarded to Dr. H. J. G. Bloom for a period of two years in the first instance from October, 1953; the A. H. Bygott Scholarship, tenable for one year, to Dr. T. A. Plumley; a University Studentship in Anatomy to A. W. Rogers (London Hospital Medical College); and a University Studentship in Physiology to J. J. Misiewicz (St. Bartholomew's Hospital Medical College).

The title of Reader in Entomology, as applied to Hygiene, in the University has been conferred on J. R. Busvine, Ph.D., D.Sc., in respect of the post held by him at the London School of Hygiene and Tropical Medicine.

The following degrees were awarded by the Vice-Chancellor on behalf of the Senate on September 30:

M.D. (INTERNAL).—Helen Ingleby.

M.S. (INTERNAL).—F. B. Cockett.

UNIVERSITY OF WALES

The following candidates at the Welsh National School of Medicine have satisfied the examiners at the examination indicated:

TUBERCULOUS DISEASES DIPLOMA.—T. B. Master, J. Morgan, C. Michie, B. Sinha.

UNIVERSITY OF LEEDS

Dr. D. G. F. Harriman has been appointed Lecturer in Neuro-pathology in the Department of Pathology.

UNIVERSITY OF SHEFFIELD

The following appointments are announced: Dr. Alison Chapman, Whole-time Assistant Medical Officer to the Student Health Service; Dr. T. Smith, Part-time Lecturer and Clinical Teacher in Obstetrics and Gynaecology; Dr. D. H. Blakey, Part-time Honorary Tutor in Obstetrics and Gynaecology; Dr. R. S. Weetch, Part-time Honorary Lecturer in Therapeutics.

Dr. M. G. Philpott has resigned his appointment as Tutor in Child Health.

The John Stokes Medical Research Fellowship has been awarded to Mr. R. Whittam.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
‡ Includes puerperal pyrexia.

DEATHS

Benton.—On December 15, 1953, at 228, Old Shoreham Road, Hove, Sussex, Austin Lewis Benton, M.B., B.S.
Crofton.—On December 11, 1953, at Hertford, Herts, John Hutchinson Crofton, M.B., B.Ch.
Dobbin.—On December 15, 1953, Dorothy Isabel Dobbin, M.D., D.P.P.

fluid must be used. The veins that are being injected are very thin-walled and are often covered by a very thin layer of epithelium. For these reasons, even with the most careful intravenous technique, it is possible that the overlying epithelium may not be strong enough to withstand even a mild inflammatory reaction following the injection of a minute dose of sclerosant.

Is Bell's Palsy Infectious?

Q.—I have encountered three cases of facial palsy in rapid succession in my practice. Is this just a coincidence, or is the condition infectious?

A.—The aetiology of the common facial palsy (Bell's palsy) is not known for certain, but many people consider it is probably infective in nature. Small groups of cases occurring together in a locality are not rare.

Home Electrolysis

Q.—Home electrolysis outfits for the removal of superfluous hair are now on the market. Are these suitable to recommend to patients for use in their own homes?

A.—The chief danger with electrolysis is over-treatment. In most cases the current needs to be passed for only a few seconds, and if the needle is held in place with the current passing for too long there results an excessive area of necrosis leading to a slough, perhaps a millimeter or so in diameter. This can only result in a scar. It does not seem very likely that a patient treating herself will cause this kind of damage provided that she is sensible and properly advised by her doctor. Infection is never likely to be a serious problem provided elementary precautions of cleanliness are taken; in any case this risk seems no more likely in the home than in a beauty parlour.

It is not, of course, every person who will be able to acquire the manual dexterity for carrying out this rather delicate operation; the seven-day free trial period should be sufficient to enable a patient to decide about this. Self-treatment of hairs on the front and central part of the face is easy for the patient herself; at the side of the cheeks not so easy; and under the chin, where superfluous hair is often present, a very difficult task.

Prickly Heat

Q.—What is the aetiology of prickly heat? What are the main diagnostic features distinguishing it from other skin rashes? What is the most successful treatment?

A.—Prickly heat is generally held to be caused by blockage of sweat ducts by keratinous plugs. Sweat is thus held back in the glands and is responsible for the papular rash. Prolonged sweating with maceration of the cells in the horny layer of the skin is the commonest precursor, but injury caused by ultra-violet light, application of chemicals, or adhesive plaster may act in a similar way. The relationship of sodium to the aetiology of the condition remains rather in doubt.

The diagnostic features are the appearance of the rash after a period of at least several days' exposure to high environmental temperature, especially if the atmosphere be humid. The body flexures, chest, back, shoulders, and abdomen are the commonest sites affected, and the rash is almost invariably symmetrical. Seborrhoeic dermatitis may sometimes be simulated, but the history and aggravation of symptoms while sweating are distinctive features of prickly heat, while there are no macular or plaque-like lesions such as are common in seborrhoeic dermatitis. In miliarial rashes caused by various local applications the distinguishing characteristics are the more limited distribution and history of exposure to the agent concerned.

Innumerable powders and lotions are recommended for the treatment of the condition, their very multiplicity being testimony of their ineffectiveness, while some of them may lead to a complicating dermatitis medicamentosa. Measures

taken to keep cool and to avoid sweating alone are likely to be effective—that is, the use of fans, light loosely fitting clothing, and the avoidance of excessive exercise, particularly during the warmer parts of the day.

Incest: Marriage to a Sister-in-Law

Q.—(a) With what relatives is it incestuous to cohabit? (b) Does the law allow marriage between a divorced man and his former sister-in-law?

A.—(a) Under the Punishment of Incest Act, 1908, Section 1 (i), a male person who has carnal knowledge of a female who is to his knowledge his granddaughter, daughter, sister, or mother, is guilty of a misdemeanour. Under Section 4 a female of or above the age of 16 who permits a person who is to her knowledge her grandfather, father, brother, or son to have carnal knowledge of her is guilty of a misdemeanour.

(b) The Deceased Wife's Sisters' Marriage Act, 1907, permits the marriage, in so far as it is a civil contract, of a man with his deceased wife's sister. It is unlawful for a man to marry the sister or half-sister of his divorced wife or of his wife by whom he has been divorced during the lifetime of the wife, or the divorced wife of his brother or half-brother, or the wife of his brother or half-brother who has divorced his brother during the lifetime of the brother or half-brother.

Parotid Enlargement in Primitive Peoples

Q.—Is there any explanation of the bilateral chronic enlargement of the parotid glands found in primitive peoples in various parts of the world? Here in Borneo it occurs not uncommonly in the Murut tribes; it arises in childhood and is definitely not due merely to an increase in adipose tissue. Mumps is not uncommon among these tribes: could that be the cause?

A.—Enlargement of the parotid glands has latterly been recognized as one of the results of protein deficiency, and it is unlikely that mumps is responsible in the cases in question. Other organs developmentally similar to the parotids, such as the salivary and lacrimal glands and the pancreas, may also be damaged. In malignant malnutrition, kwashiorkor, and allied syndromes parotitis is not uncommon.

Glycerin in Obesity

Q. Can glycerin be used as a sweetening agent in the treatment of obesity?

A. Glycerin is largely converted to glucose in the body. There would therefore seem to be no theoretical basis for its use in obesity.

"Any Questions?" Book. The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

SPONTANEOUS HYPERINSULINISM DUE TO ISLET-CELL ADENOMA

BY

K. O. BLACK, M.D., F.R.C.P.

R. S. CORBETT, M.Chir., F.R.C.S.

J. P. HOSFORD, M.S., F.R.C.S. AND

J. W. ALDREN TURNER, D.M., F.R.C.P.

(From the Departments of Medicine, Surgery, and Neurology, St. Bartholomew's Hospital, London)

Spontaneous hyperinsulinism resulting from a tumour of the islets of Langerhans is not a common condition, and the diagnosis is easily overlooked. Failure in the diagnosis usually results in the early death of the patient, while diagnosis followed by operative removal of the tumour cures the majority of patients.

Nicholls (1902) first described an adenoma of the islet cells of the pancreas, but this was an incidental finding at necropsy and no clinical details of the case were recorded. Following the discovery of insulin, Harris (1924) suggested that symptoms might be caused by excess secretion of the hormone, and the first demonstration of an insulin-secreting tumour was by Wilder *et al.* (1927); they explored the pancreas of a doctor, aged 40, who had suffered from attacks of spontaneous hypoglycaemia for eighteen months, and found a carcinoma in the tail of the pancreas with metastases in the liver. The cells of the carcinoma bore a striking resemblance to islet cells, and insulin was extracted from one of the liver metastases.

The first successful operative removal of an insulin-secreting tumour was by Roscoe Graham in 1929 (Howland *et al.*, 1929), who found a small tumour in the body of the pancreas of a woman of 52 who had a seven-years history of attacks of spontaneous hypoglycaemia. The tumour was composed of islet cells, and as it lacked a capsule it was thought possibly to be a carcinoma, but no metastases were found. This lack of a capsule has been a feature of a number of islet-cell tumours subsequently studied, and is not now regarded as an indication of malignancy. Another successful operation was performed at about the same time, for Harvey Cushing (1930), in his Lister Lectures on neurohypophysial mechanisms, mentioned that a small islet-cell adenoma which had caused recurrent attacks of hypoglycaemia had recently been removed in his clinic. Since then the condition has attracted much attention in the United States, no fewer than 38 cases being reported from the Mayo Clinic in twenty years (Lopez-Kruger and Dockerty, 1947), while reviews have been published on both medical (Crain and Thorn, 1949) and surgical aspects of the problem (Howard *et al.*, 1950).

In Great Britain the number of reported cases is comparatively small. Apart from Nicholls's early pathological observation, the first report is that of Barnard (1932), who found an islet-cell adenoma at the

post-mortem examination of a patient in whom the diagnosis had been suspected clinically but who had declined further investigation or operation; post-mortem reports have also been published by Cairns and Tanner (1933), Lawrence *et al.* (1942), Webster and Blades (1952), and Cunningham *et al.* (1952). The first successful operative removal of an adenoma in Great Britain seems to be that reported by Fraser *et al.* (1938), and nine other reports of single cases successfully treated by operation have subsequently been published (Rudd and Walton, 1941-2; Rayner and Rogerson, 1943; Haines, 1946; Dickie, 1946; Holmes *et al.*, 1946; Bishton and Malins, 1947; Murray, 1949; Wood, 1951; Smith and Cochran, 1952); and Cohen (1950) has recorded two cases. There has also been a single report of an islet-cell carcinoma with liver metastases (Brearley and Laws, 1950), and one case in which attacks of spontaneous hypoglycaemia were thought to be caused by diffuse hyperplasia of the islet cells without tumour formation (Graham and Oakley, 1950). Richardson and Russell (1952) have reported five cases from the London Hospital; operation was carried out in three of these; in two an islet-cell adenoma was removed with complete relief of symptoms, while in the third patient the tumour was a carcinoma with a metastasis in the liver.

We have had under our care in St. Bartholomew's Hospital in the course of four years three patients with attacks of spontaneous hyperinsulinism, in each of which an islet-cell adenoma has been removed, with a successful result.

Case 1

A male Post Office counter-hand aged 27 was admitted to hospital on August 16, 1947, complaining of fits. The history, obtained from the patient and his wife, started in February, 1946. He then began to have attacks of sweating, trembling, and a feeling of unusual hunger. These occurred in bed in the morning or just before the midday meal. The symptoms were relieved by taking food and usually did not last more than about 10 minutes. At first they occurred infrequently, with symptomless intervals of as long as two or three months, but they grew more frequent, and by October, 1946, were occurring at the rate of one a week. By January, 1947, the attacks had become more severe. They began to occur when he was asleep, and his wife was unable to rouse him. Once he was incontinent, and on another occasion he bit his tongue. Attacks during the day started with blurring of vision, a feeling of dizziness, and

some slurring of speech and general bewilderment. Apart from these attacks she had been normal in every way, and had no memory of the attacks.

The patient was a dissimilar twin, and the past history was uneventful except for two minor head injuries due to falls from a horse. There was no family history of epilepsy.

When examined on admission to St. Bartholomew's she was normal mentally, and there were no abnormal signs in the nervous or other systems. Blood pressure was 160/95, and the urine contained neither sugar nor albumin.

As hyperinsulinism seemed the probable diagnosis the crucial test was to induce an attack by fasting: accordingly she had no food on November 4 from 9 a.m. onwards; by 10 a.m. on November 5, after a 25-hours fast, she was drowsy and confused, could give no history, appeared vacant and flushed, and her speech was slurred. She was not, however, sweating noticeably. The pupils were widely dilated but reacted normally to light, and both plantar responses were extensor. At this time the blood sugar was 45 mg. per 100 ml. She was given 50 g. of glucose by mouth and within 20 minutes was fully awake and alert; she seemed normal mentally, her pupils were considerably smaller, and the plantar responses were flexor.

A sugar-tolerance test was carried out after this fast, with the following result. Fasting, 45 mg. per 100 ml. After 50 g. glucose by mouth: 1 hour, 190 mg.; 2 hours, 130 mg.; 3 hours, 89 mg.; 4 hours, 54 mg.; 5 hours, 48 mg.; 6 hours, 46 mg. A barium meal showed no deformity in the duodenum.

An E.E.G. on November 8 (in fasting state—blood sugar 45 mg. per 100 ml.) showed unstable alpha rhythm of very irregular amplitude, with spread into the frontal areas. Excessive generalized slow waves were present in all areas. Overbreathing slowed the alpha rhythm and greatly increased the slower frequencies, which often became paroxysmal and of increased amplitude. After 22 ml. of 33.3% glucose intravenously there was a marked reduction in the slow frequencies, and the alpha rhythm became more steady in amplitude and was reasonably stable.

On November 16 the pancreas was explored by R. S. C. A more extensive search had to be made which involved not only the mobilization of the head of the pancreas, as in Case 2, but also an incision of the peritoneum along the inferior border of the pancreas after entering the lesser sac. It was only after turning up this lower edge of the gland that the tumour was seen embedded in the posterior surface of the tail, lying just above the splenic vein. An enucleo-resection was carried out with preservation of the splenic vein. The space left was obliterated with interrupted sutures of catgut as in Case 2 and the pancreas replaced. The wound was closed without drainage. This was an error in technique, for in three weeks a left subphrenic abscess formed in the lesser sac. This was drained through a left lateral incision and the fluid contents showed large quantities of diastase. Following this, recovery was uneventful, and the patient was discharged six weeks later.

Pathological Report (Professor Blacklock).—"The tumour measures 2.5 cm. in its greatest diameter and is 0.5 cm. thick. It is well encapsulated, fragments of the pancreas being still adherent to the capsule. The tumour is rather plum-coloured on the surface, though on section there are paler fleshy areas in it. The tumour weighs 1.85 g. Microscopically the growth consists of masses of small cells resembling the cells of the islet tissue of the pancreas. The tumour is fairly well encapsulated and is a typical islet-cell tumour."

There were no hypoglycaemic attacks after the removal of the islet-cell adenoma, and a glucose-tolerance curve on January 14, 1952, gave a fasting level of 86 mg. per 100 ml., rising to 115 mg. per 100 ml. after 50 g. of glucose and falling to 74 mg. per 100 ml. two hours later.

When seen in May and in November, 1952, she was very well, had had no further hypoglycaemic attacks, and had returned to her work as a groom.

Discussion

Symptoms

The important feature in the early stages, and often throughout the whole course of the illness, is paroxysmal attacks, of which two main types occur. The less serious type was well illustrated by the early attacks in Case 1, and is thought to be due to excess liberation of adrenaline in response to a rapid fall in the blood-sugar level. These attacks consist in sweating, trembling, general weakness, and nervousness, and often palpitations and precordial discomfort without impairment of consciousness. The more serious type of attack is due to a disturbance of cerebral function, resulting from the low blood sugar, and these attacks vary greatly in type, not only from patient to patient but in different attacks in the same patient. They may consist of short confusional episodes often associated with automatic behaviour, major epileptic attacks with convulsions, periods of stupor in which bilateral extensor plantar responses may be found, or prolonged coma with, in a severe attack such as occurred in Case 2, signs of decerebrate rigidity. Cerebral attacks were the presenting symptom in Cases 2 and 3, while in Case 1 they began a few months after the onset of attacks, due to excess adrenaline secretion. Attacks of either type tend to occur some hours after a meal and are not uncommon early in the morning, as was well illustrated in Case 3, in which the two severe attacks occurred before breakfast. In general, attacks occur with gradually increasing frequency and severity, though periods of complete freedom may occur as in Case 2, in which after an extremely severe and prolonged attack there was a period of freedom lasting three months.

If the condition is not treated, more permanent changes may develop: in particular there may be a change in personality, with intellectual deterioration and emotional changes. Case 2 presented a curious mental state with poor memory, affective lability, apathy, and a general lack of co-operation, all of which features improved after the removal of the islet-cell adenoma, and within a few weeks of operation her parents thought that her mental condition had returned to normal, and shortly afterwards she resumed her work as a schoolteacher. Comparable mental changes occurred in the patient from the Maudsley Hospital reported by Fraser *et al.* (1938).

Transient focal neurological disturbances such as hemiparesis or aphasia may occur during the attacks of hyperinsulinism, and, more rarely, permanent neurological changes may develop: Case 2 had a complete left hemiplegia following a prolonged hypoglycaemic attack, and, though gradual improvement took place over the course of months, she still had a mild residual hemiparesis; a similar occurrence has been recorded by Crain and Thorn (1949). These rare permanent neurological sequelae are presumably due to actual death of nerve cells resulting from prolonged hypoglycaemia.

Lawrence *et al.* (1942) have studied the cerebral changes in six fatal cases of hypoglycaemia—three diabetics suffering from insulin overdosage, two patients dying during insulin treatment for schizophrenia, and one islet-cell adenoma unsuspected during life—and they found similar changes in all six patients. There was widespread degeneration and necrosis of nerve cells with microglial and macroglial proliferation, the most severe changes being in the cerebral cortex, the caudate nucleus, and putamen, with only slight changes in the cerebellum and brain stem. These changes are very similar to those found in cerebral anoxia and are thought to be due to failure of the normal oxidative processes in the cells from lack of glucose. Although these pathological changes are probably the basis for permanent neurological sequelae, it is difficult to understand why a hemiplegia should occur: one would expect that both hemispheres would be equally affected by prolonged hypoglycaemia, with a resulting double hemiplegia rather than a unilateral hemiplegia, and it is possible that vascular factors are also important.

Lower motor-neurone lesions may also occur as a result of hypoglycaemia and confuse the diagnosis. Silfverskiöld (1946) described two patients with islet-cell adenomas: one developed gross wasting and weakness of the hand muscles, without fibrillation, and weakness of both ankles following a prolonged hypoglycaemic attack; and the other had a bilateral flaccid foot-drop in similar circumstances. Lidz and others (1949) removed an islet-cell adenoma from a patient with severe mental changes, cerebellar ataxia, and extensive muscle-wasting in both legs, without fibrillation: after operation the mental condition and ataxia improved while the muscle-wasting remained unaltered. Tom and Richardson (1951) showed that the cause of a lower motor-neurone lesion of this type was destruction of spinal anterior horn cells occurring during prolonged hypoglycaemia in a patient in whom an islet-cell tumour was found at post-mortem examination. In their case the diagnosis had not been made during life, largely because of the confusing feature of severe localized muscle atrophy in the legs.

Diagnosis

Whipple (1938, 1944) has suggested three criteria for the diagnosis of functioning islet-cell tumours: (1) attacks of nervous or gastro-intestinal disturbance occurring in the fasting state; (2) during the attacks hypoglycaemia with a blood sugar below 50 mg. per 100 ml.; and (3) relief of symptoms immediately by the ingestion of glucose. Whipple's triad is of great value in attacks deliberately induced by a period of fasting as a diagnostic measure, but there may be deviations from it in the attacks which occur spontaneously. In some patients the time relationship of attacks to fasting is by no means obvious, as attacks may occur three hours or so after a meal without any sensation of hunger. More confusing is the fact that the blood sugar may have risen above 50 mg. per 100 ml. while the patient is still unconscious: this was illustrated in Case 3, whose blood sugar was 60 mg. per 100 ml. when she was stuporous and had bilateral extensor plantar responses. Prompt recovery from the attack is usual when glucose is given either by mouth or intravenously, but if the hypoglycaemia has been severe and prolonged this rapid recovery may not occur. Case 3 had been comatose for about 24 hours when she was admitted to St. Bartholomew's and her blood sugar was 55 mg. per 100 ml., but, in spite of intravenous glucose and a gastric drip containing glucose, her recovery was very slow, and it was at least 48 hours before she became conscious.

The most useful confirmatory test is to fast the patient for 12 to 24 hours: if an attack occurs the blood sugar must be estimated and then the effects of oral or intravenous glucose observed. Under these controlled circumstances Whipple's three criteria hold good in the majority of cases. In each of our three patients attacks occurred after 14 hours, and in Case 3 after 24 hours; in each case blood sugars below 50 mg. per 100 ml. were recorded and the attack was rapidly stopped by administration of glucose. We have used this fasting test in a number of other patients whose histories suggested the possibility of hyperinsulinism, most of whom were in fact suffering from epilepsy or hysteria, without an attack being induced and without the blood sugar falling to below 80 mg. per 100 ml.

Differential Diagnosis

Spontaneous hypoglycaemia is known to occur in a variety of conditions. These include organic hyperinsulinism, liver disease, functional hypoglycaemia, certain diseases of the endocrine glands, and a miscellaneous group of which starvation and severe renal glycosuria are examples. None, however, is so likely to enter into the differential diagnosis of islet-cell tumour. Hypoglycaemic crises are not a feature of anorexia nervosa, and hypoglycaemic symptoms are absent or unobtrusive. Addison's disease and Simmonds's disease will be recognized by their other clinical manifestations. In practice, then, the problem which confronts the clinician is to distinguish between liver disease, functional hypoglycaemia, and a tumour of the islets of Langerhans.

No difficulty arises with the hypoglycaemia of severe damage to the liver parenchyma with jaundice, but hypoglycaemia occasionally results from minor degrees of liver damage. Conn and others (1938) reported six cases of hypoglycaemia due to an ascending infection of the biliary tract. One of his patients, a man aged 47, had repeated hypoglycaemic crises ending in unconsciousness. These always occurred between 3 and 7 a.m. A biopsy taken at operation showed cholangitis with early biliary cirrhosis. The gall-bladder contained stones and pus, and its removal was followed by complete disappearance of hypoglycaemic attacks. Whipple's triad may fail to distinguish between organic hyperinsulinism and hepatic hypoglycaemia. It is therefore advisable to include radiological examination of the biliary tract and tests of the liver function in the investigation of patients with spontaneous hypoglycaemia.

Difficulty is likely to arise in differentiating organic hyperinsulinism in its early stages from functional hypoglycaemia, which is by far the commonest of all the causes of spontaneous hypoglycaemia. The distinction is an important one, because the treatment of the former is surgical whereas in the latter medical treatment is effective and surgery is to be avoided. It can usually be made with reasonable certainty on clinical grounds. Functional hypoglycaemia is of the stimulative type: the blood sugar is normal even after prolonged fasting, and hypoglycaemic attacks do not occur during the night or before breakfast. They are confined to the daytime and occur two to four hours after meals. The clinical course of organic hyperinsulinism is progressive, the hypoglycaemic crises becoming increasingly severe and frequent, whereas functional hypoglycaemia is not progressive. Undoubtedly the crucial test is the fasting test, which leads to hypoglycaemic symptoms in organic hyperinsulinism but not in functional hypoglycaemia. The glucose-tolerance test is less reliable. The fasting blood sugar is normal in functional hypoglycaemia and the blood sugar falls to subnormal levels two to four hours after the administration of glucose. A sharp rise to 200 mg. per 100 ml. or more immediately after the glucose is characteristic of the hypoglycaemia which sometimes follows operations on the stomach.

Glucose-Tolerance Tests

Glucose-tolerance tests are of less value in the diagnosis of islet-cell tumours than is a fasting test. Very varied results have been recorded in the literature (Crain and Thorn, 1949), but this may be partly due to the fact that they have been carried out under varying conditions of diet. Duncan (1947) has suggested that a standard diet containing 350 g. of carbohydrate in 24 hours should be given for the three days before a six-hour glucose-tolerance test. Under these conditions a patient with a functioning islet-cell tumour usually has a subnormal fasting blood sugar; the highest peak rarely exceeds 120 mg. per 100 ml. and the level falls to subnormal values within two hours, and these low values continue during the third to sixth hours. In our first case a standard diet was given before the glucose-tolerance test: the blood sugar rose to a peak of 125 mg. per 100 ml. and subnormal levels were not reached until the fourth hour. In the other two cases a standard diet was not given, and in fact the tolerance curve in Case 3 was carried out after a 24-hour fast. In this patient the blood-sugar level rose to 190 mg. per 100 ml. at the first hour and did not fall to a subnormal level (54 mg. per 100 ml.) till the fourth hour. In Case 2 glucose-tolerance tests were carried out on two occasions with a seven-months interval between them: the first curve was practically within normal limits except that after three hours the level was 69 mg. per 100 ml. and remained in the sixties at the fourth and fifth hours; the second test fulfilled all Duncan's criteria.

Electroencephalography

It is recognized that marked E.E.G. changes occur during hypoglycaemia: Hofer *et al.* (1946) studied 11 of Whipple's patients who had functioning islet-cell tumours. The most typical abnormality was high-voltage slow activity occurring

in synchronous bursts all over the head, with considerable improvement in the record after intravenous glucose. He found no clear-cut correlation between the degree of E.E.G. abnormality and the blood-sugar level in the five patients in whom this was studied. In our second patient the E.E.G. was recorded at intervals from the fourteenth to eighteenth hours of a fast, with blood-sugar estimations. The findings of high-voltage slow activity agreed with those of Hoefler *et al.*, and, although from the sixteenth to twentieth hours the blood sugar was rising slowly, there was no progressive improvement in the E.E.G. record or in the clinical state till intravenous glucose was administered, when both the E.E.G. and the clinical condition rapidly returned to normal. In Case 3 when the blood sugar was 45 mg. per 100 ml. the E.E.G. showed generalized slow waves which were greatly increased by overbreathing, and considerable improvement occurred in the record following intravenous glucose. The E.E.G. does not afford any great help in the diagnosis of these patients, but it is perhaps worth stressing that diffuse abnormality in an E.E.G. record of a patient in stupor or coma does not necessarily indicate a primarily intracranial cause for the coma, as both the coma and the abnormal E.E.G. may be the result of disordered brain metabolism from conditions such as hypoglycaemia.

Treatment

The treatment of hyperinsulinism due to an islet-cell adenoma is by surgical removal of the tumour when possible. Once other causes of hypoglycaemia have been excluded and the diagnosis of organic hyperinsulinism has been made, the pancreas should be explored without delay because of the possibility of malignancy, the risk of permanent damage to the central nervous system, and increasing obesity. An intravenous infusion of 5 or 10% glucose solution is set up beforehand and continued throughout the operation. Transient hyperglycaemia may follow operation: it occurred in Case 1 and was easily controlled by soluble insulin, given twice daily.

Medical treatment is notoriously unsuccessful but may be the last resort if operation is refused or if there is a malignant growth with metastases. A predominantly protein-and-fat diet with little carbohydrate, though useful in functional hypoglycaemia, will not prevent the occurrence of severe hypoglycaemic attacks from an islet-cell tumour. A large carbohydrate intake and frequent meals are necessary to prevent attacks. Attempts to destroy the beta cells by alloxan have not been encouraging, and severe toxic effects may result. Extracts of adrenal cortex and of the anterior pituitary have proved disappointing. Growth hormone was tried in Case 1: it produced some elevation of the blood-sugar level, but not enough to be of practical value. It is possible that a combination of adrenocorticotrophin and growth hormone may prove to be more effective.

Surgical Treatment

In all three cases there was a solitary tumour, removal of which brought complete relief of symptoms. A right paramedian incision was used in two cases and a transverse incision in the third, a very adequate exposure of the whole pancreas being obtained in each case.

If the tumour is not seen or felt on any part of the anterior surface of the pancreas, a thorough search must be carried out. The posterior surface of the head is examined by dividing the peritoneum on its lateral side of the duodenum, mobilizing the second part of the duodenum. In Cases 1 and 2 the tumour was felt in this position and was exposed in this way: enucleation was effected after incising the pancreatic tissue over it. An enlarged lymph node was found lying adjacent to the common bile duct in Case 2. The undersurface of the body and tail are examined by making an incision along the inferior border of the pancreas, after entering the lesser sac. In Case 3 the tumour was found on the posterior surface of the tail.

The tumours were enucleated from the pancreas and the cavity obliterated with catgut sutures. It is not to be put a

drain down to the area through a stab incision in the right or left loin, to prevent a collection of blood and ferment and to avoid abscess formation. If a pancreatic fistula forms, as in Case 1, it will close spontaneously and the surrounding skin can be prevented from becoming sore by applying suction. In Case 3 the leak produced a subphrenic abscess as a result of not draining.

From the cases reported it seems that these tumours are small (1-2 cm.), red or purple in colour, and firm in consistency compared with ordinary pancreatic tissue. They are often buried in the gland and can occur anywhere from the head to the tail. In Case 1 the search was given up at the first operation and in Case 3 it was almost given up. A lymph node may be mistaken for the tumour on palpation, but the appearance (Case 2) is quite different. No sign of malignancy was found, which from reports is a rare occurrence.

Summary

Three cases of spontaneous hyperinsulinism due to an islet-cell adenoma are described. The removal of the adenoma in each case resulted in relief of symptoms, whereas a resection of three-quarters of the pancreas in one patient had caused only temporary improvement.

The symptomatology is discussed, and it is stressed that permanent neurological damage may occur in a prolonged hypoglycaemic attack.

The crucial diagnostic test is a period of fasting of up to 24 hours. In attacks produced in this way Whipple's diagnostic triad is fulfilled, which is not invariably true in spontaneous attacks.

Four field medicines issued to British troops during the Crimean War have been added to the Pharmaceutical Society's historical museum. The bottles, labelled "The British Pharmacy, Smyrna," contain powdered rhubarb, milk of sulphur and cream of tartar, calcined magnesias (for indigestion), and ipecacuanha wine (for coughs).

INVASION OF INTERNAL MAMMARY LYMPH NODES IN CARCINOMA OF THE BREAST

BY

R. S. HANDLEY, O.B.E., M.B., F.R.C.S.

Surgeon, Middlesex Hospital; Surgeon, St. Albans City Hospital

AND

A. C. THACKRAY, M.D.

Reader in Morbid Anatomy and Histology, Middlesex Hospital Medical School

For the past 150 years isolated observers have been calling attention to the internal mammary lymph chain and its importance in the spread of carcinoma of the breast. No great notice has been taken of their words because they have not provided convincing proof. In 1946 it occurred to us that quantitative microscopical proof of the role of the internal mammary chain in malignant disease of the breast could be obtained by biopsy during the course of a radical mastectomy. The surprising results of this simple procedure have from time to time been published (Handley and Thackray, 1947, 1949; Handley, 1950, 1952). It is intended now to bring this published information up to date and to try to discern whither the facts are leading in the realm of treatment.

Anatomy of the Internal Mammary Lymphatic Chain

The internal mammary lymph nodes receive lymph chiefly from the medial side of the breast and from the region of the nipple, but there is considerable overlap in the territories drained by them and by the axillary system. Afferent lymphatics from the breast reach the chain by perforating the intercostal muscles, for the most part where the anterior perforating arteries emerge. The nodes themselves lie posterior to the intercostal muscles, and Stibbe's (1918) diagrams (Figs. 1 and 2) show their general arrangement. They are inconstant both in position and in number, and there exist many very tiny nodes which are recognizable only by the microscope. The chain begins in the sixth intercostal space, where it receives lymph from the diaphragm and liver, and it ends, again inconstantly, in a node which lies behind the sternal head of the sterno-mastoid muscle and which discharges direct into the great veins. Nodes most often occur in the second, first, and third spaces in that order of frequency, and it is to nodes in these spaces that lymph from the breast is mostly discharged.

Technique of Internal Mammary Biopsy

To remove a node for purposes of biopsy is a finicking procedure, but by no means difficult. A 1-in. (2.5-cm.) incision in the intercostal muscles, running from the edge of the sternum, midway between and parallel with the costal cartilages, will reveal extrapleural fat, imbedded in which are the lymph nodes of the chain and the internal mammary vessels; the latter usually lie about $\frac{1}{4}$ in. (6 mm.) clear of the sternum. To detach lymph nodes requires a nice touch with two pairs of dissecting forceps, particularly as the nodes are often minute; any fatty tissue removed from a plane deep to the intercostal muscles should be sectioned as it often

contains a microscopic node. The only peril attending the procedure is laceration of the internal mammary artery, but this accident should be easy to avoid, and has not occurred in the series described here. Tears of the pleura are of no great consequence if they are recognized, and this accident has occurred to us on five occasions without untoward post-operative sequels.

Material

The series on which internal mammary biopsy has been carried out consists of 150 cases. It is as continuous as it has been possible to make it. All patients being treated for the first time by surgery have been subjected to the biopsy. Second primary tumours occurring in the opposite breast, tumours in men, and tumours treated first by radiotherapy have been excluded. Of the 150 patients, 139 have been judged, on clinical grounds, to be operable; in 11 the biopsy was exploratory in

FIG. 1.—The internal mammary blood vessels and chain of lymph nodes seen from within the thorax. (After Stibbe.)

FIG. 2.—Sagittal section of the chest wall showing the pectoralis major to the left, two costal cartilages cut across, and an internal mammary lymph node lying behind the intercostal muscles. (After Stibbe.)

patients who were judged inoperable. During the time in which these numbers have been accumulating, approximately 45 additional cases have been seen in which, for one reason or another, but chiefly because of advanced spread, surgery as a primary measure has not been undertaken and no biopsy has been done; it is reasonable to suppose that, had they been included, the overall percentage of invasion of the internal mammary chain would have been higher. An analysis by quadrant, and by the numbers in which axillary metastases were found, does not differ greatly in its distribution from the large published series—for example, Truscott (1947)—and it may therefore be taken that our series is representative in these respects. One of us (R.S.H.) has done all the biopsies and the great bulk of the accompanying surgery. The latter, in the 139 operable cases, has consisted of 117 radical mastectomies, 3 Margottini operations, 3 Urban operations (see below), and 16 extended simple mastectomies. All diagnoses are based on histological evidence, with the exception of the state of the axillary nodes in one of the clinically operable cases and in 8 of the 11 inoperable cases. All these unproved axillary nodes have been reckoned as invaded. In the earlier cases only the second intercostal space was explored.

SPINAL EPIDURAL ABSCESS

BY

ALLAN HULME, F.R.C.S.

Late Senior Registrar in Neurosurgery, South-western Regional Neurosurgical Unit, Frenchay Hospital, Bristol

AND

NORMAN M. DOTT, C.B.E., F.R.C.S.Ed., F.R.S.Ed.

Professor of Neurological Surgery, University of Edinburgh

Infection of the spinal epidural fatty areolar tissue by pyogenic organisms is generally regarded as a rare condition. Although a well-recognized clinical entity, it has received little attention in British medical literature. In contrast, that of the United States contains a number of excellent reviews of the subject, notably by Dandy (1926), Gasul and Jaffe (1935), Browder and Meyers (1937, 1941), Rankin and Flothow (1946), Huesner (1948).

In 1926 Dandy found only 25 cases in the literature. Rankin and Flothow were able to review 225 cases in 1946, and two years later Huesner reported a further 20 cases.

This communication is based upon a series of 25 cases of spinal epidural suppuration, 19 of which have been treated in the department of surgical neurology, Edinburgh Royal Infirmary, between 1933 and 1952, and 6 in the Bristol Neurosurgical centre during the past four years. In Bristol during the same period there were 21 cases of spinal tumour, 10 of which were meningioma or neurinoma. This is too small a series from which to draw deductions, but it does at any rate suggest that spinal epidural abscess is proportionally a not infrequent cause of interference with spinal cord function.

Since a presentation of the entire series would be too lengthy, the following case histories have been selected to illustrate various features of the illness.

Case 1

This case indicates the usual course of events in the acute metastatic type of infection before penicillin was available.

A youth aged 18 had malaise and fever a few hours after the extraction of an infected tooth. This was followed by an increasing low lumbar backache and pain at the back of both thighs. His temperature was 102.6° F. (39.2° C.). Acute tenderness over L 4 spinous process and severe back pain were aggravated by any movement. The abnormal neurological findings were hyperreflexia in the lower limbs, bilateral extensor plantar responses, and hyperaesthesia of the buttocks and thighs posteriorly.

The lower three lumbar laminae were removed, disclosing a localized extradural abscess containing staphylococcal pus. Pus was tracking outwards along the fourth and fifth lumbar roots. The wound was only partially closed, the central portion being left open to provide free drainage. Fever and toxæmia continued, and cerebrospinal fluid (C.S.F.) escaped from the wound. The patient died 27 days after operation.

At necropsy pus was found to have extended between the necks of the right eleventh and twelfth ribs and into the psoas sheath. A sloughing patch was found on the dura opposite the abscess and there was a generalized purulent meningitis.

Case 2

This case illustrates, in contrast, the satisfactory result obtainable by early surgical intervention and the use of antibiotics.

A healthy girl of 9 years complained of pain in the back, of fairly sudden onset. Next day the pain extended into the

left thigh. Later she became delirious and was admitted to hospital with a provisional diagnosis of tuberculous meningitis. She was found to have some weakness of the left hip flexors and a depressed left knee-jerk. The left plantar response was equivocal. Lumbar puncture yielded thick staphylococcal pus from the epidural space.

Laminectomy of the second and third lumbar vertebrae was performed, and pus was found both within and external to the vertebral canal. The wound was closed in layers with indwelling tubes for instillation of penicillin into the epidural space in doses of 20,000 units twice daily for eight days. Intramuscular penicillin, 500,000 units twice daily, was continued for two weeks. The wound healed, and the patient left hospital cured, 18 days after her admission. At a re-examination eight months after operation the only residual abnormality was very slight weakness of eversion at the left ankle.

Case 3

The disastrous results of delaying operation, despite the elimination of infection by antibiotics, are indicated in this case.

A man aged 64 gave a history of septic arthritis of the knee four years prior to his recent illness; this was followed two years later by osteomyelitis of the tibia. His spinal malady began with lumbo-dorsal backache and girdle pains round his left flank and across his abdomen. Eleven days later he developed a complete flaccid paraplegia within the space of 24 hours. He also had retention of urine.

He was retained for eight days in another hospital, where a suprapubic cystostomy was done. When he was referred to the neurosurgical department three weeks after the onset of his illness he presented a complete paralysis of the lower limbs and a sensory level on the trunk at the T 10 segmental level. The x-ray film showed poor definition of the left pedicle of the tenth dorsal vertebra.

A laminectomy of the eighth to the eleventh thoracic vertebrae was performed, exposing red adherent granulation tissue on the surface of the dura and a few millilitres of pale yellow pus from which a penicillin-sensitive staphylococcus was cultured. The wound was closed with indwelling catheters down which penicillin (20,000 units twice daily for five days) was instilled. Systemic penicillin and sulphonamide therapy was given.

The wound healed by first intention, but though post-operative lumbar puncture demonstrated a complete absence of a spinal subarachnoid block there was no improvement in the neurological state.

Case 4

Occasionally, as in this case, the abscess is very extensive and may indeed involve the entire length of the vertebral canal. Despite this a most satisfactory result may be obtained.

A healthy child aged 2 years had a trivial fall. The next day she complained of pain in her right lower limb and of headache. She was unable to walk. A week later she developed fever and signs suggestive of meningitis. Purulent fluid was obtained on lumbar puncture. The lumbar puncture was repeated next day, and on this occasion frank pus, yielding a mixed growth of *Staph. aureus* and *Str. faecalis* was obtained.

Examination revealed weakness and some extensor rigidity of the lower limbs with extensor plantar responses; sensory testing, though inaccurate in such a young patient, seemed to show a depression of pain sensation up to the level of the iliac crests. Despite the clinical evidence of meningitis, the cisternal C.S.F. contained only 10 polymorphonuclear leucocytes per ml.

An exploration of the fenestration type was done between the laminae at L 1 2 and L 3 4 on the right side, and at L 2 3 on the left. Pus under slight pressure was released. A catheter was passed upwards extradurally through the entire length of the spinal canal, and a smaller tube down

into the sacral region. Further pus was released by saline irrigation. The wound was closed with these tubes *in situ*. Penicillin was instilled down the tubes in doses of 30,000 units, at first four-hourly and later 12-hourly.

Pyrexia subsided, and within nine days active movements of the lower limbs were noted. Two months later recovery was complete.

Case 5

This case presents an entirely different clinical pattern, and illustrates not only the prolonged course which may be followed in some instances but also the fluctuation in neurological signs and difficulty in diagnosis.

A girl aged 16, whose previous health had been good apart from a crop of boils, developed pain in the left lumbar region after playing games and doing gymnastics. The pain persisted and was aggravated by movement. Two weeks later she developed tingling and numbness in the lower limbs, followed by difficulty in walking, and increasing weakness progressing to complete paraplegia. There was impairment of sensation below the umbilicus, and retention of urine. A lumbar puncture yielded C.S.F. "under decreased tension," but unfortunately no record is available of the response to jugular compression, and the protein content was not estimated.

After about three months some spontaneous return of motor power began, and continued during the next three years. Lumbar puncture was repeated eight and a half months after the beginning of her illness and then showed no block and a protein of 30 mg. per 100 ml. of C.S.F. A diagnosis of "transverse myelitis" was made. Although she remained spastic and ataxic she was able to walk and had adequate bladder control.

Twelve years after the original onset of her illness she again suffered mid-abdominal girdle pains, and 20 days later developed complete numbness and rigidity of the lower limbs and retention of urine. This increase in neurological disability took place over a period of two days. Examination showed a complete flaccid paraplegia, sensory loss below T 11, and a complete spinal subarachnoid block. By myelography the block was localized at the level of the twelfth thoracic body.

Laminectomy T 7 to T 12 was performed, exposing dura covered with granulation tissue containing pockets of pus from which a penicillin-sensitive *Staph. aureus* was cultured. Normal dura was exposed above and below. The wound was closed with indwelling catheters, and treatment by local instillation of penicillin and streptomycin and systemic administration of the same antibiotics was undertaken.

During the past seven months there has been minimal return of motor and sensory functions in the lower limbs, but she remains virtually paraplegic, and no substantial improvement is anticipated.

In retrospect there seems little doubt that this patient suffered an acute attack of epidural inflammation with cord involvement at the beginning of her illness. This subsided spontaneously, perhaps aided by sulphonamide therapy, leaving a persisting low-grade infection which flared up again 12 years later without any known precipitating cause. Similar cases of prolonged duration with fluctuations in neurological disability have been recorded in the literature.

Case 6

This case of vertebral osteomyelitis was complicated by epidural suppuration.

A man aged 22 had an amputation through the left thigh for purulent arthritis of the knee and osteomyelitis of the femur. Shortly afterwards he experienced pain in the back of his neck, and noted some weakness of his right lower limb. The weakness improved for a time with massage, but four and a half months later the neck pain increased and he developed paralysis of his lower limb, partial loss of sensation below the lower cervical dermatomes, and incontinence of urine and faeces.

The neurological findings tended to be somewhat variable but on the whole progressive. X-ray films of the cervical spine showed evidence of chronic osteitis in the form of gross erosion and new bone formation in relation to the lower three cervical vertebral bodies. A marked increase in the thickness of the prevertebral soft tissues was also apparent. Lumbar puncture demonstrated a complete subarachnoid fluid block.

On exploration a chronic extradural abscess cavity with a smooth granulating wall was found. The prevertebral swelling was also explored and a small quantity of turbid fluid evacuated.

Despite drainage, the subarachnoid block remained unrelieved, and the patient died about one month after operation. Antibiotics were not available at this time. Shortly before death he developed a suprapatellar bursitis from which *Staph. albus* was cultured. It therefore seems that he continued to have a persistent pyæmia.

Case 7

The course of the illness in the more chronic type of case is illustrated by the following history.

A 45-year-old man gave a seven-months history, beginning with pain below the right scapula which radiated to the lower chest and abdomen. Three months later he sustained a heavy blow on the left lumbar region and buttock, and about a month after this experienced mid-abdominal girdle pains and an electric-shock sensation in his legs. Two weeks later, gradually increasing weakness and sensory depression in the lower limbs began. There were no sphincter or constitutional disturbances.

On examination he showed a moderate paraparesis and impairment of sensation below the eighth thoracic segment. There was no spinal tenderness. Myelography demonstrated a block at the level of the seventh thoracic vertebral body, and on exploration at this level the dura was found covered with vascular granulation tissue containing minute pockets of pus from which a hæmolytic streptococcus was cultured. The wound was closed with indwelling catheters and treatment with repeated local instillation of penicillin instituted.

Gradual improvement in neurological function followed, and recovery was complete in eight months.

Case 8

This case is an example of the rare type of infection giving rise to a true chronic granuloma.

A man aged 36 gave a history of typhoid fever complicated by erysipelas. Since that time, for five years, he had suffered from pains in the right hypochondrium which were attributed to indigestion.

For five months he had had girdle pains at about the ninth thoracic segmental level, worse on the right side. For six weeks he had experienced pain in the back of the right knee, and tingling paraesthesiae radiating from the right side of his body down to the right knee on coughing. Two days after the onset of these pains, weakness of both lower limbs, starting on the right, began and progressed over the next four days.

Examination showed a fit-looking man with a flaccid paraplegia and sensory "level" $\frac{1}{2}$ in. (1.3 cm.) below the xiphisternum. Myelography demonstrated a gradually tapering obstruction in the upper thoracic region, and at laminectomy a very vascular granuloma was exposed; this was densely adherent to the dura, and in order to relieve pressure on the cord the dura was carefully incised at the upper limit of the mass, the arachnoid being kept intact; the incision was then carried longitudinally throughout the length of the granuloma, allowing the arachnoid to bulge through. C.S.F. was seen to pass caudally beyond the obstruction.

Histologically the granuloma consisted of chronic inflammatory tissue containing aggregations of lymphocytes, and on culture yielded a Gram-negative non-motile non-lactose-fermenting bacillus which was not definitely identified.

After transitory improvement his condition deteriorated, and lumbar puncture demonstrated a subarachnoid fluid block. Re-exploration was therefore undertaken some three weeks after the first operation. The incision through the granulation tissue was found to have refilled with the same dense inflammatory mass. This was again split longitudinally and partially excised in order to free the cord, which was found to be greatly constricted at the level of the fifth thoracic lamina. There was only minimal return of motor power, and the patient died two and a half months later. Before death, *Bact. coli* and streptococci were cultured from an effusion in the knee-joint, and the blood culture yielded *Bact. coli*.

While the granuloma in this case was never definitely proved to be due to infection with an enteric type of organism, the evidence suggests that this may have been so.

Judging from the experience in this case, simple division of the constricting granuloma would appear to be insufficient to provide lasting relief of cord compression, and it seems necessary to perform at any rate a fairly generous excision of the inflammatory tissue. Even so, nutrition of the cord may perhaps be too grossly impaired by this stage for useful recovery to ensue.

Cases 9 and 10

These are examples of cases in which infection was due to direct implantation of organisms.

Case 9.—A 39-year-old man had a lumbar puncture while under investigation for headache. Some hours later he complained of pain in the back and right thigh, and two days after this he developed pyrexia with shivering which persisted despite penicillin therapy. He was acutely tender over the lower lumbar spinous processes. Epidural suppuration was suspected and exploration performed; no pus or granulation tissue was found, but a swab taken from the extradural fat showed very large numbers of polymorphonuclear leucocytes in the smear. The wound broke down and yielded thin pus, from which no organism could be cultured. Recovery was eventually complete.

Case 10.—A soldier sustained a through-and-through thoraco-abdominal wound, with the exit wound in the left buttock. The missile traversed gut, which was repaired. The patient showed a severe lesion of the cauda equina, which failed to improve. Six months after injury the cauda equina was explored and the nerve roots were freed from scar tissue. Chronic inflammatory granulation tissue was found in the epidural space. The wound was closed with tubes for instillation of penicillin. Some improvement in neurological function followed, though he remained virtually paralysed below the knees.

Aetiology and Pathology

With rare exceptions the *Staph. aureus*, usually coagulase-positive, is the causative organism. It reaches the epidural space either by the blood stream or by local extension of infection.

Haematogenous infections are derived most commonly from septic skin and subcutaneous lesions such as boils and pimples, but respiratory and urinary tract infections are among the many other possible sources of organisms.

TABLE I.—Summary of Findings

Source of Infection *	No.	%
Cutaneous or subcutaneous suppuration	8	32
Other distant foci of suppuration	3	12
Respiratory infection	3	12
Direct implantation	4	16
? Typhoid	1	4
Not known	6	24
Total	25	100
Trauma (direct and indirect) a probable aetiological factor	9	36
Operative, radiological, or post-mortem evidence of vertebral bone or joint infection	7	28

Trauma to the spine seems to play a definite precipitating part in a number of instances, perhaps by producing a haematoma in which organisms may readily multiply.

Direct infections arise most commonly as a complication of vertebral osteomyelitis. Spread from a neighbouring suppurative lesion such as retropharyngeal abscess, probably by means of a spreading thrombophlebitis, also occurs. Direct implantation of organisms by wounds or a contaminated lumbar puncture needle is an obvious possibility. The relevant findings in the present series are summarized in Table I.

Pathological Anatomy

Although any level, and occasionally the entire length, of the vertebral canal may be involved, most cases of blood-borne infection are located in the upper and mid-thoracic region. This predilection is believed to depend on the anatomical distribution of the epidural tissue, which is of greatest thickness between the fourth and eighth thoracic vertebrae and again below the second lumbar vertebra, at which level a few cases occur. Anteriorly the theca is in contact with the posterior common ligament, and since the epidural areolar tissue is restricted to its dorsal and lateral aspects the infective lesion is similarly situated. In the present series 12 cases occurred in the thoracic and five in the lumbo-sacral region. The cervical region was involved in three cases, and the whole canal in one.

In the rare *anteriorly placed abscesses*, which occur in association with vertebral osteomyelitis, longitudinal spread is limited by adherence of the dura, but for the same reason penetration of the theca may occur, leading to a suppurative meningitis or myelitis.

In *posterior abscesses* there is much less resistance to axial spread, and pus and granulation tissue may extend widely along the spinal canal; usually, however, the extent is limited to a few vertebral segments. Cohen (1938) drew attention to the possibility of the formation of gravitational abscesses in the lumbo-sacral region from a primary focus at a higher level. In these common cases the dura forms a resistant barrier to the spread of infection, so that, although a C.S.F. pleocytosis of a few hundred cells is commonly found, a purulent meningitis is uncommon.

Not infrequently pus tracks outwards into the extra-vertebral tissue planes.

Local Pathological Process

The inflammatory reaction varies from an acute fulminating infection, with severe constitutional disturbance, to a chronic condition extending over months or even years; it probably begins as a septic thrombophlebitis initiated by a coagulase-positive organism. In most cases vascular granulation tissue containing pockets of pus of very variable size is found. In more chronic cases there is a dense adherent granuloma, often closely resembling neoplastic tissue. These chronic granulomata are much less common than the acute and subacute varieties of infection.

Despite the resistance of the dural barrier, disastrous pathological changes soon occur in the *spinal cord*; these consist of liquefaction and vacuolation in the cord substance, and microscopically of all stages of degenerative change up to death and disappearance of nerve cells and disintegration of fibre tracts. It is generally believed that these changes are caused by thrombosis or stasis in blood vessels supplying or draining the cord, a view which is supported by the rapidity with which signs of cord damage progress.

In the adult, between four and ten arteries entering the cord on each side constitute the main vascular supply to their own and neighbouring segments, by way of longitudinally disposed anastomotic vessels. The venous drainage follows a somewhat similar pattern. Stasis or thrombosis in one of these important vessels is likely to produce widespread changes, which develop early in the course of the infection and progress rapidly to a stage of irreversible damage.

Clinical Features and Diagnosis

Acute and Subacute

In most cases the illness follows a fairly constant pattern of development, and the following stages may be recognized (Rankin and Flothow, 1946; Huesner, 1948): (1) the stage of spinal ache; (2) the stage of root pains; (3) the stage of impairment of cord function, leading to sphincter disturbances, and early motor and sensory loss; and (4) the stage of complete paralysis. An antecedent history of infection, frequently of a minor cutaneous nature, is often obtainable, but this is by no means invariable.

The time relations between the several stages varies. Transition from stage 3 to 4 is usually rapid, however, and may occupy only a few hours. This fact is insufficiently recognized.

The onset is often fairly rapid, and accompanied by malaise and fever. The blood shows a polymorphonuclear leucocytosis, and a positive blood culture is often obtainable.

The *back pain* occurs at the level of infection; it is often agonizing, and increased by movement, especially flexion as opposed to extension (Stammers, 1938).

Tenderness on spinal percussion or pressure at the appropriate level is a most important localizing sign. There may be local swelling or redness of the skin.

Root pains, sometimes accompanied by paraesthesiae, make their appearance within a few days, or, in some cases, less than 24 hours.

Headache is common, and neck rigidity and a positive Kernig's sign are often found.

In subacute cases, and those secondary to vertebral osteomyelitis, the period of spinal ache may be more prolonged and of less severity, and the onset of root pains may be delayed for a week or two.

Careful neurological examination at this early stage will often reveal reflex changes indicative of early pyramidal tract involvement. *Lumbar manometry* shows absent or sluggish response on jugular compression, indicating a spinal subarachnoid fluid block. The C.S.F. shows an increase in protein which is of greater degree in more chronic cases, and a pleocytosis of up to perhaps 200 cells, mostly lymphocytes. This investigation is of great importance in establishing the differential diagnosis from such non-surgical conditions as transverse myelitis, and should not be omitted. It must of course be performed with care, advancing the needle a millimetre or so at a time, and aspirating frequently lest a lumbar abscess be present. With reasonable caution there is little risk of carrying infection into the theca.

The development of stage 3, with obvious signs of impaired cord function, occurs usually within a few days of the development of root pains. Retention of urine is often an early symptom. Pain tends to diminish with development of sensory loss.

The transition to stage 4, with complete motor and sensory loss below the level of the lesion, often occurs with disastrous rapidity. In seven cases in the present series, 24 hours or less elapsed between the appearance of the first neurological abnormality and the development of stage 4.

In the *chronic type of infection* the course is much more prolonged, extending over months or even years; the signs of cord dysfunction may fluctuate, sometimes undergoing spontaneous remission. The constitutional phenomena of infection are absent, and the pattern of the illness closely resembles that of extramedullary spinal tumour.

The most important factor in the diagnosis of spinal epidural abscess is awareness of its possibility. The urgency and potential gravity of these cases must be more widely recognized.

No fewer than 12 cases in the present series had a virtually complete paraplegia when presented to the surgeons. It cannot be too strongly emphasized that, once signs of inter-

ference with cord function begin to appear, the situation is one of extreme urgency and every hour of delay diminishes the chances of recovery.

Myelography may be required to establish the precise level of the lesion when the local and neurological evidence is equivocal in this respect.

Radiographs of the spine are not often helpful, since the infection in most cases is too recent to have caused visible changes in the bones.

Treatment

Once the diagnosis is established, exploration is urgently indicated. The objects of operation are (1) to release pus, and decompress the theca and its contents; and (2) to provide means for repeated local application of antibacterial substances by means of thin indwelling tubes. In the first instance a limited opening into the vertebral canal should be made by removal of ligamentum flavum and portions of adjacent laminae at one or more levels. If pus in quantity is found, this will often suffice to allow insertion of thin rubber catheters to the extremities of the abscess cavity, for repeated aspiration of pus and instillation of antibiotics.

Where the lesion consists largely of granulation tissue containing small pockets of pus, a complete laminectomy should be performed throughout the length of the infected area. If the granulation tissue is thick and dense, excision by careful sharp dissection is indicated, in order to obviate subsequent stricture of the theca by scar tissue.

In children, in whom preservation of the laminae is of importance in order to avoid the later development of a kyphosis, the laminae may be elevated in a continuous string, preserving the ligaments, so that they may be replaced at the conclusion.

The catheters are brought out through stab incisions adjacent to the main wound. In the great majority of cases primary healing can be achieved, with appropriate antibiotic therapy vigorously applied locally and systemically. An early report on the culture and sensitivity of the organism is essential. It must be emphasized that antibiotics are in no sense regarded as a substitute for early and adequate surgical intervention.

Results

The prognosis with regard to survival has undergone a dramatic change since the introduction of the sulphonamide drugs and antibiotics. Previously a fatal outcome was the rule in all acute and subacute cases not treated surgically, and also in a large number of those subjected to operation (Campbell, 1937). In Huesner's series, before 1939 there were eight acute cases with three deaths: in a group of ten similar cases after 1939 there was only one death.

The prognosis for recovery of cord function bears a close relationship to the severity of neurological deficit at the time of operation. We have been unable to establish any clear correlation between the duration of paralysis and the degree of recovery. Our impression is that once conduction in the cord becomes severely compromised it is already too late to achieve any substantial degree of recovery in most cases. This does not imply, however, that the severely paralysed case should be regarded with any less urgency, since a number of remarkable recoveries have been recorded.

The results in the present series are given in Table II.

In Table III the severity of neurological impairment at the time of operation and the subsequent degree of functional recovery in the survivors are presented.

TABLE II.—Results

Category	No.	Died	Survived		
			Full Recovery	Partial Recovery	No Recovery
Acute	13	4	4	3	2
Subacute	7	3	—	2	2
Chronic	5	2	1	1	1
Total	25	9	5	6	5

TABLE III

Degree of Neurological Deficit Before Operation	No.	Degree of Recovery		
		None	Partial	Complete
None or slight	4	—	—	4
Moderate	4	—	2	—
Complete or very severe	7	4	3	—

One case in which disability was mainly due to severe trauma of the cauda has been excluded.

Summary

The results in 25 cases of spinal epidural suppuration, with illustrative case histories, are presented. The importance of recognition of the urgency and potential gravity of these cases is emphasized.

The survey indicates that, with early recognition and treatment prior to the onset of gross neurological abnormalities, satisfactory recovery can be anticipated in most cases; while delay until signs of severe cord damage become apparent usually results in permanent, crippling disability.

The most important factor in early diagnosis is an awareness of the possibility of the condition, and an appreciation of the rapidity with which the pathological process advances to an irreversible state.

Acknowledgments are due to Mr. G. L. Alexander and Mr. D. G. Phillips for permission to publish the Bristol cases and for helpful advice and criticism. Cases 1 and 4-10 are from the Edinburgh series and Cases 2 and 3 from Bristol.

LOW GAMETOCYTE THRESHOLDS OF INFECTION OF ANOPHELES WITH PLASMODIUM FALCIPARUM A SIGNIFICANT FACTOR IN MALARIA EPIDEMIOLOGY

BY

R. C. MUIRHEAD-THOMSON, D.Sc.

Malariaologists have long been familiar with the inconsistencies experienced when trying to infect anopheles with malaria parasites by feeding them on patients showing falciparum gametocytes—crescents—in the blood. Those subjects with the heaviest infections have not necessarily been the most infectious—in fact, they have sometimes proved completely non-infective. Many of these discrepancies have been attributed to the great disparity in the sex ratio of the crescents, to the possibility that the gametocytes are not "ripe," and so on. Up till a few years ago, however, it was fairly generally assumed that, as the number of crescents in the blood decreased, a point was eventually reached when low density alone became a limiting factor, the subject becoming non-infective at a time when crescents could still be detected in the blood film without too much difficulty (Boyd, 1949). Those ideas seem to have been so firmly implanted that carriers with very scanty

crescent infections were almost automatically rejected as a possible means of infecting anopheles in the laboratory or in the field.

Martin Young and his colleagues (1948), working with a negro population in South Carolina, showed, however, that those ideas would have to be revised considerably. They were able to infect 10 lots of *Anopheles quadrimaculatus* (nearly half of the total infective lots) at a time when falciparum gametocyte counts were less than 5 per c.mm. Of these, five cases had fewer than one gametocyte per c.mm.; and finally a few mosquitoes became infected at a time when parasites were too scanty to be detected in the ordinary microscopical examination.

Similar observations, although on a much smaller scale, were made with *Anopheles albimanus* and a negro population in Jamaica during 1950 (Muirhead-Thomson and Mercier, 1952). These observations made a particularly deep impression on us, as at that time we were unaware of the findings in South Carolina. After feeding a batch of *A. albimanus* on a 3-year-old subject who had previously been a good carrier and infecter, routine examination of the thick film taken at the time of feeding failed to reveal a single crescent, and it was dismissed as negative. The mosquito batch was kept as a matter of curiosity, and one-third of them (12 out of 37) eventually developed gland infections. Later, another subject was found to be infective at a time when only a single crescent was present in over 200 thick-film fields—0.12 crescents per 1,000 leucocytes, or less than 1 per c.mm.

Present Investigation

In the Gold Coast recently this work has been continued more intensively, using laboratory-bred *Anopheles gambiae* and working in an area west of Accra where malaria is hyperendemic. In order to find out the crescent carriers and to determine the gametocyte rate of the village population that is, the proportion showing falciparum gametocytes in first examination—thick blood films were examined rather more thoroughly than usual, no slide being dismissed as negative until at least 200, and usually more, oil-immersion fields had been examined. The gametocyte rate—or rather crescent rate—of the population examined is shown in Table I.

TABLE I.—Incidence of *P. falciparum* Gametocytes in African Population, Weijsa, Gold Coast, 1952

Age Group (Years)	No. Examined	No. with Crescents	% Positive (Gametocyte Rate)
0-1	52	21	40.4
2-4	62	16	25.8
5-9	148	22	14.8
10-14	78	9	11.5
15 and over	151	9	5.9

Although the gametocyte rates are rather higher than usual, the general trend is similar to that found by other workers in West Africa (Barber and Olinger, 1931; Young and Johnson, 1949; Bruce-Chwatt, 1951), the higher age groups, 15 years and over, having low gametocyte rates as well as low gametocyte densities. Heavy gametocyte infections were comparatively rare, only 1 out of 491 people examined showing over 200 crescents per c.mm. Shute and Maryon (1951), in a thin-film survey in Lagos, had the same experience, only 2 out of 800 children showing 200 or more crescents per c.mm. Higher figures have been recorded elsewhere (Barber and Olinger, 1931; Robertson, 1945; Bruce-Chwatt, 1951), but they are evidently exceptional.

The actual infectiousness of as many of these crescent carriers as possible was tested by feeding batches of 40-50 laboratory-bred *A. gambiae* on them, blood films being taken at the time of feeding. The mosquitoes were dissected four to seven days after feeding, when falciparum oocysts with their characteristic pigment (Shute and Maryon, 1952) could best be detected in the mosquito stomach. In a few of the more heavily infected batches some of the mosquitoes were kept until salivary gland infections developed.

In all, 73 batches of *A. gambiae* were fed on 32 crescent carriers of all ages from 4 months upward. Of these, 24 batches became infected from 14 carriers.

In previous work in West Africa the lowest thresholds of infection were recorded by Robertson (1945), who found four infections at thresholds below 3 crescents per 1,000 leucocytes; in one batch 1 out of 13 *A. gambiae* being infected cytes; when the crescent density was 0.7 per 1,000 leucocytes—that is, less than 5 per c.mm.

In the present investigation, of the total number of batches infected, nearly half (46%) were recorded at crescent densities below 3 per 1,000 leucocytes. On six occasions—that is, 25% of total infected batches—the crescent density at the time of feeding was below 1 per 1,000 leucocytes (Table II).

TABLE II.—Particulars of Mosquito Infections Obtained at Falciparum Gametocyte Thresholds Below 1 Crescent per 1,000 Leucocytes

Age and Sex of Subjects	Crescents per 1,000 Leucocytes	Mosquitoes Dissected	Positive		Mean No. Oocysts per Positive Stomach
			No.	%	
F, 2½ years	0.52	13	3	23	1.7
F, 5 "	0.20	21	2	9	1.5
M, 5½ "	0.27	20	1	5	3.0
F, 9 "	0.26	12	1	8	1.0
F, 9 "	0.10	10	1	10	1.0
M, 10 "	0.16	18	1	6	1.0

The two lowest figures recorded correspond to a density at or below one crescent per c.mm., the first crescent being found only after examination of 300-400 oil-immersion thick-film fields. Those slides would normally have been dismissed as negative for crescents, and it was only the knowledge that the subjects were actually infective to mosquitoes which made the search so prolonged and persistent.

From Table II it will be seen that of the total number of mosquitoes feeding on those subjects with low crescent counts the proportion infected is usually about 10% or less, and that the intensity of infection is also low—from 1-3 oocysts in each positive stomach. These figures will be seen in their right perspective if we compare them with what happens with the most infectious subjects found in this African village survey. In the four most efficient infectors found—whose crescent densities covered a wide range from 1.2 to 24.0 crescents per 1,000 leucocytes (roughly 8 to 150 per c.mm.)—it will be seen from Table III that the number of oocysts per positive stomach remains fairly low.

Of the 87 positive mosquito stomachs in this series, 76 (89%) had fewer than 10 oocysts per stomach, and only 4

TABLE III.—Record of Experimental Feeds on Four Most Infectious Crescent Carriers in Gold Coast Village Survey

Age and Sex of Subjects	No. of Mosquito Batches Fed	Range of Crescent Density during Most Infective Periods (per 1,000 Leucocytes)	Total <i>A. gambiae</i> Dissected	No. with Oocysts	Intensity of Infection. Oocysts per Positive Stomach		
					Max.	Min.	Mean
M, 2 yrs.	1	6.0	18	7	26	1	9.1
M, 3 "	3	1.2-4.1	50	23	28	1	5.7
M, 5 "	7	7.9-24.0	107	39	28	1	5.0
F, 9 "	5	1.7-8.2	97	18	10	1	3.4
			272	87			

(5%) had more than 20. Higher oocyst densities have been recorded elsewhere (Barber and Olinger, 1931; Robertson, 1945), but our own experience is that they are unusual, particularly after a single infective feed.

In comparing the infectiousness of these village subjects showing the lowest crescent densities (Table II) with the infectiousness of the most efficient carriers found in the survey (Table III), we can say roughly that while the best infectors will infect about 30-40% of the mosquitoes feeding on them, and produce on the average about 5 oocysts per stomach, the carriers with the lowest threshold may infect up to 10% of the mosquitoes, and produce about 1-2 oocysts per stomach. The low-threshold carriers are therefore relatively much more infective than we would imagine from their very low gametocyte densities. There is some evidence to show that such a carrier may retain a very scanty crescent infection and at the same time remain infective for long periods.

In discussing these very low gametocyte densities it must be pointed out that, as many of the figures have to be based on the finding of only one or two crescents in several hundred thick-film fields, they may possibly give a misleading idea of the true density not only in the blood film itself but also in the mosquitoes' blood meal. In fact, our findings would be altogether easier to understand if we assumed that at these low densities the distribution of crescents throughout the blood stream is very uneven.

In contrast to these low-threshold, or "cryptic," infectors, our routine tests revealed several striking examples of subjects being non-infective at a time when crescents were abundant in the blood. The most outstanding examples are shown in Table IV.

TABLE IV.—Particulars of Non-infective Feeds at Gametocyte Densities Greater than 3 per 1,000 Leucocytes

Age and Sex of Subjects	Crescents per 1,000 Leucocytes	No. of <i>A. gambiae</i> Found Non-infective
F, 4 months	3.3	22
F, 6 "	4.8	16
M, 2 years	7.7	13
F, 3 "	2.8	15
F, 7 "	3.9	17
F, 7 "	3.1	19

In our investigation in Jamaica (Muirhead-Thomson and Mercier, 1952), the subject with the heaviest infection remained non-infective for several weeks, while Martin Young and his colleagues (1948) report a similar failure with the two patients showing the highest gametocyte count. In this connexion it is interesting to note that in the Gold Coast village survey the highest proportion of non-infective carriers occurred in infants—0-1 year age group—only 2 out of 13 crescent carriers proving infective to mosquitoes. Whether this figure is really representative of that group or whether it is just a sampling error is obviously a point which will require further investigation.

Discussion

The first conclusion from all these findings is that the presence or apparent absence of falciparum gametocytes in routine blood-film examination may really give a very misleading idea of the infective status of the subject. Until further improvements in technique occur, actual infectiousness can be determined accurately only by test feeds with anopheles. In fact, one might go so far as to say that in trying to determine the proportion of malaria infectors in the African or native village community a more accurate picture might be obtained if test feeds were carried out on a large scale, at random, quite irrespective of the blood picture. Obviously, too, in implicating cryptic infectors, the larger the batch of mosquitoes used in the test the better. Even with batches of 40-50 anopheles one might still miss the occasional carrier who infects only 2 to 3% of the mosquitoes feeding on him. How fruitful a line of inquiry this random testing

might be already indicated by the first tentative tests in the Gold Coast. Out of 28 adults, two young men aged about 20-25 proved infective. In view of the low gametocyte rate of this group, and the low gametocyte densities encountered under hyperendemic conditions, adults have usually been regarded as of negligible importance as a source of malaria infection. As crescent infections may occur at all ages, including the very oldest inhabitants in the community, the usual blood picture may be giving quite an erroneous impression of the infective status of this group.

The possible role of these cryptic infectors as reservoirs of malaria has also to be considered in the light of recent observations on the distribution of anopheles bites and feeds among different human age groups. With both *A. albimanus* in Jamaica (supported by observations on *A. aquasalis* and *A. bellator* in Trinidad) (Muirhead-Thomson, 1951) and *A. gambiae* in West Africa (Thomas, 1951) it has been shown that in general there is a tendency for mosquitoes to obtain the bulk of their blood meals from older children and adults rather than from infants and toddlers. From this it would appear that an adult with a cryptic infection might be a much more important reservoir of malaria than an equally infective baby, the low infectivity being counterbalanced in nature by the greater number of mosquitoes feeding on the adult.

In trying to understand the conditions leading up to malaria epidemics, or even to seasonal waves of malaria, malariologists have long been influenced by the changing gametocyte rate of the human population as found in routine blood-film examination. It is possible that the difficulties they have encountered in trying to explain the discrepancy between low gametocyte rates and densities in the human population on the one hand, and rapidly increasing infection rates among the anopheline mosquitoes on the other hand, might be due to a much higher proportion of the population actually being infective to mosquitoes for the reasons described above.

Frohne *et al.* (1950), for example, have shown in an area in South Carolina that, despite a remarkable reduction in the parasite rate of the negro population in the proportion of 318 to 1 between 1945 and 1948, infections in wild-caught anopheles still persisted. One of the explanations suggested by these workers was that a higher proportion of the human population is infective to anopheles than is indicated by the monthly parasitaemia rates. They were dealing with a strain of *P. falciparum* which had already been shown by Young and his colleagues to be capable of infecting *A. quadrimaculatus* at extremely low gametocyte densities.

Finally, it is interesting to note that these extremely low gametocyte thresholds of infection have been encountered in three different parts of the world, using three different species of anopheles, and probably as many different strains of *P. falciparum*. One feature common to all three investigations is that the human population experimented with has been negro or of negro origin. It might be worth considering how far these results could be influenced by racial characteristics.

Summary

Observations in Gold Coast villages where malaria is hyperendemic have confirmed previous findings in Jamaica, and by American workers in South Carolina, that some carriers can infect anopheles with *P. falciparum* at a time when the density of gametocytes in the blood is so low that they may be detected only with difficulty in routine blood-film examination.

In the Gold Coast experiments these cryptic carriers formed a significant proportion—roughly one-quarter of all infective carriers. This finding, together with the fact that many good crescent carriers are non-infective to mosquitoes, suggests that the blood-film examination may prove a very deceptive guide to the real malaria infectors in the African or native village community.

The implications of these findings are discussed in the light of recent work on the uneven distribution of anopheles bites and feeds among different human age groups.

The work briefly described above forms the first phase of a research scheme carried out under the control of the Colonial Office and the Colonial Medical Research Committee. It is hoped that a more detailed report will be produced at a later date.

RHEUMATIC HEART DISEASE COMPLICATING PREGNANCY

BY

M. I. DRURY, M.D., F.R.C.P.I.

M. K. O'DRISCOLL, M.B., M.A.O., M.R.C.O.G.
M.R.C.P.I.

T. D. HANRATTY, M.D., M.A.O., M.R.C.P.
M.R.C.P.I.

AND

A. P. BARRY, M.B., M.A.O., F.R.C.O.G.

(From the National Maternity Hospital, Dublin)

Improvements in antenatal and intranatal care over the past 50 years have resulted in a great reduction in the maternal mortality rate. Advances in particular fields have altered the relative importance of many complications, because some which were formerly of the utmost gravity are now more amenable to treatment. The change is exemplified by an analysis of 328 maternal deaths occurring in 128,474 deliveries in the three Dublin maternity hospitals during the decade 1940-50 (O'Driscoll and Quinn, 1951), the chief causes of which were:

Eclampsia	41
Sepsis (usually complicated)	42
Rheumatic heart disease	35
Accidental haemorrhage	32
Post-partum haemorrhage	25
Ruptured uterus	21
Placenta praevia	17
Non-convulsive toxæmias	15

These figures demonstrate the importance of rheumatic heart disease as a factor in maternal mortality. No reference is made to other forms of heart disease complicating pregnancy, as few cases were seen and none was fatal.

To evaluate the problem of rheumatic heart disease in pregnancy a clinical survey was begun by us in the National Maternity Hospital on January 1, 1948, and, for the purpose of this communication, was concluded on January 1, 1952. During these years 250 pregnancies in 175 patients with rheumatic heart disease were studied. The patients were graded according to the recommenda-

tion of the New York Heart Association. The diagnosis, which was in all cases confirmed after pregnancy, was a clinical one, although electrocardiographic and x-ray examinations were routine. Every patient who survived was seen in 1953, so that the follow-up time varied from four years to a minimum of one year.

The average parity of these women was 4. This compares with the figure of 3.3 for all married women in Ireland. In 1,532 years of married life these women had 704 pregnancies—that is, a pregnancy every two years. Of these 704 pregnancies none was artificially terminated and only 29 failed to reach viability.

It is apparent that the number of children borne by these women was related only to their natural fertility. The series is drawn from a population which does not practise contraception, therapeutic abortion, or sterilization. The communication presents the result of uninhibited child-bearing in patients with rheumatic heart disease. Most papers on this subject are open to the criticism that indirect case selection results from these practices.

At the end of the survey 11 women had died. Five died later than one year after confinement (13, 18, 24, 36, and 36 months), and so their deaths are not thought to have been related to pregnancy. Six died during pregnancy or within one year of confinement; these deaths are considered to have been related to pregnancy. They represent a maternal mortality of 3.5%. The number of babies who left hospital alive was 229. The uncorrected foetal loss was 6.4%.

Analysis of 175 Patients

An unequivocal rheumatic history was given by 111 patients, or 63%. A strong family history was obtained in a further six cases. The incidence of the various valvular lesions was as follows:

Lesion	No. of Cases
Mitral stenosis	151
Mitral stenosis and aortic regurgitation	23
Aortic regurgitation	1

Because of the recognized difficulty in diagnosing pure mitral regurgitation (Brigden and Leatham, 1953), 10 patients with harsh mitral systolic murmurs and a personal history of rheumatic disease are grouped under the heading "mitral stenosis." In these cases the predominant defect would appear to be an incompetence of the valve. The importance of history-taking and of careful auscultation at the mitral area is illustrated by these figures.

It has often been said that the heart condition deteriorates with increasing parity. Table I confirms this, but the last column reminds us that increasing parity coincides with increasing age. This may be the relevant factor.

TABLE I

Parity	No. of Cases	Grades III and IV		Average Age
		No.	%	
1	46	15	32.6	28.5
2 to 4	83	30	36.1	33.2
5+	46	21	45.7	38.5

TABLE II

Age	No. of Cases	Grades III and IV	
		No.	%
Under 26	18	8	44.4
26 to 30	39	11	28.2
31 to 35	48	17	35.4
Over 35	70	30	42.9

Table II shows the relative incidence of severe cases in the various age groups. With the striking exception of the youngest group, the number of severe cases increased with age. We formed the opinion that recurrences of acute rheumatism may explain the disproportionately high number in the youngest group. We believe that this constitutes a real danger to young mothers. Further reference is made to this matter.

In 17 of the 29 patients seen in acute congestive heart failure there were, apart from pregnancy, the following important relevant factors:

Auricular fibrillation	4
Auricular fibrillation and acute respiratory infection	2
Acute respiratory infection	4
Acute respiratory infection and hypochromic anaemia; Hb 32%	1
Acute pyelitis and hypochromic anaemia; Hb 23%	1
Subacute bacterial endocarditis	2
Acute rheumatism	2
Pre-eclampsia; B.P. 170/110; oedema	1

Auricular fibrillation is the most important single factor in precipitating heart failure. Its presence indicates widespread damage to the myocardium. Four additional women with auricular fibrillation were not in failure. Intercurrent infection, particularly of the respiratory tract, anaemia, hypertension, and fluid imbalance are other notable causes of cardiac decompensation during pregnancy. Active rheumatic and bacterial endocarditis caused heart failure in four of the patients in this survey.

It is of interest to note the stage at which failure occurred in these 29 patients. In two it appeared in the first trimester, in seven in the second, and in 14 between the 28th and 36th weeks, but in no instance between the 36th week and the onset of labour. Five failed during labour and one during the puerperium. This experience substantiates the opinion that the strain imposed on the heart by pregnancy steadily increases to the period between the 28th and 36th weeks, and sharply decreases in the last month. It follows that induction of labour is basically an unsound procedure in the treatment of heart disease. The comparatively small number that failed during labour indicates that, given proper management, the danger of labour has been exaggerated. The fact that only one woman failed in the puerperium lends no support to the frequent reiteration that this is a time of particular risk.

Method of Delivery

Labour was induced in three women for pre-eclampsia and in no instance for heart disease. The methods used for delivery in the 250 pregnancies were as follows:

Caesarean section	7
Forceps or breech extraction	47
Laparotomy (see maternal deaths)	1 (twins)
Died undelivered	2
Spontaneous delivery	184 (5 twins)
Evacuation of incomplete abortion	4
Complete abortion	5

The incidence of caesarean section was 3%, whilst in the whole hospital service it was 1.5%. This discrepancy arose as the result of cases operated on more than once before coming under our care.

Only one caesarean section was performed for heart disease. It was in the early stages of the survey. The patient was subsequently delivered vaginally of her second baby. This illustrates the attitude towards abdominal delivery prompted by the intervening cases. The operation was performed in error resulting from inexperience of this condition. We now believe that rheumatic heart disease is never an indication for section.

Caesarean section was performed once for central placenta praevia, once for severe pre-eclampsia at 30 weeks' gestation and once for absolute disproportion. From fear of rupture of the uterus three operations were carried out on women who had undergone section at least twice previously for heart disease. The cardiac condition did not influence the decision in any of the foregoing six cases.

Six women who had undergone section previously for heart disease were delivered by the natural passages. The assisted vaginal delivery rate of 20% was twice the rate for all the hospital deliveries. The timely but not routine forceps or breech extraction is favoured. Local analgesia, supplemented when necessary by intravenous thiopentone, was used in all operative deliveries.

Maternal Deaths

Six women died during pregnancy or within one year after. A brief description of each follows:

Case 1.—Primigravida aged 25. Emergency admission at 31 weeks' gestation with subacute bacterial endocarditis complicated by embolic hemiplegia. Labour began spontaneously one week later and was terminated by breech extraction. The endocarditis did not respond to treatment, and the patient died 10 weeks after delivery from congestive heart failure. The baby survived.

Case 2.—Primigravida aged 28. Emergency admission at 30 weeks' gestation, moribund from congestive heart failure (grade IV). She was not in labour and died undelivered 12 hours after admission. This patient had mitral stenosis and aortic incompetence. She had been having frequent attacks of haemoptysis for three months before admission and had been partially incapacitated by her heart for several years.

Case 3.—Primigravida aged 24. Emergency admission at 16 weeks' gestation, moribund from congestive heart failure (grade IV). She was not in labour, and died one hour after admission. She had mitral stenosis and aortic regurgitation. No antecedent history was available.

Case 4.—Primigravida aged 23. Emergency admission at 30 weeks' gestation with cardiac decompensation (grade IV). There was considerable enlargement of the heart, tachycardia, and extrasystoles. She had aortic regurgitation and mitral stenosis. Her condition improved considerably in hospital, but frequent bouts of tachycardia were accompanied by relapse into failure. A diagnosis of active rheumatic carditis was made; she had an easy labour at term, ending in low forceps delivery. The baby survived, but the mother died six weeks later from congestive heart failure.

Case 5.—Gravida 2 aged 27. Emergency admission at 32 weeks' gestation with cardiac decompensation of moderate degree (grade III) due to acute bronchitis. She responded well to treatment, ceasing to be a cause of anxiety until three weeks before term. She then developed pneumococcal pneumonia involving the right upper lobe. This caused acute cardiac distress and a fulminating bacterial toxæmia which precipitated the onset of labour 17 hours later. Despite an easy rapid labour lasting six hours, she died five hours after spontaneous delivery in congestive failure; the baby was stillborn.

Case 6.—Gravida 10 aged 39. Emergency admission at 30 weeks with unexplained pyrexia and a twin pregnancy. Her last delivery had been by classical caesarean section for placenta praevia outside our service. On admission her general condition was poor, temperature 100° F. (37.8° C.), pulse 128, haemoglobin 23%, blood pressure 160/90, albumin, a trace; she had mitral stenosis, with considerable enlargement of the heart, and was in congestive heart failure. Subacute bacterial endocarditis was diagnosed, and she was treated with fair response. Her general condition deteriorated again at 34 weeks, and on further investigation it was clear that her symptoms were due to quiet rupture of the uterus. At laparotomy two macerated foetuses and their placentae were in the abdominal cavity, which was heavily infected. A loop of small gut was torn where it adhered to the uterus. Subtotal hysterectomy and bowel resection were performed. The patient died 24 hours later.

All six who died were unbooked patients; not one had received antenatal care at the hospital before admission to the wards in heart failure. There was a 20% fatality rate in unbooked patients. No booked patient died. This emphasizes the importance of routine examination of the heart of every midwifery patient. It also emphasizes the importance of efficient antenatal care. It has been our experience with emergency admissions that frequently neither the patient nor her doctor knew that heart disease existed until symptoms of heart failure appeared. The explanation is that many practitioners do not examine the heart of a pregnant woman because they are unaware of the frequency and gravity of heart disease. This fact demands the attention of all engaged in teaching obstetrics.

A striking feature of the fatal cases was the preponderance of the young and the primigravidae. The only exception was Case 6, who would probably have survived if her uterus had not ruptured. Was it because these women were young or because they were primigravidae that they died? Or were these matters merely of coincidence? Three of these fatal cases had aortic incompetence.

Case 1 died from subacute bacterial endocarditis 10 weeks after an easy delivery. It may be assumed that neither age nor parity was of importance here. Case 5 died in congestive failure precipitated by lobar pneumonia and aggravated by the untimely onset of labour, albeit rapid and easy. This death was not influenced by age or parity. Case 4, a primigravida aged 23, died six weeks after a normal delivery. She was under our care long enough for us to be satisfied that the deterioration of her heart was due to active rheumatic carditis. This was related to her age. Case 3 died from congestive failure at 16 weeks' gestation. She was 24 years old, and we suggest that her youth exposed her to a recrudescence of acute rheumatism. Her parity was hardly an important factor. Case 2 died similarly, in congestive failure at 30 weeks' gestation. That she was a primigravida was not likely to have been of importance, because she was not in labour. A rheumatic recurrence is offered to explain this fatality in a woman of 28 years.

It is our opinion that age and parity were matters of simple coincidence in Cases 1, 5, and 6, and that age rather than parity was an important factor in Cases 2, 3, and 4. The young mother who is by coincidence usually a primigravida is prone to reactivation of her disease, and we agree with others that this is of the greatest importance in determining a fatal issue (McKeown, 1948, 1950; Kennedy, 1950; Castleden *et al.*, 1951).

Paradoxically, most of the deaths occurred in the groups which contained the smallest number of severe cases, that is, in the younger women and women of low parity. Although most of the patients in failure were older and of high parity, only one of these died, and she as the result of a ruptured uterus. None of the women with fibrillation died. The inference is that the heart damaged by rheumatic disease is not likely to result in death if proper care be given, unless the mother's youth exposes her to the risk of reactivation of the disease.

The five women who died more than a year after delivery were all amongst the older age groups (33, 35, 37, 37, and 48 years), and all died from heart failure. They had reached the end phase of their disease. The fact that they survived their latest pregnancy by more than a year suggests that pregnancy did not contribute to these deaths.

Contraception, Therapeutic Abortion, and Sterilization

Contraception, therapeutic abortion, and sterilization are not practised in this city. There were 229 healthy surviving children born to these 175 women in the four-year period. It is of interest to consider the effect that the absence of these practices had on the maternal survival rate.

Women with heart disease are commonly advised to have only two children, and to ensure this the patient is often sterilized after the second delivery. Had this procedure been adopted in our series many operations would have been done, as a result of which one woman would have been saved from death due to rupture of the scar of a classical section carried out for placenta praevia.

All six women who died were seen too late in pregnancy or too advanced in heart failure for therapeutic abortion to be performed. Since no woman who received antenatal care at the hospital was lost, one might be justified in assuming that proper antenatal care would have been more likely to save them than therapeutic abortion.

It is unlikely that the practice of contraception would have affected the mortality from heart disease, since four

women died on their first pregnancy, and the only one who died later than the second pregnancy did not die from heart disease.

Had sterilization, abortion, and contraception been considered in the management of these cases they would have been applied to those who survived and not to those who died.

The dangers of these procedures have never been systematically presented. The indications, ages, parity, and maternal mortality figures in a series of cases treated by these methods would render an assessment of their advantages, or otherwise, possible. Until such figures appear it seems that good antenatal care can be expected to serve a mother better than either therapeutic abortion or sterilization.

Outcome of 250 Pregnancies

Of the 250 pregnancies observed, six were twin pregnancies. The outcome may be summarized as follows:

Surviving infants	229
Stillbirths	10
Neonatal deaths	6
Abortions and miscarriages	9
Died undelivered	2

Estimating the percentage of stillbirths and neonatal deaths on the number of infants delivered (245) who weighed more than 2 lb. 12 oz. (1.25 kg.), we obtain the figures of 4% and 2.4%, respectively. The corresponding figures for all deliveries in the hospital over the same period were 3.8% and 2.4%.

Two of the stillbirths were examples of hydrops foetalis; rupture of a classical section scar in a case of twin pregnancy caused the death of two infants; two infants died as the result of extensive placental infarcts due to pre-eclampsia (one of these mothers suffered from diabetes); eclampsia (one of these mothers suffered from diabetes); and a central placenta praevia caused another stillbirth; and one was a macerated twin, its fellow surviving. In none of these eight cases did the maternal heart condition affect the foetal loss. In the other two cases of stillbirth the mothers were suffering from cardiac decompensation, but it is likely that the stillbirths would have otherwise resulted: the one mother suffered from primary uterine inertia, and the foetal heart ceased after labour had lasted 80 hours; the other was suffering from an overwhelming toxæmia due to acute lobar pneumonia.

Not one of the six neonatal deaths was related to maternal heart disease. Two resulted from congenital malformations, one was caused by pneumococcal meningitis, and one by laceration of the tentorium cerebelli. One baby was found to have atelectasis following prolapse of the cord, and another suffering from laryngismus died suddenly when 6 days old. Each case was examined at necropsy.

The nine abortions or miscarriages give the surprisingly low incidence of 3.6%. The incidence of abortions and miscarriages in the hospital over the same period was 7.5%. As many women do not attend in early pregnancy and abort outside hospital, these figures may not be reliable. But the figure for the heart cases seems to be confirmed by the fact that these women had borne, in all, 704 pregnancies, including those under consideration, and only 29 (4%) had terminated before the period of viability. It can be confidently stated that none of the nine abortions or miscarriages were caused by rheumatic heart disease.

In the case of the two women who died before delivery the foetal loss can clearly be attributed to the heart condition.

Since rheumatic carditis did not affect the survival of more than four conceptions in 256 it seems fair to assume that the prospects of a healthy child in a woman who suffers from this disease is virtually the same as in one who does not. In assessing these figures it must be remembered that therapeutic abortion was not performed, so that 89.5% of all conceptions seen at the hospital resulted in surviving children.

Conclusion

As already stated, the cases recorded in this paper were totally unselected; contraception, termination, and sterilization were never practised. Furthermore, the patients were mainly drawn from the under-privileged groups, with poor home conditions and no home help, who are fertile to a degree which workers in other countries rarely see.

Diagnosis is the first and clearly the most important aspect of the problem of rheumatic heart disease in pregnancy. That it is simple is illustrated by the preponderance of mitral stenosis and the frequency of a rheumatic history. The functional systolic murmur so common in pregnancy may lead to the suspicion of disease more often than it exists, but failure to recognize existing disease is a more serious error. In the present series all of the fatalities occurred in cases which were not diagnosed until failure was established.

Rest is the natural sequel to diagnosis. Cases without significant limitation of cardiac reserve are allowed to go home. They are advised specific rest hours, which are systematically increased until they are admitted to hospital two weeks before term. Patients with limitation of cardiac reserve are admitted to hospital without delay and are not discharged until after delivery. The importance attached to rest is signified by the total of 5,250 days which the women in the present series spent in the antenatal wards of the hospital—that is, an average of 21 days before each delivery.

Digitalization, diuresis, venesection, etc., are adopted as in the standard management of heart disease. Valvotomy is now an additional weapon.

Heart disease is not regarded as an indication for induction of premature labour or for caesarean section. Forceps extraction is often employed to abbreviate the second stage of labour. Post-partum haemorrhage is never encouraged or permitted to continue, venesection being a much safer method of reducing the circulatory volume when necessary.

Summary

The case histories of 175 women in 250 pregnancies over a period of four years are analysed.

Rheumatic heart disease is a common complication in pregnancy (1.7%).

The diagnosis is a simple clinical one.

Early diagnosis is imperative if fatalities are to be avoided.

There was no maternal death in 220 booked cases.

It is considered that there is no place for therapeutic abortion or sterilization.

This survey was begun during the Mastership of Dr. A. W. Spain. We are grateful to him for his interest and stimulating advice.

A revised edition of *Social Work* is now available in the "Careers for Men and Women" series issued by the Ministry of Labour and National Service (H.M.S.O., price 1s. 6d.). Information is given on the scope of each career, the pre-entry qualifications needed, the amount, cost, and type of training required, and the professional opportunities available after qualification. Among the careers described in the booklet are almoner, psychiatric social worker, mental health officer, moral welfare worker, home teacher of the blind, and family case worker. This is a useful booklet for anyone likely to be asked for advice in the choice of a career closely related to medicine.

As has been stressed by Cicely Williams (1953) and Chambers (1953), a diagnosis of vomiting sickness is often loosely used in Jamaica to cover various undiagnosed illnesses in which vomiting or sudden death has occurred. Nevertheless, after taking this into account, there remains a definite group of typical cases showing a characteristic clinical picture.

Aetiology

The precise aetiology of the vomiting sickness of Jamaica is still very much in doubt and cannot be discussed here fully. The various hypotheses have been considered by Hill (1952). Meningitis, encephalitis, cerebral malaria, and other acute cerebral inflammatory diseases can be excluded both clinically and by post-mortem evidence. The present consensus of opinion is that the syndrome is due to the effect of an unknown poison, or possibly one of several poisons, upon subjects who are usually rather poorly nourished, especially children. Metallic poisons, botulism, "barracuda poisoning" (from fresh but diseased fish), and the staphylococcal toxin have all been suggested on occasion with no real evidence; while ill-prepared bitter cassava or unripe yams—both of which contain cyanogenic glucosides—are sometimes alleged to be responsible, although again there seems to be little proof.

The ackee (*Blighia sapida*), which is widely grown and eaten throughout Jamaica, has been shown to contain a toxic saponin when immature (Evans and Arnold, 1938). Scott (1916), in his investigation of this subject, concluded that all cases were due to the eating of unripe ackees, and he was of the opinion that the disease should be called "ackee poisoning." However, as Cicely Williams (1953, personal communication) notes: "In spite of the evidence produced by former workers that the ackee was responsible, it is difficult to reconcile this with the fact that most Jamaicans are eating ackees regularly. They eat them in large quantities. Some people eat them raw or eat the fruit before the 'pod' is opened. They even drink the 'pot-water' after boiling the ackees, without disaster in the majority of cases." Nevertheless, most observers feel that the unripe ackee should still be suspect. Finally, it may be noted that herbal infusions of "bush tea," which are universally used as beverages and medicinally, are made from a very wide variety of plants which may conceivably be sometimes misused, with toxic results.

An unusual feature of the syndrome of vomiting sickness is that it has not been described elsewhere in the world, even in the other Caribbean territories.

Actual field investigations of cases of vomiting sickness are usually inconclusive, owing to the difficulty of obtaining accurate medical histories and because of the large number of potentially poisonous plants—including the ackee tree—to be found in the bush around the average Jamaican peasant's home. The dietetic history of children under these circumstances is even more difficult to assess, as, although the family's diet may be known, during the "hungry months" ill-fed children may scavenge in the bush and experiment with wild berries, fruits, and plants.

During the first three months of 1953 a number of cases of vomiting sickness were admitted to hospital here showing a vivid and pathogenic clinical picture associated with severe hypoglycaemia. Clinical details of these cases are in the process of publication (Stuart, Jelliffe, and Hill), as is a discussion of the pathology (Hill and Bras). The following is the description of a case seen more recently.

Case Report

A 6-year-old Jamaican boy of African extraction had been quite well until 4 p.m. on the day before admission, when he had vomited once, bringing up a small quantity of undigested food. There was no abdominal pain or diarrhoea. Following this the child had appeared to be quite well and went to bed normally at 9 p.m. He passed urine during the night at 1 a.m. and 6 a.m., and on each occasion he was seen by his father, who thought he appeared to be quite well. At 7 a.m. the father called the child for his morning "bush tea," but could not wake him. The father thought the boy was in a deep sleep, but on trying to rouse him 15 minutes later the child was found to be unconscious, with his legs in rigid extension, arms tightly flexed on his

chest, hands clenched, and jaw locked. This stiffness seemed to wax and wane, lasting about 10 minutes with longer intervals between.

The rest of the family, consisting of the father and a 3-year-old sister, were in no way affected, although they had all eaten the same meals together. The patient had eaten no ackees or other possibly toxic substances during the preceding 36 hours, so far as the father was aware, although there were plenty of ackee trees and other bushes around the house.

The patient arrived in the ward at 2 p.m., when he was found to be deeply comatose with stertorous respiration. He was afebrile, with a pulse of 120 and a blood pressure of 110/60. There were no signs of meningeal irritation. The eyes tended to rove about, with a transient squint. The fundi and pupils were normal. The limbs were flaccid at the first examination and all tendon reflexes were diminished. Painful stimuli produced no response, while the abdominal and plantar reflexes were absent. The child was well hydrated and moderately nourished, with only minor stigmata of malnutrition, in particular slight angular stomatitis and cheilosis. The liver was just palpable.

During the first three-quarters of an hour after admission there were repeated attacks of stiffening of the limbs, each lasting about one to two minutes, accompanied by a rigor like shaking. During these bouts the limbs became hyper-tonic with greatly increased reflexes.

In view of experience gained with previous cases, a diagnosis of acute toxic hypoglycaemia due to vomiting sickness was made.

Investigations.—Investigations carried out immediately on admission showed: (1) Blood count: haemoglobin, 11.6 g. per 100 ml.; red cells, 3,500,000 per c.mm.; white cells, 17,000 per c.mm. (metamyelocytes 0.5%, neutrophils 85%, lymphocytes 14.5%); E.S.R., 6 mm. per hour; haematocrit, 32%; M.C.V., 91.4 μ^3 ; M.C.H.C., 36.3%; M.C.H., 31.1 μg . (2) Liver-function tests: bilirubin (total), 0.6 mg. per 100 ml.; cephalin-cholesterol flocculation test, negative; gamma-globulin (Kunkel), 5.8 units; thymol flocculation, negative; thymol turbidity, 1.2 units; serum proteins, total 7.4 g.% (albumin 4.9 g., globulin 2.5 g.); cholinesterase

Chart of the case.

(Michel), 0.7 unit. (3) Blood urea, 45 mg. per 100 ml. (4) Serum calcium, 11 mg. per 100 ml. (5) Carbon dioxide combining power, 40 volumes per 100 ml. (6) E.C.G., normal. (7) Blood sugar, 19 mg. per 100 ml. (8) Liver biopsy (immediate): almost complete absence of liver glycogen (0.7%).

Progress in hospital is summarized in the accompanying graph. Adrenaline, 5 minims (0.3 ml.), was given subcutaneously on admission and the blood sugar was estimated after 15 minutes. This showed no real change (18 mg. per 100 ml.). Treatment was then begun with an injection of 40 g. of glucose intravenously, in a 50% solution, followed by a continuous intravenous drip of 9.5% glucose solution. By 4.25 p.m. the blood sugar had risen to 700 mg. per 100 ml. and was associated with a marked glycosuria. No dramatic clinical effect was produced, although the coma appeared to be definitely lighter during the afternoon and evening. The blood sugar had fallen to 84 mg. per 100 ml. by 8.30 p.m., and thereafter remained between 80 and 100 mg. The child continued in a stuporose condition, and during the night he had two generalized tonic-clonic convulsions. Next day a further fit occurred at 5 a.m., following which the child died, the respiration stopping while the heart continued to beat for 15 minutes afterwards.

Post-mortem examination was mainly negative save for lymphoid hyperplasia in the mesentery and ileum, together with fatty change in the liver.

Discussion

The very low blood sugar and almost absent liver glycogen found in this case have also been noted in other examples of vomiting sickness investigated during the acute phase of the illness. Full clinical and pathological details are to be published elsewhere, but results from five cases, including the present one, are summarized in the Table. The rapid

Details of Five Children Admitted with Acute Toxic Hypoglycaemia in the Vomiting Sickness of Jamaica

Case No.	Age in Years	Sex	Mental Condition on Admission	Blood Sugar (on Admission) (mg. per 100 ml.)	Known Length of Coma (Hours) before Treatment	Response to Large Doses I.V. Glucose

* Present case.

onset, with or without vomiting, of various grades of cerebral depression varying from drowsiness to stupor to coma—have been observed. Some early mild cases have responded dramatically and immediately to large doses of intravenous glucose, while others have recovered after some hours of treatment.

The present case can be regarded as a fulminant example of so-called vomiting sickness—coma coming on in only one hour, if the father's story is to be believed, while vomiting was virtually absent. Clinical response to a large dose of intravenous glucose was very slight, possibly because of the relatively long period—seven and a half hours—elapsing between the onset of coma and the beginning of treatment. The prognosis in these cases seems directly related to this interval, possibly because irreversible changes can be produced if hypoglycaemia is prolonged.

The toxin responsible for this dramatic clinical syndrome is unknown, but is very probably an accidentally ingested poison, possibly from some wild plant used in one of the "bush teas." The biochemical mechanism producing the hypoglycaemia is also as yet undetermined, but it seems likely that some form of enzyme blockage may be produced,

possibly in the enzyme systems responsible for hepatic gluconeogenesis. Whatever this may be, it is temporary and potentially reversible, as if recovery occurs, either spontaneously or following intravenous glucose, it is complete.

While hypoglycaemia is the most striking biochemical finding, there may be other upsets of blood chemistry as yet undiscovered. However, the presence of very low blood sugars in these cases does offer a possible immediate line of therapy, and it seems logical that cases of vomiting sickness should now be treated as medical emergencies with intravenous injections of concentrated glucose solution as soon as possible after the onset of symptoms.

Our thanks are due to Dr. G. Bras for carrying out the necropsy, and to Dr. S. J. Patrick for analysing the liver for glycogen.

CONGENITAL ABSENCE OF BOTH KIDNEYS

A REPORT OF FOUR CASES

BY

PETER E. SYLVESTER, M.R.C.S., L.R.C.P., D.C.H.
 Research Medical Officer, Institute of Child Health,
 University of London

AND

DAVID R. HUGHES, M.B., B.Ch., M.R.C.O.G.
 Senior Registrar in Obstetrics and Gynaecology, Woolwich
 Hospitals Group

Agenesis of both kidneys is a rare condition, only 171 cases having been reported since 1663. The four cases occurring at the West Middlesex Hospital described by us bring the total to 175.

The largest number reported was 20 by Potter (1946a, 1946b). These she found in a series of 5,000 necropsies on fetuses and newborn infants, and she estimated the incidence to be 0.3 per 1,000 births. At the West Middlesex Hospital the incidence was four cases amongst 9,940 deliveries (that is, 0.4 per 1,000 births).

The absence of both kidneys is usually accompanied by other gross or multiple deformities (Hinman, 1940). The sex incidence is predominantly male. Bilateral agenesis is compatible with intrauterine life, and does not appear to affect the quantity of liquor amnii. Survival after birth is short; the average duration of life in Potter's cases was 1½ hours. One case is reported to have lived for as long as 21 days, and another for 11 days.

Case 1

The mother, aged 40 years, had four previous normal pregnancies. The last child, aged 6 years, had an undescended right testicle. The other children, one boy and two girls, were normal and healthy. There was no history of congenital deformity in either the mother's or the father's family.

The early antenatal period appeared normal, although the mother later admitted that six weeks after the last menstrual period she had taken about 2.3 g. (35 gr.) of a quinine salt in one day, followed by 85 ml. (3 fl. oz.) of an ergot mixture and two tablets of an unknown substance.

At the 35th week she was admitted to hospital with antepartum haemorrhage due to placenta praevia. The foetus presented by the breech, and the foetal heart was strong and regular. Two weeks later a lower-segment caesarean section became necessary because of severe haemorrhage. The placenta was lying centrally in the lower uterine segment, and it was noted that the liquor amnii was normal in amount.

The child, a boy weighing 2,920 g. (6 lb. 7 oz.), showed a lax skin, generalized cyanosis, and hypotonia. The skull was scaphoid, with a tense anterior fontanelle and an occipito-frontal circumference of 37 cm. (14½ in.). A misshapen left pinna was noted. No abnormality was detected in the cardiovascular, alimentary, or central nervous systems. Rapid grunting respirations, with marked intercostal and subcostal recession and scattered crepitations, persisted throughout life, which lasted 20 hours and 40 minutes.

A dissection from the anterior aspect. The kidneys and renal arteries are absent. Discoid suprarenals are shown.

Necropsy revealed no abnormalities in the brain, thyroid, thymus, heart, spleen, liver, pancreas, and gastro-intestinal tract. A haemorrhagic consolidation was present in the posterior aspects of both lungs, and aeration was present in their anterior margins.

The adrenals were discoid, and measured 4.5 cm. by 3 cm. (see Diagram). There was complete absence of both kidneys, renal arteries, and ureters. A small prostate and bladder

were present. Complete descent of the testes had taken place. The penile urethra was patent in the terminal 0.5 cm. A microscopical search for renal tissue failed to reveal its presence.

Cases 2-4

Three other cases of anephrogenesis were discovered in the records of the West Middlesex Hospital. In Tables I, II, and III the details available are summarized and are compared with those of the case described above.

TABLE I.—Summary of Pregnancies

Case	Age		Month of Conception	Parity	Abnormality of Pregnancy	Maternal Health	Amount of Liquor
	Mother	Father					
1	40	46	February	4	1 Breech 2 Placenta praevia	Good	Normal
2	18	21	August	0	Mild toxæmia	Good	No record
3	45	?	September	5	None	Mitral and pulmonary systolic murmurs	Very little
4	25	52	February	0	Mild toxæmia	Diffuse enlargement of thyroid for many years	No record

TABLE II.—Summary of the Infant Data Prior to Death

Case	Duration of Pregnancy in Weeks	Birth Weight	Sex	Weight of Placenta	Duration of Life
1	36	6 lb. 7 oz. (2,920 g.)	M	1 lb. 1 oz. (548 g.)	20 hr. 40 min.
2	34	3 lb. 13 oz. (1,730 g.)	F	12½ oz. (354 g.)	7 hr. 20 min.
3	34	4 lb. 14 oz. (2,210 g.)	M	No record	28 hr. 30 min.
4	40	5 lb. 12 oz. (2,608 g.)	M	9 oz. (255 g.)	Stillborn

Aetiology

The present knowledge of the aetiology of congenital abnormalities is reviewed fully by Warkany (1947) and Fraser and Fainstat (1951). The two main groups are: (1) genetic and (2) environmental. The latter includes nutritional deficiencies and chemical, physical, endocrine, infectious, and mechanical agents. The timing of the environmental disturbance has been shown experimentally by Ingalls *et al.* (1950) to be important in deciding the site and nature of a congenital defect. These factors are applicable to congenital deformities of the renal tract.

Arey's (1946) calendar of human development shows that by the fourth week of embryonic life the pronephros has

Discussion

It is suggested that Case 1 is an example of congenital abnormality caused by disturbed environment. Six weeks after her last menstrual period, in a regular cycle of 6/27, the mother swallowed 2.3 g. (35 gr.) of a quinine salt within 24 hours, and later 85 ml. (3 fl. oz.) of an ergot mixture and two tablets of an unknown substance. The probable age of the embryo at this time—4 to 6 weeks—covered the important developmental periods of the mesonephric duct, cloaca and ureteric bud.

Quinine salts are known to be protoplasmic poisons with a specific nephrotoxic action. They are readily absorbed into the blood stream, and Dilling and Gemmell (1929) showed that quinine crosses the placental barrier at term. Huggett and Hammond (1952) state that placental permeability of different agents varies according to the stage of development. We have been unable to trace experimental proof that quinine reaches the human ovum from the maternal blood in the first few weeks of pregnancy. However, we submit that it is not unreasonable to regard the quinine as the agent responsible for the agenesis of the kidneys in Case 1. Our assumption is that the drug acted direct on the rapidly differentiating renal tissue.

The deformity of the left pinna is interesting. Potter noted certain facial characteristics, which included large low-lying ears with cartilaginous dysplasia. In a six-weeks embryo the external ear is beginning development around the first branchial cleft. Therefore it may be supposed that the disordered differentiation of the tissues at this time was the result of an insult, the timing of which coincided with the quinine administration.

One weakness in our hypothesis is the fact that quinine and other drugs are often taken as abortifacient measures during the early weeks of pregnancy and yet bilateral anephrogenesis is rare. There are three points to make in reply. First, the drug must be taken at the correct time in the development of the renal tract; the margin of error in time allowance is probably very small. Secondly, it is necessary to assess the incidence of anephrogenesis in the embryos and fetuses of abortions. Thirdly, the dosage and concentration of the drug must be sufficiently great.

Summary

Four cases of congenital absence of both kidneys are reported. One of these cases is described in detail.

The aetiology of the condition is discussed. The fourth to sixth weeks of embryonic life are the "critical period" during which development of the kidneys is taking place, and is the time when noxious environmental factors could exert their most damaging effects.

Quinine, taken by the mother of one case in a large dose six weeks after her last menstrual period, is suggested as a possible cause of the renal agenesis.

We wish to thank Dr. M. Dynski-Klein, Mr. D. M. Stern, and Miss I. M. Titcomb for allowing us to report these cases under their care and for access to their records; Dr. A. C. Counsell for his careful pathological examinations; and Miss S. Robinson for the drawing.

USE OF UNSATURATED FATTY ACIDS IN THE ECZEMAS OF CHILDHOOD

BY

JOHN H. S. PETTIT, M.D., M.R.C.P.

Fellow in Clinical Research (Medical Research Council),
Department of Dermatology, Leeds General Infirmary

Burr and Burr (1929, 1930) and Burr *et al.* (1932) showed that the total exclusion of fats from the diet of young rats produced a deficiency disease with caudal necrosis, red and somewhat swollen feet, and scaliness in the hair of the back. At the same time the growth of the animals was arrested and there was much loss of weight. This condition was not improved by adding non-saponifiable fats to the diet, but was cured by the unsaturated fatty acids (U.F.A.s), particularly linoleic and linolenic acids.

This work stimulated Hansen (1933), who first made the suggestion that U.F.A.s might be useful in treating infantile eczema. He demonstrated that there was a diminution of these acids in the serum of eczematous children, and he claimed that the addition of U.F.A.s to their diet caused a clinical improvement which was associated with a rise in the iodine number, an index of the non-saturated fatty acids in the serum. Shortly afterwards Cornbleet (1935) reported good results in a series of 85 cases of eczema which had been treated with fresh lard by mouth, but there seems to be no reference to any control in his investigation. Taub and Zakon (1935) found no benefit in eight cases of atopic eczema (Besnier's prurigo, disseminated neurodermatitis) which they treated with linseed oil by mouth, and also pointed out that the use of linseed or cottonseed oil might be dangerous, as the patient could be sensitive to these sources of U.F.A.s. Ginsberg and Bernstein (1937) found satisfactory improvement in three adults in a group of 11 with atopic dermatitis and in four out of six children. They also pointed out, however, that two children receiving the same local treatment and no added U.F.A.s improved in the same time. Finnerud, Kesler, and Weise (1941), using fresh lard in older children and adults, had a satisfactory response in about half their cases. Hansen, Knott, *et al.* (1947) reported on the study of 225 cases of eczema, of whom 123 were under the age of 2 years, 67 were from 2 to 15, and 35 were 16 and over. During these trials they used many forms of local treatment, including boric acid, zinc paste, sulphur, resorcinol, and occasionally coal-tar. Their results were poor in only 37 of the 148 cases treated with supplementary fatty acids, while 18 of the 48 controls were unsatisfactory in the same

TABLE III.—Clinical and Pathological Findings

Case:	1	2	3	4
Head	Scaphoid skull; misshapen left ear	Asymmetrical	Considerable head moulding; bilateral accessory auditory auricles	Dolichocephaly; cranial bones friable and thickened
Respiratory system	Cyanosis; congenital atelectasis	Cyanosis; congenital atelectasis	Cyanosis; congenital atelectasis	Bilateral pulmonary hypoplasia
Cardiovascular system	No abnormality	No abnormality	No abnormality	Patent interventricular septum
Alimentary system	No abnormality	No abnormality	Intestinal adhesions; ectopic caecum	"Hour-glass" constriction of stomach
Locomotor system	No abnormality	Limited flexion and abduction of both hips; hypermobility of right knee	No abnormality	Deformed hands and feet; limbs splinted against trunk
Urogenital system	Absence of both kidneys and ureters; rudimentary bladder	Absence of both kidneys and ureters; failure of fusion of Müllerian ducts; bladder elongated	Absence of both kidneys and ureters; small bladder	Absence of both kidneys and ureters; bladder present

period. They also demonstrated that the iodine number is reduced in many cases of eczema and returns to normal on satisfactory treatment.

More recently European workers have stepped into this field with investigations and reports on lines similar to those of the earlier American articles. As early as 1942 Justin-Besançon and Laroche criticized those who saw fit to call linoleic acid "vitamin F," and also pointed out that the administration of U.F.A.s gave very divergent results and that "the conclusion that certain authors wish to draw seems insecurely based." Azerad and Grupper (1949a) summed up their experience and claimed that lard by mouth was giving extremely encouraging results, but later (1949b) they reported better results with purified linoleic acid. In 58 breast-fed infants, 18 children, and 24 adults whom they treated they obtained 52 excellent or good results, and only 17 were mediocre or negligible. It must be pointed out that the linoleic acid was only a supplementary form of treatment, and as local treatment they used "nothing except a paste or ointment of 10% tar," which they deliberately chose in view of the excellent action of tar on vesicular and weeping eczema. Touraine (1949) quotes Püttilä (1948), who found an improvement in infantile eczema treated with vitamin B₆; and Charpy (1948) combined this with the U.F.A.s and claimed there was a synergistic effect, but Hansen was unable to confirm this. Touraine also quotes Vachon (1948) as having tried the application of 3% linoleic acid in an ointment base, which was found to irritate, and he used a 1% ointment in resistant cases but said it should be employed with care. Alechinsky (1950) claimed six complete cures in 11 cases, while Dubois (1950), summing up the Continental view, pointed out that local treatment, preferably tar, was indispensable and claimed that irritation ceased in four to seven days and exudation dried in two to four days. More recently Finzi (1951) and Carletti and Scalapogna (1952) claimed good results, but in an apparently uncontrolled series of cases.

The unsatisfactory state of these claims and the associated recent publicity in this country of the use of unsaturated fatty acids, particularly linoleic and linolenic acids in liquid, ointment, and capsule form, suggested that an investigation of their effectiveness should be undertaken.

The following investigations were therefore carried out at a hospital mainly for the long-term treatment of children with severe and chronic dermatoses.

Local Application and Oral Administration of U.F.A.s

For the first investigation 27 cases of infantile and atopic eczema were used. The ages ranged from 18 months to 15 years, and so far as was possible the cases were paired in age and type of skin lesion. The babies with infantile eczema had usually been in hospital only a short time, while most of the older children had spent a considerable period in hospital. As a result of this long-term treatment any improvement which might have been attributed to the child's change of environment on admission to hospital was, in the main, avoided.

Each child was seen at the start of the trial and assessed, and after that, without the investigator's knowledge of which children were being treated, 15 children were given a daily application of an ointment with the following formula:

Linoleic acid	..	..	..	1.7%
Linolenic acid	..	..	..	0.8%
Hydrous ointment	..	..	to	100%

and orally a capsule a day:

Linoleic acid	..	..	..	0.27 g.
Linolenic acid	..	..	..	0.13 g.
Arachis oil	..	..	to	0.5 g.

The other 12 children continued the routine treatment of the hospital, usually zinc ointment with boric acid and various strengths of tar. An independent dermatologist (Dr. G. B. Dowling) also saw the patients regularly, and if the child's condition deteriorated enough to warrant a change

of treatment the case was automatically graded as 2. Each child was seen and assessed weekly, and at the end of seven weeks the progress was marked in the following way:

Improvement amounting almost to cure	..	..	..	..	..	+2
Overall improvement	..	..	..	..	..	+1
Approximately the same as at the start	..	..	..	..	..	0
Overall deterioration	..	..	..	..	..	-1
Failure, needing change of treatment	..	..	..	..	..	-2

It was not until all these cases were marked that the investigator knew which patients were being treated with the U.F.A.s. In that way any bias for or against the treatment was avoided.

The results (Table I) showed no evidence that the treatment with local and oral unsaturated fatty acids was a satisfactory substitute for the normal routine. The possibility

TABLE I

	12	11	0	1	2	Total
Cases on local and oral U.F.A.s	1	0	1	8	5	15
Cases on usual treatment	1	5	2	1	1	12

that the ointment itself might irritate was considered, but the fact that one child steadily improved while on the treatment disproved this. Later, at the end of the series, patch tests with the ointment were made in cases that had failed, but no evidence of sensitivity to the ointment was found. It was thought that this group of cases showed striking evidence against the further continuation of the trial, but in order to assess whether oral U.F.A.s in addition to the routine hospital treatment was of benefit a further investigation was made.

Oral U.F.A.s as an Adjuvant to Therapy

This group consisted of 36 cases of infantile eczema and atopic eczema, 20 of whom took a capsule of linoleic and linolenic acid daily for approximately four months. The actual time that patients were treated varied from nine to seventeen weeks. Several of the children were discharged from hospital in this time and they were automatically marked +2. Again any child whose treatment was altered because of manifest deterioration was graded 2.

TABLE II

	12	11	0	1	2	Total
Routine treatment plus oral U.F.A.	..	..	..	..	..	..
Routine treatment	7	8	1	2	0	20
	8	3	1	1	1	16

Taking into consideration the slightly smaller group of controls, it is not considered that this investigation produced any evidence that oral U.F.A.s have value as an adjunct to local treatment of infantile or atopic eczema.

Discussion

The diminution of the iodine number showing the reduction of U.F.A.s in the serum of children with eczema caused Hansen to start this long and contradictory series of investigations. The conception that a reduction in the U.F.A.s of the serum is aetiological connected with infantile eczema was doubted by Faber and Roberts (1933), who found that in eczema the cholesterol was slightly higher, the total fatty acid and the total lipid content considerably higher, and an iodine number only moderately lower than in normal controls. They did not find a degree of unsaturation as high as Hansen did, and expressed a belief that the findings were secondary rather than causative. This suggestion would seem to receive support from Hansen's own work, which shows there is a rise in the iodine number in children satisfactorily treated for eczema with nothing but local applications of tar (Hansen, 1933; Hansen, Knott, *et al.*, 1947).

The emphasis placed by nearly all authors who claim benefit from the use of these fatty acids on the fact that

local treatment is a prime necessity, and the apparent lack of any great interest in a controlled series, suggest that the benefits claimed may be due to the usual treatment, with perhaps a dash of enthusiasm.

The investigations reported here, in which all personal bias and normally varying factors were removed so far as was possible, have failed to substantiate the claims that the so-called "vitamin F" has any value in the treatment of atopic and infantile eczema. The findings of Vachon seem to be borne out, in that the ointment almost invariably irritated the eczematous skin.

Summary

A brief summary of the literature on the use of unsaturated fatty acids in the treatment of infantile and atopic eczema is followed by the details of a recent investigation.

The combined use of linoleic and linolenic acid ointment and capsules and the use of the capsules as an adjuvant to routine treatment were in no way preferable to the established methods of treatment.

My thanks are due to Dr. G. B. Dowling for allowing me to see and investigate his cases, and to the matron and nursing staff of the Goldie Leigh Hospital for their willing co-operation.

Medical Memoranda

Total Gastrectomy for Haematemesis

The object of this report is to point out the necessity for total gastrectomy in certain rare cases of haematemesis and to stress the value of oesophagoscopy in diagnosing the source of the haemorrhage.

Obvious bleeding occurs in some 20% of all peptic ulcers, and these form about 85% of all cases of haematemesis and melaena. The total mortality rate in the peptic ulcer group is roughly 8%, but in patients under 45 it is 2%. Death more often takes place from irreversible changes following prolonged anaemia than from acute anaemia, as necropsy nearly always shows the vessel occluded by clot. Hence the sheet anchor of treatment is blood transfusion, not only to prevent anaemia but also to enable the patient to withstand further haemorrhage by keeping the haemoglobin level about 80%. If this rule is followed the so-called critical periods on the third day or at any other time cease to exist, and surgery is indicated when replacement does not control the loss or if the loss continues or recurs for several days.

HAEMORRHAGE FROM FUNDUS OF STOMACH AND LOWER OESOPHAGUS

The importance of haemorrhage from the fundus of the stomach was first impressed upon me by a patient, known to be suffering from a chronic gastric ulcer for some years.

who was admitted with severe haematemesis which did not respond satisfactorily to transfusion. A partial gastrectomy was successful, but the specimen showed that the bleeding was not from the known chronic ulcer but from a small acute ulcer high up the lesser curvature which had been included in the resected area by luck, not judgment. This acute ulcer was not palpable to the gloved finger, and I doubt if it would have been noticed on gastrotomy, which in other cases has proved to be of no value.

Further, the importance to the differential diagnosis of the site of the haemorrhage was brought home by another man, known to have a chronic gastric ulcer, who was admitted with severe haematemesis not controlled by transfusion. At partial gastrectomy cirrhosis of the liver was noted. He died five days later from continued bleeding from oesophageal varices. No evidence of haemorrhage from the ulcer was found. This error might have been prevented by an oesophagoscopy examination, in which it is simple to distinguish a normal oesophagus, a normal oesophagus with regurgitated blood in it, bleeding oesophageal varices, or a stomach distended by gastric haemorrhage. In fact, since then it has saved me from making the same mistake again.

Those who are not trained in the use of the common instruments for the visualization of their patients' orifices will find no difficulty in passing an appropriate-sized oesophagoscope if they will first pass a stomach tube, aspirate, and then pass the endoscope alongside it before its removal.

Treatment.—This must be governed by the general principles already mentioned. When surgery is indicated for gastric haemorrhage from acute ulceration it is no use temporizing by doing a gastro-enterostomy (as in my house-surgeon days) or a partial gastrectomy or ligation of gastric vessels (as is often done now). I know of deaths from continuing haemorrhage after these procedures have been carried out by competent surgeons and also of recovery when nothing has been done. Acute fundic ulceration is probably as common as is acute ulceration in any other part of the stomach, and unless at laparotomy the surgeon can determine the site of bleeding he is faced with only two logical procedures: nothing or total gastrectomy. The following case histories illustrate the problem.

CASE I

An engineer aged 58 collapsed at work on March 16, 1952, and was admitted to Lodge Moor Hospital the next day as a case of "influenzal pneumonia." No cause for his collapse was found on admission, but 48 hours later he had a severe haematemesis. Blood transfusion was at once started, and he was transferred later in the day (March 19) to the City General Hospital. His pulse was 130 and blood pressure 105/60, and he was pale, cold, and clammy. Further transfusion was given, with improvement.

On March 21 he had further haematemesis and melaena in spite of a total of 8 pints (4.5 litres) of blood, so I was asked to see him with a view to surgery. His pulse was 84, blood pressure 85/55, Hb 8.8 g. (60%). He gave a history of several weeks of epigastric discomfort after food lasting an hour or so, and then complete freedom for several days before the next recurrence. I felt that the diagnosis of a chronic ulcer or carcinoma was very unlikely and suggested further conservative treatment.

However, on March 26 his condition deteriorated in spite of a total of 21 pints (11.9 litres) of blood, and laparotomy was advised.

First Operation.—On March 26, under intratracheal gas and oxygen, thiopentone, and D-tubocurarine chloride, a left upper paramedian incision was made. External exploration of the stomach and duodenum showed no lesion or evidence of scarring from an old lesion. The intestines were full of blood. The anterior stomach wall was incised from the lesser to the greater curvature roughly at its mid-point and the contents were aspirated. No fresh blood was present, but some adherent clot at the fundus was found. Nothing abnormal was seen or palpated though ungloved hands were used. The lower oesophagus also felt normal. The problem was total gastrectomy or nothing, and I chose the latter

course in the hope that the gastric haemorrhage, which was presumed to have come from the fundus, where adherent clot was found, would not recur.

The patient's condition improved for several days, though intermittent melaena occurred. On April 1 I passed an oesophagoscope into the stomach and found no evidence of bleeding or lesion in the oesophagus, but there was old clot in the stomach. Shortly after this he started to bleed severely, and as the consulting haematologist again found no evidence of blood dyscrasia I decided to do a total gastrectomy.

Second Operation.—On April 1, under a similar anaesthetic, the old incision was opened up and extended. There was a good deal of mild peritonitis due to the previous gastrotomy. Total gastrectomy was performed and a retrocolic jejunal loop was anastomosed to the oesophagus without entero-anastomosis (operative time two hours).

Recovery was uneventful and the patient was discharged on April 26 on an unrestricted diet. He had received 524 pints (29.8 litres) of blood from March 19 to April 2. He was readmitted on February 3, 1953, with acute intestinal obstruction for which section of a solitary cord adhesion from the mesentery to the posterior abdominal wall was done. In June he was at work again, the blood counts, etc., being satisfactory.

Specimen.—The stomach showed about a dozen small erosions, three or four being in the pyloric region and the rest on the posterior wall of that part opposite to and above the oesophageal opening. The haemorrhage had occurred from the largest of these fundic lesions, which measured about 1 cm. in length and 2-3 mm. in width.

CASE 2

A crane-driver aged 48 was admitted to the City General Hospital on June 27, 1952, with severe haematemesis. His history was as follows: 1930, onset of symptoms of duodenal ulcer; 1941, pyloric obstruction—gastro-jejunostomy; 1947, severe haematemesis—14 pints (8 litres) blood transfused; 1950, further haematemesis—3½ pints (2 litres) blood transfused; 1951, high partial gastrectomy for two anastomotic ulcers. I first saw him at 9 p.m., after he had vomited 38 oz. (1 litre) of blood. His condition was improving under transfusion. The Hb was 62.5%, but, as it fell to 55% in the next twelve hours in spite of drip transfusion, I decided to operate without further delay though the rate of transfusion was increased.

Operation.—On March 28, under gas and oxygen, thiopentone, and D-tubocurarine anaesthesia, oesophagoscopy was carried out. The oesophagus was normal, but there was blood in the stomach. A left postero-lateral thoracotomy was done with resection of the eighth rib. Total gastrectomy was performed with considerable difficulty in 3 hours 10 minutes. Unfortunately, the patient died some 30 hours later, but the cause of the haemorrhage was acute ulceration of the fundus of the stomach.

JUDSON T. CHESTERMAN, F.R.C.S., F.A.C.S., M.R.C.P.

Two Cases of Ovarian Cyst in Childhood

The deceptive presentation of these cases—one as retention of urine and the other as appendicitis—is of clinical interest.

CASE 1

In October, 1950, a girl aged 3½ was admitted to hospital with acute retention of urine. A week previously she had had a sore throat and diarrhoea with much mucus in the stools; this cleared up after three days, but two days later she began to have frequency, and micturition was apparently difficult and painful. The urinary symptoms increased in severity and culminated in acute retention.

On examination of the abdomen a smooth rounded cystic swelling was found rising out of the pelvis half-way up to the umbilicus. This was taken to be the distended bladder. The external urethral orifice appeared normal, there was no fever or any evidence of a neurological lesion, and an x-ray film

of the abdomen and pelvis showed nothing abnormal. With difficulty a catheter was passed and only a few millilitres of normal urine was obtained.

Under a general anaesthetic the cystic swelling previously described, which had been mistaken for the urinary bladder, became disimpacted from the pelvis, and at a subsequent laparotomy was shown to be a large multilocular teratoma of the left ovary, measuring 11 by 6.5 cm. It was removed without difficulty.

The mechanism of the production of urinary retention was possibly the same as that which occurs in retroflexion of the gravid uterus, whereby the urethra is compressed and elongated. The bladder, normally an abdominal viscus in young children, is easily displaced and compressed anteriorly by the impacted ovarian cyst. Disimpaction under anaesthesia allowed the bladder to empty easily and no further dysuria was experienced. Urinary disturbances occur not uncommonly in cases of ovarian cyst in children, but the occurrence of acute retention seems to be quite rare.

CASE 2

In June, 1951, a girl of 4 years 9 months was admitted to hospital with abdominal pain and vomiting. She had had three attacks of constipation and abdominal pain lasting two to three days in the past nine months. The present attack began three days before admission, with vomiting and lower abdominal pain. She had been constipated for three days and had been irritable and had a poor appetite. There were no urinary symptoms.

On examination she was seen to be flushed, with mild pyrexia and tachycardia. There was a tender rounded swelling arising out of the pelvis and extending 2 in. (5 cm.) above the symphysis pubis; slight muscular guarding was present over it. Rectal examination revealed a tender swelling palpable through the anterior wall of the rectum. A catheter was passed readily and 2 oz. (57 ml.) of urine was withdrawn. A diagnosis of pelvic abscess or cyst was made. Under general anaesthesia the swelling emerged from the pelvis and was freely mobile in the abdomen; it was evidently a cyst. The subsequent laparotomy revealed a right-sided unilocular ovarian cyst which had undergone torsion twice in a clockwise direction. It was removed. The left tube, the ovary, and the uterus were normal. Convalescence was uneventful, and the patient was discharged on the eighth day. (On section a simple ovarian cyst with haemorrhage into the ovary was reported.)

COMMENT

Study of reported cases shows that simple or multilocular cysts of the ovary account for one quarter to one third of all ovarian neoplasms in girls under 15 years, while granulosa-cell tumours produce symptoms of precocious puberty, and teratomas can sometimes be recognized by x-ray examination; ovarian cysts may remain unrecognized for a long time. Lower abdominal pain, distension, constipation, and frequency may occur. Torsion leading to acute symptoms may be the first indication of the presence of an ovarian cyst, and differential diagnosis from acute appendicitis may be very difficult; in fact, many series of reported cases show that this is the commonest pre-operative diagnosis, particularly as most cysts are on the right side. Steel (1931) reported 25 cases of twisted ovarian cysts diagnosed pre-operatively as appendicitis.

The most useful procedure to help in diagnosis is probably rectal examination, this fact being emphasized in many reports; it was of great assistance in these cases.

We are indebted to the late Mr. J. O. D. Wade, Professor A. G. Watkins, and Mr. R. J. Williams for permission to publish these cases.

Reviews

CLINICAL GENETICS

Clinical Genetics. Edited by Professor Arnold Sorsby. 31 Contributors. (Pp. 580+23; 311 illustrations. 90s.) London: Butterworth and Co. 1953.

The plan of this book is both novel and excellent. No space is wasted in providing what must perforce be, within any reasonable limits of length, an inadequate account of the principles of general and human genetics. It is assumed that the reader is already familiar with these, and so the first quarter of the book comprises just what such a reader would probably like to turn to next—namely, a series of more advanced essays on subjects of interest and importance relevant to the medical field. The twelve essays are very good indeed, and it may be invidious to single out particular chapters for special note; but, taking that risk, we might mention Neel on the detection of carriers of inherited disease, Mather on polygenic inheritance, Koller on cytogenetics, and Catcheside on chemical genetics; they have written the kind of contribution which is possible only when the author is discussing a subject of which he is master and when he has taken pains to make the presentation as concise and as clear as is reasonably possible.

The rest of the book is called clinical and covers the genetics of the various systems and specialisms. The whole field is covered, but naturally within the space of a single volume there must be compression, whether by omission of less important topics, or even more by rather brief summaries of what is known about some inherited conditions. Editorial difficulties must have been considerable, and there is indeed some lack of balance in the result. It is reasonable enough to compress the chapter on ophthalmology in view of Sorsby's own recent book, and a similar shortening is understandable with mental deficiency, for which subject Penrose's *Biology of Mental Defect* is available, and again in dermatology, where Cockayne's *tour de force*, although twenty years old, is still invaluable. But why should 26 pages be devoted to the alimentary system, with only six conditions to describe, and no more than 23 to the host of neurological disorders, for which there is no genetic textbook? Incidentally, both are excellent chapters, but, whereas Carter is able to marshal the evidence at leisure, Pratt has to discuss some conditions in briefest summary and omit a number altogether.

The one real failure of the book is in the bibliographies. To anyone specially interested in a particular condition the most that a single volume can provide, and what indeed this volume usually does provide, is a relatively brief, accurate, and up-to-date summing-up. The essential accompaniment is a carefully selected bibliography which will guide the inquirer to the key references. The bibliographies of this book are most uneven. Some are excellent, with the more important references specially indicated, but many are impossibly brief. Sometimes papers are quoted in the text to which there are no references in the bibliographies. Sometimes references are given to papers which are not discussed. Some authors quote the titles of the papers while others do not. It is a pity that the usefulness to the research worker of so excellent an undertaking should have been diminished by neglect of such an important point.

Once again the gremlins have been busy over genetic linkage. There is a reference to two conditions being possibly linked because they tend to occur together, an unfortunate lapse in a book in which a special chapter is devoted to the subject. The best human example for demonstrating the workings of genetic linkage is haemophilia and colour-blindness, and the reader is duly shown in Fig. 206 a pedigree in which the two genes are in repulsion, that is, in opposite chromosomes, followed by a pedigree in which they are in coupling. Then comes Fig. 207, stated to show an example of crossing-over. But, alas, it shows

nothing of the kind, for Riddell's original pedigree has been wrongly reproduced.

The book is beautifully illustrated and produced and should prove of great value to a variety of readers. But the second edition should be considerably more valuable, for then, it may be hoped, balance will be improved, errors removed, and, above all, adequate bibliographies provided.

J. A. FRASER ROBERTS.

CELL STRUCTURE AND FUNCTION

Histology. By Professor Arthur W. Ham, M.B., F.R.S.C. Second edition. (Pp. 846; 518 figure numbers, including 7 plates in colour. 80s.) J. B. Lippincott Company. 1953.
An Introduction to Functional Histology. By Geoffrey Bourne, D.Sc., D.Phil. (Pp. 188. 98 illustrations. 21s.) London: J. and A. Churchill, Ltd. 1953.

These two books have, as a common objective, the correlation of the dull subject matter of purely descriptive histology with cell, tissue, and organ function. They are primarily designed for the use of undergraduates. Both are written in clear, vivid, and unambiguous language, easily understandable by the average student, and in spite of its complexities both authors have tackled their problem with commendable success.

This is the second edition of Professor Ham's book, which is a full and comprehensive treatise on microscopic anatomy, greatly simplified by the generous use of excellent photomicrographs and clear diagrams. The bare facts of normal structure are skilfully blended with those of biochemistry, physiology, and the principles of pathology. Both structural and functional sides are up to date, and the author includes much new knowledge on such subjects as cytoplasmic nucleic acid, chromosomal structure, the function of mitochondria, submicroscopic particulates, and electron microscopy.

Professor Ham, who was a pathologist before he became a histologist, has taken every opportunity to introduce enough histopathology to help the student in correlating normal structure with common pathological processes. An outstanding chapter on the normal structure of bone, for instance, is followed by an account of fracture healing and the fate of a bone graft; an account of tissue fluid, by a discussion on oedema; the structure and functions of the skin, by a simple account of burns and skin grafting; and those readers remembering the author's many contributions to cancer research will welcome several reliable and stimulating accounts of the general characteristics of the malignant cell included in the chapters on cytology.

Dr. Bourne's slim volume must in these days of rapid biological progress be regarded as an essential companion to any purely descriptive treatise on normal histology. To the best of the reviewer's knowledge this is the only book suitable for undergraduate readers which has seriously attempted and brilliantly succeeded in bringing together the results of recent cytological research and blending them with modern physiology. A chapter on histochemical technique, with special reference to the identification of cell and tissue enzymes, will prove of immense value to students who are seriously attracted to the subject and wish to satisfy themselves of the reality of modern intracellular enzymology. We confidently predict that the author's refreshing approach will strongly appeal to all students of general biology.

GEOFFREY HADFIELD.

MANUAL OF PSYCHOLOGICAL MEDICINE

Manual of Psychological Medicine for Practitioners and Students. By A. F. Tredgold, M.D., F.R.C.P., F.R.C.S., and R. F. Tredgold, M.A., D.M., D.P.H. Third edition. (Pp. 328. £1 5s.) London: Baillière, Tindall and Cox. 1953.

Relatively few recent textbooks of psychiatry are free from some sort of aetiological bias, and most of those from the U.S.A. can be labelled as belonging to one school of thought or another. A thoroughly orthodox British descriptive psychiatry is therefore much needed. The third edition of "Tredgold" covers an even wider field than its

predecessors and it has been brought up to date so far as facts are concerned. The attitude to mental maladjustment lacks the therapeutic optimism of the present generation, and, while rejecting as false the gods of psycho-analysis, the authors have tried to do without any very consistent theme at all. The result is a competent compilation in which the different clinical entities are described in detail according to their importance in practice. This will meet the immediate needs of the student and the practitioner, but does not give him much chance to build up a frame of reference into which facts from other sources can later be fitted. This is especially true of the discussion of treatment, where enough is usually given to satisfy an examiner who does not inquire too closely, but it is not the sort of information which helps to avoid pitfalls in treating a patient.

On the other hand, the description of types of neurotic maladjustment which actually come to the consulting-room are most realistic, especially when the minor degrees of instability, psychopathy, and inadequacy are under consideration. Terms such as neurasthenia and eccentric paranoia are made to justify themselves; the section on malingering contains a wealth of experience; while the section on war neuroses extracts in a few pages the more important lessons of the recent conflict.

It is to be recommended as a thoroughly safe textbook.

ALEXANDER KENNEDY.

THE ELDERLY SICK

The Nursing of the Elderly Sick: A Practical Handbook of Geriatric Nursing. By T. N. Rudd, M.D., M.R.C.P. (Pp. 108. 8s. 6d.) London: Faber and Faber, 1953.

This is not a mere textbook of nursing for the elderly; it is far more than that. The writer has a humane and eminently sane approach to a problem which is steadily growing as the expectation of life increases. He appreciates the fact that the first essential to success in this field is to understand the working of the elderly mind, to enter into its fear of being useless or unwanted, to understand that horror of crippling is far greater than the dread of death.

It is interesting to read that only half of the old for whom hospital treatment is sought require medical or nursing treatment which could not be provided at home. The difficulty is to secure adequate supervision at home now that whole families go out to work. In the more leisurely days, before emancipation of women, it was the lot of the unmarried daughters to tend their aged and sick parents. This abominable servitude has fortunately been swept away by economic necessity; something better must be found to replace it. Homes for the aged are a crying need. The author stresses the fact that senile dementia is more likely to be the result of environment than of organic disease: loneliness and boredom are the evil influences.

The sections on incontinence, nutrition, bed sores, and diet are highly practical, and should be of great help to doctors and nurses in caring for the sick of all ages.

A. H. DOUTHETT.

MEDICAL MYCOLOGY

Atlas of Medical Mycology. By Emma Sadler Moss, M.D., and Albert Louis McQuown, M.D. (Pp. 246; 248 illustrations. £3 1s. 6d.) London: Baillière, Tindall and Cox, 1953.

This atlas is based on wide practical experience of mycotic infections in New Orleans. Its aim is to facilitate the identification of pathogenic fungi and the histological diagnosis of the diseases they produce. The authors present about 250 photographs in the style of the introductory manual of medical mycology by Lewis and Hopper. But they discuss the subject more uniformly and without the same emphasis on skin and dermatophyte infections.

The descriptive text is a concise and practical elementary summary representing generally accepted present-day teaching. A chapter on immunology is inadequate, and the use of the term "vaccine" for skin-testing antigen is likely

to cause confusion. The debatable nature of pulmonary moniliasis might perhaps have been considered, and the importance of *Aspergillus fumigatus* might have been mentioned under the pathogenic aspergilli. There are some inconsistencies in the use of capitals for specific names of fungi, and the choice of chromomycosis in preference to the more generally accepted name, chromoblastomycosis, is unusual. In discussing technical methods it is clear that the authors are impressed by the results of primary isolation of pathogenic fungi on Littman's bile-salt crystal-violet streptomycin medium. Consequently it is given considerable prominence among media more generally used. This recommendation merits attention and confirmation. The appearance of cultures under ultra-violet light is described in greater detail than is warranted for normal routine diagnosis.

It is unfortunate that the quality and usefulness of the illustrations vary widely. Many of those depicting cultures serve no useful diagnostic purpose and scales are applied without care. The detail demanded from a number of photographs has not been realized, and microscopical fields of fungous cultures could have been chosen with more discrimination. There is a brief and unusually varied bibliography, but no reference is given to it in the text.

R. W. RIDDELL

FOOD HYGIENE

Food Poisoning and Food Hygiene. By Betty C. Hobbs, B.Sc., Ph.D., Dip.Bact. (Pp. 174; 44 figures. 14s.) London: Edward Arnold and Co., 1953.

Food-poisoning has reached alarming proportions in recent years. One of the major causes is the increasing tendency to take meals in canteens and restaurants, where methods of preparing and serving food by mass production provide the mechanism for extensive outbreaks if technique is faulty. The danger to health is incalculable; the effect on human endeavour can be chaotic. An outbreak of dysentery in a hospital upsets routine, restricts admissions, and slows the tempo of the institution; the introduction and spread of infection in day and residential nurseries occur frequently, impairing their usefulness and on occasion dictating their closure for a time; widespread food-poisoning in a works canteen cripples production, with consequent loss of wages and profits. Too little attention has been paid to this serious problem of public health and national economy.

Dr. Hobbs has used her opportunities and experience as director of the food hygiene laboratory of the Central Public Health Laboratory to great advantage. She presents the facts of food-poisoning and the remedies of food hygiene simply and authoritatively. She demonstrates disturbingly the high rate of increase of infection over a period of years, although it is but right to point out that the high efficiency of the Public Health Laboratory Service is undoubtedly one cause of higher figures in that ascertainment is much improved.

But Horace's Homer nodded, and here the statement on the cover that "the number of notified outbreaks of food poisoning during the last ten years has increased at almost exactly the same rate as the number of catering establishments" must be challenged. The increase is quite definite, but the rate of increase is not nearly the same. Furthermore, a graph which appears at first sight to support the statement is found to be of unsound construction in that the vertical scale is not consistent, and the graph is therefore fallacious. There are several minor blemishes; for example, a Lancashire firm cannot properly be called a Midland firm. Descriptions of examples of outbreaks are exceedingly well done; the numerous photographs are good and in themselves instructive; opinion is sound and well balanced. There is no better book than this on food control, and the few errors but enhance by contrast the general high standard of writing and production. But, example being more efficacious than precept, I can best commend this book by obtaining a copy for myself—and this I have done.

CEREBRAL ARTERIOGRAPHY

Moniz, by performing the first successful carotid arteriogram in 1927, made possible the accurate diagnosis and surgical treatment of certain of the cerebral vascular disorders. His discovery also provided a new method of localizing, and in some cases of identifying, intracranial expanding lesions and a means of studying the cerebral circulation. After careful animal experiments he and his colleague Lima used a 70% solution of strontium bromide as contrast medium, radiographs being exposed as it passed through the cerebral vessels. This substance was soon found to be unsuitable, but with a 25% solution of sodium iodide satisfactory arteriograms were obtained, the medium being injected into the exposed common carotid artery. Sodium iodide was used until 1931, by which time over three hundred arteriograms had been performed and a considerable experience of the normal and abnormal cerebral vascular tree obtained. A 25% colloidal suspension of thorium dioxide (thorotrast) was then substituted as contrast medium, and it proved to be safer than sodium iodide although theoretically dangerous in view of its radioactivity and retention in the liver.

An important development was the introduction of percutaneous puncture of the carotid artery. But this method was of limited use with thorotrast as the contrast medium, for it is irritant if injected outside the vessel. Diodone was first used by Gross in 1939, but its use did not become extensive until Engeset perfected the percutaneous method of injection in 1944. The radiological and operative technique was further developed by Lindgren, and cerebral arteriography is now established as a routine procedure, practised and accepted in all neurological centres. Moniz in 1933 had also started performing vertebral arteriograms in order to demonstrate vessels of the posterior fossa and the posterior cerebral arteries. Four methods of vertebral arteriography are now in use. The percutaneous methods include puncture of the artery in its canal in the cervical spine, and punc-

ture between the arch of the atlas and the occipital bone. The open methods entail exposure of the vessel close to its origin from the subclavian artery or the passage of a catheter up the radial artery.

The indications and scope of cerebral arteriography were fully described by Bull in 1949.¹ Its greatest value is in demonstrating the source of subarachnoid or intracerebral haemorrhage. Congenital aneurysms of the cerebral vessels are the commonest cause of subarachnoid haemorrhage, and cerebral arteriography has made possible the surgical treatment of these lesions, which offers good prospects of cure.² Early cerebral arteriography is therefore indicated so that the aneurysm may be identified and treatment started. The examination, if performed soon after a haemorrhage, does not seem to increase the risk of further bleeding. Multiple radiographic projections may be necessary to demonstrate the smaller aneurysms, and if bilateral carotid arteriography fails to show an aneurysm vertebral arteriography should follow. Cerebral angiomas (arteriovenous malformations) may present with subarachnoid haemorrhage, epilepsy, hemiparesis, or headache, and many can be removed. Mackenzie, analysing the clinical findings in 50 proved cases of cerebral angioma, found haemorrhage to be the presenting incident in 15.³ Intracerebral haematomata, whether or not associated with aneurysms or arteriovenous malformations, may respond to treatment by evacuation, and arteriography will often show their position.

The localization of cerebral tumours depends on their proximity to the large cerebral vessels, whose displacement and distortion may be identified, or on the demonstration of pathological vessels, whose character will often suggest the nature of the lesion. In particular an exact diagnosis may often be made of meningioma, malignant glioma, or metastases. It was at one time thought that the deep tumours of the cerebral hemisphere could be localized only if abnormal vessels were shown, but now that the normal radiological anatomy of the deep veins is well recognized their displacement may indicate the site of a tumour.⁴ Carotid arteriography is indicated only if the side in which the expanding lesion lies is clear clinically or from skull radiographs. If the side cannot be determined, pneumography is the examination of choice, but has the disadvantage over arteriography that surgery is more likely to be required immediately. Vertebral arteriography is indicated only for vascular lesions of the basilar system and for expanding lesions in the distribution of the posterior cerebral artery. With the exception of haemangioblastomata, particularly when they are multiple, it is of limited value for the localization of

posterior fossa tumours, and ventriculography is nearly always the method of choice.

Complications of the procedure result from errors of technique or from the effect of the contrast medium on the cerebral vessels. Errors of technique may cause cerebral embolism or the formation of a haematoma at the puncture site. Diodone has been shown by Broman and Olsson to alter the blood-brain barrier, and this effect varies directly with the strength of the solution and the time of application.⁵ It is this effect on the blood brain barrier (or vascular spasm, which probably causes the transient hemipareses) which may complicate arteriography. This complication is more frequent in patients with severe cerebral arteriosclerosis or hypertension, and the examination may be contraindicated for them. Patients with large tumours and high intracranial pressure occasionally become unconscious after arteriography. This is probably due to oedema of the tumour and surrounding brain causing a tentorial pressure cone. In these cases arteriography may be as dangerous as ventriculography. Where clinical and radiological evidence suggests the presence of a large benign tumour, such as a meningioma, arteriography should be performed only when there are facilities for immediate craniotomy if it should be necessary.

The fact that the contrast medium is responsible for most complications points to the need for continuous search for a non-toxic water-soluble substance. "Urokon" sodium 30% (an organic iodine compound) has been claimed to be safer than diodone and is less disturbing subjectively, but in 1 of 100 patients Chamberlain reported complications.⁶ Recent advances in radiographic technique include simultaneous radiography in two planes; this facilitates examination with a smaller volume of contrast medium. Rapid serial radiography has proved to be of value in the study of the normal and abnormal cerebral circulation and in the demonstration of pathological vessels.

Cerebral arteriography has now a secure place in the diagnosis of neurological diseases, particularly the vascular disorders. It has to some extent replaced pneumography in the localization of intracranial expanding lesions, but these examinations are nevertheless complementary, the choice depending on the nature of the suspected lesion and personal preference of the clinician or radiologist. With the advance of radiographic techniques, it can be confidently predicted that the finer details of the cerebral blood vessels will be demonstrated in the living, for at present only relatively large vessels and lesions can be shown.

CORONARY DISEASE AND WORK

Since the publication of the Registrar-General's analysis¹ of occupational mortality for the years 1930-2 it has been known that mortality from coronary heart disease is considerably higher among the professional classes than among unskilled workers. This observation is all the more striking because experience of most other diseases, including most other forms of heart disease, suggests that where incidence is related to social and economic circumstances it is usually highest in the poorest classes. The striking exception of coronary disease has inevitably provoked discussion of aetiology: and emotional stress,^{2,3} diet,⁴ and the sedentary nature of work⁴ have all been suggested as contributing agents.

In a recent report⁵ Dr. J. N. Morris and his colleagues have added the useful observation that there are differences in the experience of coronary disease between workers in occupations usually regarded as belonging to the same social class. They have examined sickness and mortality records of drivers, conductors, and guards aged 35-64 employed by the London Transport, and, interpreting the first absence from work because of coronary heart disease as the first clinical episode, they have shown that about one-fifth of the cases first present as angina pectoris, about half as coronary thrombosis which is not rapidly fatal, and between one-quarter and one-third as coronary thrombosis which results in death within three days. After a detailed comparison of the morbidity and mortality experience of conductors with that of drivers, they conclude that conductors have less coronary disease, and that their disease appears at a later age and follows a more benign course. In discussing these results Morris and his colleagues consider, as it seems right to do, the possibility of both constitutional and environmental differences between persons in the two occupations. They are particularly attracted, however, by the possibility that lack of physical activity is a contributing factor in aetiology, a suggestion made by Stocks⁶ and supported by a comparison of the mortality experience of clerical workers and mineworkers.⁷ Morris and his colleagues have examined this possibility more closely, and have assembled an impressive body of evidence consistent with the view that mortality from coronary heart disease is inversely related to the amount of physical effort which the occupa-

⁷ Morris, J. N., *et al.*, *British Medical Journal*, 1952, 1, 501.

tion requires. It is clear that physical activity is not the only important factor in the aetiology of coronary heart disease; it cannot, for example, explain the higher incidence in general practitioners than in consultants.⁷ There is indeed every reason to suppose that, as in most other diseases, both genetic and environmental agents are at work, and it is most unlikely that the environmental component can be attributed to a single agent. Nevertheless the relationship between physical activity and experience of coronary disease seems firmly established, and any acceptable discussion of aetiology must take account of it.

These findings in coronary heart disease, like some others related to the aetiology of common diseases, raise an important issue. The environmental changes which have contributed so much to the decline of mortality since the early years of the nineteenth century were brought about by public authorities, and depended for their effectiveness hardly at all upon the co-operation of the individual. But many of the aetiological agents now under consideration are of quite a different character: what to eat, whether to smoke, and how much to exercise are intensely personal questions which cannot be decided solely by Acts of Parliament, and responsibility for answering them must inevitably rest to a large extent with the individual. At present the task of establishing the significance of food, smoking, and exercise in aetiology is sufficiently exacting, and the investigator should not be deterred by the practical implications of positive findings. But it is as well to recognize that when positive findings are forthcoming they suggest no easy remedy, but on the contrary raise issues, personal as well as public, for which the experience of nineteenth-century public health has hardly prepared us.

HEART DISEASE AND PREGNANCY

The management of the pregnant woman with heart disease calls for a high standard of judgment, skill, and watchfulness on the part of the attendants. The close co-operation which should obtain between obstetricians and physicians is exemplified by a joint report at p. 70 of this issue of the *Journal* on 250 pregnancies in 175 women with rheumatic heart disease seen at the National Maternity Hospital, Dublin, during the four years 1948-51. The authors say that these cases are drawn from a population which does not practise contraception, therapeutic abortion, or sterilization, and they argue that a true picture of the natural course of rheumatic heart disease in relation to pregnancy is obtained. The follow-up of the cases was unfortunately limited to a maximum of four years, but many valuable lessons are to be learnt, or rather learnt afresh, from this review.

The assessment of the probable risk of pregnancy in these women is best based, as Professor Bramwell pointed out in this *Journal* last year,¹ on the woman's exercise tolerance before pregnancy, but often the patient is not seen until the cardiac efficiency is already influenced by the pregnancy. The previous obstetric history, age, social surroundings, and personal temperament and wishes of the patient have all to be taken into account in giving guidance and hazarding a prognosis. But the immediate prognosis is governed above all by the quality of antenatal care, and MacRae's² recent description of the details of careful attention which enabled him to report 228 consecutive cases without maternal death in pregnancy or labour is worthy of close study. The heart condition can be expected to deteriorate with increasing parity, probably because of the coincident increasing age; but the severer degrees of disability occur disproportionately often in younger women, probably because of the greater chance in them of recrudescence of acute rheumatism. Auricular fibrillation, respiratory infection, and anaemia are important factors in precipitating heart failure during pregnancy. The maximum strain on the heart is between the 28th and 36th weeks; it might be profitable therefore to admit these women to hospital for rest at this time rather than for the customary two or three weeks before term. Only exceptionally does cardiac failure begin in the last month of pregnancy, and the induction of premature labour during that time is therefore irrational. In cases of mitral stenosis, valvotomy during pregnancy is likely to be increasingly performed, for in some of them it will avert the need to consider therapeutic abortion; the operation may also be preferred when severer degrees of disability show little improvement with medical treatment, or when acute pulmonary oedema has occurred or is threatened. In the management of labour the salient points are the avoidance of caesarean section except for purely obstetric indications, the use of morphine and pethidine for analgesia, supplemented later if necessary by gas and air or gas and oxygen, the shortening of the second stage by the judicious use of forceps under local analgesia, and the avoidance of post-partum haemorrhage. The lying-in period should be extended to at least three weeks, and the woman should then be referred to a heart clinic for further help and supervision, for the obstetrician is dealing with merely one episode in her life.

In the Dublin series, 11 of the 175 women died during the short time of follow-up, 5 of them more than one year after confinement. The conclusion is drawn that these five deaths were not related to pregnancy, but it seems likely that the extra burden, not of the pregnancy itself but of looking after another baby, especially in poor surroundings, materially shortened the mother's life. Of the 6 women who died during pregnancy or within one year of delivery 5 were under 30 years of age, and all were unbooked patients who were admitted as emergency cases and in poor condition. It is discouraging to read that in some cases seen neither the patient nor her doctor was aware that heart disease

¹ Bramwell, C., *British Medical Journal*, 1953, 1, 897.

² MacRae, D. J., *J. Obstet. Gynaec. Brit. Emp.*, 1953, 60, 650.

existed until complications ensued. Heart disease has become one of the commonest causes of maternal mortality, and early diagnosis and scrupulous antenatal care are imperative if fatalities are to be avoided.

MEASUREMENT OF SICKNESS

While the collection of mortality statistics could hardly be made more complete in Britain except in small particulars, the collection of morbidity statistics, other than those of notifiable infectious diseases, is slight in comparison. Malignant disease was early singled out for special study of morbidity, at first by the Radium Commission in 1930, and in recent years the net has been cast increasingly widely by the General Register Office.¹ A few weeks ago a useful study of general practitioners' records by Logan² was discussed in these columns,³ and now a further contribution to this difficult field of inquiry comes from the General Register Office.⁴ It gives information, first, on general morbidity obtained by the Survey of Sickness, secondly on admissions to and discharges from mental hospitals, and thirdly on cancer registration. The last section includes a table showing for twenty-one cancer sites and fourteen regions of England and Wales an analysis of the time intervals from the earliest symptom or sign of cancer to the date of registration or treatment. While no very precise significance can be attributed to these intervals for reasons given by the Registrar-General, they may prove to be of particular interest for comparison with figures obtained in subsequent years (these refer to 1947-8), but even these may provoke thought. For instance, by means of some simple calculations a comparison may be made for the different geographical areas between the proportion of cases with intervals of less than 24 months and the proportion with intervals of 24 months and over. For all the centres and hospitals 16.5% of the cases had intervals of 24 months and over. In the metropolitan area 15% had intervals of 24 months and over, and there was no difference between the teaching and non-teaching hospitals there. Newcastle and Liverpool also had 15%, and Leeds and Birmingham 16%. Sheffield, East Anglia, Oxford, and the South-west followed with 18%, and Manchester with 19%. Finally came Wales with 28%. The number of cases is rather small in Wales and its relative position should be accepted with reserve, but the figures do suggest the need for some special inquiry there if only to ascertain their significance more clearly. Similar comparisons may be made of these intervals between the different cancer sites, but they must at present be even more hazardous if only because of the different rates at which cancers can grow at different sites.

The figures for the mentally sick refer only to those treated in Health Service hospitals; the numbers treated in private institutions, psychiatric clinics, and prisons are unknown. At the end of 1949 there were in mental hospitals 3.4 per 1,000 civilian population, and 68% of

direct admissions were first admissions. The rate of admissions increases as age advances: for men aged 65 and over the rate was 673 per 100,000 population in the age group, compared with 300 for all men, and for women aged 65 and over it was 968, compared with 368 for all women. Like the cancer statistics those for mental illness will gain in significance as the years pass and more figures become available for comparison. This volume is the first on morbidity statistics to be added to the Registrar-General's annual review. It is a break with a 125-years-old tradition that is both welcome and worth repeating.

EXCHANGE OF PRACTICES

During the last four years the Medical Practices Advisory Bureau of the B.M.A. has made over 2,000 introductions with a view to exchange of practices, but fewer than 20 doctors have been able to conclude satisfactory arrangements. It is not difficult to find reasons for this discouraging result. A recent survey by the Bureau suggests that the majority are wanting the same thing—a more desirable area without too great a drop in income. Certainly the inducement of a bigger income is insufficient to attract doctors to industrial areas. Many will only consider an exchange if certain limiting conditions are fulfilled, and are apparently prepared to wait indefinitely in the hope of finding just what they need. At the end of last October, according to the survey, there were at least 70 doctors anxious to exchange practices. Experience shows that many of the secondary difficulties which must inevitably accompany negotiations, such as exchange of houses, the presence or lack of social amenities or of educational facilities, are not insuperable.

The preliminary steps towards exchange are necessarily confidential, and in order to give publicity to the opportunities which are available, together with details sufficient to invite inquiry, while concealing any information by which the doctor or practice could be identified, we publish in the advertisement columns of this issue (p. 24) a list comprising 70 practices offered for exchange. Introductions and advice on procedure can be obtained by application to the Medical Director of the Medical Practices Advisory Bureau. It is impossible to say whether regular publication of a comprehensive list of practices for exchange will increase the exchanges effected, but this tentative experiment of advertising a large number together will at least give a clearer picture of the possibilities of the scheme and of the available facilities.

A TREATMENT FOR ECZEMA

In making therapeutic trials investigators have often had difficulty in discounting the human factor. If the new treatment gives apparent initial success the enthusiasm of the physician is apt to give rise to the over-optimistic reports which are all too familiar and which have in many cases hampered the progress of medicine, caused much waste of time and money, and added false hopes and disappointment to the patient's burden. Thus it is that exaggerated claims for new remedies are prolific, and the disillusioning process lags too far behind. The investigation conducted by Dr. J. H. S. Pettit into

linoleic and linolenic acids in the treatment of eczema (page 79) is a happy exception. Since the first reports of this treatment—most of them, as Dr. Pettit points out, conducted without controls—the treatment has been recommended in advertisements and elsewhere for various types of eczema and for a variety of other dermatoses. As a result these preparations have no doubt been used extensively both in general practice and in hospital. A glance at Dr. Pettit's tables will illustrate the variable course of eczema under different treatments, and it is easy to see how a wrong judgment can be formed if only a few cases are treated. To add to the illusion most doctors, quite naturally, tend to remember with joy the one or two apparent cures and to forget the half-dozen cases in which nothing happened.

Clinical experience grows slowly, and it may be that further experience will eventually attach a somewhat greater value to these fatty acids than this report suggests. But it is probable that the general consensus of dermatological opinion has, by a slow accumulation of clinical impressions and by more limited trials, already reached substantially the same conclusions for which Dr. Pettit now provides statistical support. Indeed, this probably applies not only to atopic eczema but to the various other dermatoses for which this type of treatment has been enthusiastically recommended.

CHLORPROMAZINE FOR HYPOTHERMIA

In a recent annotation¹ entitled "A New Drug" we observed that clinical findings were published before the results of a pharmacological investigation of the drug in question ("4560 R.P.," now known as chlorpromazine or "largactil"), and mentioned the need for research on some aspects of the drug's action. In commenting thus we failed to do justice to the work of Courvoisier and her colleagues² at the Rhône-Poulenc laboratories. Their paper was published in January, 1953, after the appearance of the report by Laborit, Huguenard, and Aulluaume,³ to which we have already referred.¹ Courvoisier's work showed, among other things, that chlorpromazine inhibited the effect of vagal stimulation but did not appreciably diminish the action of acetylcholine. For this reason chlorpromazine was described as a ganglion-blocking agent, although no evidence was given of any action on sympathetic ganglia. Much prominence has been given to this feature of its action, and a ganglion-blocking effect has been held to explain the fall of body temperature which it causes. Both Dundee and his colleagues⁴ and Smith and Fairer⁵ in their recent papers on hypothermia in this *Journal* appear to subscribe to this view. It is, of course, true that the sympathetic fibres to the skin cause vasoconstriction in response to cold, but it has long been known

that the most important organs concerned in heat production are the skeletal muscles. Their innervation is not through the autonomic system, but through the voluntary system, and therefore the suppression of shivering by curare or other substances such as chlorpromazine has nothing to do with autonomic or ganglion blockade.

As to the question of how chlorpromazine, or a mixture of it with pethidine and promethazine, causes a fall of body temperature, one possibility is that it exerts a central action and abolishes the reflex impulses to the skeletal muscles in the same way as does any form of deep anaesthesia. There is also the possibility that it acts directly on the muscles themselves, depressing their metabolism. Evidence against this second view is given by Peruzzo and Forni,⁶ who have determined the effect of chlorpromazine on the oxygen consumption of tissue slices from liver, kidney, and brain. They found that the oxygen consumption of slices of the cerebral cortex of the rat was greatly diminished, but that that of slices of liver and kidney was unaffected. These results strongly suggest that the effect of chlorpromazine is central.

There is, however, nothing new in the finding that substances of this kind will reduce body temperature. Quinine has perhaps the oldest claim to this action, and more recently⁷ it has been shown that pethidine, procaine, diphenhydramine, and quinidine have it too. In our correspondence columns last week (p. 42) Dr. C. Langton Hower gave some timely advice to anaesthetists who are thinking of using chlorpromazine. Until careful quantitative comparisons in further animal experiments have established that chlorpromazine is definitely superior to other drugs, it would seem wise to use more familiar tools, such as pethidine, in the trial of methods of anaesthesia devised to make surgery safer for the poor-risk patient.

HOSPITALS AND THE PUBLIC

About a year ago a report of the Central Health Services Council entitled "The Reception and Welfare of In-patients in Hospitals" was sent out to hospital management committees. Commenting on this we remarked that "lack of information probably causes patients and their relatives more worry than anything else," and we mentioned some of the ways by which the bewilderment and apprehensiveness of the ordinary patient could be relieved.¹ The Portsmouth Group Hospital Management Committee has recently adopted a series of recommendations put forward by the secretary of the group with a view to improving relationships with the public. One of the dangers of a nationalized service is that hospitals should come to be impersonally regarded as a special type of workshop, with problems little different from those of an industrial concern. The burden of the Portsmouth report is that a hospital must exert itself to keep the good will of the public, and that efforts made in this direction will be well

repaid. In particular there is still room for much improvement in the reception of patients and their relatives. Out-patient departments should be brightened, and when patients have to be kept waiting for a long time someone in authority—perhaps the sister in charge of the department—should give them a full explanation of the reason for delay. All complaints, even the unjustified ones, should be sympathetically listened to and answered, so that no patient or relative has any reason to retain a sense of grievance. At Portsmouth they rightly attach great importance to the handling of telephone calls: well-trained, efficient, and helpful telephone operators can do much for the reputation of a hospital.

It has been estimated that in the Portsmouth area one person in every eight comes into some contact with local hospitals every year, and the management committee is one of the largest employers in the neighbourhood. Thus the hospital touches the lives of a large proportion of the population. Where an active "league of friends" has developed round a particular hospital so has the association of the hospital with the neighbouring community become more firmly established. It is good to learn that the Portsmouth Group Hospital Management Committee has agreed that "if the hospitals are to provide the best service, the closest co-operation and confidence of the family doctor must be enlisted." The Hadfield report² has given emphasis to the valuable suggestion that local doctors might be asked for their views on some of the difficulties which arise in the relationship between hospitals and general practitioners. Portsmouth is not the only hospital group to take action on the Central Health Services Council report, but there is still much to be done before the common complaint, "They never tell me anything," is no longer heard.

FLEXIBLE ENDOSCOPES

An idea that may revolutionize the design of endoscopes was last week the subject of a communication from H. H. Hopkins and N. S. Kafany,¹ of the Imperial College of Science and Technology, London. They describe how light may be transmitted through a bundle of glass fibres even when the bundle is curved quite sharply through an angle of 90 degrees. The simplicity of this system of transmitting light images, over that of the existing gastroscopes for instance, which have up to 50 lenses, may add great reduction in manufacturing costs to increased flexibility in performance. With a bundle 4 in. (10 cm.) long made by these workers a bending radius of less than 2 in. (5 cm.) was achieved "without any deterioration in the image quality," and the theoretically expected resolving power of 100 lines to the inch (40 to the cm.) with the fibres used is reported to have been easily obtained. Similar experiments in Holland carried out by A. C. S. van Heel are reported in the same issue. He was led to them by a consideration of the eye structure of some insects.

THE NEW YEAR HONOURS

The list of New Year Honours (see p. 95) contains, as is usual, the names of medical men and women who have achieved eminence in their profession at home, in the Services, and in many Commonwealth and Colonial countries. At the top of the list comes Lord Webb-Johnson, who is promoted to Knight Grand Cross of the Royal Victorian Order. Among the new medical knights comes Professor E. C. Dodds, F.R.S., director of the Courtauld Institute of Biochemistry at the Middlesex Hospital. He was appointed professor of biochemistry in the University of London in 1925 while still in his twenties. Professor Dodds is known all over the medical world for his investigation of the chemical and physiological properties of internal secretions, and for work which led, about fifteen years ago, to the synthesis of stilboestrol. His colleagues, here and elsewhere, will be delighted that the Queen has been pleased to honour him. The dental as well as the medical profession will be gratified by the knighthood awarded to Mr. E. W. Fish, chairman of the Dental Board of the United Kingdom. Mr. Fish, who has been dental surgeon to St. Mary's Hospital and the Royal Dental Hospital, has a distinguished record as a teacher and as an investigator of dental and oral disease. In 1952 he was president of the eleventh International Dental Congress in London. The honour of knighthood has also been awarded to Dr. F. T. Rees, who has recently retired from the post of Director-General of Medical Services, Ministry of Pensions (which is now merged with the Ministry of National Insurance). Dr. Rees joined the staff of the Ministry in 1919, and thus was closely concerned with the pensions work which followed the two great wars. Australia will soon be much in the news, and it is fitting that two Australian medical men complete the list of new knights. Dr. B. H. Swift, gynaecological and obstetric surgeon in Adelaide, has many friends in this country. A graduate of Cambridge University, he is a Fellow of the Royal College of Obstetricians and Gynaecologists, and vice-chairman of the Australian Council of the College. A few years ago he was president of the South Australian Branch of the B.M.A. Dr. H. W. Wunderly, who was elected F.R.C.P. last year, is a specialist in diseases of the lungs. Before his appointment in 1947 as Director of Tuberculosis in the Department of Health at Canberra he was a physician in Adelaide.

Some well-known names are in the list of those awarded the C.B.E., but there will be particular pleasure that a medical woman in Australia, Dr. Kate I. Campbell, is thus honoured: she is a paediatrician in Melbourne. Dr. G. A. Clark, Principal Medical Officer at the Ministry of Health, and formerly dean of the faculty of medicine and professor of physiology at Sheffield University, receives the C.B.; and Dr. H. W. Mulligan, director, West African Institute for Trypanosomiasis Research, and Dr. W. G. Wickremesinghe, who has been Acting Director of Ceylon's Health Services, receive the C.M.G.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

INVESTIGATION OF OUTBREAKS OF INFECTION

BY

R. E. O. WILLIAMS, M.D.

Director of the Streptococcal, Staphylococcal, and Air Hygiene Laboratories, Public Health Laboratory Service, Colindale

No short article can adequately cover the whole of the investigation of epidemics of communicable disease, so a number of restrictions have to be introduced. I shall deal only with diseases that occur in Britain, and largely with diseases for which the laboratory can, in the present state of knowledge, give practical help. Moreover, since it is with the investigation of localized outbreaks of communicable disease rather than with widespread epidemics that the general practitioner is likely to be concerned, the discussion is similarly restricted.

It is convenient to recognize three sorts of outbreak: one in which a number of cases occur as nearly as may be simultaneously; one in which infection appears to be spreading through the community; and one in which the so-called "dropping" cases of a disease occur at intervals. None of these histories is pathognomonic of any particular method of spread, but the explosive outbreak is often due to massive contamination of a common foodstuff, and the dropping-case type of outbreak is commonly due to a chronic carrier of the infective microbe. These two sorts of outbreak are also those in which the general practitioner may be in the best position to assist—the explosive outbreak because he is the first on the spot and therefore best placed to secure material for laboratory investigation; the dropping-case outbreak because he alone may be in a position to recognize its occurrence and envisage the common contacts of the patients.

In the investigation of a suspected outbreak of infection there are several steps. The first is the establishment of a precise diagnosis in the suspected cases, and the second is the taking of a careful history of the patients and of the outbreak. In some cases these two steps—diagnosis and history taking—indicate so closely the source of infection that for practical purposes further investigation is superfluous. More often, however, the third step is an attempt to trace the source from which the latest batch of patients became infected. At the same time an attempt is made to discover other victims of the infection who have as yet shown no signs of the disease; sometimes it is also possible to determine the susceptibility of contacts to the disease. Lastly, it may be necessary to try to find out how the infection was spread—by direct contact or by indirect methods such as food, drink, air, or fomites.

Diagnosis and History

An accurate diagnosis and an accurate history for the individual patients are the first requirements. In many cases the "diagnosis" may be the name of a well-recognized disease. In others, however, it may be a syndrome, observed to occur in epidemic fashion, but not yet widely recognized. In the latter group accurate definition of the syndrome is most important.

The history needs to include the dates of onset of the disease in each individual patient; details of his activities at the times when, judged from the ordinary incubation period of the disease, he must have been infected; and

details of his activities immediately before he fell ill, when he was probably already infective.

In addition to the history of the illness in individuals, we need to construct a history of the incident as a whole, and this has to take account of the persons who were not ill as well as those who were. It is important, especially in outbreaks that may be food-borne, to assess the number of persons exposed to infection, and in all kinds of epidemic a comparison of the attack rates in various groups of the population—different classes in a school, different ages, the two sexes, the various wards in a hospital—may often give a strong lead to the subsequent bacteriological investigations.

In some instances diagnosis and history may be all that is possible, for want of methods for cultivating the responsible microbes or other means of laboratory confirmation. Even so, it may be possible to infer the way in which the disease is spread and methods for its prevention.

However, there are numerous occasions when laboratory help is indispensable to the proper investigation and control of the epidemic. Laboratory help comes first in helping to establish the diagnosis of the disease, and at this stage it has two functions. The first is to put a precise name to the patient's illness—to convert the label of "P.U.O." to the diagnosis of typhoid fever, to distinguish the streptococcal from the non-streptococcal sore throat, to recognize the true virus influenza among the host of "flus." These distinctions can often, with experience, be made on clinical grounds alone, especially in the face of a general epidemic, but the laboratory should be able to make the distinction with more certainty and in the atypical cases. For this to be most useful the laboratory must be prepared to issue, and the practitioner to accept, preliminary reports which may be subject to some revision when the tests are complete.

The second function of the laboratory is the "type identification" of the infecting organism. In many cases the members of a species of pathogenic bacteria or viruses can be classified into a number of types which are stable under natural conditions. Then, if two patients are found to be infected with one species of microbe but of two different types, we can conclude that they became infected from different sources and are not part of one epidemic. If both are infected with one type they may well have acquired the infection from a common source, but the

TABLE 1.—Microbes that Cause Epidemics and Can be Classified Into Types

Microbe	Disease	Typing Method Employed on Microbe
<i>Salmonella typhi</i>	Enteric fever	Bacteriophage
<i>Salmonella paratyphi</i>	"	"
Other <i>Salmonella</i> species	Food-poisoning	Serology
<i>Escherichia (Bacterium) coli</i>	Some gastro-enteritis in infants	"
<i>Shigella</i> species	Dysentery	"
<i>Streptococcus pyogenes</i> (Lancefield's group A haemolytic streptococci)	Scarlet fever, sore throat, puerperal sepsis, etc.	"
<i>Staphylococcus aureus</i>	Food-poisoning, sepsis, etc.	Bacteriophage
<i>Streptococcus pneumoniae</i> (pneumococcus)	Lobar pneumonia	Serology
<i>Corynebacterium diphtheriae</i>	Diphtheria	Morphology, culture, serology, and physiology
Influenza virus	Epidemic influenza	Serology

degree of certainty that can be put on this conclusion depends on the frequency with which the various types occur in the population.

Of the microbes that cause epidemics, those for which type identification is possible are listed in Table I, but a warning may be added here. The techniques of type identification are commonly difficult and the materials needed are usually available in only a few specialized laboratories. This means that there may be a few days' delay before the results of the tests can be given to the practitioner or medical officer of health. It also means that requests for type identification ought to be restricted to investigations where enough material has been collected to make the results useful.

Search for Source of Infection

The diagnosis and the history should indicate what sort of outbreak is occurring, and what investigations are needed to trace its source, to prevent further cases in the immediate future, and to prevent the occurrence of further outbreaks.

In outbreaks apparently due to infection of a common foodstuff an attempt is first made to demonstrate bacterial contamination of the food remnants, and then a search is made for carriers among the persons who had handled the food. In outbreaks consisting in dropping cases of bacterial infection a search may be made for chronic carriers among contacts and perhaps also for intermittent contamination of food. When there is evidence that a disease is spreading from case to case through a community we are concerned to discover those remaining susceptible to infection and also the potential dispersers of infection; in some examples of this type it may be possible to control the outbreak by isolating all infected persons, but often specific protection of the remaining susceptible persons may offer more hope of success.

Laboratory assistance in the investigation of the source of outbreaks is thus most often required in a search for healthy carriers and for other animate or inanimate sources of the causal organism.

Truly chronic healthy carriers are particularly important in the propagation of typhoid fever, and they also play a part in the spread of streptococcal and staphylococcal infections. In food-poisoning due to salmonellae, and in dysentery, chronic carriers are unimportant, but patients recovering from the disease may continue to excrete the organisms and infect others.

In attempting to pin responsibility for an epidemic on a carrier discovered during investigations made after cases have occurred, it may be difficult to be certain that the carrier was not really a victim rather than the cause of the outbreak, but in either case he may still be a cause of further spread if opportunities occur.

In surveys for possible dangerous carriers it is most important, though often difficult, to examine everyone who may have been concerned. The kitchen staff may include a number of part-time members who are often understandably reluctant to submit to examination; repeated inquiry may be needed to establish the full complement.

The specimens to be obtained from suspected carriers in investigations of some of the more important infections are given in Table II. In the enteric fevers especially, the carrier state may sometimes be recognized by finding a

TABLE II.—Specimens Required from Suspected Carriers

Disease	Specimens
Enteric fever	Faeces and urine Serum for detection of raised antibody titre in chronic carriers or convalescents
Salmonella food-poisoning	Faeces
Dysentery	
Staphylococcal infections and food-poisoning	Swabs from nose and throat, from skin of hands, and from any active or healing septic lesion
Streptococcal infections ..	Swabs from nose and throat and any septic lesion
Diphtheria	Swabs from nose and throat (or wound)

raised serum antibody titre (Widal reaction, typhoid Vi antibody titration), but the interpretation of these tests is often confused by antibodies resulting from earlier prophylactic inoculations. A raised titre of typhoid Vi antibody, however, is found only in persons who are still carrying the living organisms.

A raised antibody titre to the streptococcal toxin, streptolysin O, would similarly indicate recent infection with haemolytic streptococci, but this test is not widely used in a search for streptococcal carriers, partly because elevation of the titre is not invariable even with severe streptococcal infections, and partly because streptococcal infections are so common that only a method giving retrospective type-specific diagnosis would be useful. No such test has yet reached the stage of practical application. Other diseases in which antibody titration may be helpful include influenza, psittacosis, Q fever, undulant fever, and Weil's disease.

Relative Dangers of Carriers

With the intestinal infections, all carriers are commonly regarded as potentially dangerous. On the other hand, healthy persons who yield only small numbers of haemolytic streptococci, even of the pathogenic group A, are of little danger to their fellows, and there is good evidence that heavy nasal carriers are the persons particularly apt to spread the infection.

The hope animating any search for carriers among the contacts of the patients in an outbreak is that we may find a single person infected with the microbe causing the outbreak, and that he or she had the opportunity to spread the disease. Sometimes this hope is realized, and removal or neutralization of the carrier may, provided all the victims are accounted for and prevented from further dispersal, end the epidemic. Often, however, several carriers are found; one of these may perhaps be the source and the others victims—a distinction that may sometimes be possible from the history of the outbreak.

The presence of numerous carriers may also indicate that the microbe has already spread widely through the population, and may indeed have already infected many or all of those susceptible. In some circumstances this may indicate that the epidemic is burning itself out; in others, such as a hospital ward, it may show that the only ways of preventing further infection are by specific protection of the remaining susceptible patients or by closing the pathways along which infection is transmitted, including the isolation of infected persons.

Specific protection may be by the use of general chemoprophylaxis or, in diphtheria and smallpox particularly, by immunization. With diphtheria, indeed, it is also possible to distinguish the susceptible persons from the immune persons by means of the Schick test.

Animal Reservoirs

In considering the source of some epidemics, animals have to be considered. The *Salmonella* organisms responsible for food-poisoning may be pathogens or harmless commensals of domestic animals—the risk from infected duck eggs is so well known now that an infected patient who has had a duck egg within the past few days is often hardly questioned further. Epidemics of psittacosis arise from contact with sick birds, not only parrots; epidemics of bovine tuberculosis and Q fever start with infection derived from cattle or, in the latter case, other animals; and infection in Weil's disease is derived from rats.

Method of Spread of Infection

Inseparable from the investigation of the source of the epidemic—using "source" for the person or animal in whom the microbe was previously living—is the investigation of the way in which the organism was spread. We can distinguish spread by food and drink, by direct or indirect contact, by the air, and by insect vectors. With the possible exception of flies, spread by insects is so rare in this country

that it is not considered here. The distinction between these methods usually has to be made from the history of the outbreak and from comparison of attack rates on different groups of people who had various degrees of association with one another, or were exposed to various possible sources of infection.

Food-borne outbreaks are commonly, though not always, abrupt in onset; accurate history-taking often leads to a clear indication of the source of the infection. The enteric diseases and food-poisoning are always spread by infected or toxic food, and in the investigation of such outbreaks collection of samples of foodstuffs is important; these should be sent to the laboratory immediately, because, if kept, the pathogenic organisms may be overgrown by saprophytes. With diseases like typhoid fever, however, which have an incubation period of 10 days, it is quite likely that contamination of food or water with the typhoid bacillus has ceased by the time that investigations are begun. Some help may still be given by laboratory investigations, which may reveal, for example, faecal contamination of water supplies, faulty food-handling habits, or inadequate heat treatment of milk or ice-cream, and so indicate methods for the prevention of further outbreaks.

In both "dropping-case" and "spreading" outbreaks in hospitals hopes of prevention lie in investigation and the closing of the routes of infection, especially by improvements in the aseptic routine. For this it is often necessary to spend a great deal of time in the affected department, quietly observing the routine as it is followed; it will often be found to differ from that prescribed by authority.

In investigating outbreaks in hospitals and schools it is often possible to obtain evidence of widespread dissemination of the epidemic microbe on bed-clothes, in floor dust, on surfaces, and in the air; and bacteriological investigations of fomites may suggest the route of transmission. It is well to remember, however, that the finding of, for instance, large numbers of streptococci in the floor dust of a school suffering an epidemic of scarlet fever does not necessarily imply that the victims were infected by dust-borne streptococci; it may be that the streptococci in the dust are no more than a by-product of dispersal from carrier to new host by much more direct means.

In one special case the method of transmission of infection may be discovered, but not the person from which the infection is derived. This is the syringe-transmission of infective hepatitis: the causative virus may be carried in the blood of apparently healthy persons and be transferred to others by inadequately sterilized hypodermic syringes or needles; the infecting dose of virus is so small that it may be contained in an almost imperceptible amount of blood.

Conclusion

Clearly, methods for the investigation of all epidemics cannot be prescribed in a short article; all that can be done is to indicate some of the broad lines of approach, and the part that the laboratory can play in the investigations. The medical officer of health, on the epidemiological side, and the laboratory, on the microbiological side, can give guidance to the practitioner on the specimens that should be examined and the investigations that may profitably be made in any particular outbreak. The part played by the Public Health Laboratory Service, which was constituted to give assistance in the investigation of epidemics, was described by Dr. M. T. Parker in a previous article in this series (October 10, 1953, p. 823).

The investigation of outbreaks of infection has often consisted solely in the analysis of numbers of cases and of attack rates on the various sex and age groups of a population that are readily accessible in the, often inadequate, written records. Analyses of attack rates are essential, but to show their real value they have to be done in the first few hours of the investigation, for their first purpose should be to guide the field and laboratory investigations. The source of any but the simplest of epidemics can rarely be found unless the investigations are started as soon as there is

reasonable suspicion of the existence of an epidemic, and it will certainly not be found without a concerted clinical and laboratory investigation on the spot. With information gained from such full investigations, retrospective analysis may be expected to indicate the way in which further outbreaks may be prevented.

Next article on Clinical Pathology.—"Examination of Faeces for Infection and Infestation," by Dr. K. B. Rogers.

Refresher Course Book.—The first collection of articles in the Refresher Course for General Practitioners (fully revised) are available as a book containing 55 chapters, price 25s. MEDICAL AND SOCIAL PROBLEMS OF THE AFRICAN IN INDUSTRY

BY

J. H. JACKSON, M.B., B.S.

The industrial and mining development of the greater part of the African continent is still in its infancy. Full development will result in its attaining a position of great economic and strategic importance in the world, but cannot be carried out without native African labour. The future prosperity of Africa rests upon this, unless some equally suitable type of labour can be found. No true thought or consideration has been given to this fact by those in whose hands the existing development of the continent up to the present has lain. This seems to have been due to ignorance of the economic and social hazards of a policy of *laissez faire*, combined with the fact that labour supply has exceeded demand and the sources have been primitive peoples with a high reproductive rate whose mental horizons and economic needs were until recently of the lowest possible order.

Social Conditions

To-day in a large part of the African continent the industrial and mining development which has taken place has created terrible social conditions associated with poverty, malnutrition, disease, and crime. The terrifying proportions of these social evils appal the mind when viewed in the nakedness of their true facts. The social burden of the corrective measures necessary to deal with the situation now in existence is likely to be extremely heavy if the measures required are to prove effective. Indications are that such measures are beyond the means of the community as at present constituted. The social unrest which must inevitably spring from the continued existence of these conditions is likely to lead to economic and political disaster.

Whether sufficient knowledge or foresight could have been expected from those responsible for the creation of the present conditions one cannot say. Nevertheless I am of the opinion that a repetition of the mistakes elsewhere can be avoided by a knowledge of those of the past. It is the intention of this paper to discuss the medical and social impact of certain procedures which have been adopted to obtain native industrial labour, and the ultimate effect which they are likely to have if imposed upon primitive native peoples. It is based upon five years of general practice in an area where some of the conditions described exist. If it prevents similar conditions arising during the future development of the relatively untouched African territories then its purpose will have been well served.

Migratory Labour

In a large part of Southern Africa a system of migratory labour for the mines, industry, sugar plantations, etc., has been in existence from the outset. It will serve no purpose here to describe and discuss the factors which have resulted in the creation of native reserves where a large proportion of the population is crowded, where the land is eroded and exhausted, and, with present methods of cultivation, incapable of supporting agriculturally the population on it, and where no industries whatsoever exist capable of contributing to the local economy. Suffice it to say that they exist to-day in their stark reality. From these reserves 30 to 40% of the able-bodied males go annually to work elsewhere, leaving their women to till the land. These men depart for a period of six to nine months, sometimes for one to two years, to labour for the means necessary to give them and their distant families the barest of livings. No modern nation, even in the face of the direct military necessity, could maintain such numbers in the field. Certainly it would not be willing to maintain such a force outside its borders in peacetime. The social, medical, economic, and moral results of this migratory labour are catastrophic, and the system cannot be condemned too strongly.

The incidence of venereal disease is high amongst Africans in those areas where European civilization and industry have become firmly established. The published figures are in fact staggering when compared with those from other areas. It is undoubted that the introduction, spread, and high incidence of syphilis amongst the native peoples of Southern Africa is directly related to contact with the European and his industry, served by migratory labour. Apparent also is the lack of attention paid to the warnings of those medical men whose writings provide the evidence of this (Kark, 1949; Sax, 1952). The excellent survey of the social pathology of syphilis in Africans by Kark (1949) presents the facts admirably. To combat the amount of venereal disease now in existence in certain areas demands an extensive organization of social, medical, and educational workers. Moreover, the essential features of migratory labour among backward peoples are such as to prevent any effective control by such measures. Effective legislative measures to prevent the spread of disease can be placed on the statutes, and exist, but to put such measures into effect would result in social, economic, and legal chaos.

Malnutrition

The increasing dependence of the native in the reserves upon migratory labour, his ignorance of proper farming methods, and its sequelae—neglect, overstocking, and soil erosion and exhaustion—combined with a natural increase in population, have produced an intense and increasing problem of malnutrition. Unless checked this of itself is likely to have far-reaching effects, and it is already taking its toll. The selective action of malnutrition on the native female of the reserves has been noted (Jackson, 1952). That a process of racial degeneration due to malnutrition may be taking place can be supported by reasoning alone, and has been suspected (Gillman and Gillman, 1951; Jackson, 1952; Jones, 1952). Two processes are probably involved.

(a) The fertilized ovum is to some extent independent of the mother, even while *in utero*, and makes every effort to satisfy its own biological demands for development and growth. The high incidence of miscarriage and premature birth among malnourished African women is known (Gillman and Gillman, 1951; Ross, 1952). That the high abortion rate can be solely attributed to venereal disease is doubtful. It is conceivable and highly probable that the genetically larger foetus with a greater biological demand will be unable to satisfy its needs from a malnourished mother and consequently will undergo foetal death and be lost through abortion. This process, if operative, is likely to be highly selective under intensive malnutrition and will be a potent factor in racial degeneration.

(b) The summation from generation to generation of the environmental influence of diet in man where there is a long

gestational period must also play a part in general somatic deterioration. It must be remembered that the predominant part played by carbohydrate, and particularly by maize in certain areas, is conducive to degenerative changes in the mother and possibly in her infant.

Malnutrition in the native results in a high incidence of preventable disease. This includes premature ageing, tuberculosis, skin infections, general inefficiency, and backwardness. The most important single factor contributing to the high incidence of tuberculosis in the African is malnutrition. The incidence of tuberculosis in the native of Southern Africa is the highest in the world. In areas where maize is the staple article of diet insanity is a sequel to the malnutrition, and the insidious mental degeneration consequent upon such a diet must contribute to general mental backwardness of the people.

It has often been said that African labour is not cheap. This statement is true because the labour is inefficient and there is a high wastage, but it needs qualifying by an assessment of the medical and social handicaps which contribute to the inefficiency. Too much has been expected of the African. One is surprised, taking all circumstances into consideration, that he has accomplished, and continues to accomplish, as much as he does to-day.

Detribalization

There is growing up in Southern Africa a class of men often referred to as detribalized natives. They are most numerous in the towns, but their counterparts are beginning to appear in the reserves. The term is used frequently with an implication of regret and depreciation, as though they were social misfits. This is strange. In actual fact they are the natural products of civilization and industrialization and will appear wherever the natives are employed by industry. Upon them will turn the fate of Africa. The tragedy of Southern Africa to-day is that the logistics of their advent played no part in the development of the country. There is to-day an amorphous mass of human material living without tradition, social structure, or allegiance in slum conditions exhibiting the worst forms of human degradation, poverty, malnutrition, and disease. These masses have grown up around all the large European residential and industrial centres. There was no planning, and the problem is practically out of control. From these areas have radiated social diseases which have contaminated the most distant tribes (Kark, 1949; Sax, 1952).

The detribalized natives are in an unenviable and tragic position, for no place was made for them, and their natural heritage has been denied them. No attempt has been made to guarantee them a social structure and a feeling of belonging to a society within the natural order of their existence. As a group they are without a name or a home.

A Problem for the Future

From the foregoing and from the literature quoted an investigator will obtain the impression, and rightly so, that the progress of civilization in Africa has resulted, so far, in a progressive burden of social maladjustment, disease, poverty, and malnutrition for the African people. One might say that if the African is suspicious of the intentions of European civilization he is, judging by the results, justified from a medical point of view.

In any discussion of social medical problems, particularly concerning a continent of multiracial and multitribal inhabitants, it is difficult to avoid confusing politics and preventive medicine. I doubt, in actual fact, whether they can be dissociated, unless the discussion of the problems outlined be regarded as education of the races involved on the nature of the prospects before them. One thing is certain that for the safety and economic prosperity of the African continent capital and labour from all races must combine to produce harmony and to avoid the potential dangers which lie ahead. For those territories which are yet undeveloped, planning will ensure a stability and prosperity which will exceed anything yet accomplished in the continent. The

prosperity of any section accomplished at the expense of the legitimate human needs of another, at the expense of the soil, or of any other resource, is exploitation and will finally result in chaos. There may or may not be a remedy. The economic drain of preventable disease, both social and secondary to ignorance, poverty, and malnutrition, will, unless checked, prove a burden eventually on any society. In a multiracial interdependent society its results in one section are likely to be disastrous for all. It is apparent from the literature quoted that members of the medical profession are concerned about the medical prospects in Africa. To adopt the attitude that everything will come right in the end in areas where such conditions exist is an admission of defeat. In areas where it does not exist but may arise such an approach would be tantamount to negligence.

The future of Africa is the heritage and the responsibility of all races within its bounds. The problems are theirs.

MEDICAL NEW YEAR HONOURS

The names of the following members of the medical profession were included in the New Year Honours List published in the *London Gazette* on January 1.

G.C.V.O.

LORD WEBB-JOHNSON, K.C.V.O., C.B.E., D.S.O., T.D., M.B., Ch.B., F.R.C.S. President of the Royal College of Surgeons of England, 1941-9.

Knighthood

EDWARD CHARLES DODDS, M.V.O., M.D., Ph.D., D.Sc., F.R.C.P., F.R.S. Courtauld Professor of Biochemistry, University of London.

ERIC WILFRED FISH, C.B.E., M.D., D.Sc., F.D.S. Chairman of the Dental Board of the United Kingdom since 1944.

FREDERICK TAVINOR REES, C.B.E., M.C., T.D., M.R.C.S., L.R.C.P. Lately Director-General of Medical Services, Ministry of Pensions.

BRIAN HERBERT SWIFT, M.C., M.D., F.R.C.S.Ed., F.R.A.C.S., F.R.C.O.G. In recognition of his valuable services to public hospitals and to the University of Adelaide.

HARRY WYATT WUNDERLY, M.D., F.R.C.P., F.R.A.C.P. Director of Tuberculosis, Commonwealth Department of Health, Canberra.

C.B. (Military Division)

EDWARD PHILIP NAGLE CREAGH, M.B., B.Ch., M.R.C.P. Major-General, late R.A.M.C. Honorary Physician to the Queen.

VYVYAN STEWART EWING, C.B.E., M.B., Ch.B. Air Vice-Marshal, R.A.F.

WILLIAM RALSTON DUNCAN HAMILTON, O.B.E., M.D. Major-General, late R.A.M.C. Honorary Physician to the Queen.

ROBERT WALSH MUSSEN, C.B.E., M.D., F.R.C.P. Surgeon Rear-Admiral.

C.B. (Civil Division)

GEORGE ALBERT CLARK, V.R.D., M.D. Principal Medical Officer, Ministry of Health.

C.M.G.

HUGH WADDELL MULLIGAN, M.D. Colonel, late R.A.M.C. Director, West African Institute for Trypanosomiasis Research, Colonial Research Service.

WALTER GERALD WICKREMESINGHE, O.B.E., M.R.C.S., L.R.C.P. Lately Acting Director of Health Services, Ceylon.

C.V.O.

WILFRID PERCY HENRY SHELDON, M.D., F.R.C.P.
WILLIAM ELTON TUCKER, M.B.E., T.D., M.B., B.Chir., F.R.C.S.

C.B.E. (Military Division)

CHRISTOPHER CROWLEY, M.B., B.Ch., D.P.H. Group Captain, R.A.F.

ROBERT JAMES ROSIE, M.B., Ch.B. Brigadier, late R.A.M.C. Honorary Physician to the Queen.

ERIC THOMAS SUTHERLAND RUDD, M.B., B.Ch., F.R.C.S.Ed. Surgeon Captain, R.N.

CAMPION AUBREY RUMBALL, O.B.E., F.R.C.P., D.T.M.&H., D.P.M., L.D.S. Air Commodore, R.A.F. Honorary Physician to the Queen.

C.B.E. (Civil Division)

CYRIL JOHN AUSTIN, O.B.E., M.B., Ch.B. Lately Medical Superintendent, Leprosy Hospital, Makogai, Fiji.

KATE ISABEL CAMPBELL, M.D. For services to medical science in Australia.

WILLIAM GEORGE CLARK, M.B., Ch.B., F.R.C.P.Ed., D.P.H. Lately Medical Officer of Health, Edinburgh.

JAMES THOMAS CURRAN, M.B., Ch.B. Group Physician Superintendent, Lennox Castle and associated institutions, Lennoxtown, Stirlingshire.

THOMAS HALL JAMES DOUGLAS, F.R.F.P.S., Hon. F.D.S. Chief Dental Officer, Department of Health for Scotland.

THOMAS FERGUSON, M.D., D.Sc., F.R.C.P.Ed., F.R.F.P.S., D.P.H. Professor of Public Health, University of Glasgow.

CHARLES MONTAGUE FLETCHER, M.D., F.R.C.P. Physician and Senior Lecturer, Postgraduate Medical School of London.

MUSTAFAH BIN OSMAN, M.B. State Medical and Health Officer, Kedah, Federation of Malaya.

O.B.E. (Military Division)

JOHN MORLEY HOLFORD, M.B., B.Chir., M.R.C.P. Surgeon Commander, R.N.

EUSTACE ALWYNNE ROWLANDS, V.R.D., M.B., B.S., F.R.C.S., F.R.A.C.S. Surgeon Commander, Royal Australian Naval Reserve.

DAVID WRIGHT, D.S.O., M.B., Ch.B., F.R.C.S.Ed., Lieutenant-Colonel, R.A.M.C. In recognition of non-operational services in Japan in connexion with operations in Korea.

O.B.E. (Civil Division)

WILLIAM ARTHUR ANDERSON, M.B., Ch.B., J.P., of Queens-town, New Zealand. For services to the community.

GEOFFREY OSBORN BARBER, M.B., B.Chir. Lecturer in General Practice, St. Mary's Hospital Medical School.

LOUIS GERARD BLAZÉ, L.R.C.P.&S.Ed. Lately Acting Deputy Director of Health (Medical Services), Ceylon.

REGINALD MURRAY DUNSTONE, M.B., Ch.B., J.P. For public and social welfare services in the Commonwealth of Australia.

MACORMACK CHARLES FARRELL EASMON, M.D. Senior Medical Officer, Sierra Leone.

DENNIS HERBERT GEFFEN, M.D., D.P.H. Medical Officer of Health, St. Pancras and Hampstead.

JOHN THOMSON GUNTHER, M.B., B.S. Director of the Department of Public Health of the Territory of Papua and New Guinea.

GOPAL HARIDAS, M.D., M.R.C.P. For services to the St. John Ambulance Brigade and movement in Singapore.

SAMUEL HORTON OLUWOLÉ JONES, M.B., Ch.B., D.T.M.&H. Colonial Medical Service. Director of Medical Services, Gambia.

JOHN WILSON McCAGIE, L.R.C.P.&S.Ed., L.D.S. Lately Senior Medical Officer, Ministry of Pensions.

VATAPAKAT RAMANMENON NARAYANA MENON, M.B., B.S. Medical Officer, Dindings, Federation of Malaya.

The Reverend Sister MARGARET MARY NOLAN, M.Ch., M.A.O., F.R.C.S.I., F.R.C.O.G., D.T.M.&H., D.P.H. For medical and missionary work in Nigeria.

BERTIE SOUTAR SIMPSON, M.B., Ch.B., F.R.C.S.Ed., J.P. Consultant Surgeon for the County of Sutherland.

JAMES ANDERSON SMILEY, M.D., D.I.H. Factory doctor for East Belfast. Special Lecturer in Occupational Health and Lecturer in Forensic Medicine, Queen's University, Belfast.

HENRY GEORGE TRIAY, M.D., D.C.H. For medical services in Gibraltar.

HUBERT CAREY TROWELL, M.D., F.R.C.P. Colonial Medical Service Specialist (Physician), Uganda.

WILLIAM HENDERSON WATSON, M.D. Medical Officer in Charge, Mental Hospital, Nyasaland.

M.B.E. (Military Division)

ANTHONY ST. CLAIR REX DE COSTA, M.B., B.S. Captain, Ceylon Volunteer Force.

CHRISTOPHER BERKELEY WYNN-PARRY, B.M., B.Ch., D.Phys.Med. Acting Squadron Leader, R.A.F.

M.B.E. (Civil Division)

RATU JIONE ANTONIO RABICI DOVI, M.B., Ch.B. Medical Officer, British Solomon Islands Protectorate.

VISHNUPRASAD BALKRISHNA PANDIT, L.C.P.S. Senior Sub-Assistant Surgeon, Uganda.

ETHEL JOYCE SAWARD, M.R.C.S., L.R.C.P. For medical services in Jamaica.

CHARLOTTE ANNIE STUART, M.B., B.Ch., D.T.M.&H. Principal Medical Officer, Church Missionary Society Hospital, Cairo.

RAPHAEL LAWRENCE TIRUCHELVAM, M.R.C.S., L.R.C.P., D.T.M.&H., D.P.H. Acting Director of Social Services, Ceylon.

ARTHUR STANLEY WINT, M.B., B.S. For services to sport in Jamaica.

Kenneth Mellanby, Sc.D., who was appointed O.B.E. in 1945, has been promoted to Commander of the Order of the British Empire in the New Year Honours List. He has recently relinquished the post of Principal of University College, Ibadan, Nigeria, to which he was appointed in 1947.

Nova et Vetera

BATTLE OF EPONYMY

Eponymous structures in anatomy may sometimes give trouble. For on occasion the structure may be named after a person who does not deserve such a chance to immortality, or the structure as originally described is quite different from the current view. The common description of Hesselbach's triangle is a triangle delimited by the inguinal ligament below, medially by the lateral edge of the rectus abdominis muscle, and laterally by the fold of peritoneum raised by the inferior epigastric artery. Such a triangle is described in the first edition of Jones Quain's *Elements of Descriptive and Practical Anatomy*, London, 1828, immediately after mentioning Hesselbach's name with regard to hernia externa or indirect inguinal hernia.

In fact, however, Franz Caspar Hesselbach (1759-1816), professor of surgery at Würzburg, in his *Anatomisch-Chirurgische Abhandlung über den Ursprung der Leistenbrüche*, Würzburg, 1806, and more clearly in 1814,¹ originally described the triangle differently. His definition, which is clarified in the plates, was a triangle bounded below by the horizontal ramus of the pubic bone, medially by the lateral edge of the rectus abdominis muscle, and laterally by the femoral vein and inferior epigastric artery. He distinguished external and internal (direct) inguinal herniae and femoral herniae, and described the abnormal obturator artery. Hesselbach pointed out that the two lower corners of the triangle he described were important, and gave his reasons. The medial corner, between the margin of the rectus abdominis and the pubis, where the abdominal wall is weakened by the superficial inguinal ring, is the site of origin of a direct inguinal hernia. The lateral corner, between the pubic ramus and the femoral vein, is the site of the neck of a femoral hernia. In view of this precise statement it is strange how the modern view of the triangle arose and how early the change was made.

Hesselbach is usually given the distinction of having been the first to define the difference between indirect and direct inguinal herniae, but Astley Cooper² in 1804, and two years earlier than Hesselbach's book, quoted the London surgeon, Henry Cline (1750-1827) as having made the observation in his surgical lectures at St. Thomas's and Guy's Hospitals in 1777. A search through five manuscripts of students' notes of Cline's lectures, one dated 1785 and another 1791, at the Royal College of Surgeons has confirmed this. Astley Cooper also confirmed the observation from his own experiences.

¹Neueste anatomisch-pathologische Untersuchungen über den Ursprung und das Fortschreiten der Leisten- und Schenkelbrüche, Würzburg, 1814.

²The Anatomy and Surgical Treatment of Inguinal and Convental Hernia, London, 1804.

In the 1806 book Hesselbach mentions another name for the inguinal ligament—the ligament of Fallopius. Joseph Hyrtl (1810-94), professor of anatomy at Vienna, in his *Onomologia Anatomica*, Vienna, 1880, has a comment on this. "I do not understand why the structure, which was known by Vesalius (Book 2, chapter 31, of the *Fabrica*, 1543) and excellently described by Fallopius (an Italian anatomist, 1523-63) in his *Observationes Anatomicae*, Venice, 1561, between the iliac spine and the symphysis pubis is called 'ligamentum Poupartii.' François Poupart (a French surgeon, 1661-1709) had the temerity or ignorance to describe this ligament as something new, thus earning the gratitude of his compatriots." However, 90 years earlier, a Frenchman, Antoine Portal (1742-1832), who on the title page of his *Histoire de l'Anatomie et de la Chirurgie*, Paris, 1770, is described as "lecteur du Roi, Professeur de Médecine au Collège Royal de France, Professeur d'Anatomie de Monseigneur le Dauphin, de l'Académie Royale des Sciences, etc., etc." had already written in favour of Fallopius's name for this ligament: "C'est ce ligament que l'ignorance a fait attribuer à Poupart, qui a vécu cent ans après: quelle erreur! quelle faute d'histoire! des Anatomistes modernes, fameux d'ailleurs, sont cependant sujets à de pareilles méprises." Despite this, for many years it has been Poupart who has usually won what might be called this international battle of eponymy.

My thanks are due to Professor J. D. Boyd and Mr. W. Le Fanu, Librarian at the Royal College of Surgeons, for their help.

MILK KEYNES.

Preparations and Appliances

AN IMPROVED UNDINE

Mr. L. G. SCOLAR, of London, W.1, writes: The sterilization of a glass undine has always been a source of annoyance to sisters and nurses, largely because it is such a difficult thing to grasp with forceps. If held by the spout it usually breaks, and if the inlet is grasped the nurse has her fingers scalded by the boiling water, which runs down the forceps as she inverts the undine. The photograph shows an undine which Messrs. Clement Clarke, of Wigmore Street, London, W.1, have made for me. The chief feature is a bridge or handle between the spout and the inlet. By this it can be held with forceps, picked out of a boiling sterilizer, and inverted. It is of uniform size, and contains 5 fl. oz. (140 ml.). There is a wide base to give it stability, and the inlet points outwards rather than upwards so as to minimize the collection of dust. Being made of "pyrex" glass, it is stronger and has greater thermal resistance than those made of ordinary glass.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Radiology and Lumbar Disks

SIR.—The review in your leading article (*Journal*, December 19, 1953, p. 1363) entitled "Radiology and Lumbar Disks" gives an excellent picture of current attitudes towards the diagnosis of this fashionable complaint. In the same issue under "The Doctors' Diseases" (p. 1372) you report Mr. E. A. J. Heath as saying that in the experience of an insurance company the diagnosis of prolapsed disk was on the increase. He further stated that the condition showed a considerable augmentation of the period of disability when compared with that due to lumbago, sciatica, and sacro-iliac strain in 1937. I could therefore have wished your survey might have extended to assess the results of treatment based on the newer aetiology.

Most clinicians, especially those whose experience stretches back 30 or 40 years, would agree that, up to date, the human race has not benefited as much as might have been hoped from the demonstration of the mechanical cause of several conditions previously incorrectly labelled. I can say that among the Metropolitan Police the period of disability or incapacity from complaints diagnosed or suspected as being due to prolapsed disk conforms to the figures given by Mr. Heath.

If these statements are accepted, they appear to offer a challenge to our current methods of managing the condition. The answers will no doubt vary. I agree that now that the first enthusiasm for operation has passed the selection of cases which justify surgery is slowly finding its level. In the less severe examples without gross neurological signs two factors may be responsible for causing unnecessarily prolonged disability. The first is premature diagnosis. Many practitioners are all too ready to attribute "lumbago" or "fibrositis" of the buttock to prolapsed disk and to inform the patient of this possibility. A hospital assignment is the natural sequence. Often enough I am faced with a policeman who appears to be fit for duty after an attack of lumbago: in accordance with his sensibility to a diagnosis which suggests that there is something radically wrong with his spine he may or may not agree. Frequently, however, he says: "Oh, I have an appointment next week to have an x-ray and see a specialist," and, not unreasonably, he thinks he should remain on the sick list. The second factor is the commonly prescribed system of treatment for fairly severe cases. I am inclined to think that prolonged partial immobilization in plaster followed by the provision of a restrictive belt is a too frequent routine. It seems that limited rest, traction, and exercise to restore muscle tone and function are not as generally employed as they might be.

Whatever value may be attached to my suggestions I would submit that we should recognize that, though the aetiology of sciatica and the like may be established, the resultant form of treatment has, up to date, been productive of as much, if not more, harm than good to the community.

I am, etc.,

Faversham, Kent.

MAX PAGE.

SIR.—May I be permitted to comment on your leading article, "Radiology and Lumbar Disks" (*Journal*, December 19, 1953, p. 1363)? After careful study I found it difficult to decide whether it contained a plea for the more extensive use of myelography, and concluded that this was probably the case. It seemed to be based upon the need to exclude—or reveal—the presence of a tumour in patients suspected of suffering from a protruded lumbar disk. The incidence of tumours misdiagnosed as protruded disk, according to the quoted figures, was 4.3% at the Lahey Clinic and about 8% at the Mayo Clinic. But these cases

were nevertheless dealt with by operation—presumably satisfactorily. Would the writer recommend myelography in every case of suspected lumbar disk protrusion in order to demonstrate pre-operatively tumours in those patients ultimately brought to operation? If that be the case, since the writer makes the statement (and many would agree with it) that "four out of five cases get better when treated conservatively," myelography would be carried out for a condition which occurs in probably not more than 1% of the cases. The statement is made that there is a prejudice against myelography in many centres in Britain, especially amongst orthopaedic surgeons. This is a most fortunate "prejudice" and the use of this word perhaps implies the writer's leaning towards this procedure. He states later that at most neurological centres myelography is held to be an essential investigation; I can hardly credit this, and wonder on what experience he bases such an opinion. And essential in which cases?

Finally, he quotes Barr that catastrophes can only be avoided by routine myelography. Is this closing remark a recommendation? If so, it needs critical examination. What are the catastrophes to be avoided? Those which arise from a lack of careful assessment of the history (so often neglected) and physical signs? A routine investigation—in all patients complaining of posterior crural pain, or of those coming to operation with a carefully considered diagnosis? It would be a retrograde step if, after "twenty years" of experience, those who treated patients were to employ as a routine a procedure which (with present contrast media) is not without danger, is not entirely reliable for the diagnosis of lumbar disk protrusion, and is usually redundant. One had hoped that in this country medicine had now achieved a more critical outlook. Myelography is a valuable method of investigating the spinal canal, and it may be helpful in the investigation of a small proportion of cases of suspected lumbar disk protrusion. The quickest way of bringing it into disrepute is to use it as a routine procedure.—I am, etc.,

London, E.1.

D. W. C. NORTHFIELD.

SIR.—Your leading article on radiology and lumbar disks (*Journal*, December 19, 1953, p. 1363) leads me to believe that nobody in Britain has yet seen fit to put on trial the methods described by Hasner, Schalmitzek, and Snorrason.¹ These gentlemen, working at the State Hospital, Copenhagen, have evolved what they call a functional x-ray examination of the spine, and, as its name implies, the rationale is to examine the spine radiologically from a functional point of view—namely, in its main positions of flexion, extension, and lateral bending. In the first two positions the films are taken in the lateral view, whilst in the third position they are taken in the antero-posterior view.

When the normal spine bends in whatever direction, the vertebrae angulate on each other, the angles converging to the concavity of the spine. In cases of prolapsing or degenerating disk there is either parallelism of the vertebral bodies or paradoxical angulation—i.e., the angle formed between the two vertebrae converges to the convex side of the spine. In a series of 90 cases these workers were able to demonstrate 86 abnormal disks by their functional x-ray examination. Of 13 patients submitted to operation the functional x-ray findings were confirmed in 12, whereas straight x-ray only revealed 6 cases. In this same series of 13 cases, myelography failed to reveal one case which the functional x-ray discovered, and vice versa.

I would have thought that there was sufficient evidence of the merit of this method to warrant its being taken up in this country.—I am, etc.,

Salford, 7.

HYMAN DAVIES.

REFERENCE

¹Acta radiol. (Stockh.), 1952, 37, 141.

SIR.—In your leading article on radiology and lumbar disks (*Journal*, December 19, 1953, p. 1363) you state that an enormous "disk" literature has grown up in the past 20 years and that opinions still differ widely on diagnosis, treatment, and prognosis. However, there is one aspect of

this disorder on which there is complete agreement, that is the gross severity of sciatic pain. For this reason I would like to suggest a rapid method of treatment that requires no particular manipulative skill.

The problem of replacing a herniated disk, as I see it, is to reduce the intervertebral pressure below the level of that exerted by the tissues on the displaced disk. Intervertebral pressures are evidently at their lowest when there is full adaptation for muscular activity. The initial response to an effort stimulus is an extensor movement. This includes contraction of the erectors spinae muscles—bracing oneself for an effort, as it is usually known. The movement is a sustained contraction but is, none the less, a movement. The spinal column is thus extended and supported, and strain is distributed evenly along the whole column. On the other hand, intervertebral pressures are probably at their highest when the extensor muscles are relaxed. Anybody who has had the experience of heading a ball relaxed, or "flatfooted" as it is called, is unlikely to forget the jarring sensation along the spine and sacro-iliac joints. No such effects ensue when one "goes up" to the ball. With full extension the muscles take over the burden of the joints. For a like reason it is less fatiguing to walk for an hour than to stand still for a quarter of that time. When the extensors are relaxed the spine is flexed and the intervertebral pressure tends to be greater at the anterior aspect of the disk. Physical effort, such as lifting a weight, without the preliminary protective extensor contraction will increase the pressure on the anterior portion of the disk and retropulsion is liable to occur. In other words the immediate or precipitating cause of disk displacement is the failure of the patient to react in a normal way to an effort stimulus.

The treatment then is to restore the initial extensor response. The patient lying in the prone position is encouraged to extend the lower limbs and contract the plantar muscles. He is then asked to raise his head (without arm help) and at the same time to expire fully. Expiratory movement synchronizing with the initial extensor movement is the normal respiratory response to an effort stimulus. The diaphragm should be relaxed as much as possible. My manipulative reinforcement of these extensor efforts on the part of the patient is merely to raise the sciatic limb slightly at the knee and at the same time to apply moderate pressure of a few seconds' duration to the lumbo-sacral region. One such attempt at disk replacement is sufficient. I have had no failure in the few cases I have experimented on. In fact I believe it possible for a determined, fully co-operating patient to replace a disk without any manipulative help. The earlier the patient is treated the better and quicker the results.

This method of treatment can do little harm in the 5-8% of cases of sciatica due to tumours—usually of the benign type. As for the occasional tubercular cause, a careful history and clinical investigation should be of help. An additional safeguard in this type of case would be the failure of the patient to co-operate—the extensor response being rather feeble in tubercular subjects—in other words, no co-operation, no manipulation.—I am, etc.,

Callan, Co. Kilkenny.

WILLIAM HERON.

Ulcerative Colitis

SIR.—I was much interested in Mr. Stanley O. Aylett's article on the surgery of ulcerative colitis (*Journal*, December 19, 1953, p. 1348) and in the annotation on that subject in the same issue of the *Journal* (p. 1364). Ileostomy, of course, is a beastly operation and Mr. Aylett is to be congratulated on having devised a substitute for it. But what has happened to appendicostomy? Time was when I saw quite a number of cases of ulcerative colitis of all degrees of severity, and my experience was that an appendicostomy followed by lavage of the colon with saline was far the best treatment. The operation was usually done by Mr. Lockhart-Mummery, and many of the patients wore a tube for months or even years, washing out the colon as required and meanwhile carrying on their ordinary vocations in perfect comfort. I think the results were quite as good as those claimed by Mr. Aylett.

Why, then, has the operation fallen into disuse? It can hardly be, as apparently is the case with gastro-enterostomy, that the modern surgeon has lost the "know how" (to use a horrid Americanism) of it, for the technique is really quite simple. It is, perhaps, merely a case of going out of fashion, there being, as we all know, fashions in operations just as

there are in women's hats. Or has appendicostomy joined the ghostly company of "forgotten treatments" about which I have often thought a valuable essay might be written by someone willing to wade deep enough into the morass of old medical literature? Perhaps Mr. Aylett or some other active abdominal artificer will kindly enlighten me.

As to the statement in the annotation that "it is now widely recognized" that sufferers from ulcerative colitis "are people characterized by emotional immaturity, often having a pathological parental attachment," I can only say, "Dear, dear, who'd have thought it?" That such a distressing malady can induce mental disturbances is understandable, for has it not been said that nothing saps the morale of an army more than an epidemic of dysentery, but that a pathological parental attachment can cause, or even predispose to, ulcerative colitis demands more credulity than I, at least, possess. Is this not another example of the tendency in the modern concept of psychosomatic disease for the "psycho" element to steal the limelight from the somatic?—I am, etc.,

Stretley, Berks.

ROBERT HUTCHISON.

SIR.—The article on the conservative surgery of ulcerative colitis by Mr. Stanley O. Aylett (*Journal*, December 19, 1953, p. 1348) is of particular interest to me because I have been treating these cases by the method described by Devine since 1950. The results have also been completely satisfactory, with the one exception in which there was a pre-operative rectal stricture. This still needs regular dilatation and there has recently developed a superficial anal fistula.

In his original article, Devine maintained that stricture was not a contraindication because by this method (a spur crushing technique between low rectum and terminal ileum) the stricture could be eradicated by the fact that half its circumference would then consist of normal ileum. Mr. Aylett's point concerning future inflammatory troubles in this type of rectum is borne out by this case, who otherwise is a happy, healthy young woman soon to be married (a point considered in choosing her original surgical procedure). My other five cases, which were all cases referred by physicians because of chronicity, colonic stricture, pyoderma, and, in one case, multiple arthritis and profound toxæmia, are now all well with an average of two to three bowel movements per day and, when last examined, a healthy rectal mucosa.

I have found that, by leaving a long devitalized loop on the proximal ileum and using this to drain the ileal content via a Paul's tube, and by applying the spur crushing clamp through the open rectal stump and a small hole in the ileum just proximal to the gangrenous loop on the second post-operative day, the spur can be obliterated very early, even while the loop is still draining most of the ileal content clear of the abdominal skin. Aluminium paste, hexamethonium, and early closing of the open ileo-rectal stoma on the fourteenth post-operative day are all aids in getting an early rectal defaecation.

There is no doubt that by this technique and by using an extensive mobilization of the rectum a much more complete colectomy can be subsequently performed. One reads of criticisms of this method in which the critic describes "having to undo the ileo-sigmoid anastomosis" before establishing ileostomy. This declaration, I have always felt, reveals in part the cause of dissatisfaction which has resulted in criticism.—I am, etc.,

Great Yarmouth.

Malaria in Ex-Servicemen

SIR.—Although Dr. C. F. J. Cropper's suggestion (*Journal*, December 5, 1953, p. 1269) for the standardization of the treatment of malaria may be acceptable to some, one rather fears that those doctors with experience of tropical diseases will question his inclusion of vomiting amongst the cardinal signs of this disease. The admitted difficulty in diagnosis surely arises from the fact that there is frequently no

cardinal sign. Otherwise how can one account for the amount of research on diagnosis which is still going on, and is still being published in the medical press of the world?

However, if we are to standardize treatment, let us also standardize the diagnosis without the awkward nautical feat of stressing cardinal points, while remembering—with vomiting—*inter alia* the work of Paladini¹ in diagnosis: "Malaria diagnosis by contraction of the muscles of the face during abdominal palpation."—I am, etc.,

Dublin

H. B. WRIGHT.

Infection and Poliomyelitis

SIR.—With reference to your leader (*Journal*, December 5, 1953, p. 1258) upon the above-mentioned subject, the evidence which you quote from American sources that the virus of poliomyelitis is spread by close contact, and that the path of its spread is narrow, has been shown by me to be true in this country.

An epidemic of acute poliomyelitis occurred in a rural area of Kesteven, Lincs, in 1950, and involved 99 confirmed cases with 13 deaths.^{1,2} It was shown that, whereas the spread of poliomyelitis had formerly been attributed to many causes—i.e., to droplet infection or to infected water and foods, milk, ice-cream, etc.; by public swimming baths; by flies; infected dust or dried excreta; by fingers and the communal use of articles recently contaminated by infectious secretions or excretions, or defective personal hygiene—this outbreak in Kesteven demonstrated beyond all doubt that the predominant method of spread of poliomyelitis is by personal contact via the respiratory route.

In all, 114 cases were notified (99 corrected) mostly in the third quarter of 1950. The epidemic originated in the village of Digby (population 1,134), in the rural district of East Kesteven, which had 16 cases. Eleven days after the onset, the disease spread to an adjoining village where 10 cases occurred. Three days later nine cases began to be notified in another village 1½ miles from Digby. In the second fortnight of the outbreak seven more villages were affected, all within four to five miles of Digby. In the third fortnight three other villages were involved, while in the fourth fortnight two more villages were attacked by the disease.

That poliomyelitis was spread in this outbreak by personal contact with infectious persons was proved by the transport of infection between villages over bus routes. All the confirmed cases were resident on organized bus routes, there being no other common mode of transport; some were known to have travelled by bus during the incubation period of the disease. Detailed inquiries showed that there were also links, direct and indirect contacts, between many of the cases, extending over a wide area. In a very high proportion of those affected with poliomyelitis, close personal contact with a declared case or infected household was established.

In the last paragraph of your leading article, in relation to the control of poliomyelitis, you state that quarantine of contacts is the obvious attack, but, if this is to be effective, contact with other people must cease. Doubt is expressed as to whether the movements of adults should be restricted compulsorily, if in fact this can be done at all. I agree that the movements of adult contacts may be difficult to control, especially in city life. Further, there are no restrictions in law upon the movements of such contacts. However, in an article in *The Medical Officer*³ I gave details of the comprehensive measures, including restrictions upon child and adult movement, which were adopted during the Kesteven epidemic. As a measure of their efficacy it is of interest to record the fact that this epidemic was confined to the rural district where it originated and did not spread to other parts of the county.

It is true that much can be done on a voluntary basis by supervision of contacts by trained staff, publicity, and informed public opinion to control this disease, as implied in your leading article. In particular, since close personal contact has been shown to be the predominant factor in the spread of this disease, the M.O.H. and his colleagues in general medical practice will in future be in a better position to give appropriate advice with regard to prevention. Moreover, valuable time may be saved to the M.O.H. in the early stages of an outbreak, as it may not be necessary, unless he has special reasons, for him to devote time to investigations, which are likely to prove futile, into the possibility of water, food, etc., having been the vectors of infection.

When a serious outbreak of poliomyelitis occurs, it is quickly brought to the notice of the public in the area

concerned that they are being attacked by a disease which paralyses or kills. In view of the great amount of press publicity, local and even national, which is given to this aspect, the active co-operation of adult contacts, as well as parents of child contacts, and the public at risk, is not difficult to secure with regard to all precautions which should be taken.—I am, etc.,

Sleaford, Lincs.

A Cosmetic Amputation

SIR.—Sir Heneage Ogilvie (*Journal*, December 12, 1953, p. 1322), referring to the amputation of the index or little finger along with part of the metacarpal, rightly condemns this operation in the manual worker. Obviously, where breadth of hand is an important factor in a man's ability to grasp large objects, the loss of the metacarpal head reduces his working capacity. On the other hand, where a patient's employment calls for the minimum of disfigurement, the gradual tapering produced by the oblique section through the metacarpal is much less noticeable than the abrupt stump produced by disarticulation at the metacarpal phalangeal joint.

If the oblique section is carried out with good plastic surgical technique, there is no reason why the scar should limit the movements of the adjoining finger, or remain tender for an abnormal length of time. These faults suggest technical errors. If sufficient padding of subcutaneous fat and interosseous muscle is left to cover the cut surface of the metacarpal, and the scar is placed towards the dorsal surface, no limitation of movement should result. Neuromata rarely develop if the digital nerves are shortened and allowed to retract well into the soft tissues, where they will not be exposed to pressure or friction. Tenderness and retraction of the scar are complications which arise when the latter is placed too much toward the volar surface or has become adherent to the cut surface of the bone.

Our practice in every case is to discuss with the patient the relative merits of the two operations in relation to his or her work before coming to a decision on a matter of such importance.—I am, etc.,

Basingstoke.

Distinguishing a Psychopath

SIR.—Dr. A. Shepherd invites criticism of my view of the psychopath in relation to mental disease (*Journal*, December 19, 1953, p. 1379). I would differ from him a little by dividing mentally ill patients into psychotics, neurotics, and psychopaths. (Any of these patients may belong to the mentally defective group mentioned by Dr. Shepherd.) I would qualify the general classification I have given by stating that the psychotics have a disturbance principally of knowing, the neurotics of emotion, and the psychopaths of action. This classification of the symptoms of the abnormal mind is in harmony with long and well established custom in the psychology of the normal mind, which regards cognition (knowing), affection (feeling), and conation (action) as different aspects of the same process.

Any given mental illness, therefore, may present as a disturbance of knowing, feeling, or action. Some, or even most, mentally ill patients show obvious disturbance of all these three aspects of the mind; but there are many who present an apparent predominance in one aspect, and of these it is of course the psychopaths who come into conflict with the law. The judge then wishes to know if the psychopath is mentally ill. By the classification I have given, the psychopath is mentally ill. But the law does not easily accept that view and often asks, in effect: "Is this psychopath also psychotic? Has he, apart from his disturbance of normal actions, also got disturbance of knowing such as

would be covered by the M'Naghten rules? If so he can surely be regarded as mentally ill, but otherwise should he not be punished?" Dr. Desmond Curran, giving evidence before Mr. Justice Hilbery (*Journal*, November 28, 1953, p. 1224), appeared to agree with this legal view, and affirmed that a psychopath "is distinct from a person suffering from a distinct disease of the mind."

The situation is, however, illogical if we accept that abnormal behaviour can derive from a mind functioning normally. The clinician, in his own province, should, I submit, accept that a psychopath is mentally ill, even though the evidence suggests that the actions of the patient are more disturbed than his thoughts or feelings. The clinician should also, of course, try to arrive at a diagnosis of the mental illness of the psychopath, as of the psychotic or neurotic. The psychopath, for instance, may be suffering from schizophrenia, or he may be an hysterical psychopath, an epileptic, a hypomaniac, or a case of paranoia. And an attempt should be made to give to each illness its appropriate treatment, even though the illness may be manifest more in action than in thought or feeling.

Nevertheless, when the psychopath comes into conflict with the law, the important question remains: "If abnormal behaviour is to be regarded as a form of mental illness, is the appropriate treatment punishment?" The answer in most cases would still appear to be, and perhaps always will be, "Yes." But it is to be earnestly hoped that treatment by punishment will not so often exclude other treatment of the ailing mind.—I am, etc.,

Leicester.

C. E. H. TURNER.

Glycosuria and Hyperglycaemia

SIR,—In the article on glycosuria and hyperglycaemia (*Journal*, December 19, 1953, p. 1367) the author advocates examination of two samples of urine, the second one one and a half hours after a carbohydrate meal, as a means of distinguishing between glycosuria and the presence of reducing substances other than glucose.

It has been standard practice in the R.A.F. since about 1940 to give 50 g. glucose immediately to any patient whose urine has shown reducing substances without ketones on routine examination. A further specimen of urine is tested one and a half hours later, and if the degree of reduction is not increased it is assumed that the reducing substance was not glucose.

This extension of the principle outlined by Professor Gray has practically eliminated the former common experience of glucose tolerance tests being inflicted on patients who prove to have no glycosuria.—I am, etc.,

Aylesbury.

W. P. STAMM.

Insulin Zinc Suspensions

SIR,—Dr. Ian Murray (*Journal*, December 19, 1953, p. 1377) writes that it seems desirable that both protamine zinc and globin insulins should be withdrawn and be superseded by zinc suspension insulins. But why?

The articles and letters which you have published show no real advantage in the suspension insulins, and surely it is unnecessary and wrong to plunge the diabetic community, not to mention the doctors and consultants who serve them, into the confusion of using one of seven different insulins, as Dr. R. D. Lawrence (*Journal*, November 28, 1953, p. 1215) pointed out. No doubt similar control can be obtained by both the suspension and protamine insulins, but it appears that, on the whole, more of the suspension insulins, sometimes much more, is needed. This will add to the expenses of the Health Service.—I am, etc.,

Hove.

G. M. WAUCHOPE.

The Pituitary and Graves's Disease

SIR,—In his paper on the clinical trial of methimazole in treatment of thyrotoxicosis (*Journal*, December 12, p. 1300) Dr. Lindsay A. G. Davidson makes the surprising dogmatic statement: "At the present time it is generally accepted that the thyroid gland in thyrotoxicosis is producing excess thyroxine in response to stimulation by excess pituitary

thyrotrophic hormone." In support of this he gives references to Samson Wright's *Applied Physiology*¹ and Means's *The Thyroid and its Diseases*.² In the interests of accuracy it is worth drawing attention to what these authorities actually said.

Samson Wright (p. 990) says: "The initiating factor which causes the thyroid to become overactive has not been identified, but emotional stress acting via the hypothalamus on the anterior pituitary may sometimes play a part." Also (p. 980): "It is believed by some that emotional tension causing hypothalamic overactivity leads to oversecretion of thyrotrophin and the development of Graves' disease."

Means (p. 293) states that: "The aetiology of Graves' disease is quite unknown, but one may be permitted to speculate about it." This he does (p. 553), but nowhere does he say what Dr. Davidson attributes to him.

Moreover, in an annotation of recent work entitled "Pituitary-Thyroid Relations in Graves's Disease,"³ the gist is that the results of several quoted authorities suggest that in Graves's disease the stimulus to the thyroid does not come from the pituitary. I am, etc.,

Cambridge.

Sterilizing Ampoules

SIR,—In your issue of December 5, 1953 (p. 1269), a letter by Professor L. P. Garrod condemns the practice of "sterilizing" ampoules in disinfectant solutions. With this I am in entire agreement, particularly with regard to spinal anaesthesia. Not long ago, a new box of ephedrine was opened and an ampoule discovered with no fluid in it. The ephedrine was crystallized out on the inside of the glass. No crack or flaw was visible to the naked eye. If it is possible for this to occur, or for antiseptics to diffuse through a fault in the glass ampoule, then it is also possible for bacteria to gain entry. This may be serious enough when the contents of an ampoule are given parenterally, but it could be lethal intrathecally.

For some time past it has been my practice to wrap ampoules of cinchocaine ("nupercaine") in a swab and place it alongside the syringes and spinal needles. The whole is boiled in distilled water for half an hour, in a sterilizer kept solely for this purpose. Heavy cinchocaine, of course, is allowed to cool before injection, but light cinchocaine is left in the sterilizer so that it is at the right temperature when given. In the event of a faulty ampoule, the only disaster which can arise is the injection of sterile distilled water and the humiliation of a failed spinal. To date, no ampoules have been faulty, nor damaged by boiling, and the quality of the spinal anaesthesia has not been altered. There have been no post-spinal complications from boiled cinchocaine. I am, etc.,

Edgware.

D. RICKLESS.

Antibiotics in Bacteraemia

SIR,—There is a statement in Dr. M. Anthony Peyman's letter concerning antibiotics in bacteraemia (*Journal*, December 19, 1953, p. 1376) which I feel cannot go unchallenged. He says: "Thus it is perfectly possible for a patient to be cured of a bacterial infection by an antibiotic while *in vitro* tests demonstrate the organism to be insensitive to that antibiotic." While I agree that this may be true in some cases with regard to the tetracyclines aureomycin and terramycin, I have never known a case of bacterial infection with a proven penicillin-resistant or streptomycin-resistant organism be cured by these antibiotics; and I maintain that it is a waste of time and antibiotic to persist with treatment when laboratory tests show that an organism is resistant to either of these antibiotics. In general, the rule still holds that one should be guided by the laboratory tests in treating a case with antibiotics, keeping in mind that exceptions with regard to aureomycin and terramycin are possible.—I am, etc.,

Guildford.

A. LAWRENCE.

Medresco Hearing-aids

SIR,—I am sure none of your readers could have been misled by Mr. A. E. Stevens's use (*Journal*, December 19, 1953, p. 1376) of the results of our inquiry.¹ He says that "only 18% of the aids issued were ever taken to work," but he omits to point out that as many as 54% of the patients do not even take *themselves* to work. Only 46% of the patients are, of course, in employment and therefore in a position to take their aids to work. In fact the report said nothing about taking aids to work. It said: "Of the Medresco users who were workers 44% used their aids *when working*." Mr. Stevens's calculation of the 18% is an excellent example of the misuse of statistics.

To correct any false impression this may have given, another sentence might be quoted from the article: "With as many as 91% of the patients claiming to understand all or most of what is said when using the aid, it is scarcely surprising to find that the service has been enthusiastically received." Perhaps we should have added—"by the patients."—I am, etc.,

London, W.C.1.

Controlled Hypothermia

SIR,—I have read with great interest the two papers in the *Journal* of December 5, 1953 (pp. 1237 and 1244), on controlled hypothermia.

I think it is to be regretted that the term "cocktail" has been introduced into medical literature. Unfortunately the French have had the bad taste to make use of this expression and you may be sure that it will soon find its way into their popular press and will lend itself to cheap jokes and advertising for "cocktails" as an adjuvant in modern surgery.

British medical journals combine sobriety with humour of a subtler kind. The "cocktail" might well have been omitted from an interesting report on a new form of treatment.—I am, etc.,

Basel.

ERICH ZIMMERLI.

Appendix in the Hernial Sac

SIR,—Professor Lambert Rogers (*Journal*, December 12, 1953, p. 1324) draws attention to a recent article by P. G. Creese¹ in which Claudius Amyand, of St. George's Hospital, is given due, if belated, credit for the first appendicectomy, which he performed in 1735. Some months ago in searching the *Philosophical Transactions* for early accounts of the acute abdomen I chanced on Amyand's account "of an iliac passion occasioned by an appendix in the ilion."² This is a clear description of the necropsy of a boy of 10 who died of peritonitis following acute inflammation of the structure later to be known as Meckel's diverticulum. It is almost certainly the first account of disease of this vestigial structure. I was so struck by this report that I looked for other case records written by Amyand and was rewarded by the discovery of his report of the successful removal of the appendix from a terminal sac.³ Amyand has, therefore, two distinct claims to fame.

It is quite clear that in medical textbooks statements of alleged historical accuracy are copied without reference to originals. The much quoted case of Mestivier⁴ is an example of inaccurate quotation and is of little importance in the history of appendicitis. Mestivier described a patient who developed a large abscess in the right side of the abdomen. The abscess was opened and much pus was evacuated. The patient died and at necropsy the caecum was found to have necrotic patches ("parsemé d'escarres gangreneuses"). The appendix contained a corroded pin, but there is no mention of the appearance of the organ, of inflammation, or of perforation. Mestivier suggests that the pin by irritation may have caused the illness (. . . "que c'étoit-elle qui, irritant sans cesse les différentes tuniques qui entrent dans sa composition, y avoit déterminé tous les accidents de la maladie . . ."). This case is frequently quoted as the first in which operation was performed for appendicitis, as the first account of appendicular inflammation, or as the first

example of perforation due to a foreign body. It is read in the original it is, as I translate it, merely an entry about of a foreign body in the appendix.

It is surprising that the rediscovery of Claudius Amyand as the first appendicetomist should apparently have eluded the historians of St. George's Hospital and of British surgery. We must pay tribute to the searchers who found Dr. Creese and thank him for bringing to light this interesting and graphic item of surgical history.—I am, etc.,

Liverpool, 7.

SIR,—Judgment, based on implication, is always tricky and often fallacious, as in Mr. Raymond Helsby's comments (*Journal*, December 26, 1953, p. 1434) on the details of a case of true strangulation of an appendix in a femoral sac which I gave in the *Journal* (November 28, 1953, p. 1216). The excision of the appendix from "below" was simply an *ad hoc* manoeuvre to deal with the particular set of circumstances presenting—with the appendix and cone of caecum temptingly displayed. The implication drawn about the habitual use of this method was quite erroneous, as witness the fact that in over 12 years of operating under a wide variety of circumstances I have used the low approach only four times, including the case in question. Perhaps, however, Mr. Helsby's object in writing was primarily to use the letter as a medium for advocating McEvedy's approach, of which he is clearly a devotee. I, also, am familiar with and appreciative of its merits. However, in operating upon strangulated femoral herniae I almost invariably use a crease incision over the inguinal ligament, then, as a first step, dissect the sac out from below for several reasons: (1) It allows safe evacuation of the toxic, infective, and frequently haemorrhagic fluid present in the sac, instead of draining it to the peritoneum. (2) It allows clearing of oedematous and adherent fat from the sac, rendering its reduction easy and neat. (3) It allows inspection of the contents providing useful information before reduction. (4) It allows a combination of manipulations from below and above (as the next step is exposure of the canal from above by the usual route through the floor of the inguinal canal) giving greater control over safe reduction.

It was in making this preliminary inspection from below that I decided, on finding both canal and herniated organ small, just to complete the operation from this angle. I omitted these details from the description of the case, as I was mainly interested in describing the pathology, which was not the usual inflamed appendix in a hernial sac, but a genuine strangulation of a loop of the organ.—I am, etc.,

Wolverhampton.

HENRY B. YOUNG.

Royal Medical Benevolent Fund Christmas Gifts

SIR,—It is a very great pleasure to report that the amount contributed to the Christmas Gifts Fund was most satisfactory and exceeded that of all previous years. It is impossible for me to thank the contributors personally for their generous response to my appeal, but through you, Sir, I should like to thank all your readers who have helped. I am especially grateful to the many B.M.A. Divisions and Branches, medical societies, and local medical committees who either forwarded donations from their own funds or arranged for collections to be made at an autumn meeting.

The many messages of good will sent with donations show how much this Christmas effort of the Royal Medical Benevolent Fund is approved of by the profession. It is hoped that as each Christmas comes round this work of kindness and good fellowship will be continued. I ask those who read the Christmas Appeals in future to bear in mind the intense pleasure and gratitude felt and expressed by those who benefit from the Appeal. I desire to express my own very sincere appreciation of the generosity which has been shown.—I am, etc.,

WEBB-JOHNSON,

London, S.W.15.

President, Royal Medical Benevolent Fund.

Obituary

WILFRED SHAW, M.D., F.R.C.S., F.R.C.O.G.

Dr. J. B. GURNEY SMITH writes: Wilfred Shaw, whose obituary was printed in the *Journal* of December 19, 1953 (p. 1380), was certainly one of the many original personalities who have graced the honorary staff of Bart's. He had a very concise mind, which was readily reflected both in his clinical lectures and on his ward rounds, which always drew large numbers of students. In the theatre he was always bold and fearless, especially if the operation was of a dramatic order such as removal of a large ovarian cyst or a caesarean section. One of his most striking attributes was a wonderful sense of humour, and many of his pungent quips are as fresh to-day as when they were first uttered. Life was never slow when he was about. He was a notable successor to a long line of eminent Bart's physician accoucheurs, comprising Matthews Duncan, Sir Francis Champneys, Herbert Williamson, and my own very revered and beloved chief, John D. Barris. His going creates a gap which it will be difficult to fill, and all Bart's men who knew him will feel that they have lost a real friend.

G. A. S. H. writes: Probably because of his pungent wit, behind which lay his inherent kindness, Wilfred Shaw proved himself a brilliant teacher to whom I turned repeatedly for fresh advice. Above all, he had that rare capacity for setting people at ease, and of encouraging their confidence within a few minutes—a fair tribute, I feel, to his character, as well as to his acknowledged supremacy in his own branch of medicine. I know that I was fortunate to be able to work under him.

Flying Officer A. L. C. DUNCAN was tragically killed on November 7, 1953, in a shooting incident at Buraimi in the Persian Gulf. He was a young man of exceptional promise in his profession and will be greatly missed. Alexander Leslie Cameron Duncan was born on June 6, 1928, and was educated at Jordanhill College School and at Glasgow University, where he graduated M.B., Ch.B. in January, 1952. In his student days he was a violinist in the university orchestra. After graduation he held house-surgeon and house-physician posts at Stonehouse Hospital, Lanarkshire, and Bridge of Earn Hospital, Perthshire, and was an outstandingly good resident. His capacity for work appeared unlimited, yet he could remain cheerful and unruffled under the most harassing conditions. He was kind and gentle towards his patients and their welfare was always his first consideration. He had intended to become a general practitioner, and with his enthusiasm for work and his qualities of sympathy and humanity he would undoubtedly have done a great deal of good in that role. In the Royal Air Force, which he entered last March for his period of National Service, he held several posts in the Canal Zone and latterly served with the Trucial Oman Services, setting up surgeries in the native villages and meeting and overcoming difficulties with his usual good humour and imperturbability. Although he was at Stonehouse Hospital for only six months, he is unlikely to be forgotten, and the deep sympathy of his ex-colleagues there is extended to his parents, brother, and sisters.—T. G. G.

The death of Dr. HUTCHISON BURT on December 1, 1953, at the age of 49 was a tragic loss to his family and to the specialty of psychiatry in the West Riding of Yorkshire, where he was medical superintendent of Stanley Royd

Hospital, Wakefield, and consultant psychiatrist to the Leeds Regional Hospital Board. A Scotsman, Hutchison Burt was born on January 8, 1904, and was educated at Ayr Academy and at Glasgow University, where he won many class honours and graduated M.B., Ch.B. in 1926 with distinction in forensic medicine. After three and a half years of wide experience in general practice in Ayrshire he took up psychiatry as assistant medical officer at Gilgall Hospital, under the late Dr. G. Douglas McRae. In 1933 he left Scotland for the industrial north of England to pursue his specialty at Wakefield Mental Hospital, where he worked until his untimely death, becoming senior assistant in 1938, deputy medical superintendent in 1947, and medical superintendent in 1949. He took the D.P.M. of Leeds University in 1934. One of his special interests was pathology, and he had published work on dysentery carriers.

The patients and staff of the hospital, the character of which he helped to shape, held him in high regard. He fostered the recreational interests of the nurses and was himself a notable cricketer in the hospital team. Since 1949 he had been honorary lecturer in psychiatry to Leeds University and was keenly interested in teaching. Shortly before his death he had begun to take an interest in the psychiatric training of the students at the School of Remedial Gymnasts at Pinderfields General Hospital. Because of the great dearth of psychiatric social workers, he, in collaboration with Professor C. Fraser Brockington, organized courses of study for unqualified mental health workers for the West Riding County Council. He was interested also in mental deficiency as a branch of psychological medicine, and many of those concerned with problems of mental defectives will miss his advice. In the region he worked assiduously to develop and extend the influence of the mental hospital into the community and helped to establish many out-patient clinics in the area as far apart as Doncaster, Leeds, and Pontefract. He never spared himself in the service of others, and although for many years in poor health he gave himself cheerfully to his patients. The peace of mind he must have brought to countless of the distressed is incalculable. He leaves a widow and two schoolboy sons.—P. F. F.

The death occurred on December 19, 1953, at his home near Sittingbourne, Kent, of Dr. S. W. INNES SMITH at the age of 56. A member of an old Scottish family, Stuart William Innes-Smith was born at Sheffield on July 4, 1897, the elder son of the late Dr. R. W. Innes-Smith, whom he succeeded as surgeon to many of the great steelworks in Sheffield. He also carried on the works' ambulance movement originated by his father. Shortly after leaving Epsom he joined the Army and served as a combatant in the first world war, being awarded the Military Medal for gallantry in action. After the war he studied medicine at Edinburgh and Sheffield Universities and qualified M.R.C.S., L.R.C.P. in 1925. He then went into practice in Sheffield until, shortly before the last war, he emigrated to a remote part of Southern Rhodesia, where he was medical officer in an area the size of Wales. He performed many operations in a tiny clinic with only a native orderly to assist him, and he also did much dental and forensic work. During the last war he held a commission in the R.A.F., and in 1948 he returned to England. He was disillusioned to find that at the age of 52 it was difficult to obtain an appointment under the National Health Service, so he became a ship surgeon and in the course of his duties accompanied troops to Korea. Latterly he travelled to and from New Zealand. He was a kindly, generous, and sympathetic man and will be mourned by many of the poorer people of Sheffield, whom he helped during the period of depression before the last war, and by countless patients and friends both in this country and abroad. Despite a long and serious illness, during which he never complained, he did not give up work until three weeks before his death.

Medico-Legal

DEATH NOT DUE TO SWAB

(FROM OUR MEDICO-LEGAL CORRESPONDENT)

On October 8, 1953, Mrs. Mary Petty, a married woman 38 years old with four children, died in the Bradford Royal Infirmary. At the inquest held by the Bradford city coroner, Mr. R. S. Bishop, the verdict was recorded that the cause of death was general peritonitis due to multiple perforations of the large bowel due to ulcerative colitis (natural causes).

At necropsy a surgical swab 17½ by 11½ in. (45 by 30 cm.) was found. Dr. J. Eastwood, who performed the necropsy, thought at the time that the swab was inside the intestine, but Professor C. J. Polson, of the Department of Forensic Medicine of Leeds University, after consultation with Dr. Eastwood, came to the conclusion that it had probably been lying in the abdominal cavity beside the intestine and closely applied to it by fibrinous adhesions. The strong probability, he considered, was that the swab had been introduced during the delivery of Mrs. Petty's fourth child by caesarean section in March, 1953. He thought it most unlikely that such a swab could have entered through the mouth, and that, if it had, symptoms of digestive disturbance could not have been delayed until the third week of July, 1953, the first time they had become apparent. There was ulceration of the lower part of the large bowel at the recto-sigmoid junction well below the position in which the swab was found, and there were natural changes found capable of causing intestinal obstruction. Where the swab was found there was no sign of obstruction. There was also ulceration and perforation of the colon at the recto-sigmoid junction. Professor Polson concluded that the presence of the swab did not cause the disease from which Mrs. Petty died, and had no effect in accelerating her death.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on November 21 the degree of D.M. was conferred on P. B. S. Fowler.

The Welsh Memorial Drawing Prize in Anatomy has been awarded to Richard Charles Cook, scholar of Merton College.

UNIVERSITY OF CAMBRIDGE

Dr. G. A. Gresham has been appointed a University Demonstrator in Pathology with tenure from October 1, 1953, for three years.

UNIVERSITY OF LONDON

The following have been nominated, appointed, or reappointed as representatives of the University on the governing bodies of the institutions indicated in parentheses: Dr. J. F. Smith (Guy's Hospital Medical School); Sir Francis Fraser (Board of Management of the London School of Hygiene and Tropical Medicine); Professor A. A. Moncrieff, Professor J. Z. Young, F.R.S., and Mr. R. C. Davenport (Court of Governors of the London School of Hygiene and Tropical Medicine).

The following have been recognized as teachers of the University in the subjects indicated in parentheses: St. Thomas's Hospital Medical School, Dr. H. E. de Wardener (Medicine); University College Hospital Medical School, Dr. B. G. B. Lucas (Anaesthetics); St. Mary's Hospital Medical School, Dr. M. W. L. Owen (Anaesthetics).

Probationary recognition as teachers of the University in the subjects indicated in parentheses for two years from November, 1953, has been granted to the following: University College Hospital Medical School, Dr. W. B. Balderston (Dental Surgery); St. Mary's Hospital Medical School, Dr. R. H. Heptinstall (Pathology).

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—¹D. A. Alderson, ²C. J. Edmonds, ³C. J. Hayter, ⁴P. J. Huntingford, ⁵Gillian A. J. Lomax, ⁶D. J. Parry, ⁷A. C. Pollard, ⁸V. M. Rosenoer, ⁹F. T. Sai,

Wright, R. W. P. Yates, T. G. Young, W. O. C. Young.

¹With honours. ²Distinguished in pathology. ³Distinguished in medicine. ⁴Distinguished in applied pharmacology and therapeutics. ⁵Distinguished in surgery. ⁶Distinguished in obstetrics and gynaecology.

UNIVERSITY OF BIRMINGHAM

Dr. J. A. H. Waterhouse, Lecturer in Human Genetics, has been given the title of Reader in Medical Statistics.

Dr. P. L. Krohn has resigned his Readership in Endocrinology in order to accept a Nuffield Gerontological Research Fellowship, to date from October 1, 1953, in the Department of Anatomy.

Dr. W. D. Carruthers has provided funds to establish an annual prize in social medicine to the value of five guineas. The prize

is in memory of the late Dr. Bostock Hill, professor of hygiene and public health from 1893 to 1919.

The following appointments are announced: Dr. Douglas B. Brewer, Senior Lecturer in Pathology, Dr. R. Lannigan, Lecturer in Pathology, and Dr. E. A. Smith, Research Fellow in Social Medicine, all from October 1, 1953; Dr. E. J. Hamley, Lecturer in Physiology from December 1, 1953; Dr. E. A. Cooper, University Research Fellow in the Department of Medicine from October 16, 1953.

Dr. P. B. Marshall, Lecturer in Pharmacology, Dr. J. L. Stafford, Lecturer in Pathology, and Dr. K. White, Lecturer in Physiology, have resigned their appointments.

UNIVERSITY OF SHEFFIELD

The following appointments are announced: Dr. T. J. Rendle-Short, Full-time Lecturer in Child Health; Dr. K. S. Holt, Full-time Tutor in Child Health; and Dr. D. H. Anderson, Part-time Clinical Teacher in Chest Diseases.

Dr. Irving Gordon, of the New York State Department of Health, has been appointed Visiting Senior Lecturer in Bacteriology during his visit to the University during the present session.

Dr. J. Mackinnon has resigned his appointment as Research Assistant in the Department of Medicine.

At a degree Congregation held on December 15, 1953, the following degrees were conferred:

M.B., Ch.B.—S. H. Harrison, T. G. Kershaw, G. F. Mackenzie, G. F. C. Rosser, P. Sykes, Helen F. Taylor, P. Taylor, D. W. Warrell, Cynthia M. Worrall.

QUEEN'S UNIVERSITY, BELFAST

Dr. R. A. Womersley, M.R.C.P., has been appointed to a lectureship in medicine in the University.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the College held on November 12, with Sir Reginald Watson-Jones, Vice-President, in the chair, Professor Lambert Rogers was appointed as the Bradshaw Lecturer and Professor F. Wood Jones as the Thomas Vicary Lecturer for 1954.

The death of Mr. R. H. Burne (Hunterian Trustee and past Physiological Curator) was reported and the Council unanimously adopted a resolution of condolence.

Professor F. C. Wilkinson was co-opted as the Member of the Council representing Dental Surgery in place of Sir William Kelsey Fry.

The Begley Prize was awarded to Margaret M. Heley (Royal Free).

Licences to practise were conferred upon the successful candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London (*Journal*, December 26, 1953, p. 1437) and to I. P. Vaughan.

Diplomas were granted, jointly with the Royal College of Physicians of London, in Medical Radio-Diagnosis, in Medical Radiotherapy, in Child Health, and in Ophthalmology, to the successful candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London (*Journal*, December 26, 1953, p. 1437).

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Faculty held on December 7, 1953, with the President, Dr. Andrew Allison, in the chair, the following were admitted Fellows of Faculty: *qua Physician*, Saw Mra Aung, H. W. Boyd, T. Cochrane, A. F. Toboku-Metzger; *qua Surgeon*, J. P. Fraser, S. R. Ganeshiya.

ROYAL COLLEGE OF SURGEONS IN IRELAND

On November 20 the Fellowship of the College was conferred on E. G. Leahy and A. McCalister.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION

The following candidates were successful at the November examination for the Diploma in Psychological Medicine:

D.P.M.—Part I: M. J. Raymond, H. K. Rose, G. S. Stirling. Part II: J. D. C. Currie, R. S. Ferguson, T. E. Hall, I. E. J. McLauchlan, M. J. Raymond, A. Smellie, Elizabeth Shoenberg.

ROYAL AUSTRALASIAN COLLEGE OF PHYSICIANS

The following, having satisfied the Board of Censors in Australia, were admitted to the Membership of the College in October, 1953: J. Benecke, G. L. Bennett, J. W. Bennett, R. B. Blacket, W. H. Cary, G. W. Cooper, D. L. Hobson, K. S. Millingen, N. M. Newman, R. F. O'Shea, J. G. Richards, P. M. Robertson, L. C. A. Watson.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending December 19 (No. 50) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1953					1952				
	Eng & Wales	Land	Scot	N. Ire	Eire	Eng & Wales	Land	Scot	N. Ire	Eire
Diphtheria	16	1	5	0	2	23	3	7	1	1

STILLBIRTHS	199	25	19			202	22	26		

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenza pneumonia.
‡ Includes puerperal pyrexia.

Vital Statistics

England and Wales in 1952

Of the Regions and large conurbations Greater London had the lowest death rate in 1952 (10 per 1,000 population), in spite of its December fog, and the West Midlands conurbation (including Birmingham) came next with a rate of 10.2. At the other end of the scale were the West Yorkshire conurbation (including Leeds and Bradford) with a rate of 13.1, and North Wales with a rate of 12.8. The rate for the whole of England and Wales was 11.3. For infant mortality Greater London again had the lowest figure (22 deaths per 1,000 live births), while the Merseyside conurbation had the highest figure (35) followed by South Wales (34). The rate for the whole of England and Wales was 28.

These figures are from the Registrar-General's *Statistical Review for the Year 1952, Tables, Part I, Medical* (H.M.S.O., 10s.), the first review for many years to appear within a year of the period to which it relates.

Week Ending December 26

The notifications of infectious diseases in England and Wales during the week included scarlet fever 949, whooping-cough 1,424, diphtheria 15, measles 611, dysentery 309, acute poliomyelitis 29, paratyphoid fever 1, and typhoid fever 0.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus ----, the figures for 1953 thus —. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

Infectious diseases were less prevalent in England and Wales during the week ending December 19. The falls in the number of notifications were 452 for whooping-cough, from 2,756 to 2,304, 162 for scarlet fever, from 1,446 to 1,284, and 105 for measles, from 883 to 778.

The largest declines in the incidence of whooping-cough were 113 in Lancashire, from 333 to 220, 53 in Glamorgan-shire, from 136 to 83, 44 in Staffordshire, from 138 to 94, and 35 in Norfolk, from 79 to 44. The only large fall in the local trends of scarlet fever was 52 in Lancashire, from 242 to 190. 16 cases of diphtheria were notified, being 5 fewer than in the preceding week. The chief features of the returns of diphtheria were falls in Staffordshire from 7 to 4 and in Lancashire from 4 to 1, and a rise in Durham from 2 to 5. The only fluctuations in the trends of measles of any size were falls of 37 in Staffordshire, from 119 to 82, and 30 in Cumberland, from 87 to 57.

51 cases of acute poliomyelitis were notified during the week. These were 7 fewer for paralytic and 1 fewer for non-paralytic cases than in the preceding week. The largest returns were Lancashire 8, Wiltshire 4, and Middlesex 4.

In contrast to the other infectious diseases the number of notifications of dysentery increased by 18, from 485 to 503. The largest centres of infection were London 95 (Islington 21, Lewisham 10, Wandsworth 9), Lancashire 71 (Bolton C.B. 31, Manchester C.B. 16), Yorkshire West Riding 47 (Bradford C.B. 24, Shipley U.D. 9), Surrey 39 (Egham U.D. 18, Frimley and Camberley U.D. 18), Essex 30 (Barking M.B. 17), Durham 30 (Lancaster R.D. 23), Norfolk 27 (Norwich C.B. 27), Leicestershire 25 (Leicester C.B. 23), and Middlesex 20.

Industrial Accidents and Diseases

The number of workpeople (other than seamen) in the United Kingdom whose deaths from accidents in the course of their employment were reported in November, 1953, was

124, compared with 124 in the previous month and 129 in November, 1952.

The number of cases of industrial diseases in the United Kingdom reported during November was as follows: lead poisoning, 4; other poisoning, 0; anthrax, 7; epitheliomatous ulceration, 8; and chrome ulceration, 15; total, 34. There were no deaths.—*Ministry of Labour Gazette*, December, 1953.

Medical News

Cataract and Glaucoma.—Professor Arnold Sorsby's report on "The Causes of Blindness in England, 1948-50" (H.M.S.O., 1953) and his more recent analysis in the Ministry of Health's report for 1952 have made it abundantly clear what a high place cataract and glaucoma now occupy in causing blindness in this country. In round figures 3,000 persons were placed on the Blind Register during the year 1951-2 because of cataract and 1,500 because of glaucoma. These two conditions account for over 40% of the new registrations in England and Wales. What is less well known and far more disturbing is that probably much of this blindness could have been prevented. According to a recent Ministry of Health circular to regional hospital boards and management committees, asking for an urgent review of the arrangements for the treatment of such cases, four out of every five patients with cataract placed on the Register in 1951-2 had received no treatment. At the lowest estimate, the circular puts the number of these "whose sight might well have been saved by surgical treatment" at 1,000. One reason for this state of affairs may have been the long waiting-list for ophthalmic beds. Although between 1950 and 1952 the number of ophthalmic hospital beds in England and Wales had risen from 3,975 to 4,391, the waiting-list during that time jumped from 6,000 to 31,000. With glaucomatous patients early diagnosis is recognized as being the prime need. To facilitate this the circular suggests the establishment of special glaucoma clinics in ophthalmological departments.

Fellowships in Clinical Research.—The Medical Research Council is inviting applications for a further series of Fellowships in Clinical Research, tenable at centres in the United Kingdom during the academic year 1954-5. These Fellowships are open to suitably qualified medical graduates who desire to prepare themselves for a career in clinical research. It is intended that each Fellow appointed under the scheme should be given an opportunity to study methods of research in the basic subject most relevant to his particular clinical interest. The awards will be made for a period of one year in the first instance and will be renewable annually in approved cases up to a maximum of three years in all. Stipend will be at the rate of £850 per annum, rising by annual increments of £75 to £1,000 per annum, with superannuation provision in addition. Candidates for these Fellowships, which are ordinarily restricted to British subjects resident in the United Kingdom, must be medically qualified and clinically experienced, and should preferably have worked for a period in a department in which clinical research was in progress. Applicants will be invited to submit their own proposals as to type and place of work, but the Council will be glad to advise successful candidates on the selection of suitable centres of study and to assist in placing them in departments or laboratories where the desired training and experience can be obtained. Applications must be sponsored in each case by the head of the appropriate department in the candidate's university or medical school, and an undertaking will be required that a suitable academic post in a clinical department will be available to the candidate in that institution on satisfactory completion of the period of study under the Fellowship. Forms of application for these Fellowships may be obtained from the secretary, Medical Research Council, 38, Old Queen Street, London, S.W.1, with whom applications should be lodged as soon as possible, and in any event not later than March 1.

Viomycin.—A limited supply of viomycin, a new antibiotic with properties similar to streptomycin, will shortly be available to N.H.S. hospitals through the usual antibiotic distribution centres. Viomycin was developed in the United States. Its main indication is for cases of tuberculosis where the bacilli are found to be drug-resistant or where the patient is intolerant of conventional chemotherapy. It is contraindicated if there is impairment of renal function or non-tuberculous renal disease. Like other drugs used in the treatment of tuberculosis, viomycin quite commonly provokes toxic reactions, though generally these are transient and reversible.

Dalby Memorial Prize. On the recommendation of the Council of the Section of Otolaryngology of the Royal Society of Medicine, the Society's Dalby Memorial Prize has been awarded to Mr. Terence E. Cawthorne for the best original work in otology during the previous five years.

Nuffield Dental Fellowships.—Details of the Nuffield Foundation's dental fellowships and scholarships are given in our advertisement pages this week at p. 49. One of the purposes of these fellowships is to enable selected graduates in medicine and science to receive training that will qualify them to undertake teaching and fundamental research on dental health and disease.

The "Half-Minute" Thermometer.—The British Standards Institution has rung the knell of the half-minute and the one-minute clinical thermometers. Because of the errors that may follow blind reliance on such timing instructions, a new Standard has been issued. Clinical thermometers will in future be marked "quick," "medium," or "stubby."

Sierra Leone Mission Hospital.—A gift of £40,000 by the former Lord Mayor of Newcastle, Alderman J. G. Nixon, to the Methodist Missionary Society has made possible the rebuilding of a 100-bedded mission hospital at Seghwema, Sierra Leone. Alderman Nixon recently went to West Africa to open the hospital.

COMING EVENTS

Mount Everest.—Mr. R. C. Evans and Dr. M. Ward will deliver a Hunterian Lecture on "The Ascent of Mount Everest: Medical Studies," on Wednesday, January 13, at 5.30 p.m., at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2.

NEW ISSUES

Abstracts of World Medicine.—The January issue (Vol. 15, No. 1), which is now available, contains abstracts of important papers on both medical and surgical subjects drawn from journals published in some 20 different countries and in all five continents. In addition to the various branches of clinical medicine and surgery, the subjects covered include pathology, bacteriology, pharmacology, and chemotherapy, and there are also sections dealing with medical genetics, public health, industrial medicine, anaesthetics, radiology, and the history of medicine. Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; a specimen will be sent free on request.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, January 11

INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture demonstration by Dr. J. Stengel.
MEDICAL SOCIETY OF LONDON. 8.30 p.m., discussion: Physical Basis of Mental Illness, to be introduced by Dr. R. A. J. Asher and Dr. T. A. H. Munro.
ROYAL COLLEGE OF PHYSICIANS OF LONDON. 5 p.m., Watson Smith Lecture by Dr. J. T. Ingram: Significance and Management of Psoriasis.
ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: The Hypertensive Patient. Astigmatism. Bifocals.

Tuesday, January 12

CHLSEA CLINICAL SOCIETY.—At South Kensington Hotel, 7.30 p.m., dinner, followed by a discussion on Sleep, to be opened by Sir Francis Walsh, F.R.S., and Dr. Denis Williams.
ILFORD MEDICAL SOCIETY.—At King George Hospital, Ilford, 8.45 p.m., film: A Two Year Old Goes to Hospital. Discussion to be opened by Dr. H. M. S. Davidson.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. G. Cochrane: Leprosy.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Professor Donald Baird: Impact of Social Conditions on Labour.

Wednesday, January 13

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Histopathology of Fungal Infections.
MIDLAND MEDICAL SOCIETY.—At Selly Oak Hospital, Birmingham, 8.15 p.m., clinical meeting.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Hunterian Lecture by Mr. R. Charles Evans and Dr. Michael Ward: The Ascent of Mount Everest: Medical Studies.
ROYAL EYE HOSPITAL.—5.30 p.m., Mr. L. H. Savin: Ophthalmic Operations and their Indications (3).
ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Finlayson Memorial Lecture by Professor L. J. Witts: Anaemia and the Alimentary Tract.
ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Dr. D. F. O'Neill: Lecture-demonstration in Psychiatry.
SOCIETY FOR APPLIED BACTERIOLOGY.—At Institution of Civil Engineers, 10 a.m., business meeting, 2.15 p.m., joint meeting with Microbiology Group of Society of Chemical Industry. Symposium: Industrial Methods of Sterilization. Papers by Dr. M. Ingram, Mr. Osman Jones, Dr. R. Maxwell Savage, and Mr. G. Sykes.

Thursday, January 14

ALFRED ADLER MEDICAL SOCIETY.—At 11, Chandos Street, W., 8 p.m., Mr. R. W. Raven: Psychological Reaction to Surgical Disease.
BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., Dr. J. Blair Hartley: Significance of Placental Calcification.
BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. E. A. Carmichael: Hemispherectomy and Localization of Function.
INSTITUTE OF CHILD HEALTH.—5.30 p.m., Dr. H. N. Davy: Behaviour in Epilepsy.
INSTITUTE OF LARYNGOLOGY AND OTOLARYNGOLOGY.—5 p.m., Professor F. C. Ormerod: Use of Antibiotics and Chemotherapy.
LIVERPOOL MEDICAL INSTITUTION.—3 p.m. and 8 p.m., Mr. Charles Evans: Everest, 1953.
LONDON UNIVERSITY.—At Middlesex Hospital Medical School, 5 p.m., special university lecture in Human Anatomy and Morphology by Professor J. Pasteels (Brussels): Present Views on Embryonal Induction.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Dr. W. C. Cockburn: Early Field Investigations of Typhoid Vaccines.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor R. Milnes Walker: Place of Venous Shunts in the Treatment of Portal Hypertension.
ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor L. J. Witts: Anaemia and the Alimentary Tract.
ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., neurology demonstration by Dr. J. H. Paterson.
SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION.—At West Park Hospital, Epsom, 7.30 p.m., clinical meeting. Papers by Dr. J. Zelmanowits, Mr. M. Klein, Dr. O. F. Garai, and Dr. M. K. Beattie.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF BIOCHEMISTRY.—Physiology Theatre, 4.45 p.m., Public Lecture by Professor Jean Brachet (Brussels): Role of Ribonucleic Acid in Morphogenesis.

Friday, January 15

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members.
FACULTY OF RADIOLOGISTS.—At Royal College of Surgeons of England, 2.15 p.m., Radiodiagnosis Section Meeting. Dr. P. G. Keates: Physical, Physiological, and Hormonal Aspects of Hydronephrosis; Dr. C. J. Don: Bronchography in Pulmonary Tuberculosis.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. R. G. Cochrane: Leprosy.
ONIER CLUB OF LONDON.—At 11, Chandos Street, W., 7.45 p.m., Professor J. M. R. Cormack, M.A.: Black Magic (in honour of Sir James Frazer, January 1, 1854-1941). Discussion: Professor Raymond Firth, H.E. Mme. Subandrio, and Dr. Michael S. M. Fordham.
POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor R. Milnes Walker: Lesions of the Small Intestine.
ROYAL EYE HOSPITAL.—5 p.m., Miss M. Savory: Differential Diagnosis of Corneal Lesions.
ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., Dissertation by Mr. K. Chapman: Toxaemia of Pregnancy.
UNIVERSITY COLLEGE LONDON: DEPARTMENT OF PHARMACOLOGY.—At Physiology Theatre, 5.30 p.m., Public Lecture by Professor Werner Koll (Göttingen): Experimental Studies on Analgesics—Tooth Stimulation and Other Methods.

Saturday, January 16

BIOCHEMICAL SOCIETY.—At Department of Chemical Pathology, Postgraduate Medical School of London, 11 a.m., 325th meeting. Scientific papers.
SOUTH-EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY.—At Farnborough Hospital, Kent, 10.30 for 11 a.m., extraordinary general meeting. Dr. D. G. Madigan will speak on his experiences in America.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Batten. On November 26, 1953, at Queen Charlotte's Hospital, London, W., to Mary, wife of Henry Batten, M.B., F.R.C.S., a daughter—Jane.
du Heaume.—On December 30, 1953, at Enfield, Middlesex, to May (formerly Giffin), wife of Brian du Heaume, M.B., B.S., D.Obst.R.C.O.G., a daughter—Susan.
Lewes.—On December 29, 1953, at Bedford General Hospital, to Daphne (formerly Wailes), wife of David Lewes, D.M., M.R.C.P., a fourth daughter—Christina.
McLaren. On December 19, 1953, to Patricia Annette, wife of William J. McLaren, F.R.C.S., of Tranquille, British Columbia, Canada, a third son—Niall Fullerton.
Vowles.—On December 16, 1953, at the Royal Infirmary, Cardiff, to Mary (formerly Knowles), M.B., Ch.B., D.C.H., and Keith D. J. Vowles, M.B., F.R.C.S., a brother for Robert—Andrew John.
Woodall.—On December 17, 1953, to Jennifer, wife of John Woodall, M.B., B.S., of The Lodge, Cray Hall, North Cray, Kent, a son—Christopher John.

DEATHS

Douglas. On December 10, 1953, at his home, 38, Prestbury Road, Cheltenham, Glos., Kenneth Harrington Douglas, M.R.C.S., L.R.C.P., formerly of 41, Prospect Hill, London, E., aged 80.
Ewen.—On December 15, 1953, Gerald Anglin Ewen, M.R.C.S., L.R.C.P., of Ryde House, Twickenham, Middlesex, aged 43.
Schaefer.—On December 14, 1953, in a nursing home, London, Hans H. Schaefer, L.R.C.P.&S.Ed., L.R.F.P.S., of 251, Hertford Road, Enfield Highway, Middlesex.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Coronary Disease and Dental Analgesics

Q.—Are local analgesics for dental operations contraindicated in those with coronary artery disease? Are any special precautions advised in such cases?

A.—There is no reason why the average patient with coronary artery disease should not have a local analgesic of this sort. Where there is a history of a recent heart attack it is perhaps better to avoid the adrenaline. In any case the concentration of adrenaline in the solution should not exceed 1 in 200,000. Solutions commonly supplied for dental use often have a higher concentration of adrenaline than this.

Blood Pyruvates

Q.—What is the value of a blood pyruvate estimation? What conclusions can be drawn if the level is raised, particularly in relation to peripheral neuritis?

A.—Pyruvic acid is formed as an intermediary in the oxidation of glucose by the tissues. Vitamin B₁ (thiamine) is required for its further oxidation, and if this vitamin is not available in adequate amounts pyruvate accumulates in the blood. The estimation of blood pyruvate levels is therefore of interest as a means of assisting in the diagnosis of vitamin B₁ deficiency states. In the more chronic and less severe forms of thiamine deficiency the fasting blood pyruvate level is usually within the normal range; raised levels can, however, be demonstrated in many such patients if a "loading" dose of glucose is first given.

It must be realized also that conditions other than a deficiency of this vitamin can also cause impaired pyruvate oxidation with a resulting rise in the blood pyruvate level. In a patient with peripheral neuritis a raised level cannot by itself therefore be taken to indicate thiamine deficiency, although it would support this diagnosis. If, however, parenteral treatment with thiamine for, say, two weeks results in a return to normal of a previously elevated level, it would seem likely that a deficiency of this vitamin had existed. As the clinical response of such patients is often slow, blood pyruvate estimations before and after thiamine therapy can often provide a more rapid and surer indication of response to this therapy.

Malaria Prophylaxis

Q.—What is the best malaria prophylactic for a European family visiting a malarious area? Please give details of dosage and frequency of administration, including any variations of these for infants and children. Are mosquito nets necessary if chemoprophylaxis is thorough?

A.—Proguanil is probably the best antimalarial for a European family visiting a malarious area. The drug is prepared in tablets containing 100 mg. or 25 mg. Where proguanil-resistant strains of *P. falciparum* have been demonstrated, chloroquine should be taken instead.

The dosage of proguanil for adults is 100 mg. daily. Exceptionally—for example, in a big individual—twice this dose may be needed. For children, the dosage from birth to the second birthday is 25 mg. daily, and from the second to fifth birthday 50 to 100 mg. daily. Prophylaxis should begin a fortnight before entering the malarious area and continue for one month after leaving the area.

Most people find it easier to form the habit of taking a drug daily than once or twice a week. If, however, the latter is desired, chloroquine is advised. The drug is usually

prepared in tablets containing 250 mg. of the diphosphate. The dosage of chloroquine diphosphate for adults is 500 mg. once weekly. For children: from birth to the third birthday, 62.5 mg. once weekly; from the third to the sixth birthday, 125 mg.; over 6 years, 250 mg.; and over 10 years, the adult dose.

Alternative antimalarials are mepacrine and pyrimethamine ("daraprim"). The adult dose of mepacrine is 100 mg. daily, started a fortnight before entering the malarious area and continued for a month afterwards. Mepacrine is not as convenient as proguanil for children. Birth to second birthday: total dosage of 50 to 75 mg. in divided daily doses. From second to sixth birthday: total weekly dosage of 100 to 200 mg. in divided daily doses. From sixth to tenth birthday: total weekly dosage of 200 to 300 mg. in divided daily doses. From tenth to fifteenth birthday: total weekly dosage of 300 to 400 mg. in divided daily doses. Over 15 years, adult dose. The adult dose of pyrimethamine is 25 mg. once weekly. Half this dose has been found successful in children.

All drugs should be taken at some meal during the day with a good draught of fluid. Absorption is not affected by moderate quantities of alcohol. After cessation of suppressive therapy with any of the above drugs attacks of falciparum malaria should not develop. Vivax malaria may, however, appear and require radical therapy.

Some form of mechanical protection against insects is always desirable, even when drug suppression is successful. There are many insect-borne diseases other than malaria.

Artificial Materials for Hernia Repair

Q.—What are the advantages and disadvantages of using materials such as nylon or wire for the repair of large hernias in place of fascia lata?

A.—Those surgeons who use nylon and wire for the repair of large hernias regard the ready availability of the materials as a chief advantage. It is, however, doubtful whether a lattice or filigree of any foreign material is really as effective as a barrier of the patient's own tissues. The questioner refers to the use of fascia lata, a method introduced by the late W. E. Gallie and satisfactory in his hands. Those surgeons who object to his method have two main criticisms: first, the extra time taken in removing the fascial strip and the added risks of sepsis; and, secondly, the tendency for the inguinal ligament to be damaged by the large fascial needle, especially in patients with friable tissues. An effective barrier of the patient's own tissues can, in most cases of inguinal hernia, be provided by a rectus sheath slide operation, and many believe that this offers the advantages of a fascial repair with none of its disadvantages.

Lattices of nylon and wire all tend to fragment after a variable period of time. If the lattice is made very close critics of the method will point to the tendency for the inguinal ligament to be frayed by frequent passage of the needle. On the other hand, if the lattice is of a wide mesh, the tissues can readily bulge through the suture material. The tendency for nylon knots to slip can be irritating, and this objection is not entirely rectified by the use of braided nylon. Stainless steel wire tends to become fragmented by movement and electrolysis in the tissues, and is less in vogue than it was a few years ago. Tantalum similarly fragments on movement. Filigrees of tantalum or stainless steel also break up and tend to separate from their attachments; recurrences are therefore sometimes seen at the edge of a filigree. Silver wire is rarely used to-day: it is subject to all the objections already mentioned, with the additional one of occasionally staining the overlying skin black owing to the deposition of silver sulphide. There is some evidence to suggest that wire filigrees are more useful for difficult umbilical and incisional hernias than they are for large inguinal hernias. The critical surgeon recognizes that there is very little valid statistical evidence about the recurrence rates following different types of repair. The collection of truly comparable cases is not easy, and some

of the methods used have not been tried for long enough to enable their true worth to be assessed. It is notable that much of the earlier enthusiasm for tantalum and stainless steel wire has died down owing to appreciation of the various difficulties already mentioned. The use of relatively rigid materials in the reinforcement of mobile structures introduces inevitable complications, and many surgeons (probably a growing number) are recognizing the virtues of repair with the patient's own tissues, provided this can be effected without tension. An understanding of the fundamentals of plastic surgery is certainly an advantage in planning the repair of large and difficult ruptures.

Nocturnal Priapism

Q. A healthy man of 56 complains that for over 20 years he has been troubled with a full penile erection every time he sleeps. It is not associated with erotic sensations or dreams of any kind. If he partially wakes, he is conscious of the condition and its discomfort, which does not alter unless he reaches a point of wakefulness that he describes as about half-way between sleep and full consciousness, when the erection immediately ceases. If he sleeps and wakes a number of times, the condition recurs each time. Is there any special significance in his complaint? I can find no cause.

A.—These cases of nocturnal priapism in an elderly or middle-aged man are exceedingly puzzling. In only a few cases does one find any physical explanation, such as an irritative lesion of the posterior urethra or an enlarged prostate. Sometimes, but not often, there is a psychological explanation, but as nothing has been said in this case to indicate that the patient is suffering from a thwarted sex life, I assume a psychological factor does not explain it.

To sum up, therefore, it is quite usual to find no explanation in these cases. They begin mysteriously and end mysteriously.

Nutrient Enemas

Q.—Are nutrient enemas e.g., 5% dextrose properly absorbed?

A. A solution of 5% dextrose is absorbed when given rectally. The colon, however, can absorb only 1 to 2 litres of fluid daily, so that a total of 75 g. (300 calories) glucose is the maximum that can be administered by this route. There can be few circumstances when it is not preferable to give glucose intravenously, as there is then no doubt about the degree and speed of its absorption. Proteins, peptides, and fats are not absorbed by the colon, and their administration by this route is not only useless but may be harmful, as the putrefactive bacteria break down those substances and form toxic products which may be absorbed.

Correction.—The authors of the article "Cortisone and A.C.T.H. in Treatment of Non-rheumatic Conditions" (*Journal*, January 2, p. 1) regret the omission of acknowledgments to Professor R. E. Tunbridge for access to the case records of two cases of Simmonds's disease and one of adrenal virilism.

*effective
new treatment
for seborrhoeic
dermatitis
of the scalp*
**CHECKS
SCALING**
*for 1 to 4 weeks
... promptly
relieves itching*

81 to 87 per cent of all cases of seborrhoeic dermatitis of the scalp—as well as 92 to 95 per cent of cases of common dandruff—were completely controlled with Selsun during clinical trials with more than 400 patients. Selsun quickly restores the scalp to a healthy condition and, after the initial period of treatment, keeps it completely free of scales and the secondary symptoms of itching and burning for one to four weeks with each application. This product is frequently effective in cases where the usual sulphur-formula products fail to bring satisfactory results. Yet Selsun is much simpler to use—being quickly and easily applied while washing the hair, and then rinsed out completely. Selsun thus leaves the hair clean and odorless, with no problems of linen staining or hair discoloration. Toxicity studies showed that no ill effects resulted from the external use of Selsun in the manner recommended, even in cases where the scalp was abraded. Selsun is supplied in 2 and 4 fluid ounce bottles.

STUDIES OF A GENERAL PRACTICE (II)* THE DOCTOR'S JOB IN AN URBAN AREA

BY

E. MAURICE BACKETT, B.Sc., M.B., B.S., M.R.C.P.

J. A. HEADY, M.A.

AND

J. C. G. EVANS, M.B., B.S.

(From the Social Medicine Research Unit of the Medical Research Council)

In the course of a study of the various methods which can be used to investigate general practice, the activities of a single National Health Service practice were followed for one year. This paper presents results selected from the study, to describe some of the more quantitative aspects of the doctor's job in connexion with his patients and their diseases.

Because the study had as its main purpose an assessment of the various methods which could be used, it was not thought necessary (nor was it a practical possibility) to try them out, to begin with, in more than one place. For this reason no attempt has been made to generalize from the results here presented, for they show only what went on in this one practice. They are put forward in much the same manner as a clinical case study is put forward, to suggest how one part of the doctor's job may be described and measured, and to illustrate some ways of thinking about what may be happening in an urban practice and in the medical care of some 3,000 ordinary people.

The Practice

During the year of the study (April, 1950, to March, 1951) the practice had an average population of 3,084 registered persons and was increasing slightly in size. Of these persons 72% consulted the doctor during the year. Working with the principal was a trainee assistant, and there was also available the occasional help of another practitioner, who lived on the outskirts of the practice and who undertook a few visits and surgeries by arrangement. A prefabricated building in the garden was used as a waiting-room and contained also an additional surgery for the trainee assistant and a small office for the part-time receptionist-secretary. The practice, which was situated in a North-west London borough, was highly concentrated, in that some 95% of registered individuals lived within a mile of the surgery, over which the principal was living. The area is mainly residential, but the terraced houses are interspersed with numerous small

factories and laundries. It is a relatively poor area where much of the housing is scheduled for demolition and an impressive rehousing programme has already started. During the period of study the practice probably had much the same age, sex, and occupational pattern as the immediate local population, but it was somewhat poorer than the borough as a whole.

Method of Study

The principal and his assistants became part-time members of the team which was conducting the study, and undertook to supply records of their work throughout the test year. The necessary recording took place in three stages.

(1) The age, sex, and social characteristics of the population were ascertained and recorded, and the existing records brought up to date. This was a considerable task, because it entailed many home visits and at least one letter to every registered person. It was made difficult also because, unknown to the executive council or to the doctor, the council's records contained the names of 15% more persons than were actually found to be present in the practice. The medical record envelopes in the surgery files exceeded the number of persons present by even more than this large amount of "official inflation," and contained about 19% more than the total, thus rendering useless nearly one M.R.E. in five.

(2) A simple basic form was completed by each doctor after every consultation. This form served to identify the patient and doctor concerned, the time and place of the consultation, whether in the patient's home or in the surgery, the diagnoses made, and the services rendered. In addition, every six weeks, for one week, members of the research team "sat in" on all consultations and recorded in greater detail what went on. The detail included records of telephone conversations, the writing of letters, preparation of lists of patients to be visited, and so on. The collection of these more intensive records gave a rest to the doctors and acted as a "control" as well as an amplification of the simpler records. As a result of this control it is estimated that

*The first paper, a description of method, was the subject of a discussion in the General Practice and Epidemiological Sections of the Royal Society of Medicine (Backett, Shaw, and Evans, 1953).

TABLE I.—Number of Consultations in Surgery and as Visits, Distinguishing Age and Sex of Patient and Percentage of Visits

Consultations	Age Group in Years								Total	
	0-14		15-44		45-64		65+		(All Ages)	
	M	F	M	F	M	F	M	F	M	F
In the surgery (a)	1,012	947	1,854	2,499	1,053	1,531	502	706	4,421	5,683
As visits (b)	877	1,073	474	605	563	569	463	967	2,377	3,214
Percentage of visits in total of (a) + (b)	46%	53%	20%	19%	35%	27%	48%	58%	35%	36%

This table excludes the 93 consultations which took place other than in the surgery or at visits. The grand total is, 15,695—that is, 15,788—93. The average population of the practice was 3,084. All tables and figures refer to the year April 1, 1950, to March 31, 1951, in a N.W. London practice.

over 99% of all consultations were recorded. The doctors were encouraged to make many notes, and, perhaps because the record card usually took less than one minute to complete and stated only the barest minimum, this was often done. These notes later proved particularly useful in sample studies, designed to test the value of various ways of classifying the material.

(3) All records of consultations were transcribed on to patient record cards, which thus came to contain the health histories of each registered individual in the practice during the year. All the items on these patient records were then classified and cards for machine tabulation were prepared.

The basic records were adequate to describe the work of the doctor in terms of the main services involved. Every six weeks there was far greater detail available from the intensive records mentioned above, and to fill out these two pictures sample studies of consultation timing, of the extent of the use of apparatus, elementary time and motion studies of the doctor's day, and a fuller inquiry into the health of a random sample of the families in the practice were undertaken. While results from these other studies are not included in this paper, it is recognized that without such additional material the job of the busy G.P. cannot adequately be described.

The Unit of Work

It is possible to relate the doctor's work, the type of disease, and the patient, through a series of simple codes if the consultation is taken as the basic unit of work. The term "consultation" includes all meetings between doctor and patient in which advice was given, whether such meetings were by chance or arrangement, and it also includes meetings between doctor and patient while the latter was in hospital, telephone inquiries, and the like. During the year of study 15,788 of these consultations took place. This number, with the services involved, letters, referrals, prescriptions, etc., represented 100% of the work of the doctors for the purposes of this part of the study. It is well recognized that this may be by no means all the work of the practice, but sample analyses of the more detailed records suggest that this way of organizing the material embraces almost all of the doctor's job that can easily be measured. Purposely omitted is the maintenance of equipment and the many other chores which, though playing some part in terms of both time and energy, are not specifically associated with the doctor's work with his patients. Also omitted are some of the "social-work" aspects of his job, which it is hoped to discuss elsewhere. Selected results from the analyses are presented below. They show where and when the consultations took place, with what groups of patients, and with what diseases and groups of diseases. Finally, some of the services which were rendered during consultations are mentioned, and two tables are presented which link the work done in the practice with groups of patients suffering from various types of disease.

Place and Time

Most of the 15,788 consultations took place during the normal working day, but 120 were made at night, between 8 p.m. and 8 a.m., the large majority before midnight. During so-called "off duty" periods at week-ends or during bank holidays 140 consultations took place.

The number of consultations which are held in the patient's home reflects several important aspects of the doctor's job. First, the apparent or real seriousness and urgency of the case may be reflected in this figure. Second, it may show how much time is available to the doctor and indicate how busy he is (distances from the surgery are hardly important in this closely knit practice). And, finally, it is reasonable to speculate—as McKinlay (1950) does in connexion with visits to the elderly—that the extent of intimate understanding of the family situation which comes from visits to the homes of his patients will be reflected in this figure. Thus the proportion of these visits in the whole of his work may help to illustrate, albeit crudely, the quality of his care.

In order to explore these ideas further, the proportion of all consultations which took place in the patient's home has been made the basis of a series of tabulations. It will be recognized at once that this proportion is of use only when comparing habits of work with populations roughly comparable for need and custom; and comparison, for example, of a middle-class and a working-class practice in this way might well be useless. In the practice under observation 36% of all consultations were made in the patient's home, a figure which is comparable to that given by Pemberton (1949). The distribution of this percentage for both sexes and at different ages (Table I) shows that a large proportion—some 50% of all the work involved in treating the children and the elderly—was carried out in the patient's home, compared with about 20% among the younger adults.

Work in Treating Different Groups of Patients

With the exception of a small number of persons (1.7%) for whom occupational data were not available, the age, sex, and social characteristics of every registered individual were known. These data were related to the number of consultations and to the "contents" of the consultations, such as the number of prescriptions, etc.

Fig. 1 shows the consultation rate for the year per 100 registered persons for each sex at different ages. It shows how the work of the doctor is related to the age of his patients and the excess of work (measured as consultations) with females over that with males. The excess in the consultation rate for children (aged 0-14) over that for young adults can be very largely explained, by a great excess amongst the very young children (aged 0-4), though this is not the complete explanation for the boys.

If the work of the practice is divided among those registered it gives an average of some five consultations per registered person in the year, a figure comparable to that found by McGregor (1950), and by Bradford Hill (1951) for 1938, and somewhat in excess of that found by Fry (1952). Since 28% of these registered persons were either not ill or not ill enough to consult the doctors during the year, the more realistic average is seven for each patient. Even such a

corrected average may be misleading and a more realistic picture of the use made of the doctors' services emerges only when the percentage of persons having various numbers of consultations is examined.

The percentage of all the males in the practice who had no contact with the doctors in the year is greater at each

FIG. 1.—Consultation rate for the year per 100 persons registered. 3,084 persons and 15,788 consultations are represented.

age than the percentage of females. At the extremes of age this difference is less marked than between 15 and 64 years. Among children aged 0-4 years only 12% did not see the doctor at least once in the year. Among persons who saw the doctors at all, more consulted them on one occasion than on two, and more on two than on three, and so on (Fig. 2). In other words, the most frequently occurring number of consultations for any person was one, and the next most frequent two.

Fifty-six per cent. of males and 46% of females consulted the doctors on fewer than three occasions—that is, not at all, once, or twice—while in contrast 13% of males and 18% of females consulted on 10 or more occasions. Some patients, however, contributed proportionately much more than others to the work of the practice: of those aged 65 and over (rather under 10% of the practice), 25% of the males and 32% of the females saw their doctor on 10 or

TABLE II.—Percentage of Persons of Each Sex in Each Age Group Having Various Numbers of Consultations with the Doctor in the Year

Age Group	Percentage of Persons with Stated Number of Consultations							
	None		1-2		10-19		20 or More	
	M	F	M	F	M	F	M	F
0-14 years	24	20	19	16	13	18	4	2
15-44 "	35	25	28	26	6	11	1	2
45-64 "	36	27	22	19	10	15	6	6
65+ "	29	25	18	21	14	18	11	14
All ages	32	24	24	22	9	14	4	4

Only the extremes of the distribution are shown. Omitted from each age and sex group are those clustering round the mean, namely the percentage of persons who had between 3 and 9 consultations in the year.

Each figure is the percentage in the age group indicated of all persons of that sex. Table based upon the number of persons registered for at least the whole year—that is, 2,844 persons.

TABLE III.—Number of Consultations in the Year. Proportion of Persons and the Work Involved in Treating Them

No. of Consultations	Age Group in Years								All Ages	
	0-14		15-44		45-64		65+		(a) % of Persons	(b) % of Work Involved

(a) Is the number of persons in the age group with the stated number of consultations in the year, expressed as a percentage of all the persons in the age group. (b) Is the work involved in treating the persons in (a) expressed as a percentage of all the work with the age group. (c) Cannot be precise because tabulation of the work involved with each separate number of consultations was prohibitive. The figures given are approximate. The figures are based upon information about persons registered for at least the whole year, or who died during the year—that is, 2,844 persons.

more occasions in the year. Moreover, nearly one in eight of these elderly people had 20 or more consultations.

Table III shows the approximate proportion of all the work of the practice which is involved with patients consulting various numbers of times. This idea is further illustrated in Fig. 3.

It will be seen that 12% of the work of the doctors among children, for example, was involved with that 3% of persons who had 20 or more consultations, which was four times the average number of contacts for that age group (5). Or again, while only one-fifth of the middle-aged men and

FIG. 2.—Percentage of persons having various numbers of consultations in the year. Note: (1) The chart is based upon the number of persons registered for at least the whole year—that is, upon 2,844 persons. (2) The percentages shown are "rounded off" to the nearest whole number. (3) 4% of the population had 20 or more consultations in the year.

FIG. 3.—Number of consultations in the year. The proportion of persons and the work involved in treating them (summary of Table III). Note: (1) The columns show the relative proportion of persons and work for different numbers of consultations in the year. (2) The figures are for all ages together. (3) The figures are based upon information about persons registered for the whole year—that is, 2,844 persons.

women in the practice saw the doctor on 10 or more occasions during the year, three-fifths of all the work involved with this age group was concerned with this relatively small number of people (19% of people, 61% of work). Similarly, while 29% of the elderly saw the doctor on 10 or more occasions, these were responsible for 74% of the work with that age group. Taking the practice as a whole, half of all the work involved only that sixth of all the patients (some 500) who saw the doctors on 10 or more occasions, and 18% of all the work concerned only 4% of the patients (125) who consulted 20 times or more.

Work in Treating Different Types of Disease

Diagnoses were classified by a short list of 28 categories arranged to permit comparison with other lists in more general use. As an attempt to explore further the implications of the various diseases and to develop methods of study of their effects upon the individual and family, each diagnosis was also classified according to its *seriousness* and its *duration*. Serious diagnoses were of diseases in which there was evidence of a major threat to the life or livelihood of the patient or which required considerable readjustment in his life or that of his family. Each of these criteria was, of course, further defined operationally. Such conditions as pulmonary tuberculosis, cancer, established peptic ulcer, and pneumonia were always classified as serious. It was realized that a definition such as this, based in part on other than purely medical concepts of seriousness, might include many diagnoses which were not serious when judged from a pathological point of view. In practice this effect was found to be very small, for the large majority of serious conditions as defined reflected major organic disease.

Again, certain conditions were always regarded as chronic, and other conditions were placed in this category only when there was evidence of a duration of three months or more. Conditions which were chronic by definition included organic heart disease, bronchiectasis, varicose veins, and the like. All other conditions were classed as acute and were further divided into acute infective and acute non-infective conditions. From this classification it will be seen that each diagnosis made at a consultation, which was, of course, counted only once during the year, could be described in three ways: (1) as belonging to one of the 28 elements in the diagnosis code; (2) as being acute infective, acute non-infective, or chronic; and (3) as being either serious or not serious.

Where more than one diagnosis was made at a consultation it is not possible to say what fraction of the consultation was concerned with which diagnosis. It is therefore not possible to state with any precision what proportion of all the consultations in the year was concerned with any given diagnosis group. But the range or limits between which this proportion lies can be shown by dividing all consultations into (a) those in which the given diagnosis occurs on its own, and (b) those in which it occurs together with at least one other diagnosis: (a) is a minimum count of all the work concerned with the given diagnosis, and (a+b) a maximum count. Expressing (a) and (a+b) then as a percentage of all consultations gives a minimum and maximum to the percentage of work involved with the given diagnosis. For example, the common cold, when it occurred alone, was the diagnosis in 4% of all consultations. The proportion of consultations in which the common cold occurred either alone or with some other condition was 8.5%; the range was therefore between 4 and 8.5% of the total work for the year.

Diagnoses of interest in this respect are peptic ulcer and chronic or recurrent dyspepsia, which accounted for 1% of all diagnoses and involved between 1 and 4% of the work of the practice. Psychiatric diagnoses (5% of the total) often occurred with other diagnoses, and involved between 1 and 7% of the work, while cardiac and vascular conditions (excluding varicose veins) were 3% of all diagnoses and entailed between 2 and 10% of the work of the practice.

Skin disease was indicated in 11% of all diagnoses and involved between 6 and 12% of the work. Some 5% of diagnoses were of arthritis, fibrositis, rheumatism, etc., and these involved between 3 and 8% of the work of the practice. For acute respiratory infections, which were rather less than one-third of all diagnoses, it was only possible to state that they accounted for between 20 and 40% of the work of the practice. These wide limits are, of course, a measure of the frequency with which these infections occur together with some other condition.

When the work of the practice is classified by diagnoses in this way, there is a large measure of agreement between the proportion of all the diagnoses which fall into each group and the proportion of the work of the practice which was involved. The picture which this classification by itself gives of the work of the doctor is not a good one, and it is more likely to prove useful when there is added a qualitative description in terms of the seriousness and duration of the conditions which have been treated.

Fig. 4 shows the percentage of 15,788 consultations classified as work with diseases grouped as acute infective, acute non-infective, or chronic, and also the relative proportions of consultations and diagnoses. In 12% of consultations, diagnoses from more than one of these three groups were made—for example, an acute infective condition and a chronic condition at the same time. These consultations have been referred to as work with "mixed" conditions. No attempt has been made to break them down further, although it is recognized that fractions of such consultations "belong" to the main groups concerned.

It will be seen that the care of chronic disease, which formed less than 20% of the diagnoses made by the doctors in this practice, involved at least 30% of all their consultations and, because of the contribution of the work with "mixed" diagnoses, probably rather more. Almost half of all the diagnoses made were of acute infective conditions, and roughly the same proportion of all the work of the practice was involved in treating them. When diagnoses and work are classified by the seriousness of the condition the disproportion between the number of diagnoses and the amount of work is more striking.

FIG. 4.—Percentage of diagnoses and consultations showing broadly the type and duration of the condition diagnosed. Note: (1) Each single diagnosis is classed as either acute infective, acute non-infective, or chronic. (2) There may be several diagnoses in any one consultation. Where several diagnoses are made and these come from more than one of the three broad groups seen above, the consultation is referred to as work with "mixed" diagnoses. 12% of all consultations fell into this category. (3) Because of this the percentage of consultations with acute infective, acute non-infective, and chronic conditions will be seen to represent an approximate and minimal figure. (4) The total of 6,122 diagnoses upon which this chart is based excludes 85 "diagnoses" in which there was no illness and prophylactic inoculation was involved. The 144 consultations which were concerned with these 85 "diagnoses" are also omitted.

FIG. 5.—Percentage of diagnoses and consultations showing the seriousness of the condition diagnosed. Note: (1) Each diagnosis was classed as either serious or not serious. (2) Each consultation was classed as serious if one of the diagnoses made during it was serious. (3) Prophylaxis is omitted from the totals of "diagnoses" and consultations. The figure is based, therefore, upon 6,122 diagnoses and 15,644 consultations.

Fig. 5 shows this most important contrast. While only 16% of diagnoses were considered to be "serious," the work involved in dealing with them amounted to 43% of all the work of the practice for the whole year.

Services

The services which were rendered during a consultation have been analysed initially under the headings of examination, prescription, referral to hospital or some other agency, certificates of various types, and non-medical advice and help. Each of these groups of services has been examined in much greater detail for one week in every six, and full consideration of them in this practice must wait upon an analysis of this material. Preliminary review suggests that the findings in this study will not exceed greatly the figures reported by Fry (1952) and others. For example, at least one certificate was given for every 4.5 consultations, and only about half of these were National Insurance certificates. Referrals outside the practice were at the rate of rather over 35 for every 100 registered persons in the year, and most of these patients were referred only once. It is of interest to note that the referral rate at ages for each sex shows a maximum of 57 per 100 persons in elderly males, the comparable group of elderly females having only 38 referrals per 100 persons during the year.

During 10,889 out of 15,788 consultations, one, or more than one, prescription was made. This is equal to a prescription rate of about 7 for every 10 contacts with the doctor or at least five prescriptions for every person who consulted the doctors during the year, and rather under four for every person registered.

Prescription rates when analysed according to the seriousness and duration of the condition concerned go further to describe the prescribing habits in this practice. Prescriptions were given in 73% of "non-serious" consultations (based, of course, upon the "seriousness" of the diagnoses made during the consultation) and in only 65% of "serious" consultations. These differences in the amount of prescribing during serious and non-serious work were found whether the work was with diagnoses of acute infective, acute non-infective, or chronic conditions. Many of the serious acute non-infective conditions, such as injuries, will of course be referred to hospital or casualty clinic without need of a prescription, and this may explain the difference in this group. No such simple explanation is to hand for the larger amount of prescribing in the other less serious groups. It is possible that the difference here is due partly to hospital prescribing for those more seriously ill and partly to the longer duration of serious illnesses; the number of prescriptions in each episode of illness being more nearly constant.*

Work in Treating Groups of Patients with Various Diseases

The recording system which was used, and which has been briefly described above, allows not only the relating of the doctors' work to groups of patients and then to the groups of diseases, but the production of tables which show how much work was done with the different groups of patients when they were suffering from various types of disease. In this way it is possible to build up further the picture of the role of the G.P. in this "population." Table IV gives the proportion of persons, diagnoses, and consultations which occupied the doctors of this practice during the year, and shows that, of all patients, the young adult involved them in the smallest amount of work.

It will be seen that there were proportionately slightly more diagnoses made among the male children, but that this involved the doctor in much the same proportion of consultations as might be expected from the number of persons concerned (however, the large number of visits

*In order to examine this and kindred suggestions the material from the study is being analysed to show the number of episodes of illness as well as upon the basis of the consultation, diagnosis, etc.

TABLE IV.—Percentage of Persons, Diagnoses, and Consultations Showing for Each Sex the Proportions at Different Ages

	Age Group in Years								Total	
	0-14		15-44		45-64		65+		All Ages	
	M	F	M	F	M	F	M	F	M	F
Registered persons ..	24	23	48	44	20	22	8	11	100	100
Diagnoses ..	32	23	40	43	18	22	10	12	100	100
Consultations ..	28	23	34	35	24	23	14	19	100	100

3,084 persons are represented. This is the average population for the year. Prophylaxis is omitted from the totals of diagnoses and consultations. The table is based, therefore, upon 6,122 diagnoses and 15,644 consultations.

which were made to the homes of children must not be forgotten). At the other end of the age range, as might be expected, for the elderly, the number of diagnoses was not strikingly disproportionate, yet the work involved was in excess of that to be expected upon the basis of the numbers of persons of that age (and, again, the number of visits was disproportionately high).

As has been shown, there was more work in this practice with females than with males, and this was due to a greater use of the doctors' services by the women, as well as to the larger number of them who were registered (on the average each female consulting the doctor did so approximately once a year more often than each male). Comparison of the proportion of work with each sex that was involved in treating various types of illness shows a marked similarity throughout. In both males and females the milder acute infections occupied nearly one-third of the consultations (33% in males, 31% in females). The next largest group was the serious chronic conditions, which involved 25% of the doctors' work with males and 22% of the work with females. Serious acute infections involved roughly the same proportion of the work with males as with females (12% for males and 10% for females).

Such averages are of course subject to "great variation with age, and examination of the relative amount of work involved in treating different types of disease at various ages emphasizes this (Table V).

TABLE V.—Percentage of Consultations at Different Ages Showing Type and Seriousness of the Condition Concerned

Age of Patient (Years)	Seriousness	Type of Condition				Total
		Acute Infective	Acute Non-infective	Chronic	"Mixed"	
0-14	S	17	0	1	2	100
	NS	64	12	1	3	
15-44	S	7	3	18	6	100
	NS	32	21	6	7	
45-64	S	10	2	34	9	100
	NS	16	13	10	6	
65+	S	10	2	53	11	100
	NS	7	7	7	3	
All ages	S	11	2	23	7	100
	NS	32	14	6	5	

S = Serious. NS = Not serious. Prophylaxis is omitted. 15,644 consultations are represented.

The doctors spent proportionately more time on the treatment of the acute non-infectious conditions, such as injuries, in the younger adults than they did with any other age group, yet these young people caused them less work than patients of other ages. Again, the non-serious acute infections of children are seen to occupy nearly two-thirds of the doctors' consultations with that age group (64%)—twice the average for the whole practice. At the other end of the scale, over half the work with elderly folk (53%) was in treating serious chronic conditions—over twice the average for the practice.

Comment

Four much-discussed aspects of the work of the general practitioner have been measured and illustrated by examples from this particular practice. They are the concentration

of a large proportion of the work among a relatively small number of patients, the large amount of work with serious disease, the large amount with chronic disease, and the effect of the age of the patient upon the amount and type of work.

Concentration

The 16% of registered persons who were responsible for over half of the work of the doctors may be regarded, for this year at least, as the "hard core" of sick people in this practice. It might be thought that these people, who were more often and more seriously ill than the general run of patients, were a group of elderly and chronic sick for whom, perhaps, little could be done, yet over half of them were under 45 years of age and more than a quarter were children. The presence of this relatively large group of younger people, for whom treatment necessarily holds more hope, and the fact that they caused about one-quarter of all the work of the practice, draws attention to them as a body of patients of particular interest to the general practitioner. This group would be still more interesting if it could be shown that the same persons or the same families were identified in this way from year to year.

Another way to consider the preventive and therapeutic problems which were presented by this "hard core" is to approach it from the point of view of the number of persons involved—that is, in terms of the size of the problem for the G.P. If each person registered with the practice had been equally concerned in the doctor's work, it is unlikely that an intimate and personal knowledge of all the 3,084 would have been possible. However, only three-quarters of those registered caused any work at all, one-sixth were responsible for half of the work, and one-twenty-fifth (125 persons) for one-fifth of the work. In this there is a strong suggestion that the size of the doctor's list was, in this case, a poor indication of the number of persons among whom the bulk of the work was distributed. Moreover, since the 500 persons responsible for half the work had in fact an average of 16 consultations each, these general practitioners had a good opportunity of getting to know them and of practising good medicine with them.

Seriousness

The classification of a diagnosis as "serious" or "not serious" was carried out conservatively, and whenever there was doubt about the category in which to place it the diagnosis was classed as "not serious." The proportion of the total which was finally grouped as "serious" (16%) is not surprising, but the proportion of the work associated with these diagnoses (43% of the total) implies at least that in this case the general practitioners were themselves undertaking a substantial amount of serious work. If similar conditions were found to exist elsewhere it might become possible to refute the implication contained in such statements as "the general practitioner is a specialist in the trivial."

Chronic Disease

About one-third of all the work was with chronic disease. This type of work is often the least rewarding from the point of view of the doctor and the most difficult from the point of view of its attendant social problems, yet in the medical care of the chronic sick the G.P. and the family bear the major part of the responsibility. In this practice the doctors were often the only persons who were in a position to appreciate fully the needs of the family in which there was chronic illness and to co-ordinate the many services which were becoming available. Since the chronic disease burden of an ageing community is likely to increase (at any rate with the present lack of the means of prevention), these doctors must look forward to spending a very substantial part of their time and energy in the treatment of this type of illness.

Influence of Age of Patient

The most frequent users of the doctors' services were those over 65 years of age, with the young children and the middle-aged next, and the younger adults consulting least often.

The extent of this rather obvious effect of age is seen more clearly than in such generalizations, however, when the duration and seriousness of the work are examined. Thus two important trends with the age of patient were apparent in this practice. In work with children 64% was with non-serious acute infections, while in the elderly only 7% was classified in this way. Serious chronic illness, on the other hand, involved the doctors in only 1% of all work with children but in 53% of the work with those aged over 64. Thus between the extremes of age there was a proportionate difference of some nine times between the amounts of work involved in treating less serious short-term infections and of fifty times in treating serious chronic illness. These examples confirm in numerical terms how important the age composition of the patient population is to the practitioner. From the doctor's point of view the easiest patient on his list is obviously the younger adult, in the treatment of whom a relatively small amount of work is involved, and for whom, as has been shown in Table I, the smallest proportion of visits is undertaken. However, not only do patients of different ages need different amounts of medical care, but (and perhaps more important) the type of work which is involved in giving this care, and the kind of medical interest and satisfaction to be derived from it, differ greatly from age to age.

Summary

The work of a medium-sized practice in North-west London was studied for one year as part of an examination of the different methods which can be used in general practice research. Special records were kept by the doctors concerned and completed after each consultation, which thus became the basic and most easily counted unit of work. The number and "contents" (certificates, prescriptions, etc.) of such consultations were related to the age, sex, and social characteristics of the registered population, and to the diseases from which they suffered. These diseases were classified according to a list of 28 elements, and also as acute or chronic and serious or not serious according to defined criteria. Selected tables and figures are presented to illustrate how such material may be used to answer questions about the amount and type of work that is involved in running a practice of this size. No attempt is made to generalize from this study, but there is no reason to believe that the medical needs of the 3,000 registered persons differed greatly from those of the population of the rest of the borough.

The whole of the work of the practice, so far as this study was concerned, centred upon the 15,788 consultations which took place during the year. This is roughly the same as 100 consultations a week for every 1,000 registered persons. Half of this work was concentrated among 16% of the population (some 500 persons) who consulted the doctor on 10 or more occasions during the year. One-fifth of all the work was accounted for by 4% (some 125 persons) who consulted 20 or more times. Of all the diagnoses made during the year 16% were of serious disease, and the work involved in treating them amounted to 43% of the total work of the practice. Chronic disease caused 30% of the work, and acute infections accounted for another 43%. Much of this latter was in the treatment of acute respiratory infections. Over half of all the work with those aged over 64 was concerned with chronic serious disease, while less than 1% of the work with children was involved with this type of condition. Nearly two-thirds of the work with children was in treating the less serious acute infections, while only 7% of the work with the elderly was of this type.

Prescriptions were given during nearly 11,000 consultations—an average of at least five prescriptions for

every person consulting the doctor, or seven for every ten consultations. At least one certificate was given for every 4.5 consultations, and only about half of them were for official purposes. Referrals were at the rate of 35 per 100 persons in the year, and most of these patients were referred only once. The elderly male patients with a referral rate of 57 per 100 persons were referred most often.

We wish to thank Mr. L. Moss, the director, Mr. J. E. Fothergill, and Mr. D. Marshall, of the Social Survey, for doing the tabulating for us. We are also grateful to Mrs. G. Neale for her help in computing. Professor R. M. Titmuss did much of the early and more difficult work of the study and has since been a valued adviser. We are also grateful to Mr. F. J. Ashford, clerk of the Middlesex Executive Council, who went to much trouble in helping to determine who was in the practice. We would like to thank Dr. G. Tabuteau, Dr. Anthony de Silva, and Dr. D. R. Livingston, who helped the principal in the practice during the year and who also took part in the investigation. Dr. J. N. Morris, the director of the Social Medicine Research Unit, has been a constant adviser, and we are grateful to him and to other members of the staff of the unit.

TRAINING GENERAL PRACTITIONERS IN PSYCHOTHERAPY

BY

MICHAEL BALINT, M.D., Ph.D., M.Sc.

Consultant, Tavistock Clinic, London

Present Situation Regarding Psychotherapy in General Practice

It is generally agreed that at least one-quarter of the work of the general practitioner consists of psychotherapy pure and simple. Some investigators put the figure at 50%, or even higher; but, whatever the figure may be, the fact remains that the present medical training does not properly equip the practitioner for at least one-quarter of the work he will have to do.

Although the need for a better understanding of psychological problems and for more therapeutic skill is keenly felt by many practitioners, they are reluctant to accept professional responsibility in this direction. The most frequent reason advanced is that they have too much to do and it is quite impossible for them to sit down and talk with one patient for an hour at a time, week after week. Impressive as it sounds, this argument is not, in fact, firmly based. It is true that establishing and maintaining a proper therapeutic relation needs much more time than prescribing a bottle of medicine. In the long run, however, it can lead in many cases to a considerable saving of time both for the doctor and for his patient (and for the National Health Service). In the Appendix two cases are quoted to prove this point.

What actually happens at present in most of the so-called psychological cases of general practice is an almost mechanical prescribing of phenobarbitone if the patient is not depressed, and of some "tonic" if he is. If this fails, various specialists are consulted, usually resulting in "reassuring" reports that nothing organically wrong has been found. Eventually a psychiatrist is also consulted, often not so much as a

deliberate policy as *faute de mieux*. This situation, however, is created as much by the difficulties of the psychiatrist as by those confronting the general practitioner. It is common knowledge that the psychiatric services are pathetically unequal to the ever-increasing demand; they are flooded with patients, and consequently the psychiatrist must pick and choose. If a patient is picked he is put on the waiting-list, eventually taken on for treatment, and, more often than not, lost completely to the practitioner. If the patient is not picked the report sent to the doctor hardly ever helps him in his psychotherapeutic task except advising him to give sedatives or tonic.

Thrown back on his own resources, the doctor, often shamefacedly, prescribes some placebo or gives a "reassuring" pep talk. (It is a common joke to ask, "Reassuring—but to whom?") Then there are the advocates of common-sense psychology who advise the patient to have a holiday, to change his job, to pull himself together, to leave home, to get married, to have a child or not to have any more children but use some contraceptives, etc. None of these recommendations is necessarily wrong, but the fallacy behind them is the belief that an experienced doctor has acquired enough well-proved "common-sense" psychology to enable him to deal with the psychological problems of his patients. But minor surgery, for instance, does not mean that a doctor can pick up a well-proved carving-knife or a common-sense carpentry tool and perform minor operations. On the contrary, he has to observe very carefully the rules of antisepsis and asepsis, he must know in considerable detail the technique of local and general anaesthesia, and must have acquired reliable skill in using scalpel, forceps, and needle, the tools of the professional surgeon. Exactly the same is true of psychotherapy in general practice. The uses of empirical methods acquired from everyday life are as limited in professional psychotherapy as are carving-knife and screw-driver in surgery.

Experiences in Teaching Psychotherapy to General Practitioners

In the past twenty-five years or so, psychiatrists in many countries have run courses for general practitioners, courses which were often arranged because of the pressing and ever-increasing demand for them.

The results of these courses have been generally disappointing. This is a surprising outcome, for the general practitioner of some years' standing is a very good trainee. He has had time to assess the value and limitations of what he has learnt at his medical school and hospital, he has also had a fair amount of frustration and success in his practice, and he has seen enough of human suffering to make him sensitive. (Seen from this angle general practitioners are much better material for training in psychotherapy than young medical students.) The reason for the failure of these courses would appear to be that theoretical lectures, even when based on, or illustrated by, case histories or clinical demonstrations, hardly give more to the general practitioner than what he can get from reading books. Strongly influenced by the traditional medical training based on lectures and clinical demonstrations, both practitioners and psychiatrists forget, in a mutually attractive teacher-pupil relation, that psychotherapy means acquiring a new skill and not learning some more theories and facts. Nothing is easier or more satisfying for a psychiatrist than to take a patient's case and deliver a lecture about the theoretical implications, the unconscious dynamics, and the likely diagnosis of the patient. Moreover, such teaching is gratifying indeed to both. The

specialist can shine, and the practitioner feels enriched and reassured. But this gratifying collusion is disappointing in the long run because in reality it is too facile and does not give the means of effecting therapeutic changes.

Instead of allowing this teaching-being-taught atmosphere to develop, the aim of such a course should be to help the practitioner to acquire a new skill. This means a considerable, though limited, change in the personality of the doctor. The doctor has to discover in himself an ability to listen to things in his patients that are barely said, and, in consequence, he will start listening to the same kind of language in himself. This fairly difficult change of attitude is not needed if the doctor does not have to do the listening himself, but is taught and told what other people have found out about the "human mind"—namely, the theories of psychodynamics, of personality development, of transference patterns, and so on. In the same way as a new physical skill can be learnt only in the actual situation while dealing with the problems in it, so is it with the acquisition of a psychological skill. This is why concentrated full-time courses lasting for some weeks have proved to be of very limited value. The general practitioner must use his own current experience as a basis for learning the new skill. Past experiences are unsatisfactory for this purpose, since the memory of an emotional involvement is always less alive, less vivid, than the actual experience itself.

So far, so good; but the skill to be acquired involves understanding and guiding the development of the two-person (patient-doctor) relation, and the presence of a third person would fundamentally change this situation. This condition automatically excludes the presence of the tutor. Therefore the material on which the whole training has to be based is the doctor's report of what happened in the interview situation between him and his patient. This necessary condition implies a number of uncertainties. The doctor has not yet learnt what to look for and he is somewhat self-conscious and apprehensive because of his lack of skill and understanding; like everyone else, he too is apprehensive of criticism, and, consciously or unconsciously, tries to make his activities appear in the best light and to minimize his shortcomings and mistakes. On the other hand, in order to train him, his blind spots, shortcomings, and mistakes have to be brought out quite clearly and discussed as frankly as possible. It is difficult enough to do this in any sphere of physical activity which is near to the core of the personality—say, for instance, in dancing, social behaviour, or table manners—but it is still more difficult in the psychological sphere, where the whole personality is always involved. Moreover, any such personality change needs time, and it is impossible to hurry it. The only training which systematically caters for these difficulties is the psycho-analytic training, which provides for a personal analysis lasting for many years and amounting to several hundred hours.

Experience at the Tavistock Clinic, where courses in psychotherapy for general practitioners have been given for more than twenty years, has confirmed the limited value of "teaching" psychotherapy. Consequently in the last few years a new approach has been tried—namely, to shift the emphasis from "teaching" to training, using group methods to achieve to a certain extent, although admittedly not completely, the necessary changes in personal attitudes.

At first the aim was a very modest one, amounting only to the awakening of an awareness of psychological factors, enabling the practitioners to give a better and deeper assessment of their patients' problems and illnesses. According to the doctors' reports, the result has been a great saving of their time, much less need for complicated hospital examinations (hence a considerable saving for the National Health Service), and, last but not least, some help to the patients. Admittedly all this amounted only to something of a better diagnostic skill. But, having achieved a better diagnostic skill, the practitioners then wished to know how to treat the patients. This demand was not unexpected, as, with a greater awareness of the problems, the practitioners'

desire to do something to alleviate them was bound to follow. To answer this demand a two-year course in psychotherapy was organized. I now report briefly on the principles and methods used in this course. My main reason for doing so at this stage is that I believe similar courses may be contemplated elsewhere, and I felt that the approach developed may be of value to others and an exchange of ideas about the problems involved would improve the quality of the work.

Training in Psychotherapeutic Skill: (a) First Attempts

We started by advertising "introductory courses in psychotherapy for general practitioners" in the medical press, and every practitioner interested was admitted to one of the courses, each taking in, on an average, 8 to 12 doctors. Each course lasted for a term and consisted of weekly case conferences of two hours each. No systematic theory was given. The practitioners were asked from the start to describe any recent "psychological case" they had had to treat, and the discussion was kept so far as possible concrete—that is dealing with the individual problems of the patients in question. For some doctors this was enough; one or two dropped out during, and a few more at the end of, the first term. The remainder were the ones mentioned above who asked for more. To provide this further training, the weekly case conferences were continued, but each conference session was now followed by a tutorial meeting on the general outlines of psychodynamics, based mainly on psycho-analytic concepts. Both events took place on the same afternoon, and lasted from 2 to 5 or 5.30. This arrangement continued for two terms, and as the demand for still more training persisted it was decided to institute a two-year course.*

The method used in our training scheme was developed and tested to a fair degree jointly by Enid Balint and myself while training for the Family Discussion Bureau a group of social case-workers who were trying to help people with marital problems. The human problems facing these workers were roughly the same as, although in some relevant points simpler than, those of the general practitioners. Some of the similarities were the starting situation—namely, a patient in trouble coming for help and a professional offering understanding, the developing patient doctor or patient worker relation, especially the need for controlling the doctor's or worker's subjective involvement in this relation and so on. What was different was the usual presence of illness, often physical, in the doctor's material, and the all-important fact that the general practitioner cannot "pass the buck." Unlike general practitioners, social workers and, for that matter, specialists may say—and as is well known they often do say—this or that patient is not "my cup of tea"; "I am not interested in this kind of illness"; "I cannot find any justification for his complaints"; "the illness is so slight, or so severe, or so progressed, that it is a waste of my time to treat the man"; "give him some reassurance and ½ gr. phenobarbitone thrice daily and leave me alone"; etc. The general practitioner, come what may, must see his patient through, sometimes even to the bitter end; he cannot "refer him back" with an easy and empty cliché.

Before describing our scheme I wish to discuss at some length the implications for training of this factor, as its realization profoundly influenced our attitude.

(b) Practitioners and Their Relation to Specialists

The first of these implications is that the general practitioner must remain in his practice during his whole training. This rightly emphasizes the mutual roles of the psychiatrists on the one hand and the practitioners on the

*In fact, our total intake was 36 doctors. Of these, seven were left after their first and a further five after their second term, leaving 15 who are doing the present two-year course.

other. Both of them are doing their jobs, neither of them is so important that for his sake the other must make sacrifices; their jobs and their roles are those of peers. A further consequence is that the general practitioner remains in full and unrestricted control of his patients, he is the one who is running the show; the psychiatrist accepts the fact that his own role is that of an expert assistant, not that of a manager, and still less of a superior mentor or teacher.

Although this approach preserves, even enhances, the practitioner's dignity, it is only with great difficulty that it can be accepted by him. One reason is the burden of responsibility, sometimes really severe, that it involves. It is so much easier to farm out responsibility, to say, "I have asked all the important specialists and none of them could say anything of importance; I really need not be better than the bigwigs." No such escape is permitted in our course. Although the opinions of specialists are asked for and listened to, they are not accepted as final or binding; they are criticized for what they are worth, and then the doctor in charge is asked to decide what is to be done with the patient and to accept undivided and unmitigated responsibility for his decision. Often the decision influences the patient's whole future. This fact too must be borne in mind.

No wonder that the practitioners, as often as not, do not like to shoulder this heavy burden. What is more surprising is the willingness of the psychiatrists (in fact of all specialists) to enter into a collusion with the general practitioner in order that this responsibility may be dissipated, if I may say so, into thin air. The patient with psychological complications is often seen by several "eminent" people, each of whom gives his opinion about one or other part of the problem, but the final responsible decision is seldom explicitly stated even if it has to be taken. If possible no decision is taken; things are left hanging until fateful events supervene and make the decision anonymously, allowing everybody to feel that after all it was not his word that counted. On the other hand, if things turn out well everybody concerned may feel that his contribution was highly important, if not the decisive one.

One feature of our scheme was to unmask this anonymity by making the practitioner accept that he is and must remain in charge of his patient. If the doctor needed more help than the course could give him he was free to refer his patient to the clinic for consultation only. The patient was then tested by a psychologist and interviewed by a psychiatrist (usually the leader of the course), but only if the doctor was willing to continue the treatment. The results of the tests and of the psychiatric interview were then brought up in our conferences and mercilessly scrutinized. The final test of their value, which kept psychologist and psychiatrist equally on their toes, was the standard question of how much help in his further treatment of the patient did the doctor get from their reports.

This is a severe test indeed, as I can testify from first-hand experience. Neither I nor the psychologists who took part in this scheme found it easy to accept that some of our reports were merely nice phrases, repeating in a different form the facts known only too well to the doctor, and giving him hardly any help in his difficult task. This sobering realization of the shortcomings of our work is only one of the many lessons that general practitioners can teach us specialists.

The "collusion" and anonymity mentioned above is an excellent way out of this often very trying self-criticism. The specialist need not see the futility of his reports, and may rest perched on his "eminent" pedestal; the doctor may grumble and feel justified in his contemptuous opinion of the useless and pretentious specialist, and no one need do anything. Our scheme, by bringing face to face as equals specialists and practitioners, has made this escape impossible. Admittedly we, as everyone else, have had cases in which very little or nothing could be done; this fact then had to be accepted explicitly and in full and open responsibility.

I have already mentioned another kind of escape, the establishment of a teaching-being-taught atmosphere. This temptation, although very attractive to both practitioners and psychiatrists, should in most cases be resisted. When listening to a case an experienced psychiatrist can almost always without any great effort make a "clever" diagnosis and even foretell with reasonable accuracy what will happen in the doctor-patient relation for the next period. If he indulges in such a "conjuring trick" he severely interferes with the doctor-patient relation and inhibits the doctor's powers of observation and ease of handling the case. The doctor will then try either to confirm the psychiatrist's prophecy or to prove it to be incorrect, according to the actual relation between them. In any case the individual doctor and the group are deprived of the opportunity of finding out for themselves the advantages or disadvantages of one or the other ways of handling the problem.

(c) Present Training Scheme

The weekly case conferences are the mainstay of our scheme. About 10-12 are held in each of the three terms. To secure intensive participation and, on the other hand, to obtain varied enough material, we found it advisable to have groups of six to eight doctors. In addition to the conferences we offer to any doctor who asks for it individual supervision of his cases—that is, about an hour a week of "private" discussion. While the conferences are taken by the leader of the course, the individual supervision is provided—aided by some external help—by other clinic consultants. Psychotherapeutic technique is highly individual. In order to avoid the danger of muddling the practitioner by the often widely diverging views and approaches of the various consultants, the supervisors were asked to attend some of the case conferences before taking on any doctor for supervision. It was explicitly stated that they were not expected to subordinate their individual views to those of the course leader; on the contrary, they were asked to take part in the case discussions as frankly as they wanted. The reason for their attendance was that they should acquaint themselves with the atmosphere of the conferences, and, on the other hand, that the doctors should have the opportunity of finding out who they would like to supervise their cases. As these supervisions are expected to run on well-known lines, I wish to restrict my report to the psychodynamics of the case conferences.

I have already pointed out that we try to avoid so far as possible the ever-tempting teaching-being-taught atmosphere. Our aim is to help the doctors to become more sensitive to what is going on, consciously or unconsciously, in the patient's mind when doctor and patient are together. This kind of listening is very different from "history-taking," and here we encountered much difficulty when trying to free the doctors from the automatic use of this kind of approach. The main difference is that history-taking is concerned almost exclusively with objective events or with events that can easily be expressed in words—that is, events towards which both doctor and patient can adopt a detached "scientifically objective" attitude. The events that are our concern are highly subjective and personal, often hardly conscious or even wholly beyond conscious control; also, as often as not, there exists no unequivocal way of describing them in words. Nevertheless these events exist, and, moreover, they profoundly influence one's attitude to life in general and still more so to falling and being ill, accepting medical help, etc.

"Automatic Patterns"

It may safely be said that these events, happening all the time in everybody's mind, are only partly sensible adaptations to the ever-changing environment; to a large extent they are governed by almost automatic patterns originating mainly in childhood but influenced by emotional experiences in later life. The first task for our scheme was to awaken in the doctors an awareness of these automatic patterns, and then to enable them to study more and more in detail how these patterns influence the patient's attitude towards his

own illness, and on the other hand, how they colour or even determine his relations to any human being, and especially to his doctor.

Another factor affecting the patient's developing relation to his doctor is the doctor's response, which also is partly governed by automatic patterns. The interplay of these two sets of patterns, whether and how they "click" with each other, determines to a large extent the efficiency of any treatment. Its influence is less important in short-lived acute illnesses, but almost crucial in chronic ones. In order to achieve a better fit, and with more patients, the doctor must have a wide choice of responses, which means that he must become aware of his own automatic patterns and gradually acquire at least a modicum of freedom from them.

What is Needed

Intellectual teaching, however good and erudite, has hardly any effect on this process of liberation and general easing up. What is needed is an emotionally free and friendly atmosphere in which one can face the experience that quite often one's actual behaviour is entirely different from what has been intended and from what one has always believed it to be. The realization of this discrepancy between one's actual behaviour and one's intentions and beliefs is not an easy task. But if there is good cohesion between the doctors in the group, the mistakes, blind spots, and limitations of any individual member can be brought into the open and at least partially accepted by him. The group steadily develops a better understanding of its own problems, both collectively and individually. The individual can more easily face the realization of his mistakes when he feels that the group understands them and can identify with him in them, and when he can see that he is not the only one to make mistakes of this kind. Moreover, it takes only a very short time for the group to discover that the technique of each member, including the psychiatrist group leader, is an expression of his personality, and so, of course, are his habitual mistakes.

Admittedly crises occur from time to time, when one or other member finds it difficult to accept the full implications of some of his ways of handling his patients, or the realization of some facets of his personality that he had been only dimly aware of. These, however, can be borne, as they are also group events and do not solely concern the individual. It has been easy to describe this state of affairs, but it is rather difficult to explain its dynamism. So long as the mutual identifications of the members are fairly strong, any individual member can face strains because he feels accepted and supported by the group. His mistakes and failings, although humiliating, are not felt as singling him out as a useless member; quite on the contrary, he feels that he has helped the group to progress, using his failings as stepping-stones.* Crises may occur when there is some tension between one or the other member and the rest of the group which the leader has not detected soon enough (I would add that neither his role nor his psychiatric training confers on the group leader an absolute immunity against this hazard), and, instead of re-establishing good cohesion, his criticism may help to widen the gulf.

Signs of this isolation or tendency to isolation and the accompanying touchiness can be regarded as the equivalents of what psycho-analysis calls resistances. On the one hand, they are premonitory signs that some major personal attitude of the individual is being tackled in the group situation; on the other hand, by the way in which the isolation is achieved and maintained, they show what the problem is. In the same way the reaction of the integrated group towards such an attempt at isolation reveals the other side—that is, the counter-transferences of the group to the particular personality problem. The way in which a member isolates

himself, as well as the way in which the group deals with it, must be shown up. They represent very valuable material for studying interpersonal relations, and their full realization is a necessary condition to the re-establishment of a workable cohesion.

If such crises occur too often, or leave a bitter resentment behind, it is a sign that the pace of training has been too exacting and that the group has been made to work under considerable strain for some time. It is an equally ominous sign, however, if no crises occur at all; it means that the sensitivity and grasp of the group are not developing, the group and its leader are in real danger of degenerating into a mutual admiration society where everything is fine and we are nice, clever, and sensible people. It is a fact that acquiring psychotherapeutic skill is tantamount to discovering some hard and not very pleasant facts about one's own limitations. This unpleasant strain must be faced, and the group develops as long as it can face up to it, and stops developing as soon as it tries to avoid it. It is the task of the group leader to create an atmosphere in which each member (including the leader) will be able to bear the brunt when it is his turn to bear it.

It is a precondition of our technique to establish this kind of atmosphere in the group, and it is only in such an atmosphere that it is possible to achieve what we term "the courage of one's own stupidity." This means that the doctor feels free to be himself with his patient—that is, to use all his past experiences and present skills without much inhibition. At the same time he is prepared to face severe objections by the group and occasionally even very searching criticism of what we call his "stupidity." Although every report and case conference is definitely a strain and an effort, the result is almost always a widening of one's individual possibilities and a better grasp of the problems.

Importance of Timing

One of the most important factors in this kind of training is timing, which in the first approach means not to be in a hurry. It is better to allow the doctor to make his mistakes, perhaps even to encourage him in this, than to try to prevent them. This sounds rather foolhardy, but it is not; all our trainees have had considerable clinical experience, and this "sink or swim" policy was justifiable. Apart from not undermining the confidence and dignity of the doctor, it has the added advantage of providing ample material for discussion, since everybody was seeing patients all the time and was anxious to report his findings and discoveries, his successes and difficulties. As I have confessed, this policy may have been too much for some doctors, and we had a fair number of "casualties" who did not wish to continue.

If the timing is good enough, the doctor feels free to be himself and will have "the courage of his own stupidity." Gradually he becomes aware of the type of situation in which he is likely to lose his sensitivity and ease of response, or, in other words, to behave automatically. Meanwhile the reports of the other doctors have shown him what other ways might be adopted in similar situations. The discussion of the various individual ways, demonstrating their advantages and limitations, encourages him to experiment. (One practitioner announced the result of such an experiment thus: "I have done a real 'Smith' in this case—and it worked," meaning he had adopted the attitude he felt Smith usually adopted.) Every such experiment means a step towards greater freedom and better skill.

Attitude of the Group Leader

Perhaps the most important factor is the behaviour of the leader in the group. It is hardly an exaggeration to say that if he finds the right attitude he will teach more by his example than by everything else taken together. After all, the technique we advocate is based on exactly the same sort of listening that we expect the doctors to acquire. By allowing everybody to be themselves, to have their say in their own way and in their own time, by watching for proper cues—that is, speaking only when something is really ex-

pected from him and making his point in a form which, instead of prescribing the right way, opens up possibilities for the doctors to discover by themselves some right way of dealing with the patient's problems, the leader can demonstrate in the "here and now" situation what he wants to teach.

Obviously no one can live up to these exacting standards without some shortcomings. Fortunately there is no need for perfection. The group leader may make mistakes—in fact, he does quite often—without causing much harm if he can accept criticism on the same, or even somewhat sharper, terms as he expects his group to accept. This must be watched very carefully, and any hesitation by the group in exposing the leader's mistakes must be pointed out. Obviously this freedom cannot develop if the leader tries to hedge or to explain away his failings. It is a very wholesome sign if the group can run the leader down, even if they have some fun at his expense, if only they can do so without rejecting him or turning hostile to him. (Incidentally, this frank criticism is another way in which practitioners can teach us specialists.)

The Training Technique

One more word about the number of doctors who dropped out. The technique described here is still in its experimental stages—that is, it is crude and harsh. We are fully aware of this and we have decided to accept the risks involved. Our first consideration has been to develop a technique that is workable for a fair enough proportion of the doctors interested, in order to test out whether such a training technique is possible at all. The results of the two pilot projects—the Family Discussion Bureau scheme for social workers and the Tavistock Clinic scheme for general practitioners—are highly encouraging, although as yet not final. As soon as our technique is fairly securely settled, our next concern will be to examine our "casualties"—that is, the reasons why so many of our entrants have to leave us. It is true that psychotherapy in the same way as, for instance, surgery, is not within everybody's reach; nevertheless our "casualty rate" is too high. Conversely, this means that our training technique is, for the time being, inelastic and too exacting for a great number of practitioners.

There is, however, one very important difference between this kind of training and any other training in one or other of the many specialties in medicine. Any advance in therapy demands a new skill from the doctor, even if it amounts only to learning the correct ways of prescribing a new drug. In other words, mastering a new therapy means a change. But, whereas the changes required by new techniques in any of the other branches of medicine do not touch much upon the doctor's personality, the technique of psychotherapy involves the personality fairly deeply. From this angle the action of some doctors who dropped out is perhaps a sensible defence against an unauthorized violation of their private mental life, a defence that must be treated with respect. The diametrically opposite danger is that the group training may degenerate into therapy pure and simple. We are fully aware of this possible complication, which, in fact, is present in every form of psychiatric training, but as our scheme is a very young one we have not had to come up against it.

Summary

A training scheme in psychotherapy is described, in which the emphasis has been put on acquiring a personal skill instead of on teaching. The aim is to make the general practitioners aware of what their patient wants to convey to them, not so much by his words as by his whole behaviour, and of how their own general behaviour and actual responses influence what the patient can actually tell them. We have tried not to teach them what psycho-analytic or any other theory could say about the working of the human mind; instead we have

aimed at enabling them to be free enough to feel and understand what is going on between the patient and themselves in their surgery.

APPENDIX

It is generally recognized that it is rather difficult to describe in a condensed and concise form the subtle work of psychotherapy in any given case. That is the reason why only two case histories are given here as illustrations. The first describes the events and the consequences of what we called "the collusion of anonymity" between the general practitioner and his consultants. The second case tries to give an impression of the stage to which psychotherapeutic skill and understanding of our course have developed. When judging the case history, the reader must bear in mind that the work reported here was done in the third month of a course which is planned to last two years. Both case histories were compiled by the doctor treating the patients. Since, according to our idea, the doctor's personality plays also an important part in every therapy, I start each case with a short characterization of the doctor in charge.

Case 1

The doctor attending this case works in a partnership. His partner is a straightforward practitioner who wants to get on with the job. The reporter, however, is interested in the psychological implications of the illnesses and has a fair knowledge of the current psychiatric ideas. He reports:

"A married childless woman aged 32 has been on my partner's list since 1946. She complained then of epigastric and chest pains. In April, 1946, my partner sent her for investigation to an eminent physician, who reported: 'You will be glad to hear that this patient's chest x-ray film is quite normal. She seems very pleased at this, and I think most of her symptoms are functional, and I hope that the reassurance that I have given her may be of some help.' A short while after this the patient was unhappy about the condition of the chest, as the pain returned, and she was sent for x-ray examination to a chest clinic. The physician to the chest clinic reported in May, 1946: 'You will be pleased to learn that there is no evidence of pulmonary or pleural tuberculosis. I think the epigastric pain originates in the abdominal wall—that is, it is probably muscular or fibrous in origin. Massage might now be tried.' Massage was accordingly tried, but with little success.

"She was a frequent visitor to the surgery, and was seen by me first in October, 1946. I thought then that her symptoms might be due to 'chronic appendicitis.' I referred her to a gynaecologist first, who wrote in 1947: 'This lady is rather puzzling. She has been under Dr. L., who had her completely investigated and found nothing; I must admit I can find nothing abnormal, and from the gynaecological point of view I have drawn a blank. Whether in view of her constant pain in the right side and her chronic constipation there is the possibility of appendix trouble, it is difficult to say, but if you wish I will ask one of the surgeons, etc.' A surgeon was accordingly asked, and he said, in October, 1947: '... I have advised her to come into hospital for the removal of the appendix.' Appendicectomy was carried out in December, 1947. She came to see me practically every week with a variety of pains, sometimes in the right iliac fossa, sometimes in the back, and drove me frantic with seemingly irrelevant chatter and unwillingness to leave me during a busy surgery. I sent her to see a well-known orthopaedic surgeon on account of her persistent backache. He said in January, 1948: 'She has a supple back, although there is some slight tenderness in her lumbar muscles. I am arranging for her to have some treatment in the physiotherapy department.'

"She attended my surgery every week regularly, had still the same complaints as before, and began, to my puzzlement, to be rather aggressively flirtatious with me. I then told her one day, rather abruptly, that there was little more I could do for her and that it would be best if she went back to her job as a sales assistant and not come back to see me for some time. I did not see her again until 1950. She came then with her old complaints of pains again and in the attitude of a penitent child ('Didn't you miss me,' and 'I hope you won't be cross with me any more'). She still came every week, again became flirtatious and tried to put her foot on mine, and one day put her hand on mine. I

*In psychiatric terms, the depression caused by the realization of one's shortcomings must be fully accepted; identification with the common group ideal must remain, now as before, a desirable and attainable aim, but the group leader must watch very carefully when and how one or the other member is forced or allowed to slide into a paranoid position of the one who has been "singled out."

rebuked her, and she cried. She came back the following week and in subsequent weeks, receiving five to ten minutes' chat and a bottle of medicine on each occasion.

"Since then, owing to a greater awareness of personality disorders on my part, she has been given a one-hour interview in which, *inter alia*, she told of her childhood, of a father who was in the Navy and away from home most of the time, of a much-loved younger brother who died at the time of the onset of her symptoms, of her dyspareunia since the beginning of her marriage, and her complete inability to have sexual intercourse since her brother's death. Further investigations are in progress. Her attitude to me since that interview has much changed: there are no more efforts to flirt and there is an improvement in her symptoms. But it took four years to get that hour, and an appendicectomy. *Mea culpa!*"

Case 2

The doctor in charge of this case is a well-experienced and rather cautious general practitioner. Although he seemed to be sincerely interested in his patients' psychological problems he was careful, until coming to the course, not to get too much involved with them. He attended for three terms, hardly missed a conference, and, although following the discussions with great interest, even to quoting his own experiences, never tried any real psychotherapy with his patients. Then suddenly he decided to start with one case, and on the same day the case of which the following is his report occurred in his practice. It was this case which he started reporting with the phrase, "I did a real Smith—and it worked."

"The patient, a boiler coverer, aged 26, was a quiet, thin, pale, neat, inoffensive young fellow. Married three weeks before. Severe headaches. No relief in tab. codein. Pain 'behind eyes'; feels 'something wrong with brain.' Cannot go to sleep, and wife has to sit with him and hold his hand. Worries about 'floods.' For the last two months he could not go to the cinema; he gets lost in the film and suddenly 'comes to,' gets a 'crowded-in feeling,' feels panicky, screen seems to recede, and he has to rush out of the cinema. He also fears boilers now and is jumpy when working on them. He has always found it hard to make friends and is content to be by himself.

"No sex life before marriage. Satisfactory now for him, but wife has to be manually masturbated to achieve orgasm. ('I feel funny telling you that.') Feels content sitting in in-laws' house now, in spite of noise of numerous children, but is not so happy about going out. His wife has recently recovered from pulmonary tuberculosis and is at work again. The patient is very 'fussy'; does all the housework himself because he likes to do it, not of necessity. Gets a 'kick' out of giving his wife breakfast in bed.

"Family History.—Mother died when he was 3 years old, and he and his two elder brothers were sent to an orphanage, where he stayed until 14. Father had tabs and was blind. When the patient left the orphanage he became the maid-of-all-work at home. It was he who did the shopping and cooking and cleaning. He led his father about all the time, not his brothers. (This I remember very well, as I used to treat his father and knew the family set-up well.) His only hobby was motor-cycling, and he always took his father out on the motor-cycle. He thinks his father's blindness was due to war injuries and experiences. He himself often wondered what it was like to be blind, and often did a 'silly thing'—drove his motor-cycle blind to see what it felt like. His father's mother was blind (he was told) and she was also the youngest in her family.

"He dislikes his elder brother intensely and the dislike is reciprocated. This brother always acted the big boss: he expected to be waited on, 'took everything for granted,' and expected the patient to wait on him like a slave. The brother does not drink nor smoke, and is a highly critical sort of chap. He even supervised the patient's courtship, told him when he should get home at night, and strongly advised him against marriage. The brother's marriage broke up after three weeks and was 'annulled' (that was the word he had heard used.) The patient was afraid of him, but now they are not on speaking terms and pass each other in the street.

"Two weeks ago the patient was admitted to hospital for investigation because of the severity of the headaches. He was discharged after a few days, being told it was his 'nerves.'

"Hospital Notes (seen by me).—Came to hospital in taxi as he could not walk owing to severity of headaches. Admitted: ? sinusitis; ? migraine. Investigated, and no organic cause found. C.N.S. clear. Discharged. To be seen again next week. ? Psychiatrist."

"March 13, 1953.—He reported to me immediately after he left hospital, complaining that headaches were still persistent and

that he could not get to sleep. 'I don't know why I should be like this; after all, it is the first time in my life I have been free from financial worry—for example, paying off motor cycle and wife is over her I.B. and is working. Thus I can have little luxuries I could not afford before.'

"Immediate Interpretation After Taking History.* Assured not organic and nothing to do with father's blindness. 'You have always been pushed around since childhood and always in an inferior position. The Cinderella of the family. You had no right to be all right. You always had to carry a burden and had no right to affection (which you really craved). Now you are suddenly free of your tasks (through which you were playing out your inferior position) and you are immediately obsessed with guilt. So you have to atone with a symptom—the obvious one being headache behind eyes associating yourself with your father, to whom you were attached (and perhaps unconsciously resented). 'I thought of that myself.'

"March 16.—Saw the patient again. He said he felt 'marvellous.' No headaches; knows it is not organic now and understands symptoms are due to his previous life; sleeps through the night and goes off to sleep immediately; not frightened in a crowd, and is very grateful.

"May 7.—The patient has been back at work since March, is very happy with his wife, sleeps well, and has no complaints at all."

Postscript when reading the proofs. Report of the practitioner on October 22: "Man not seen for several months, only wife, who reported that he was fine. He occasionally gets headaches, which do not amount to anything, and he continues working. He is much easier to live with, and from the point of view of the wife he is a complete cure."

MYELOMATA OF BONE A REVIEW OF 25 CASES

BY

A. NAYLOR, Ch.M., M.Sc., F.R.C.S.

Consultant in Orthopaedic Surgery, Bradford and Keighley Hospitals

AND

F. E. CHESTER-WILLIAMS, F.F.R.

Consultant Radiotherapist, Bradford Regional Radium Institute and Bradford and Keighley Hospitals

Myelomata are said to be the rarest form of bone tumour (Geschickter and Copeland, 1936; Cade *et al.*, 1947), yet of 25 cases here reported 24 have been treated in this hospital group over the past five years, and one of us (A. N.) has had nine under his care in the past two years. During this same five-year period 13 cases of osteogenic sarcomata of bone (including three cases arising in Paget's disease) have been treated in the Bradford Regional Radium Institute. Osteogenic sarcoma is given considerable prominence in medical textbooks, yet it is apparent that its incidence is less than that of myelomata of bone. We suspect the incidence of the latter is not so uncommon as is usually suggested, and believe that many cases are wrongly diagnosed as secondary carcinomata or never diagnosed. Four cases in this series were diagnosed only when the patient was admitted in extremis. One is apt to associate myelomata with the textbook picture of multiple discrete osteolytic lesions in the skull, clavicle, vertebrae, and ribs, but this is usually the terminal picture. Hence one finds that most cases have a history lasting one to two years before the diagnosis is made. Early diagnosis is difficult because the condition is often asymptomatic for a long period, while signs and bio-

*This interpretation was what the doctor described as: "I did a real Smith."

chemical changes are very variable and not all are present in an established case. We wish to emphasize that one or more negative investigations do not exclude the condition, and the whole gamut of confirmatory tests is required before we can be confident of its absence.

While textbook descriptions stress the multiplicity of the lesions, and this is no doubt the commonest type, solitary and diffuse forms of the condition are encountered. The tumours are soft, reddish purple in colour, and vascular, although central necrosis may be present in large tumours (Case 4). They consist of ovoid or pyriform cells with a nucleus which has a nucleolus and a typical "clock" or cartwheel appearance due to dense chromatin.

We find the disease to exist in three forms: (1) a solitary form in which a large tumour is present; (2) a diffuse form in which the lesions are small and cause a diffuse decalcification of the affected bone; and (3) a multiple form into which the others usually develop when the plasma cells are aggregated into discrete nodules forming localized osteolytic lesions.

Myelomata Initially Solitary

Willis (1941) enunciated the criteria which determine the diagnosis of solitary myeloma—histological diagnosis, radiographs of the entire skeleton at regular intervals, and the absence of Bence Jones proteose from the urine. Only 23 cases of proved solitary myeloma have been described (Lumb, 1952). Many described as such have subsequently become multiple. The solitary tumours are large and affect the long bones and spine (Chesterman, 1935; Willis, 1941) as opposed to the affection of the flat bones and ribs by the multiple form.

There is little doubt that many myelomata are solitary initially, but the picture of multiple myelomata usually develops. It is therefore probable that this form and those which appear to be initially multiple are a single pathological entity, the rate of metastasis being extremely rapid in the multiple form, which is the end-stage of the disease. Some pathologists, however, maintain that multiple myelomatosis is a multifocal systemic disease without metastasis (Lumb and Prosser, 1938) and that the solitary myeloma is a separate entity. This view is difficult to reconcile with our experience and the other recorded cases of solitary tumours which ultimately disseminate (Cutler, Busch, and Cantril, 1936).

Case 1.—In November, 1944, a man aged 36 fell on to his sacrum. In July, 1945, he developed severe pain in the lumbo-sacral region and both legs. X-ray examination revealed the presence of a multilocular cystic tumour involving the entire sacrum. The sacrum was expanded and the cortex eroded anteriorly. Trabeculation was present. Biopsy on July 21 showed typical plasmacytoma. The blood picture was normal. Deep x-ray therapy was given. He remained well and there were no deposits in the ribs until July, 1951. Sternal puncture then showed myelomatosis to be present. In August he was given a course of stilbamidine and deep x-ray therapy, which relieved his pain a little. The patient is still alive, but is confined to bed owing to his rapidly deteriorating condition. Comment: This tumour remained solitary for seven years, but ultimately the typical multiple form developed.

Case 2.—A woman aged 63 was first seen in 1947. She complained of pain in the right loin for two years and had

recently noticed a lump in this situation. An x-ray film showed rarefaction of the twelfth rib. Kahn test negative. Tumour excised—section showed a tumour of undifferentiated round cells and no definite pathological diagnosis made. Two years later she had a similar mass over the left sixth rib. Bence Jones protein absent from urine. Mass excised but no definite pathological diagnosis made. On March 30, 1950, a further mass was removed from a rib which proved on section to be a myeloma. The patient died one year later.

Case 3.—In May, 1948, a man aged 41 fell from a ladder and attended hospital. X-ray film revealed solitary cyst in the upper end of the femur. The other long bones, ribs, and skull were not examined radiologically. Biopsy revealed the presence of a plasmacytoma. Deep x-ray therapy was given. In August he was readmitted and died within twelve days. X-ray examination revealed punctate osteolytic lesions in ribs, skull, and pelvis. Urine: Bence Jones protein and albumin present. Blood: Hb, 55%; W.B.C., 6,000; moderate rouleaux formation; total protein, 12.8 g.% (albumin 3.0 g., globulin 9.8 g.); A/G ratio, 1:3.27. Necropsy confirmed the diagnosis of multiple myeloma.

Case 4.—This case represents the closest approach to the solitary plasmacytoma in this series. The patient, a man aged 28, was seen on February 21, 1952. The first symptom was pain below the knee, present for the previous nine weeks. It was worse when he walked. Examination revealed tenderness over the tibial condyle, no effusion in knee, and full knee movements. An x-ray film showed a

FIGS. 1 and 2.—Case 4. Myeloma of tibia.

multilocular cyst in the upper end of the tibia extending down the shaft, but not expanding the cortex. On later review two small translucent areas could be seen below the main cyst (Figs. 1 and 2). Films of the skull, ribs, and long bones showed no other tumour. Urine: Bence Jones protein absent. Biopsy: typical plasmacytoma—central necrosis of the tumour present at operation; Unna-Pappenheim staining showed typical plasma cells. Sternal puncture, normal. Blood: acid phosphatase, 1.3 units; alkaline phosphatase, 4.3 units; total plasma protein, 6.8 g.% (albumin 3.8 g., globulin 2.8 g.); A/G ratio, 1.5:1. An x-ray film four weeks later showed two small translucent areas in the skull. Deep x-ray therapy was given. The symptoms cleared and he walked without pain or limp. The tumour has not enlarged and no further changes have occurred in other bones. Plasma protein is still unchanged. Comment: This case would appear to resemble that described by Chesterman, but the two nodules in the skull suggest that multiple lesions will appear at some future date.

In the cases described above, Bence Jones protein was absent in two, and present in one when multiple lesions had appeared. It is probable that changes in plasma globulin and A/G ratio are late changes and present only when there are multiple deposits.

Multiple Myeloma

The established multiple myelomatosis may appear in circumscribed or diffuse forms, and again the latter may develop into the former. The picture of the circumscribed variety is that which we have been apt to assume from our textbooks as the only type, but the well-established picture of multiple osteolytic lesions in the skull, pelvis, scapulae, ribs, and other bones appears to be a late stage in the disease. Unfortunately diagnosis before this stage is reached is not always possible, as many diagnostic features may be absent; and, as there is often a paucity of symptoms, or none, its presence is often unsuspected. The presenting symptoms are variable, but localized pain, especially persistent backache, was a feature in many, and paraplegia was present in two of our cases. It is possible that the discrete punctate form is preceded by a diffuse form producing general decalcification. Then discrete nodules produce osteolytic areas.

Case 5.—Man aged 56. Presenting symptoms and signs: ascites and ulceration of mouth. Diagnosis: cardiac failure and thrombosis. Ultimately diagnosed as multiple myeloma. Died without treatment. Blood picture: Hb, 47%; E.S.R., 83 mm.; W.B.C., 8,600; marked rouleaux formation present. Sternal puncture, plasma-cell myelomatosis. Blood urea, 40 mg. per 100 ml. Total protein, 11.5 g. (albumin 1.9 g., globulin 9.6 g.); A/G ratio 1:5. X-ray films showed multiple punctate osteolytic areas in skull, ribs, and pelvis. Urine: Bence Jones protein absent.

Case 6.—Man aged 42. Presenting symptoms: proptosis and headaches. X-ray films revealed multiple punctate areas of erosion in the skull. No changes in ribs and other bones. Blood protein and A/G ratio unchanged initially, but after two months the total protein was raised and the A/G ratio became 1:3.8. Course of stilbamidine given. Died four months later. Note: Normal proteins initially.

Case 7.—Woman aged 64. Presenting symptoms: lassitude and dyspnoea for six weeks. Died within two weeks of attendance at hospital. Sternal puncture positive for myeloma. X-ray films showed punctate areas in ribs and skull. Plasma-protein estimations and presence or absence of Bence Jones protein not recorded.

Case 8.—Woman aged 58. Presenting symptoms: nausea and cough for six weeks. Died two weeks after hospital admission. X-ray films showed multiple punctate areas of erosion in ribs, skull, and pelvis. Blood picture: Hb, 80%; W.B.C., 10,000; urea, 120 mg. per 100 ml.; protein not estimated.

Case 9.—A man aged 53 had backache for four months and then developed weakness and paraesthesia in one leg after three months. Paraplegia developed and he was admitted. Examination showed paraplegia due to lesions at level of D8. X-ray films showed osteolytic lesions in ribs and skull, with compression of D7 vertebral body. Disk spaces intact. Blood: protein 7.4 g., A/G ratio normal; acid phosphatase 1.5 units. Urine: Bence Jones protein absent. Deep x-ray therapy and stilbamidine given. Readmitted eight months later; no change in paraplegia; deposits in shoulder girdle and cervical spine. Died 13 months after first attendance.

Case 10.—Man aged 58. December 8, 1950: presenting symptoms: cough for six weeks and tumour of angle of mandible extending to ramus. X-ray film showed obstruction of angle of mandible with erosion of ramus. December 14:—biopsy: typical plasma-cell myeloma. January 15, 1951: x-ray film showed erosion of first rib. February: course of deep x-ray therapy given—3,000 r to mandible and shoulders. May 9: x-ray films showed defect in upper end of femur; no destructive lesion in spine. Incontinence

of urine. Suprapubic cystotomy performed. Test for Bence Jones protein not performed. Further deep x-ray therapy and nitrogen mustard given without effect. Patient died on July 27, 1952.

Case 11.—Woman aged 64, referred from radiotherapy department May, 1949, with 2 osteoclastoma of sternum. Presenting symptoms: backache, pain in chest and arms for six months. X-ray film showed loculated tumour in manubrium sterni. No other radiographs of bones taken. Deep x-ray therapy given. In November, 1949, pain had been relieved but tumour unchanged. X-ray examination showed translucent areas in several ribs and right clavicle. Urine: Bence Jones proteose present. E.S.R., 47 mm. Total plasma protein, 6.6 g. (albumin 2.9 g., fibrinogen 0.17 g., globulin 2.9 g.); A/G ratio 1:1. Course of nitrogen mustard therapy given in January, 1950. In July, 1950, x-ray examination showed no further changes. Patient died September, 1951; own doctor stated cause to be "coronary thrombosis due to hyperpiesis."

Case 12.—Man aged 68. Presenting symptoms: breathlessness, diplopia, and numbness of face for three weeks. X-ray film of skull showed punctate areas typical of myelomatosis. No lesion in pelvis. Total protein, 7.5 g. (albumin 5.7 g., globulin 1.8 g.); A/G ratio, 3.1:1. Alkaline phosphatase, 4.4 units; acid phosphatase, 0.9 unit; blood urea, 210 mg. per 100 ml.; E.S.R., 13 mm.; W.B.C., 12,000; Hb, 90%. Urine: Bence Jones proteose absent. Sternal puncture: typical of myelomatosis. Died two weeks after initial observation.

Case 13.—Woman aged 47. Presenting symptoms: feeling of weakness for many years, backache for six months, exophthalmos. Blood: cholesterol, 250 mg. per 100 ml.; total protein 7.9 g. (albumin 6.2 g., globulin 1.7 g.); A/G ratio, 3.6:1; Hb, 90%. Sternal puncture: normal. Urine: Bence Jones proteose absent. X-ray film of skull: punctate areas typical of myelomatosis; no lesion in other bones.

Case 14.—Woman aged 64. May 12, 1952: presenting symptoms: pain in right lower ribs. Blood: Hb, 48%; R.B.C., 2,900,000; W.B.C., 4,400; total protein, 11.0 g. (albumin 5.1 g., globulin 5.5 g.); A/G ratio, 1:1. Urine: Bence Jones proteose present. X-ray films showed multiple destructive lesions in ribs and skull, with generalized decalcification. Stilbamidine and deep x-ray therapy given. Last seen July 30, 1953. Pain then considerably relieved.

Case 15.—Man aged 71. July 30, 1952: presenting symptoms: repeated epistaxis and melæna. X-ray films showed multiple small areas of translucence in skull, right humerus, and right femur. Blood: total protein, 7.95 g. (albumin 2.65 g., globulin 5.3 g.); A/G ratio, 1:2. Course of deep x-ray therapy given.

Case 16.—Woman aged 59. Presenting symptoms: low back pain for eighteen months, unrelieved by bed rest or plaster immobilization. X-ray films showed general decalcification of lumbar and dorsal spine and pelvis. Blood: total proteins, 8.0 g. (albumin 3.9 g., globulin 3.8 g.); A/G ratio, 1:1; calcium, 10 mg. per 100 ml.; phosphorus, 3.2 mg. per 100 ml.; Hb, 68%; W.B.C., 9,000. Some months later x-ray films showed typical punctate areas in ribs, pelvis, and skull. Sternal puncture: typical myelomatosis. Urine: Bence Jones proteose absent. Deep x-ray therapy relieved pain. Died three months after treatment. Comment: This case demonstrates the diffuse decalcification, followed by the appearance of the typical multiple osteolytic lesions.

Case 17.—Woman aged 60, seen in 1950. Presenting symptoms: pain in dorsal region for about three months. Had kyphosis and tenderness at D9-10. X-ray films showed collapse of D9; no lesions in ribs. Thought to have secondary carcinoma, but no primary lesion found. Six months later x-ray examination showed no further radiological changes; no lesions in ribs or humerus. Twelve months later, x-ray films showed punctate areas in dorsal and lumbar spine, skull, and long bones. Sternal puncture: typical myelomatosis. Urine: Bence Jones proteose

present. Blood: total protein, 6.0 g. (albumin 5.2 g., globulin 0.8 g.); A/G ratio 6.5:1. The patient is still alive. Has had a course of stilbamidine without demonstrable effect. No deep x-ray therapy given. Note normal serum proteins when all other typical changes were present.

Case 18.—Woman aged 56. Admitted February 18, 1953, with fractured shaft of right femur. There had been pain in the knee for the two previous months. X-ray films showed a fracture through a large cyst at junction of lower and middle thirds of femur. X-ray films of ribs, clavicle, scapula, and skull showed multiple osteolytic areas with no new bone formation. Uroselectan showed normal renal function. Urine: no Bence Jones proteose present on repeated testing. Blood: W.R. negative; blood urea, 27 mg. per 100 ml.; total protein, 5.7 g. (albumin 2.97 g., globulin 2.4 g.); A/G ratio, 1.2:1 (same when repeated after three weeks). E.S.R., 45 mm. per hour. R.B.C., 3,800,000; W.B.C., 10,000; Hb, 69%. Sternal puncture: positive for myelomatosis. Biopsy of nodule in left acromion process showed plasma-cell myeloma.

Case 19.—Woman aged 66. Admitted with history of increasing shortness of breath and weakness for a year. Doctor had noted that she was anaemic six months previously, and started some liver injections with no improvement. Three months previously she developed severe backache, which was aggravated by any attempt at movement, and was admitted in this condition. Had vague aching in most joints. No marked physical features. Bence Jones proteose—positive. Total serum protein, 7.2 g. (albumin 3.4 g., globulin 3.8 g.); A/G ratio, 1:1.1. Blood urea, 40 mg. per 100 ml. X-ray film showed no change in skull. Some compression of D5, 6, and 7, with decalcification. Generalized osteoporosis of dorsal and lumbar spine. Osteolytic areas in ribs and sternum. Sternal marrow puncture: 90% of cells were plasma cells. Blood count: Hb, 22%; leucocytes, 3,800.

Case 20.—Woman aged 69. Presenting symptoms: shortness of breath and feeling of tiredness for six months. Physical examination showed no definite features. X-ray films of skull, femora, and pelvis showed bone detail within normal limits. Old fracture of right clavicle and left eighth rib. Area of rarefaction in left clavicle. Sternal puncture: numerous lymphoid cells and abnormal early cells; ? localized deposit of leukaemia. Bence Jones proteose—negative; trace of albumin in urine. Blood: total plasma protein, 9.3 g. (albumin 1.3 g., globulin 7.7 g.); A/G ratio, 1:5.9; Hb, 48%; leucocytes, 7,300 (lymphocytes 2,701; polymorphs 2,236; myelocytes, 1,633). The patient died two months after admission. Necropsy: skull normal; sternum filled with whitish nodules; vertebrae contained similar white areas of marrow in lumbar region and upper end of femur. Sections taken showed myeloma, although cells resemble lymphocytes.

Case 21.—Woman aged 56. Presenting signs: pain in neck, radiating into occiput and to left shoulder and left clavicle. Developed stiff shoulder, which was treated and which has improved; but she still has some pain in the neck. Has noticed prominence of inner end of clavicle. X-ray film showed soap-bubble rarefaction of inner end of clavicle. Biopsy showed myeloma cells. Sternal puncture: myelomata; many atypical plasma cells. Bence Jones proteose—negative; trace of albumin in urine. Blood: total plasma protein, 10.1 g. (albumin 3.1 g., globulin 6.58 g.); A/G ratio, 1:2.1. X-ray film shows small area of rarefaction in the ribs. Skull: one area of rarefaction. Femur and lumbar spine: N.A.D. Dorsal spine: no areas of destruction.

Diffuse Type

Case 22. Woman aged 66. Presenting symptoms: pain in dorsal and lumbar regions for two years; increasing kyphosis for past six months; poor general condition, with

marked kyphosis. X-ray films showed general decalcification of dorsal spine. No destructive lesion in ribs or spine. Sternal puncture: positive for myelomatosis. Patient developed paraplegia within one month of examination and died.

Case 23.—Woman aged 68. Presenting symptoms: (1) dorsal pain for eighteen months, x-ray film one year previously showing osteoarthritic change, for which physiotherapy gave some relief; (2) increasing kyphosis over the past six months. X-ray films showed general decalcification and collapse of all dorsal vertebrae. No other destructive lesion in spine or ribs. Blood: total protein, 10.3 g. (albumin 3.8 g., globulin 5.88 g.); A/G ratio, 1:1.5; Hb, 48%; W.B.C., 3,000; calcium, 10.5 mg. per 100 ml.; phosphorus, 4.8 mg. per 100 ml.; alkaline phosphatase, 4.6 units. Sternal puncture: typical of myelomatosis. Urine: Bence Jones proteose absent initially, but present three weeks later. Stilbamidine therapy given. Died within two months of conclusion of course.

Case 24.—Woman aged 72. Presenting symptoms: exhaustion for two years; low back pain for nine months. X-ray film showed diffuse decalcification of dorsal and lumbar spine with collapse of D12. Disk spaces intact. Ribs decalcified, but no destructive lesion. Three months later, x-ray examination showed further collapse of D12 and fractures of ribs, but no changes in skull. Sternal puncture: typical myelomatosis picture. Blood: Hb, 55%; W.B.C., 4,000; blood urea, 72 mg. per 100 ml.; total protein, 12 g. (albumin 3.8 g., globulin 8.2 g.); A/G ratio, 1:2.36; E.S.R., 67 mm.; serum calcium, 13.8 mg. per 100 ml.; phosphorus, 3.5 mg. per 100 ml.; alkaline phosphatase, 10.4 units. Urine: albuminuria present; Bence Jones proteose absent. No treatment given. Diagnosis confirmed at necropsy.

Case 25.—Man aged 67. Presenting symptoms: low back pain for six weeks. Nothing abnormal on examination. X-ray film showed collapse of D11; chest and ribs, N.A.D. Blood: Hb, 83%; W.B.C., 4,100; E.S.R., 55 mm.; total protein, 7.8 g.; A/G ratio normal. Thought to be secondary carcinoma, but no primary neoplasm discovered. Deep x-ray therapy given, with relief of pain. X-ray examination two months later showed no further changes. Four months later patient developed severe pain and anaemia. Blood: Hb, 51%; W.B.C., 4,600; total protein, 10.6 g. (albumin 2.1 g., globulin 6.5 g.); A/G ratio, 1:3. X-ray films showed general demineralization of spine and ribs, but further collapse of D11, with collapse of L1 and 2. Sternal puncture: negative. Died two months later. Comment: Note the late appearance of serum protein changes.

Discussion

From a study of these cases we see that the large solitary myeloma occurs in the younger age group (average 40 years), but ultimate spread to the multiple form was experienced in all our cases. The diffuse form occurred in subjects over the age of 60 and proved to be the most difficult type to diagnose. The sex ratio in the solitary type was 3 males to 1 female, whilst in the multiple type the female sex predominated (11 females to 7 males). Of the discrete multiple type, two (Cases 16 and 17) were initially diffuse, and discrete punctate lesions developed after an interval, while simultaneous general decalcification was present in Case 14.

Local pain is the most common initial symptom, but pathological fracture and paraplegia are frequent presenting symptoms. The destruction of isolated vertebrae is apt to be confused with secondary carcinoma, and full investigation must be carried out in all cases. This should consist of: radiographic examination of the skull, ribs, and vertebrae; estimation of the total serum proteins and serum albumin and globulin; examination of the urine for Bence Jones proteose; and sternal marrow puncture.

The presence of Bence Jones proteose in the urine is a useful confirmatory test, but is often negative in the multiple cases, and its absence is of no significance in diagnosis. Further, it may be present rarely in other conditions—for example, secondary carcinoma of bone and myelogenous leukaemia.

In our series the test was positive in seven and negative in seven of the cases in which multiple lesions were present. It is negative while a myeloma remains solitary. This approximates to the figures given by Bayrd and Heck (1947), who found the test positive in 53% of the cases.

The serum-protein changes, when present, are diagnostic. There is usually a rise in the total serum protein, due to increase in the globulin fraction, leading to reversal of the albumin/globulin ratio. In the multiple cases in our series these changes were present in 13 and absent in 4, whilst they were not recorded in 4 cases. The change took place at a very late stage in Case 25. A normal serum-protein value does not exclude the diagnosis of myeloma, and the test has no prognostic value.

The blood picture varied extensively, but a severe reduction of the red-cell count was present only in the later stages of the disease in the multiple lesions, while little change in the white-cell count was experienced. A count within or near normal limits may be obtained in the presence of myelomata. A high E.S.R. was often recorded, and this may be associated with the increased serum globulin, as is the phenomenon of the increased rouleaux formation often seen in this disease. Sternal puncture was performed in 14 cases, with a positive diagnosis of myelomatosis in 12 of these.

In reaching a diagnosis we wish to emphasize the need for radiological examination of all bones and completion in all the tests discussed. Biopsy is usually required in the solitary type, as radiological differentiation from osteoclastoma is usually impossible. In lesions of the vertebrae we noted that decalcification followed by compression and destruction occurred, but the intervertebral disks were not affected. In this respect the condition resembles secondary carcinoma and differs from a tuberculous lesion. The frequency of backache as an initial symptom is noteworthy, and the condition should be borne in mind as the cause of such symptoms in the elderly, especially in the presence of osteoporosis and where the pain is unrelieved by rest or immobilization.

Treatment

The results of all forms of treatment make dismal and depressing reading, as these are of no avail in preventing the ultimate death of the patient. One wonders if the patients would not live equally long without treatment. Tennant (1945) described the case of a patient who was still alive five years after diagnosis and who had received no treatment. In our series one was still alive after the appearance of myeloma of the spine two years previously, although a course of stilbamidine had been given recently; while one was still alive seven years after deep x-ray treatment of an initially solitary tumour.

Of those initially solitary, in this series two were given deep x-ray therapy, one being still alive seven years after initial treatment, the other being still alive one year after treatment. One patient died without treatment, and the remaining case did not survive local excision.

It would seem that deep x-ray therapy is of no value in prolonging life in the multiple form, at least when administered when the full clinical picture is present. It is probable that this is the end-stage, and all treatment then will be of no avail. Deep x-ray therapy is of palliative value in relieving localized pain. Eight cases had such therapy alone, and seven survived an average of only nine months, the longest survival being two years. Three had deep x-ray therapy combined with stilbamidine, and died without the treatment having any appreciable effect on the course of the disease.

We have no proof of the value of stilbamidine in the treatment of myelomatosis. Three were treated with stilbamidine alone, and two died within two to four months of treatment. One was still alive six months after therapy. Nitrogen mustard administration also had no therapeutic value.

Consideration of this series of cases suggests that myelomata are not rare, but if the possibility of the presence of the condition is not realized diagnosis is belated. Early and full investigation should be made with this in mind. Full radiological investigation is also of value from the prognostic aspect, as cases in which the myeloma is initially solitary have a longer survival. Successful treatment of malignant disease requires early diagnosis, yet, with myelomata, we have tended to diagnose only the fully established condition. An analogous position would be where diagnosis of carcinoma or sarcoma is made only when metastases are present: when such a condition is reached treatment is of no avail. Hence we can expect little else if we wait until the similar dissemination has occurred with myelomata before we begin treatment.

We believe that the present textbook description of multiple myeloma is that of the end-stage of the disease and that it is analogous to the condition of general carcinomatosis. For efficient treatment we must diagnose the lesion at a much earlier stage. This problem still remains, but if we bear in mind that myeloma is a much more common condition than it was thought to be, we may be able to observe its early manifestations.

Summary

Twenty-five cases of myeloma of bone are reviewed to call attention to their frequency, as it is thought that they are not so rare as one is led to believe.

The difficulty of diagnosis of a disease which is often present in the absence of symptoms is discussed.

Treatment at present available has a questionable effect on the ultimate fate of the patient, but deep x-ray therapy has a definite place in the relief of pain and may prevent the onset of paraplegia when given to affected vertebrae. A case surviving seven years is recorded.

We are indebted to our staff colleagues at the Bradford Hospitals and to Dr. J. W. Hirst, of Huddersfield, for permission to review cases under their care.

In his annual report for 1952 Dr. W. S. Walton, medical officer of health of Newcastle-upon-Tyne, describes the unsatisfactory housing conditions in that city. Though progress has been made in the building of new houses, "the city has a very long way to go before the living conditions of many of the inhabitants can be brought up to what might be termed ordinary reasonable English health standards of the mid-twentieth century." Out of every 100 households in the city 38 do not possess a separate bath, 18 are without separate water-closet, and 17 have no piped supply of water. About 18,800 of the 87,800 households in the city at the time of the 1951 census lived in one- or in two-roomed "dwellings." The index of persons per room—0.88 in Newcastle—is one of the highest for any area in England and Wales.

HAEMOPTYSIS, BRONCHIECTASIS, AND FOREIGN BODY IN LUNG

BY

BERNARD LAURANCE, M.B., M.R.C.P., D.C.H.

Senior Registrar, Bristol Royal Hospital for Sick Children;
Tutor in Child Health, University of Bristol

Parents and doctors are often amazed by the variety of objects, other than food, that children delight in placing in their mouths. Some of these are swallowed, but a few are inhaled, and the consequences are then usually dramatic. If not coughed up and out immediately, early bronchoscopy may be urgently necessary.

Occasionally, however, there is merely a short, easily forgotten episode of choking after such an inhalation. No more is thought of the incident until, maybe years later, the patient presents with symptoms and signs of segmental putrid bronchiectasis, in which the inhaled foreign body may be found. Jackson and Jackson (1950) mention 1,485 patients with bronchial foreign bodies; in 200 the diagnosis was overlooked for periods ranging from one month to forty years. Other and similar cases are reported by Leary (1950) and by Glennie, Dark, and Lindars (1952).

As foreign bodies are commonly inhaled by children, if a mother insists that her child has "swallowed something down the wrong way," or with something in its mouth has choked, gagged, or coughed, attention should be paid to the story and every practicable investigation be carried out to exclude the presence of a foreign body in the respiratory tract; laryngoscopy and bronchoscopy may be essential, as often there are no immediate radiological changes in the lungs. However, apart from possibly revealing the impacted material, radiology may help further in the diagnosis by showing an alteration in aeration of the affected lung. It is essential in this procedure to obtain, in addition to a lateral radiograph, a postero-anterior radiograph of the chest both in inspiration and in expiration (Asherson, 1940).

In the three patients whose clinical histories are given below, the foreign bodies were probably present for 12 months, 5 months, and 6 weeks respectively before being removed. All were composed of vegetable matter, and none could be seen radiologically. In the second patient, however, radiological evidence of obstructive emphysema was obvious, and in the third patient there was clinical and radiological evidence of pulmonary collapse. The first case was unusual in that the patient had recurrent severe haemoptyses—a departure from the typical clinical syndrome which merits special emphasis.

Case 1

On July 1, 1951, a boy aged 5 choked over a piece of "grass in seed." His mother tried to retrieve it by putting her finger down his throat, but, being unable to make him cough it up, assumed he had swallowed it. Five days later he complained of colicky central, and later right-sided, abdominal pain, loss of appetite, and constipation. He also had a painful cough and almost continual generalized chest pains.

On July 7 he was admitted to hospital. Examination then revealed a flushed ill-looking boy with a temperature of 102.4 F. (39.1° C.) and obvious respiratory distress. Respirations, at a rate of 30 a minute, were grunting and inverted,

his alae nasae were working and there was slight cyanosis of his lips. The chest showed diminished movement, and impaired percussion note and air entry on the right side, with a pleural rub and crepitations at the right base. The tongue was dry and furred, and oral fetor was present. There was some guarding and tenderness in the right upper abdomen. Throat and mouth swabs showed normal mixed flora. The Hb was 13.3 g. (90%); W.B.C. 23,500 per c.mm. (83% neutrophils). Degenerated pus cells and a few organisms were seen in the sputum. Culture yielded a moderate growth, chiefly *Streptococcus viridans*. Mantoux 1 in 1,000 was negative. An x-ray film of the chest showed pleural effusion at the right base with probably consolidation in the anterior segments of the right lower lobe.

As the boy was obviously ill on admission, he was placed in an oxygen tent and treated for supposed pneumonia with "sulphatriad" and penicillin. Chest radiographs taken two days after admission showed an abscess cavity with a fluid level in the right lower lobe and a right pleural effusion. As there was no apparent response to treatment after 48 hours, chloramphenicol was given, and 48 hours later, again because of lack of clinical response, it was replaced by aureomycin. This was continued for two weeks, sulphadiazine being given for the first six days of this course. He remained very unwell, with a high swinging temperature. Subsequent chest radiographs showed a second abscess cavity to have formed alongside the first, with accompanying consolidation of the right middle lobe and increase in size of the right pleural effusion. Pleural aspiration was attempted, but no pus was obtained. Because he was so ill treatment with chloramphenicol was repeated, but with no better result than before.

Eighteen days after admission he coughed up a little sticky yellow sputum for the first time and produced a larger quantity on subsequent days, from which a culture yielded a moderate mixed growth of *Str. viridans*, *Staphylococcus aureus*, and a scanty growth of *Candida*. His temperature soon settled, and with physiotherapy he became more active and his appetite improved. A chest radiograph showed some residual pleural thickening at the right base only. On September 11 he was discharged to convalescence. There he remained well until October 3, when he developed a loose cough and shortly afterwards had repeated small haemoptyses. There were clinical and radiological signs of partial collapse of the right lower lobe, so that on October 31 he was readmitted to hospital.

At this time he was afebrile, looked fairly well, and, apart from the above signs, the only new feature noticed since his previous admission was early finger- and toe-clubbing.

Bronchoscopy on November 2 showed that the whole tracheo-bronchial tree was hyperaemic, and a purulent discharge was observed coming from the right main bronchus. A bronchogram done on November 15 showed poor filling of some segments of the right lower lobe.

The boy had repeated and alarming haemoptyses, though remaining afebrile. On November 24 he coughed up about 6 oz. (170 ml.) of blood with a piece of tissue which was reported histologically to be "vegetable matter." There were no further symptoms until two weeks later, when he had a moderate pyrexia. A second bronchoscopy on January 4, 1952, under "cover" of aureomycin, showed no changes from those seen previously, and thereafter he was afebrile, fairly well, and, in fact, was discharged on January 22 to a convalescent home. After a short period he produced increasing amounts of pink-stained sputum which later became frankly blood-stained. On February 11 this amounted to about 4 oz. (114 ml.) in 12 hours. He was therefore again admitted to hospital, where he was found to be pale and slightly cyanosed, with a significantly greater degree of finger-clubbing, a mucopurulent nasal discharge, and clinical signs of collapse of the right lower lobe. Culture of his sputum yielded a profuse growth of "mixed organisms" sensitive to aureomycin only.

On February 14 the third bronchoscopy showed the right bronchial tree full of foul fetid pus. Further radiological

investigations, including tomograms, showed no more than collapse at the right base. Considerable difficulty was experienced in controlling secondary staphylococcal lung infection, but a further bronchoscopy on May 21 showed this was now much less, and despite general clearance of the exudate a foreign body was not found. Haemoptyses,

FIG. 1.—Case 1. Cavity in posterior basal segment of right lower lobe in which an ear of corn (inset) was found.

varying from 6 to 19 oz. (170 to 540 ml.) in 24 hours, continued, and on July 3 the right lower lobe was removed. On examination and dissection of the excised tissue it was noted that the lobe contained a cavity in the posterior basal segment which was in direct communication with a bronchus and might well have been a fusiform dilatation of a bronchus. It was filled with vegetable matter resembling an ear of wild barley (see Fig. 1).

Case 2

A female infant aged 18 months, the only child of healthy parents, had a cold in August, 1952, and a cough had since persisted for which her own doctor saw her in November. She was then febrile, and examination of the chest showed significantly diminished air entry over the left mid-zone posteriorly. Despite an inconclusive diagnosis she was treated with penicillin, and the temperature returned to normal. Subsequently, a radiograph of the chest was reported to show "epituberculosis of the left upper zone." At this stage she was referred to hospital.

Her listlessness had returned and her cough was more severe. Examination at this time, approximately five months after the onset of her cough, revealed a moderately well nourished but pale and somewhat wasted child in whom the only abnormal signs were confined to the respiratory system.

FIG. 2.—Case 2. Compensatory emphysema in left mid-zone of chest. (Foreign body found in left lower lobe bronchus.)

There was no finger-clubbing or evidence of mediastinal displacement. Movement and air entry were diminished on the left, but the percussion note was considered to be equal on the two sides of the chest and no adventitious sounds were detectable. Radiological examination showed collapse of the left upper lobe and part of the left lower lobe, and indicated also some compensatory emphysema of the remaining portion of the left lung (Fig. 2). The left hilar shadow was enlarged. It therefore seemed that there was obstruction to the left lower lobe bronchus, either the result of hilar adenitis due to tuberculosis or pertussis, or as the result of an inhaled foreign body. Tuberculosis was excluded by negative Mantoux tests. On direct questioning a "choking attack," was remembered by the mother and thought to have occurred with a sweet. This was thought to favour the presence of a foreign body, and the child was consequently admitted for bronchoscopy on December 26. The haemoglobin was 12.4 g. (84%) and the white-cell count 12,700 per c.mm. (neutrophils 9,600).

A bronchoscopy was performed on December 31. Vascular granulation tissue was seen in the left lower lobe bronchus, and below it a foreign body; this was removed and was subsequently shown to be a burr (fruit of *Agrimonia eupatoria*).

Subsequently, auscultation showed that air entry over the affected part of the chest had improved. There followed a short period during which signs of left lung collapse recurred, but with the aid of intramuscular penicillin and physiotherapy clinical and radiological recovery was complete. A bronchogram done later showed no abnormality.

Case 3

A boy aged 21 developed a cough at the beginning of January, 1953. As his six siblings were thought to have whooping-cough at the time, his cough was attributed to this infection. He developed signs of bronchitis, which resolved when treated with sulphadiazine. However, a week later his cough returned and signs of collapse of the right lower lobe were detected. Despite courses of chloramphenicol and penicillin, these signs persisted and he had a constant fever. He was therefore referred to hospital on February 12. He was afebrile and looked pale. Abnormal physical signs were confined to the respiratory system. Signs of collapse of the right lung base were found clinically and confirmed radiologically. After admission the Mantoux 1 in 10,000 and 1 in 1,000 was negative; the E.S.R., 44 mm. in 1 hour (Westergren); haemoglobin, 78% (11.6 g.); white cell count, 13,700 per c.mm. (neutrophils 6,800).

As the collapse of the right lower lobe was known to have been present for at least six weeks a bronchoscopy was performed on February 23. The right stem bronchus was obstructed by vascular granulation tissue, in the centre of which lay a friable white foreign body. This was removed in one large and several small pieces and appeared to be a nut. No gross damage to the wall of the bronchus could be seen. Re-expansion of the collapsed portion of lung was aided by physiotherapy, and three weeks later the collapsed lobe appeared clinically and radiologically to be fully aerated. On April 9 a bronchogram showed a mild degree of bronchiectasis of all the right middle and lower lobe bronchi. Physiotherapy was continued, and a bronchogram taken six months later showed the bronchial tree to have returned to normal.

Discussion

Ears of corn, grasses, and other vegetable matter may easily be inhaled; they may prove to be more dangerous than some inorganic or hard organic substances such as bone or teeth, particularly as vegetable matter may swell by imbibition and increasingly irritate the tracheo-bronchial mucosa. Often, in a matter of weeks or months, exuberant granulation tissue forms around such matter, and this reactionary mucosal swelling, when touched, bleeds easily, and

usually indicates the presence of a foreign body. This type of bronchial granulation tissue was seen in Case 1.

Inhaled material may travel far along the respiratory tract, and there are several reports of foreign bodies ultimately reaching the pleural cavity (Graham, 1929; Davidsohn, 1931) without the appearance of symptoms. Occasionally the inhaled foreign body has gradually penetrated the thoracic parietes and presented as a chest-wall swelling (Seydell, 1937; Sehring and Shaw, 1948) which might have the characters of a pointing empyema.

Mayo (1836) reported that "a boy, aged about 12, who was travelling in a carriage, happened to have an ear of rye in his mouth: the carriage being jolted, the ear of rye disappeared: it had dropped into the lungs, where it produced abscess." At necropsy the offending ear was found in an abscess involving the lungs and liver. Lung abscesses are, however, uncommon in children. Thus Brock (1952), in an analysis of 477 cases of lung abscess, found that only 15 (3.1%) occurred in children under 14 years of age, and none of these were considered to be due to foreign bodies. The same author quotes other workers for details of the incidence of lung abscess in children, with a variation from 2.6% to 18.3%. In a total of 2,250 lung abscesses reported in the American literature (Smith, 1934), of 59 abscesses in infants and children only 1 was recognizably due to an inhaled foreign body. Hence, on the evidence available, lung abscess would not appear to be a common sequel to the inhalation of a foreign body.

Owing to the anatomical distribution of the bronchial tree, foreign bodies are more common in the right than in the left lung and are particularly rare in the right middle lobe.

As stressed already, the symptoms may be delayed for a very variable period, possibly for weeks or even months. Cough is common and later becomes productive. Occasionally the sputum is blood-streaked, but frank and recurrent haemoptyses of several ounces at a time, such as occurred in Case 1, are distinctly unusual. A search of the literature has revealed only three other examples of haemoptysis occurring as the result of foreign bodies in the lungs. This is perhaps rather surprising considering how often the presence of a foreign body in a bronchus promotes the formation of vascular granulation tissue, which bleeds so easily when touched through a bronchoscope.

Flandin and Poumeau-Delille (1932) report the case of a patient aged 24 who was investigated for tuberculosis on account of recurrent haemoptyses. Eventually radiological examination revealed a needle in his lung. Linneweh (1935) reports a rather similar case. In 1918 a man aged 28 sustained a grenade splinter wound in his neck. Over the next 17 years he was investigated for recurrent haemoptyses and, finally, following a fatal haemorrhage, it was found that this splinter had travelled to the right main bronchus and had eventually penetrated a major blood vessel. Steiner (1947) reports a most extraordinary case of a patient who introduced a metal sound into the vagina in order to procure an abortion; this was lost and "forgotten about." Eventually the sound migrated to the left lung and caused severe haemoptysis. It was removed at operation, but the patient died one month later.

Despite three bronchoscopies the correct diagnosis in Case 1 was not made for a considerable time. This case was further misleading in that the patient appeared to recover for a time after coughing up the first foreign body; his relapse was due to a suspected second foreign body which could not be seen. It should be stressed, therefore, that, in a patient who may have inhaled a foreign body, full radiological investigation and expert bronchoscopy may be required, and even then the object may be beyond the range of view. If symptoms and signs persist after the removal of a foreign body the presence of a second one should be suspected. As bronchiectasis is sometimes a sequel to the inhalation of foreign material, a bronchogram should always be done once all such material has been removed. Case 3 exemplifies this.

Summary

The reports are presented of three children who inhaled foreign bodies. In the first, lung abscesses developed which were followed by severe and alarming recurrent haemoptyses. After 12 months' illness a lobectomy revealed an ear of corn in the removed lung. The other two patients had persistent coughs. In the second there were clinical signs of obstructive emphysema, and in the third signs of pulmonary collapse. After removal of a foreign body from the latter patient, bronchiectasis was found to be present.

The literature is reviewed and the following points are stressed: (1) The rarity of lung abscess in children even as a complication of inhaled foreign bodies. Chronic suppuration of unknown aetiology, occurring in the right lung especially, should, however, suggest the presence of a foreign body. (2) Haemoptysis is an uncommon complication of an inhaled foreign body. (3) The value of a complete radiological investigation and the importance of expert bronchoscopy in children alleged to have inhaled or choked over any object. (4) As bronchiectasis is often a sequel to the inhalation of a foreign body, bronchography is usually essential after the foreign body has been removed.

I wish to thank Professor A. V. Neale for continual encouragement and help in the preparation of this paper and for permission to publish details of Case 1. My thanks are also due to Dr. Beryl Corner for permission to publish details of Cases 2 and 3; to Mr. Ronald Belsey, who bronchoscoped the three patients and performed the lobectomy on the first, for his encouragement and permission to publish surgical details; to Dr. R. J. Sandry for the pathological report in Case 1; and to Miss Jean Sheach for x-ray films and reports. I am indebted to Dr. J. Apley for correcting the draft manuscript for me. The photographs were kindly supplied by the Bristol University department of clinical photography.

The City Analyst of Birmingham, Mr. H. H. Bagnall, has been looking into the potency of the oral penicillin tablets sold in local pharmacies. During five months last year 82 samples were examined. Twelve samples had less than 80% of the prescribed potency. Of these, four contained less than 10% of the stated amount of penicillin, which Mr. Bagnall interprets by saying that "a patient stands a one in twenty chance of being supplied with tablets entirely devoid of any therapeutic value." The cause of the loss of potency appears to have been moisture admitted when the manufacturers' sealed containers were opened to dispense smaller numbers of the tablets. In his report (for the Third Quarter of 1953) Mr. Bagnall points out that this state of affairs is likely to be widespread in the country, but only in the largest centres is it possible for city analysts to undertake the research necessary to uncover it. As a solution, he suggests the establishment of about half a dozen regional laboratories to monitor the dispensing of the "wide range of new drugs listed in the *Pharmacopoeia* which have never yet come under the purview of the public analyst."

TUBERCLE BACILLI RESISTANT
TO ISONIAZIDVIRULENCE AND RESPONSE TO TREATMENT
WITH ISONIAZID IN GUINEA-PIGS

BY

D. A. MITCHISON, M.B.*

Lecturer in Bacteriology, Postgraduate Medical School of
London

Barnett, Bushby, and Mitchison (1953a, 1953b) found among strains of tubercle bacilli an apparent relation between their degree of resistance to isoniazid and their virulence in guinea-pigs and mice. Strains with a high degree of resistance were of low virulence, whereas those with only a slight increase in resistance were fully virulent. However, only three out of the eight strains employed were recently isolated from human lesions. Furthermore, even with these three strains the virulence of sensitive cultures isolated from the same patients before treatment with isoniazid was not tested. To meet these objections the virulence of eight pairs of freshly isolated sensitive and resistant strains has been investigated in guinea-pigs. The response to treatment at a level comparable to that used in man was also found by treating half of the animals with 4 mg. of isoniazid per kg. per day, given by subcutaneous injection.

Methods

Strains.—The eight pairs of sensitive and resistant strains were obtained from the sputum of eight patients in the Medical Research Council (1952) trials of isoniazid. The sensitive strains, obtained before treatment with isoniazid, had been subcultured not more than three times over a period of up to six months before preparation of the inoculum. The resistant strains, obtained during or up to three months after treatment with isoniazid, were isolated on isoniazid-free Löwenstein slopes and were then subcultured twice on slopes containing isoniazid in concentrations shown in Table II. In this way admixture of organisms with a lower degree of resistance was eliminated.

The inoculum for infecting the guinea-pigs was obtained by suspending the growth from 12- to 17-day-old Löwenstein cultures in Tween-albumin medium. Quantitative sensitivity tests on Löwenstein medium and viable counts on oleic-acid-albumin agar were set up from all the suspensions as described by Barnett *et al.* (1953b).

Guinea-pig Experiments.—An injection of 0.1 mg. (moist weight) of each strain was given into the right thigh of six guinea-pigs. One subgroup of three of these animals received no treatment and the other three were given 2 mg. of isoniazid per kg. subcutaneously at both 10 a.m. and 5 p.m. daily, except on Saturdays, when only one dose was given, and on Sundays, when none was given. Treatment was begun immediately after infection and was continued till the animals either died or were killed. Pairs of guinea-pigs, consisting of one treated and one untreated animal, were killed after 6, 10, and 14 weeks. If any animal died spontaneously, none was killed in that subgroup at the next appointed time. At the necropsy a histological examination was made of the spleen, liver, and lungs of all animals in which there was little or no macroscopic tuberculosis, and of some of the remaining animals with visible disease. The degree of tuberculosis was scored out of a possible total of 100 as described by Barnett *et al.* (1953b). Portions of the spleens from animals infected with the resistant strains and from treated animals infected with the sensitive strains were cul-

*In receipt of a grant from the Medical Research Council.

tured on Löwenstein slopes, and a sensitivity test to isoniazid was carried out by the Medical Research Council (1953) method on any growth of tubercle bacilli that appeared. Serum isoniazid concentrations were estimated by Dr. S. W. A. Kuper, of the Brompton Hospital, using the method of Cuthbertson, Ireland, Woolf, and Kuper (1954).

Results

Sensitive Strains. All the untreated guinea-pigs infected with the sensitive strains developed widespread tuberculosis, which was often fatal within nine weeks, as shown in Table I. The average score for the amount of tuberculosis

TABLE I. Results in Guinea-pigs Infected with Eight Sensitive Strains

Strain	Viable Units Injected Oleic-acid-albumin agar	Untreated Guinea-pigs Dying from Tuberculosis		Average Amount of Tuberculosis out of 100

Ru	4.9 × 10 ⁶	1	50	79	0
Fy	3.8 × 10 ⁶	2	60, 62	76	27

varied from 53 to 89. Among the guinea pigs infected with the sensitive strains and treated with isoniazid there were 18 out of 24 with no macroscopic or histological evidence of tuberculosis. In the remaining six animals there was some tuberculous involvement at the site of inoculation or in the inguinal glands. The average scores, shown in Table I, varied from 0 to 3.1. These findings demonstrate the protective ability of isoniazid in the dosage used.

Resistant Strains. The results of the quantitative sensitivity tests on all eight of the resistant strains, together with one typical sensitive strain, are shown in Table II. The amount of tuberculosis in the guinea-pigs infected with the resistant strains is shown in Table III. In animals with

* Two animals died from tuberculosis on the 64th and 77th days.
† One animal died from tuberculosis on the 83rd day.

scores of up to 20 there was a caseous abscess at the site of inoculation and a variable amount of caseation in the draining lymph nodes. The liver, spleen, and lungs, though macroscopically normal, often contained small tubercles or collections of histiocytes and lymphocytes. A score of 20 to 50 indicated macroscopic disease in the spleen, liver, and lungs, though less than would be found in animals infected with a fully virulent strain. Widespread generalized tuberculosis was present in animals with a score of over 50.

Virulence and Degree of Resistance.—As can be seen from Table III, an increase of resistance to isoniazid was associated with a decrease in the virulence of the strains. The scores of the amount of tuberculosis in untreated animals ranged from 78, caused by the strain with the lowest degree of resistance, to 10 to 15 caused by the four strains with the highest degrees of resistance. This relation can best be shown by including with the present results those obtained by Barnett *et al.* (1953a, 1953b), using other resistant strains, and also the results on a further two highly resistant strains (Table IV). One of these was obtained

TABLE IV.—Relation Between the Virulence and the Degree of Isoniazid Resistance of 17 Strains of Tubercle Bacilli

Virulence	Degree of Isoniazid Resistance

Intermediate	0	1	1	0
Low	0	1	2	7*

* Three of these strains were variants of the laboratory strain H37Rv.

from a patient under treatment with isoniazid and the other was a resistant variant of the H37Rv strain obtained from Professor R. Knox, of Guy's Hospital, and used by Goulding and Robson (1952). Both were injected into two untreated guinea-pigs, which were killed after 10 weeks. In spite of differences in the time between infection and killing, all these strains could be classified into three categories of virulence: high or just subnormal (scores of above 50), intermediate (scores from 20 to 50), and low (scores below 20). A well-marked correlation between the degree of resistance to isoniazid and loss of virulence is shown.

Stimulation of Virulence by Treatment.—The individual scores of guinea-pigs infected with the six strains of the present series which were of relatively low virulence are shown in Table V. In untreated animals the disease tended

— : Normal spleen, liver, and lungs.

to heal, as demonstrated by the fall in the average scores and the decrease in the proportion of animals showing lesions in the spleen, liver, or lungs during the period from 6 to 14 weeks after infection. The average scores of treated guinea-pigs killed at 6 and 10 weeks were the same as those of similar untreated animals. However, among animals

killed at 14 weeks the score in those that were treated was 22, whereas in those that were not treated it was 11. This higher average in the treated animals was due to those infected with strains L, H, and Fy. It can be seen that these three strains were slightly more virulent in the untreated animals than were the remaining strains. Thus there is a suggestion that, among resistant strains of low virulence those which were the more virulent appeared to have had their virulence increased by treatment with isoniazid between the 10th and 14th weeks after infection.

Response to Treatment.—Treatment with isoniazid afforded partial protection to the animals infected with strain O.T., which grew on 0.2 μ g. per ml. but not on 1 μ g. per ml.; their score was 30 (Table III). The scores in the treated animals infected with three strains, McK, L, and McK, capable of growth on 1 μ g. per ml. but not on 5 μ g. per ml., were in each case higher than in the untreated animals. Whether or not the strain can grow on 1 μ g. per ml. therefore seems to determine whether the infection will respond *in vivo* to treatment at 4 mg. per kg. per day.

Viable Counts.—Barnett *et al.* (1953b) found that two highly resistant strains gave much lower viable counts on oleic-acid-albumin agar than on Löwenstein medium. These differences were thought to be due to abnormal nutritional requirements of the strains. In the present investigation (Tables II and III) the counts on oleic-acid-albumin agar were equal to or slightly greater than the counts on Löwenstein medium except with the resistant strain Ru, which yielded counts of 3.7×10^6 and 1.5×10^7 respectively per mg. of bacilli.

Spleen Cultures.—Out of 21 spleens from treated guinea-pigs infected with sensitive strains, 2 yielded growth of tubercle bacilli. One of these strains was sensitive to isoniazid. The other grew on 0.2 μ g. per ml. but was inhibited by 1 μ g. per ml. None of the 19 cultures recovered from animals infected with the resistant strains showed any alteration in the degree of resistance from the strain injected.

Serum Isoniazid Concentrations.—The serum isoniazid concentration of guinea-pigs injected with doses of 2 mg. per kg. are shown in Table VI. For comparison mean

TABLE VI.—Serum Isoniazid Concentrations in Patients and Guinea-pigs

Time After Dose	Average Serum Isoniazid, μ g./ml.		
	Patients; Oral		Guinea-pigs; Subcutaneous
	1.4-2.6 mg./kg.	2 mg./kg.	10 mg./kg.
1 hour	0.9	2.3	9.9
2 hours	1.2	1.7	5.4
4-17 "	0.8	0.7	—
No. of patients or animals on which each average based	10	3	2

values for isoniazid concentrations, performed by the same method, in sera from 16 patients receiving 1.4 to 2.6 mg. per kg. by mouth were taken from the figures of Cuthbertson *et al.* (1954). If allowance is made for differences in the speed of absorption due to the different routes of administration it will be seen that the values obtained in man and in guinea-pigs were very similar. The serum concentrations in guinea-pigs injected with doses of 10 mg. per kg. were substantially higher.

Discussion

The low virulence to guinea-pigs of strains of tubercle bacilli resistant to isoniazid has also been reported by Barry, Conalty, and Gaffney (1953), although they did not state the degree of resistance of their strains isolated from patients. Since these strains also lack virulence in mice

(Barnett *et al.*, 1953b) and in rabbits (Domagk, quoted by Klee, 1953) it would seem probable that they would be of low virulence in man. However, patients in the Medical Research Council (1952) trials who developed resistant strains (growth on Löwenstein slopes containing 1 µg. of isoniazid per ml.) benefited less from treatment with isoniazid than did those whose strains remained sensitive.

There seem to be three possible explanations for the apparent contradiction. In the first place, even the most highly resistant strains set up large abscesses at the site of inoculation and usually minimal regressive lesions in the spleen, liver, or lungs. Thus these strains are not completely avirulent. Secondly, when strains from patients appear highly resistant in sensitivity tests there may be bacilli with a lower degree of resistance, and therefore higher virulence, in areas of the lungs containing progressive tuberculous lesions. Thirdly, the virulence of resistant strains may be increased by treatment with isoniazid; this may have occurred in the guinea-pigs infected with strains L, H, and Fy, although the numbers of animals were too small to allow a firm conclusion. It has also been reported in mice in three out of four experiments (Barnett *et al.*, 1953b).

Strains growing on Löwenstein slopes containing 1 µg. of isoniazid per ml. did not respond to 4 mg. per kg. per day. The serum isoniazid concentrations of guinea-pigs receiving this dose were similar to those of patients on the same dosage, used in the Medical Research Council (1952) trials. Thus it is reasonable to assume that such strains would also not respond to treatment with isoniazid when present in human lesions. Unfortunately some of the strains growing on 1 µg. per ml. but not on 5 µg. per ml. were still of fairly high virulence (Table IV). An increase in the dosage of isoniazid would be unlikely to inhibit these strains in patients, since they did not respond to a treatment level of 20 mg. per kg. per day in guinea-pigs (Barnett *et al.*, 1953b).

Strains growing on 0.2 µg. per ml. but not on 1 µg. per ml. have been classified as of doubtful resistance in the Medical Research Council (1953) trials. There is justification for this classification, since on 4 mg. of isoniazid per kg. per day such a strain partially responded to treatment, and on 20 mg. per kg. per day there was almost complete response (Barnett *et al.*, 1953a).

Summary

In a study of eight pairs of strains of tubercle bacilli sensitive and resistant to isoniazid it was found that the higher the degree of resistance the lower was the virulence in guinea-pigs. Treatment with isoniazid in a dose comparable to that used in man protected animals infected with sensitive strains, and partially protected animals infected with a resistant strain growing on 0.2 µg. per ml. but not on 1 µg. per ml. It did not protect animals infected with resistant strains growing on 1 µg. per ml., and may, indeed, have increased the virulence of some of these strains.

I am greatly indebted to Dr. D. F. Barrowcliff, Group Pathological Laboratory, Warwick; Dr. M. Laidlaw, Robroyston Hospital, Glasgow; Dr. P. H. Martin, Public Health Laboratory, Ipswich; and Mr. G. Usher, Clare Hall Hospital, South Mimms, for supplying strains of tubercle bacilli used in this investigation. Miss M. Monk provided valuable technical assistance. The isoniazid was provided as "nydradiz" by Messrs. E. R. Squibb, London.

BACTERICIDAL ACTIVITY OF STREPTOMYCIN AND ISONIAZID AGAINST TUBERCLE BACILLI

BY

BALBIR SINGH, M.B.*

AND

D. A. MITCHISON, M.B.†

(From the Department of Bacteriology, Postgraduate Medical School of London, W.12)

Garrod (1950) concluded that streptomycin, in concentrations attainable therapeutically in the body, was rapidly bactericidal to cultures of *Mycobacterium tuberculosis* growing in Tween albumin liquid medium. The speed of killings became more rapid with increasing concentrations of streptomycin. More recently, Mackaness and Smith (1953) have described the bactericidal action of streptomycin, isoniazid, and a combination of these two drugs on similar cultures.

The purpose of the present investigation was to investigate the action of streptomycin and isoniazid, both alone and in combination, on Tween albumin cultures of tubercle bacilli. An attempt was made to use concentrations of these drugs comparable to those found in treated patients.

Methods

Screw capped bottles containing 20 ml. of the H37Rv strain of *Mycobacterium tuberculosis* grown for nine days in modified Dubos and Davis Tween albumin medium (Medical Research Council, 1948) were centrifuged for 10 minutes at 1,000 r.p.m. to remove the larger aggregates of bacilli. The supernatant fluid was removed, and stained films from it showed that 80% of the organisms were single or in pairs.

A volume of 0.5 ml. of this supernatant was added to 4.5 ml. of Tween albumin medium containing various concentrations of streptomycin, isoniazid, or a combination of both drugs in screw capped bottles. A control bottle containing no drug was included in each experiment. The bottles were incubated at 37° C. in a hot air room. At intervals, 0.5-ml. samples were removed from these bottles for viable counts on oleic acid albumin agar plates, using a calibrated dropping pipette and loop as described by Mitchison (1953). The diluent employed was Tween albumin medium. The plates were sealed with wax coated "cellophane" tape and were incubated for four weeks at 37° C. The numbers of colonies were then counted with a plate microscope.

Where the presence of resistant organisms was suspected sensitivity tests to streptomycin and isoniazid were carried out by the Medical Research Council (1953b) methods. In one experiment the cultures which appeared to contain dead organisms were injected into guinea-pigs. These were killed after 10 weeks and examined for macroscopic evidence of tuberculosis.

Results

Streptomycin.—The bactericidal action of streptomycin alone in concentrations of 2, 20, and 200 units per ml. is shown in Fig. 1. The number of viable units, that is, discrete organisms or clumps developing into single colonies in the cultures was diminished by a thousandfold after contact with two units per ml. for seven days, 20 units for three days, and 200 units for one day. Thus the higher the concentration of streptomycin the more rapid was the

bactericidal activity. The viable count on the culture containing 2 units per ml. began to increase after the 10th day. Streptomycin-sensitivity tests carried out on subcultures from two colonies obtained on the plates inoculated

FIG. 1.—The bactericidal action of streptomycin.

FIG. 2.—The bactericidal action of isoniazid.

FIG. 3.—The bactericidal action of streptomycin and isoniazid alone and in combination. S.2=Streptomycin 2 units per ml. S.20=Streptomycin 20 units per ml. I.0.2=Isoniazid 0.2 µg. per ml. I.2=Isoniazid 2 µg. per ml. I.0.2, S.2=Isoniazid 0.2 µg. plus streptomycin 2 units per ml. I.2, S.20=Isoniazid 2 µg. plus streptomycin 20 units per ml.

after 21 days showed a fourfold increase in resistance. Viable counts on the cultures containing 20 and 200 units per ml., when sampled on the 15th and the 4th days respectively, yielded no growth; neither did subsequent samples of these cultures.

Isoniazid.—The bactericidal action of isoniazid alone in concentrations of 0.2, 2, and 20 µg. per ml. is shown in Fig. 2. The number of viable units in the cultures was diminished by a thousandfold after contact with 0.2 µg. per ml. for five days, 2 µg. per ml. for two and a half days, and 20 µg. per ml. for two days. Thus, although the speed of the bactericidal action was slightly increased by higher concentrations of isoniazid, this effect was less marked than with streptomycin. It should be noted that there was about a tenfold decrease in the viable counts during the first 24 hours with all three concentrations of isoniazid. The viable count on the culture containing 0.2 µg. per ml. began to increase after the 13th day. Subculture on to Löwenstein slopes containing isoniazid concentrations showed that the organisms present were resistant, being capable of growth on 0.2 µg. per ml. In

a similar manner a resistant strain capable of growth on 50 µg. per ml. was obtained from the culture containing 2 µg. per ml. Viable counts on the culture containing 20 µg. per ml. yielded no growth on the 13th, 21st, and 27th days.

Streptomycin Plus Isoniazid.—The bactericidal actions of streptomycin alone in concentrations of 2 and 20 units per ml., of isoniazid alone in concentrations of 0.2 and 2 µg. per ml., and of both drugs in combinations of these concentrations were tested simultaneously. The results are shown in Fig. 3. The bactericidal activity of isoniazid in concentrations of 0.2 and 2 µg. per ml. was about the same as that of 2 units of streptomycin per ml., but the activity of 20 units of streptomycin per ml. was distinctly greater. However, the combination of 0.2 µg. of isoniazid and 2 units of streptomycin per ml. was much more active than either alone, and was equal to or slightly greater than the activity of 20 units of streptomycin per ml. The combination of 2 µg. of isoniazid and 20 units of streptomycin per ml. was even more active, though the increase in bactericidal activity of this combination as the concentrations of the drugs were increased tenfold was less marked than with streptomycin alone.

Isoniazid-resistant strains capable of growth on Löwenstein slopes containing 50 µg. of isoniazid per ml. were eventually obtained from the cultures containing 0.2 and 2 µg. of isoniazid per ml. alone. The remaining cultures failed to yield growth in their viable counts and guinea-pigs injected with them failed to develop tuberculosis.

Discussion

The streptomycin concentration of 20 units per ml. and the isoniazid concentration of 2 µg. per ml. are both about equal to maximum serum levels (Medical Research Council, 1948; Elmendorf *et al.*, 1952), and the two lower concentrations of 2 units of streptomycin per ml. and of 0.2 µg. of isoniazid per ml. are both four to eight times the maximal concentration that inhibits the growth of sensitive tubercle bacilli (Medical Research Council, 1948; Mitchison, 1952). Thus the concentrations that we have used can be regarded as equivalent for both drugs, and are about equal to maximal and minimal therapeutic serum levels.

At the maximal serum concentrations streptomycin was more rapidly bactericidal than isoniazid, though at the minimal levels there was little difference in their activity. The concentration of both drugs in tuberculous lesions would be less than the peak serum level, so that here the activity of both drugs would probably be nearly the same.

As shown in Fig. 2, and in two further unpublished experiments, isoniazid appeared to have caused a marked fall in the viable counts after 24 hours' contact. A similar fall in Fig. 3 was not shown, probably because the count at 0 days was unsatisfactory, being done on only one plate. Mackaness and Smith (1953) found a delay of 48 hours before the onset of any marked fall in their viable counts. The difference might be due either to the presence of smaller bacillary aggregates in our suspensions or to the organisms being in a different growth phase.

There was an increase in bactericidal activity as isoniazid concentration was increased, as shown in Figs. 2 and 3 and also found in a third unpublished experiment. We cannot account for this difference between our results and those of Mackaness and Smith, who found that the bactericidal effect of isoniazid was independent of the drug concentration. The increase in activity with increasing drug concentration was, however, more marked when streptomycin was used. One would therefore expect an increase in therapeutic dosage of streptomycin to be more beneficial to patients than a similar increase of dosage of isoniazid.

As shown in Fig. 3, the bactericidal activity of a combination of streptomycin and isoniazid at minimal therapeutic concentrations was as great as the activity of the maximal concentration of streptomycin alone, and the activity of maximal concentrations of both drugs together was greater than that of either alone. Thus one would expect treatment

*Colombo Plan Fellow.

†In receipt of a grant from the Medical Research Council.

of patients with a combination of streptomycin and isoniazid to be more effective than treatment with either drug alone, even in the early stages, when development of resistant strains of tubercle bacilli would probably not have occurred.

When either streptomycin or isoniazid alone was added to our cultures, in most experiments resistant strains eventually replaced the sensitive bacilli which had been killed. When the two drugs were added together resistant strains did not emerge. These results are analogous to the observation that a combination of streptomycin and isoniazid prevents or delays the development of resistant strains in pulmonary tuberculosis (Medical Research Council, 1953a).

Summary

At concentrations four to eight times those necessary to inhibit growth of tubercle bacilli the bactericidal activities of streptomycin and isoniazid were the same. At concentrations ten times higher, corresponding to maximal serum levels, the activity of streptomycin was greater than that of isoniazid. The activity of the combination of both drugs was higher than that of either alone, and prevented the growth of resistant strains of tubercle bacilli.

PROGNOSIS OF DEPRESSION TREATED BY ELECTRIC CONVULSION THERAPY

BY

HUGH F. JARVIE, M.B., B.Sc., D.P.H., D.P.M.

Beit Memorial Research Fellow

(From the Department of Neurology, Radcliffe Infirmary, Oxford, and the Cheadle Royal Hospital)

Electric convulsion therapy (E.C.T.) is now widely used in psychiatric practice, and its efficiency, especially in the treatment of depressive states, would seem to be beyond dispute. It is certainly the commonest method of treatment employed by the in-patient psychiatric unit.

In England and Wales approximately 60,000 people are admitted to mental hospitals annually, and probably at least one-third have E.C.T. at some time during their stay; nor does this figure take into account the number who receive it as out-patients or in private practice.

It is therefore a matter of some importance that the long-term results of this treatment should be critically assessed. The present paper describes the position at the end of three years of a series of cases of depression treated in a mental hospital, the majority of which received E.C.T., and the effects of that treatment are evaluated.

Material and Method

The patients studied consisted of 114 "typical" cases of a series of 130, the clinical features of which have already been published (Jarvie, 1950). They represented the routine admissions to the Cheadle Royal Hospital of people suffering from depression who came under my care from May, 1947, to April, 1949. Of the 130 cases, 16 were regarded as "atypical" in that they showed unusual, bizarre, or

schizophrenic features, and the diagnosis of "depressive state" would probably not have been accepted in their case by many psychiatrists. The results in this atypical group will be published elsewhere, as they are of more specialized interest.

The 114 cases were an entirely heterogeneous group of consecutive admissions and included cases which could have been placed in most of the recognized clinical subgroups: manic-depressive, involutional, anxiety-depressive, reactive. Their ages ranged from 21 to 78, but the majority (74) at the time of admission were 50 years of age or older. They included cases having both recurrent and first attacks. The age and sex distribution is shown in Table I. In view

TABLE I. Age and Sex Distribution of Cases Studied

Group	No. of Cases	Sex		Age Group											
		M	F	20-29	30-39	40-49	50-59	60-69	70-79	Totals	Recovered	Improved	Dead	Relapsed	Unstable
No E.C.T.	17	9	8	2	7	2	4	7	2						
E.C.T.	71	28	43	2	7	16	23	21	2						
Improved	26	12	14	2	6	5	7	6	2						
Totals	114	49	65	4	13	23	34	34	6						

of the difficulty that exists, except in extreme cases, of making a rigid differentiation of clinical types, it was felt it would be of little value to attempt an analysis of the effects of E.C.T. on different subgroups. Consequently the results presented here are those of the whole series without reference to diagnostic grouping.

The method of inquiry was as follows. On the third anniversary of the patient's discharge from hospital a questionnaire was sent to the nearest relative and to the patient's doctor. The information asked for was the same in both cases, except that the doctor was asked to give the certified cause if death had occurred. The purpose of the double questionnaire was to obtain a cross check on the information received. From the results obtained in this way any further sources of information were followed up—for example, by inquiry to hospitals or consultants who had been concerned with the patient. The case-notes of the parent hospital also form a source of information when, as in many cases, the patients had returned for further in-patient or out-patient treatment.

Results

Of the 114 cases, 97 received a course of E.C.T., after which 71 (73%) were discharged recovered and 26 (27%) were discharged improved. The number of convulsions administered and the duration of stay in hospital (in weeks) are shown in Table II. The remaining 17 patients either did

TABLE II. Number of Convulsions and Duration of Stay in Hospital of Cases Receiving E.C.T.

Group	No. of Convulsions			Stay in Hospital (Weeks)		
	Min	Max	Median	Min	Max	Median
Recovered	2	14	7.5	2	21	7
Improved	6	21	7.5	1	17	8

not receive E.C.T. or received such small amounts that it was regarded as not affecting the course of the illness. This last group is considered first.

Cases Not Receiving E.C.T.

In seven cases treatment with E.C.T. was withheld for physical reasons, all cardiovascular: atheroma, congestive cardiac failure, aortic aneurysm, aortic stenosis, cardiac syncope, and hypertension. In one other case the treatment was stopped after four convulsions, as the patient developed Stokes-Adams attacks during its administration. At the end of three years six of these eight patients were dead—

four from natural causes and two from suicide; one was a patient in another mental hospital, and one was well so far as the psychiatric illness was concerned.

Of the nine remaining cases which did not receive E.C.T. the following was the position at the end of three years: no information, 3; still in hospital, 1; completely well, 3; fairly well, 2.

E.C.T.—Cases Discharged Recovered

At the end of three years the position with regard to the 71 cases which received E.C.T. and were discharged recovered was as follows:

No adequate information	7 (10%)
Dead	5 (7%)
Well—Completely	25 (35%)
Fairly*	9 (13%)
Relapsed	25 (35%)
34 (48%)	

*Nine cases were regarded only as fairly well for the following reasons: (a) still on sedatives, 2; (b) failed to return to work, 1; (c) evidence of unstable episodes of short duration, usually of depression and/or elation, 6.

Of the five deaths, four were due to coronary artery thrombosis and one to lobar pneumonia.

Cases Relapsing

The interval (in months) between discharge and recurrence of symptoms is shown in the Chart. It is interesting to note that the relapses reached a peak within the first six months, then became less frequent, so that between 18 and 24 months none was recorded. From then onward the incidence of relapses began to rise again. This suggests that cases relapsing within 18 months of discharge are mainly true "relapses" of cases apparently well but really inadequately treated, while those whose symptoms recur later are having further genuine attacks.

Seven cases were still well after a further single course of treatment, in six consisting of more E.C.T. and in one

Interval between discharge from hospital and recurrence of symptoms in 25 cases which relapsed after being discharged recovered.

of symptomatic treatment with sedatives and euphoriant drugs. In all seven cases the recurrence of symptoms occurred within a year of discharge.

Four cases had broken down again just at the end of the three-year period and were under treatment in hospital at the time of inquiry.

One patient had been admitted to another hospital, where she still remains. In her case the symptoms recurred six weeks after discharge from the Cheadle Royal Hospital.

Of the remaining 13 cases, 12 had required further in-patient or out-patient supervision on two occasions: four of them had received one further course of E.C.T., and the remainder two further courses. Subsequently two of these cases had the operation of prefrontal leucotomy. Only one of these 12 cases was regarded as being well at the time of inquiry. The remaining patient had been readmitted to hospital on seven occasions within the three-year period and had received seven courses of E.C.T., consisting of a total of 39 convulsions.

E.C.T.—Cases Discharged Improved

Twenty-six cases were discharged only improved after what was regarded at the time as an adequate course of E.C.T. At the end of three years the position with regard to this group was as follows:

No adequate information	7 (27%)
Dead	2 (7.7%)
Well without further treatment	1
Well after relapse treated with E.C.T.	3
Still not symptom-free:	
In same condition as on discharge; no relapse, no more E.C.T.	6
Still unwell after relapse treated with E.C.T.	4
Prefrontal leucotomy	3
10 (38.4%)	
3 (11.6%)	

Of the two deaths, one was due to carcinoma of the colon and the other to a glioblastoma.

Physical Sequelae

Apart from the deaths and the one patient who developed epilepsy, organic sequelae which could even be remotely ascribed to the treatment were surprisingly few.

In this series the treatment had in every case been given unmodified—that is to say, without the aid of muscle relaxants or anaesthetics. In only one case was a definite fracture encountered during the administration of the treatment. This was in a lady of 65 who fractured her right humerus. Since then she has developed a painful swelling of both hands, presumably arthritic, although she had not been troubled with this before. It is of course difficult to decide how much these changes are due to the effects of the fracture or E.C.T. and how much to the natural processes of ageing.

Two patients complained of pain in the back which seemed to be genuinely organic in origin. Although minor degrees of compression fracture of the mid-dorsal vertebrae may have been missed, it is again difficult to decide without fuller investigation whether these complaints were not based on natural changes unconnected with the treatment.

Although not specifically asked for in the questionnaires, no complaints of persisting amnesia or other intellectual defect were recorded. Most of the patients in this series came from the Registrar-General's social classes I and II, and many have returned to work of considerable responsibility which they have carried on effectively and efficiently.

The deaths require some comment. Four of the seven were due to coronary artery thrombosis. Again it is difficult to implicate the treatment as an aetiological factor in precipitating death in these cases. One patient was known to have a pre-existing heart lesion, while the other three died at intervals of 3, 16, and 24 months after treatment. They were aged respectively 42, 61, and 66 at the time of death. It is not surprising that cases of unsuspected cardiovascular anomaly pass unnoticed in patients of the older age groups.

As has already been stated, the actual administration of E.C.T. in the crude and unmodified form gave rise to anxiety in only one case—namely, that of the lady in whom it was stopped because of the development of Stokes-Adams attacks during it. Even she managed to survive for two years after its administration.

The patient who developed a glioblastoma complained of symptoms two and a half years after discharge and died nine months later. The tumour, of considerable size, was found at necropsy in the temporal lobe.

One patient developed epilepsy. On discharge she was known to have received the largest number of convulsions—

a total of 60. Her case was complicated by the fact that a few weeks before her initial treatment with E.C.T. she appeared to be recovering from some infection involving the nervous system, as the following case history shows. There was no family history of epilepsy in her case.

A woman of 27 was admitted to the Chaddle Royal Hospital in November, 1942, suffering from melancholic stupor. She remained a patient until the early part of 1944. During this time she received 54 convulsions. Two months before admission she was reported to have had "catarrhal jaundice," and on admission she had nystagmus and bilateral extensor plantar responses. A lumbar puncture produced a clear fluid with 64 cells per c.mm., lymphocytes predominating, and a raised protein. Blood and C.S.F. Wassermann reactions were negative. Six months later the C.S.F. was normal, and when she was examined on readmission in 1947 there were no persisting neurological signs. A further course of six convulsions was given, and 21 months later she had her first grand mal attack.

Discussion

This study confirms the value of E.C.T. as a therapeutic agent in the treatment of depression.

It has to be remembered that most of the cases in this series were severely ill, otherwise mental hospital treatment would not have been regarded as necessary. Many on admission to hospital were calculated suicidal risks, and several had made an active attempt at suicide before admission. In the 71 cases discharged recovered after a course of E.C.T., 15 (21%) had made such an attempt, while in the 26 cases discharged improved 9 (34.6%) had done so. Only two attempts at suicide, both unsuccessful, were reported in the available follow-up material of these 97 cases.

On the grounds of suicidal risk alone, therefore, treatment with E.C.T. can be said to have returned many socially useful people to a happy and effective life much more quickly than would have been the case if a natural remission had been awaited. Nevertheless, the limitations of the treatment must be recognized. In the first place, although the number of cases of depression which make a good initial response to E.C.T. is high (73%), every case does not respond completely, although on the whole nearly all of them show sufficient response to be regarded as improved. Secondly, a high proportion (35%) of cases discharged recovered relapse within the relatively short period of three years. Many of these cases are true "relapses" in that they represent the recurrence of symptoms in an attack which has been inadequately treated and in which superficial improvement has been regarded as recovery. Several of these cases respond to a further single period of supervision (on the average, of 10 weeks' duration) and an additional course of E.C.T. (on the average, eight more convulsions).

In any unselected group of depressions treated with E.C.T. there will be a hard core of cases in which the administration of this form of treatment will be of only limited value. These cases will consist of two main groups—those which fail to produce more than a minimal response to E.C.T., although apparently adequately treated, and those which seem to respond to E.C.T. but which relapse after a short time and continue to relapse at intervals, in spite of further courses of E.C.T. Thus one woman in the series had received a total of 39 further treatments and had been readmitted to hospital on seven occasions during the three-year period. In the 10 years which had passed since her first attack she had a total of 11 admissions to hospital and was known to have had 65 convulsions.

In chronic relapsing cases of this nature, with decreasing intervals of well-being, it is obvious that the continued administration of E.C.T. can hardly be justified. In such cases cerebral surgery must be seriously considered as an alternative form of treatment, and the good but limited response to E.C.T. which these cases show gives the measure of probable success. The reasons why a number of cases of depression should make only a limited initial response to E.C.T., so that they can be regarded as having improved rather than recovered, are obscure and probably complex. While a few of the 26 cases discharged improved were probably inadequately treated, reasons other than this must be adduced to explain the failure of response in the

remainder. From the study of this group there was some evidence that many were people of poor personality caught up in serious personal difficulties.

In spite of the fact that the mode of action of E.C.T. is apparently physiological, it is important that we should not get too far away from the concept of depression as a dynamically orientated illness.

The assessment of any form of treatment must be made against the background of the natural history of the illness. It should therefore be remembered that depression is a self-limiting disease, and patients often come for treatment when the brunt of the illness is over. Nevertheless, the response of most cases of depression to E.C.T. is rapid and effective and can be observed after the first few convulsions.

On the whole, E.C.T. is an effective form of treatment for the majority of cases of depression uncomplicated by serious physical disease, although its limitations in 30-40% of cases should be recognized. Physically, it is fairly innocuous, and apart from traumatic events in the course of its administration and the occasional disturbing cardiac episode, it is very safe. These events should be materially reduced by the administration of the treatment in the modified form. The only serious complication would appear to be epilepsy, and this cannot be a common one. It does not occur unless large numbers of convulsions are administered (Sundqvist, 1951). On the whole, for this and other reasons, the continued administration of E.C.T. as a therapeutic agent in any one case over a long period of time is undesirable.

Summary

The results of a three-year follow-up study of 114 cases of depression treated in a mental hospital are reported.

Ninety-seven cases were given E.C.T., and the immediate and remote results of this treatment are analysed.

It is concluded that E.C.T. is an effective form of treatment in most cases of depression, but its limitations in some 30-40% of cases should be recognized.

Physically, it is an innocuous form of treatment, but one serious complication reported is epilepsy.

I am indebted to Dr. J. A. C. Roy for enabling this study to be made. I am grateful to Miss Joan Williams, medical records secretary at Chaddle Royal Hospital, for her willing co-operation in issuing questionnaires and collecting information, and to Dr. W. Ritchie Russell for much helpful criticism in the presentation of this material.

New regulations made under the National Insurance (Industrial Injuries) Acts by the Minister of Pensions and National Insurance extend the insurance cover against pneumoconiosis. The regulations, which came into operation on January 11, give effect to recommendations made by the Industrial Injuries Advisory Council in their report on pneumoconiosis (Cmd. 8866). Up till now benefit for pneumoconiosis has been available only to persons who since July 5, 1948, have worked in occupations which have been scheduled because they are known to be capable of giving rise to the disease. Under the new regulations benefit is also available to persons who have never worked in a scheduled occupation but who are suffering from pneumoconiosis due to the nature of their work since July 5, 1948, in some other dusty occupation. Before being referred to the pneumoconiosis medical panels, claimants from unscheduled occupations will be required to provide a medical certificate or similar evidence to show that there is a reasonable cause for suspecting they are suffering from pneumoconiosis. Those who are totally disabled by pneumoconiosis but whose period of exposure ended before July 5, 1948, may be entitled to an allowance under the Pneumoconiosis and Byssinosis Benefit Scheme, 1952.

MUCOCELE OF THE APPENDIX

BY

J. H. JOHNSTON, M.B., F.R.C.S., F.R.C.S.I.

Senior Surgical Registrar, Liverpool Royal Infirmary

Mucocele of the appendix is an uncommon condition. Woodruff and McDonald (1940) reported its incidence as 0.3% of appendicectomies in the Mayo Clinic over a period of 24 years. The disease was described by Rokitsky in 1842 and by Virchow in 1863. Werth in 1884 first described pseudomyxoma peritonei associated with cystadenoma of the ovary, and in 1901 Fraenkel recorded the same condition in a case of appendix mucocele.

Case 1

A man aged 76 was admitted to hospital in October, 1952, complaining that for 24 hours the rupture in his right groin had been painful and irreducible and that he had been vomiting. There were the typical signs of a strangulated right inguinal hernia, but rectal examination revealed the presence of a large firm swelling in the rectovesical pouch. At operation the hernial sac was found to contain strangulated but viable small intestine. The bowel was reduced and the abdomen explored by a finger inserted through the neck of the sac. A firm smooth mass, which was palpable, extended from the right iliac fossa into the pelvis. The peritoneal cavity was opened through a transverse incision above the inguinal canal, disclosing the mass, which proved to be a large mucocele of the appendix. It was delivered with some difficulty, as it was adherent to its surroundings, and was removed. The hernia was repaired and the incision closed. On subsequent questioning the patient denied any history of previous abdominal pain or dyspepsia. He collapsed and died suddenly of a coronary thrombosis on the fourth day after operation.

The appendix (see illustration) measured 6½ in. (15.8 cm.) in length and 7½ in. (19 cm.) in its greatest circumference. It contained a colourless jelly-like substance, and the lumen

Photograph of the appendix in Case 1.

was completely occluded at the base by a short fibrous stricture. Histological examination showed that the wall was only 1/16 in. (1.6 mm.) thick. The serous coat was normal, but the muscle was entirely replaced by hyaline connective tissue with many cholesterol clefts. The lining epithelium consisted of a single layer of tall columnar cells secreting mucus.

Case 2

A woman aged 38 was admitted to hospital in June, 1951, with a history of central abdominal pain and vomiting of four days' duration and more recent pain in the right iliac fossa. The temperature was 100.2° F. (37.9° C.) and the pulse rate 90 a minute. There were tenderness and muscle guarding in the right iliac fossa and hypogastrium; rectal examination revealed tenderness of the pelvic peritoneum but no palpable tumour. The pre-operative diagnosis was appendicitis with perforation and peritonitis. At operation thin pus was found in the peritoneal cavity. The appendix was much enlarged and was surrounded by mucoid material,

which was also present in the pelvis. The left ovary contained a small cyst. Appendicectomy was performed and the abdomen drained. Recovery was uneventful. Section of the specimen showed that a pre-existing mucocele of the appendix had become acutely inflamed and had ruptured.

In September, 1952, 15 months after appendicectomy, the patient was readmitted complaining of swelling of the abdomen which had been progressing for nine months. On examination there was a central cystic tumour in the hypogastrium extending from the pubis to the umbilicus. Pelvic examination revealed that the uterus was of normal size; the large cyst was palpable through the left anterior fornix, and a smaller cyst was found in the right appendage. At operation the peritoneal cavity contained large quantities of mucoid substance which was exuding from a perforation of a multilocular cyst of the left ovary. The right ovary contained an endometrial cyst. Bilateral salpingo-oophorectomy was carried out. Histological examination showed that the large ovarian cyst was a pseudomucinous cystadenoma. Subsequently radiotherapy was applied to the abdomen.

Discussion

The essential factors in the development of appendix mucocele are obstruction of the lumen and sterility of its contents. In most cases the obstructing agent is a fibrous stricture at the base of the appendix which completely occludes the lumen and is the result of former appendicitis. On occasion the lumen is narrowed but not totally obliterated, since a mucocele may fill with barium in the course of an opaque-meal examination (Vorhaus, 1930). Wilson (1950) estimated the degree of occlusion necessary for the formation of appendiceal diverticula and found that an internal circumference of 4 mm. was the critical level at which obstruction and retention of secretions occurred. Wangenstein *et al.* (1937) recorded a resistance to the flow into the caecum of fluids injected into an appendicostomy and suggested the possibility of functional obstruction due to a sphincter mechanism at the appendix base. Carcinoid tumour (Topping, 1937), carcinoma of the caecum (Muir, 1931), and endometriosis (Shemilt, 1949) are rare causes of the condition.

The appendix contains a jelly-like material, pseudomucin, which is a glucoprotein distinguishable from mucin by reduction tests and by staining with mucicarmine. Its presence may be due to abnormal secretion by the mucosa or, since all gradations of staining and reduction reactions occur, the change from mucin to pseudomucin may be a gradual extracellular one. The content of a mucocele is usually sterile on culture. Wells (1936) produced the condition in rabbits by ligation of the appendix base, leaving the blood supply intact. In the experiments of Cheng (1949) and Grodinsky and Rubnitz (1941), however, simple ligation resulted in acute appendicitis, and development of mucocele required preliminary sterilization of the lumen by irrigation with saline, penicillin, or sulphaguanidine solutions. In long-standing cases the pseudomucin becomes inspissated, and calcification may lead to the formation of a large appendiceal calculus (Bunch, 1945).

In experimental mucoceles the muscular coat is hypertrophied in the early stages, but in the fully developed condition the muscle is thin and almost, or entirely, replaced by fibrous tissue, which may become hyalinized and eventually calcified. Diverticulum formation is common and is probably an early occurrence, as Wilson (1950) has shown that an actively contractile muscularis is essential to raise the intra-appendicular pressure and that passive distension of the appendix is ineffective.

Pseudomyxoma peritonei, which also follows rupture of a pseudomucinous cyst of the ovary, is the most important complication of appendix mucocele and is characterized by the presence of masses of colloid in the peritoneal cavity either lying free or enclosed in membranous adhesions. This material is identical with the contents of the mucocele and may be localized to the region of the appendix or widespread. The initial cause of the condition is perfora-

tion of the appendix, usually through a diverticulum, but the large quantities of pseudomucin which may be found have led to speculation concerning its origin. There are three possibilities.

1. The serosal cells may be stimulated by the presence of colloid to secrete an identical substance. This seems unlikely. Trotter (1910) stated that the peritoneal lining cells could assume columnar forms but believed that their reaction was of the nature of a foreign-body peritonitis and limited to the formation of enclosing adhesions.

2. The peritoneal pseudomucin may result from its continued discharge from a perforation of the mucocoele, but if this were so the complication would be halted by removal of the appendix. It may, however, recur after appendicectomy and eventually lead to the death of the patient.

3. The most probable explanation, in both appendiceal and ovarian types, is that mucus-secreting cells escape into the peritoneal cavity and, becoming implanted there, continue to secrete. Such cellular elements are difficult to find histologically in the peritoneal colloid, but the hypothesis is supported by the experiments of Grodinsky and Rubnitz (1941), who injected the contents of mucocoeles into the peritoneal cavities of other animals and produced progressive pseudomyxoma peritonei, while if the contents were first passed through a Seitz filter to remove the cells the condition did not develop.

Woodruff and McDonald (1940), in a study of 146 cases, divided appendix mucocoele into two groups. In the first the mucosa consists of a single layer of columnar cells. Rupture of such a mucocoele leads to a localized type of pseudomyxoma peritonei which does not recur after appendicectomy. In the second, smaller group the mucosa is hyperplastic owing to the presence of papillae covered with large columnar cells containing hyperchromatic nuclei. This is regarded as a grade 1 adenocarcinoma, and perforation causes dissemination of malignant cells and a diffuse, progressive peritoneal lesion.

Pseudomyxoma peritonei of appendiceal or ovarian origin differs, therefore, only in degree of malignancy from the coelomic spread of colloid carcinoma of the alimentary tract.

The occurrence of mucocoele of the appendix and pseudomucinous ovarian cyst in the same individual has been recorded many times. Bailey (1916) and Ries (1924) described cases with both lesions present simultaneously and discharging colloid into the peritoneal cavity. In Eden's (1912) patient an appendix mucocoele was found two years after operation for a ruptured pseudomucinous cyst. The double condition is usually complicated by pseudomyxoma peritonei, and it is likely that one lesion results from transcoelomic implantation of mucus-secreting cells released by perforation of the other, although the reason for selective involvement of these viscera alone is not clear. Willis (1952) considers that the probable sequence is rupture of a primary ovarian cyst which causes colloid and cellular spread in the subserous tissues and thus involves the appendix leading to mucocoele. In Case 2, however, the perforated appendix preceded the large ovarian cyst, although a small cyst was noted at the first operation. Hentz (1932) recorded a case with both lesions but without peritoneal colloid, and suggested that cells passed from the ovary to the appendix by lymphatic channels.

Other complications of appendix mucocoele are acute inflammation (Case 2), intussusception (Ward-McQuaid, 1949), volvulus (Jones and Carmody, 1936), and occurrence in a hernial sac (Juvara and Borcescu, 1948).

The clinical features of uncomplicated mucocoele are vague and symptoms are often absent. There may be a history of recurring pain in the right iliac fossa and a mass may be palpable in the abdomen or the pelvis. Radiology may show calcification of the appendix wall or of its contents, or a soft-tissue shadow displacing the caecum or producing a filling defect may be visible with an opaque meal. Rarely does the mucocoele fill with barium.

The treatment is appendicectomy; in the female, especially when the mucocoele is perforated, the ovaries are examined for concomitant pseudomucinous cyst. Occasionally the dense adhesions of the appendix necessitate resec-

tion of bowel for its removal. When the complication of pseudomyxoma peritonei is present the myxomatous material is removed so far as possible, and post-operative radiotherapy to the abdomen is carried out in an attempt to destroy the disseminated mucus-secreting cells. Drainage of the peritoneal cavity is avoided because of the tendency to secondary infection. A more accurate prognosis may be given in such cases if the appendix mucosa is examined for the presence or absence of papillomatous formations.

Summary

Two cases of mucocoele of the appendix are described, one of them associated with pseudomyxoma peritonei and with pseudomucinous cyst of the ovary. The pathogenesis, complications, and clinical features of the condition are discussed.

I am grateful to Mr. W. M. Beattie and Mr. C. H. Walsh for permission to record Case 2; to Dr. J. Carr Brundret for the histological reports; and to Mr. J. Cosbie Ross for advice in the preparation of this paper. I have to thank the central photographic department of the University of Liverpool for the photograph.

A CASE OF ULCERATING HODGKIN'S DISEASE

BY

T. G. EVANS, F.R.C.S.D.

Lately Surgical Registrar, St. Luke's Hospital, Bradford

The ulcerative form of Hodgkin's disease is so rare and so difficult to diagnose that the following case is worthy of record.

Case Report

A woman aged 44 was admitted to St. Luke's Hospital, Bradford, in July, 1948, complaining of a painful swelling on the anterior chest wall, over her sternum, of twelve months' duration. The swelling had gradually become larger, recently fluctuant, and had been aspirated two weeks before admission. She also complained of painful stiffness of the neck for about three years, and aching of both arms for twelve months. The spleen was not palpable and no glands were enlarged. The E.S.R. was 18 mm. in one hour; haemoglobin, 85%; W.B.C., 16,000 per cmm. (polymorphs 83%, lymphocytes 12%, monocytes 5%); platelets normal. The Wassermann reaction and Kahn test were negative on two occasions. X-ray examination showed erosion of the left sternoclavicular joint and adjacent sternum, with no new bone formation.

The fluctuant swelling was incised, pus and necrotic bone were curetted out, and the wound was closed. The wound healed by first intention. The pus obtained was sterile on culture and no organisms were found in the smear. A provisional diagnosis of a tuberculous lesion was made, and the patient was discharged home four weeks later, to await a bed at a sanatorium.

In March, 1949, she was readmitted from the sanatorium with the abscess from the sternum increasing in size and pointing in two places. Incision with curettage was performed, a large quantity of necrotic debris being evacuated. The appearance favoured the diagnosis of gumma, despite the negative Wassermann reaction and Kahn test. Examination of the pus again showed no tubercle bacilli or other organisms, and section of the curettings of the ulcer wall revealed necrotic tissue. A consultant venereologist diagnosed the ulcer as gummatous in nature despite the absence of other signs of syphilis. He gave a course of bismuth, penicillin, arsenicals, and iodides with no response. She was discharged home in April, and kept under out-patient surveillance.

In July she was readmitted as an emergency case following haemorrhage from the abscess, the cavity being packed to control it. Repeated examination of the pus showed no evidence of tubercle bacilli or actinomycosis. Guinea-pig inoculation was negative. No glands were palpable elsewhere in the body.

In August the swelling over the sternum had developed into a large ulcer, approximately 1 in. (2.5 cm.) in depth and 5 in. (12.5 cm.) in diameter, with an elevated edge and an uneven floor covered with necrotic granulations. A biopsy of the edge of the ulcer was taken, and the section report was as follows: "The histological picture is that of a chronic granulomatous lesion probably tuberculous in origin. The caseous material consists of degenerate cells with mucus and a few pus cells. No tubercle bacilli or other organism seen." The lesion was still thought to be tuberculous in nature.

Until June, 1951, progress was uneventful and the ulcer showed no change. She was then readmitted again for treatment of further haemorrhage from the ulcer. A recent swelling was found to be present below the right clavicle and a few discrete glands were palpable in the neck. This was the first appearance of glandular enlargement. No other glands were palpable and the spleen was not enlarged. A biopsy of one of the cervical glands was carried out, the pathological report on the gland being as follows: "Histological section shows marked fibrosis and complete loss of architecture. There is a proliferation of reticulum cells with several multinucleated cells and many eosinophils. The findings are in keeping with Hodgkin's disease."

In July an abscess was forming over the inner end of the right clavicle (see illustration). The patient was seen by Dr. Chester-Williams and transferred to the Radium Institute for a course of deep x-ray therapy.

In September the course had been completed and she showed a remarkable change; she had gained over 56 lb.

Showing the ulcer over the sternum, with an abscess forming over the right clavicle.

(25.4 kg.) in weight, but her pain was still troublesome. The ulcer had shrunk considerably in size, and in October this improvement had been maintained. X-ray examination of the cervical and dorsal spine showed no abnormality, but both clavicles showed absorption at their medial ends. The mediastinum was within normal limits, but the anterior ends of both first ribs were absorbed and showed no evidence of regeneration. Three months later the ulcer had practically healed.

In April, 1952, there was considerable local improvement, but she had severe pain over the fourth dorsal spine. Some supraclavicular infiltration was present, and her general condition was failing.

In October she had a painful swelling in both posterior triangles of her neck. The lower edge of the ulcer was extending, with a painful swelling over the lower end of the sternum. In November she had further subcutaneous swelling on the right chest wall and some loss of power in the right arm, with considerable induration in the supraclavicular regions.

In April, 1953, she attended for her eighth course of deep x-ray therapy. The ulcer had broken down again and was 1½ by 2½ in. (3.8 by 6.4 cm.) in size. There was a large soft swelling to the right of the ulcer and two smaller swellings on the left side and over the lower end of the sternum. Her general condition was deteriorating, and in the past year she had lost 35 lb. (15.9 kg.) in weight.

Discussion

The first observation of an ulcerative lesion in Hodgkin's disease was reported by Grosz (1906), and in the following 21 years only 26 cases had been recorded. Price (1946) states: "The skin is only rarely involved; and when it is, or when, with equal rarity, the nodes undergo caseation or suppuration, this is due to the secondary infection by pyogenic organisms or by tubercle."

The difficulty of diagnosis is emphasized by a perusal of various case reports (Alderson, 1917; Cole, 1917; Kierland and Montgomery, 1941). Goldman (1940), in an analysis of 212 cases of Hodgkin's disease, did not mention the presence of ulcerating lesions. Seneor and Caro (1937) comment that ulceration occurs in three different ways: (1) Ulceration of limited extent developing in a number of small nodules in the skin. (2) Extensive ulceration developing in the skin by extension from underlying involvement of lymph nodes, bones, and other tissues. The case recorded seems to be from this group. (3) Extensive ulceration developing in large infiltrations appearing in the skin without involvement of the underlying structures.

The ulcer may appear before obvious glandular involvement elsewhere, as in the case now recorded, and may cause considerable confusion in differential diagnosis. The differential diagnosis is between gumma, epithelioma, sarcoma, tuberculosis, and mycosis fungoides. The typical ulcerative lesion of Hodgkin's disease has sharply defined rounded borders, but may be irregular, serpiginous, or linear. The edge is elevated and the margins are undermined or sharply punched out to resemble a gumma. Usually, as in this case, the ulcer is deep, with an uneven floor, covered with abundant purulent necrotic material or granulation tissue which bleeds freely when touched. Pain is variable, but in this case was severe. Affection of the neck, thorax, and axillary regions is most common, but the condition can be widespread.

The diagnosis is usually made by biopsy, but the case described illustrates that this is not infallible, and is dependent on demonstration of the characteristic Dorothy Reed or Sternberg cell.

Radiotherapy, as in this case, makes the ulcer melt away (Moriame, 1949), but recurrence is usual.

Summary

A case of the rare ulcerative type of Hodgkin's disease is described, illustrating the extreme difficulty experienced in diagnosing this atypical form of the disease.

My thanks are due to Mr. A. Naylor for his encouragement and advice, and to Dr. F. E. Chester-Williams for permission to record this case.

Medical Memorandum

Renal Complications after Using Sulpenin

Combinations of penicillin and sulphonamides have been in clinical use for more than a year. No serious toxic effects have been reported, and the manufacturers know of only a few mild reactions occurring in a small number of instances. The following case report seems to be the first example of a serious toxic effect following the use of "sulpenin."

CASE REPORT

A married woman aged 73 was admitted to hospital on March 7, 1953, with the following history. In the previous ten days she had had "influenza," and mild bronchopneumonia, for which her doctor had prescribed sulpenin, the total amount given before admission being 28 tablets (14 g. sulphonamide). Twenty-four hours before admission she had suddenly developed epigastric pain, which had increased in intensity. It "spread through to the back," but did not radiate to the shoulders. The character of the pain was described as severe, with exacerbations. She had never had anything like this previously. Several times in the previous 24 hours she had vomited a small amount of mucoid fluid. Throughout this period she noticed a diminution in the quantity of urine passed, and what was voided was bloody (she admitted that she had not been drinking very much for the past two days). She had been constipated for five days. In 1916 laparotomy and appendectomy had been performed, and in 1917 gastric ulcer had been diagnosed radiologically.

On examination she had the appearance of an ill, moderately dehydrated old lady. The tongue was dry and brown. The neck and chest, cardiovascular system, and central nervous system were all normal. Her blood pressure was 160/90 mm. Hg, pulse rate 80, temperature 99° F. (37.2° C.), and respirations 22. In the abdomen there was an upper right paramedian healed scar. Muscular movements were diminished, tenderness was acute in the epigastric area, but not in either loin, bowel sounds were diminished, no mass or abnormal viscus was palpated, and no fluid was detected. Rectal examination was normal. A straight x-ray film of the abdomen did not show air under the diaphragm or any intestinal abnormality. A diagnosis of anuria due to sulphonamide intoxication was made.

On March 8 the cystoscopy findings were: residual urine in the bladder 3½ oz. (100 ml.); some trigonitis; right ureteric orifice oedematous and blocked with bloody material, no efflux being present; left ureteric orifice oedematous without efflux. Attempted catheterization of the right ureter failed. There was a block 1.5 cm. from the vesical opening. A left ureteric catheter passed easily and was left *in situ*.

An indwelling gastric tube was left *in situ* for 24 hours, but yielded practically no material on aspiration. She was given oral fluids, 1 oz. (28 ml.) hourly for 12 hours, after which time the amount was doubled each 12 hours; 500 ml. of M/6 sodium lactate was administered intravenously. After the cystoscopy no urine was passed for 17 hours, at which time spontaneous diuresis took place. (The left ureteric catheter was left *in situ* for 72 hours, but no urine drained through it.) In the next 24 hours she passed 35 oz. (1 litre) of urine. She was discharged on March 13.

Investigations. March 7: microscopy of urine removed from bladder on cystoscopy revealed it to be acid in reaction, with a microscopic haematuria. No sulphonamide crystals were seen. March 9: urine turbid, red-brown, pH 6.2; deposit abundant red blood cells, with no excess of leucocytes and no crystals seen; alkaline reserve, 40.4 vols. CO₂%. March 11: urine deep red, pH 5.6; still large numbers of red blood cells. On March 13 the report was similar. Intravenous pyelography showed good function on both sides, with normal renal outlines. The concentration of dye excreted was better on the left than on the right.

COMMENT

The simultaneous administration of two antibacterial agents is now an accepted principle of therapeutics. The drugs employed are many, proceeding from mixtures of synthetic agents, such as sulphonamides, to mixtures of sulphonamides with various antibiotics. Sulpenin is one of these; each tablet contains penicillin, 100,000 units, sulphadiazine, 0.25 g., and sulphamerazine, 0.25 g. The dose administered for infection of average severity is two tablets every four hours.

Garrod (1953) outlined the principles and the problems of this kind of therapy. He gives the following indications for its use: prevention of acquired resistance, achievement of synergism, prevention of toxic effects, mixed and double infections, and, rarely, the urgent undiagnosed case. The main difficulty is to avoid the production of resistant strains of infecting organism, but penicillin sulphonamide mixtures tend to do this much less often than do other combinations.

This case emphasizes the fact that combinations of antibacterial agents do not abolish the capacity of the individual drugs to produce their specific toxic actions on the host. It seems likely that sulphadiazine was probably the responsible fraction, as its solubility in urine of pH 6.5 is less than half that of a comparable dose of sulphamerazine at that pH. Recent work has cast some doubt on the routine use of sulphonamide mixtures alone. Weinstein and Murphy (1952) state "that combinations of sulphonamides may have little clinical usefulness in many instances, since they are often not as effective as the single agents which compose them." This raises the question of what sulphonamide is best combined with penicillin. Of the sulphonamide preparations now available, sulphasomidine (6-*p*-aminobenzene sulphonamido)-2:4-dimethylpyrimidine), the isomer of sulphadimidine, would seem to be worth combining with penicillin. It has a greater solubility in acid urine than any other sulphonamide, the degree of acetylation is only 10-15%, the blood level remains consistently high, and side effects are slight.

The clinical picture was not entirely typical in that no signs or symptoms referable to the loins were obtainable: a superficial examination suggested the presence of an intra-abdominal condition. A careful history provided the answer.

In the treatment carried out along standard lines it is significant to note that return of renal function occurred first on the non-catheterized side. Although the condition was what is often classified as an obstructive type of anuria, spontaneous diuresis occurred within 24 hours. The left ureteric catheter, *in situ* for 72 hours, did not drain urine in that period. It is possible that traumatic oedema of the ureteric mucosa, already partly damaged by a saturated solution of sulphonamide, was the cause of this depression of function. This experience would tend to support the view of those who recommend, after an initial cystoscopy, the application of the principles of the Bull regime to cases of sulphonamide anuria.

This case was under the care of Mr. Cameron MacLeod, to whom I am indebted for permission to publish.

Reviews

SURGERY IN WARTIME

Surgery: History of the Second World War. Edited by Sir Zachary Cope, B.A., M.D., M.S., F.R.C.S. United Kingdom Medical Series, compiled under the direction of an Inter-Services Editorial Board. Editor-in-Chief: Sir Arthur S. MacNalty, K.C.B., M.D., F.R.C.P., F.R.C.S. who has written the Foreword for this volume. (Pp. 772; illustrated. 80s.) London: Her Majesty's Stationery Office. 1953.

This volume must surely be one of the greatest records of all time of the art of healing. It is far more than a mere record of surgical skill. It is the story of how a whole nation came to the help of those who had risked their lives in its service, of medical skill without parallel, devoted to those whose courage has never been surpassed. A fortunate combination of circumstances, rapid transport, blood transfusion, penicillin, gave the surgeon opportunities he never before possessed, but without the willing co-operation of the whole nation the amazing results he obtained could never have been achieved.

The volume opens with an admirable review by Ogilvie of the novel problems of the war and of the novel means by which they were overcome, and this is followed by a chapter on the general treatment of war wounds, dealing especially with the difficult conditions imposed. Lionel Whitby contributes a chapter on blood transfusion, in which he rightly claims that in no previous war has there ever been such a system, where blood was collected from thousands of healthy donors, kept in store, processed, and dispatched all over the world wherever it might be needed. And never before has there been produced such a balance sheet as he here presents of the origin, destination, and achievement of pints of blood from more than 750,000 donors. Largely to those donors did our wounded owe the 80 to 90% chance of life which they enjoyed.

In a great book the greatest chapter of all is that on abdominal injuries. It could have been written only by Gordon-Taylor. The width of outlook, the grasp of detail, the clarity with which he paints a most complex scene, demanded a depth of experience and a breadth of travel, and perhaps a classical background, which no one else possesses. He traces the story from the early days when morphine was the only resource to the splendid achievement of later years, when among over 5,000 abdominal casualties in the B.L.A., from June, 1944, to the armistice, recovery was obtained in 70%. It was not the achievement of any individual or of any one group, but of team work to which there is no parallel, covering transport, surgical technique, anaesthesia, chemotherapy, nursing, evacuation, and rehabilitation. From the purely surgical standpoint the chapter is packed with information of vital importance to all who have to deal with abdominal injuries of any kind, many indeed of the cases arising in air raids in this country.

The chapter on the treatment of burns by Zachary Cope and Morley is of high value and may well be accepted as expressing standard practice for years to come. It is very naturally followed by a discussion by Harold Gillies and his colleagues on plastic surgery and the organization of plastic units. The article by Kelsey Fry on maxillo-facial injuries gives a wonderful demonstration of what can be done in conditions which not long ago would have been regarded with utter despair.

We have been able to touch upon only a few of the highlights in a book whose every page is full of interest. It deserves the close study of every surgeon in the country, and perhaps especially of those of the younger generation, that they may realize how difficulties which appear insuperable may be overcome by determination and co-operation. And in the last chapter of all, where Julian Taylor tells of how he and his colleagues carried on their work in the Japanese prison camp of Singapore, they may learn something of the great ideals which have inspired our profession since the days of Hippocrates.

HENRY SOUTTAR.

CHEMICAL PATHOLOGY

Clinical Chemical Pathology. By Professor C. H. Gray, D.Sc., M.D., M.R.C.P., M.R.C.S., F.R.I.C. (Pp. 138, 10s. 6d.) London: Edward Arnold and Co. 1953.

This is the best book I have met on chemical pathology for students. It is neither a mere collection of diagnostic tips and laboratory techniques nor a treatise in which a student cannot see the wood for the trees. The range covered is rather limited—renal function, acid-base balance, fluid balance (two chapters), liver function, blood sugar, calcification, digestion and absorption of fat, the chemical pathology of the alimentary tract, endocrine disease, and miscellanea.

The first four chapters are particularly good. The chapter on blood sugar is the least satisfactory; Professor Gray may be prudent in avoiding discussion of the fundamental nature of diabetes, but surely it is not wise to recommend Soskin and Levene for further reading without some antidote. The laboratory techniques given are not more than are needed by students who do not propose to take up laboratory work. A table of normal values of blood constituents is given.

J. R. MARRACK.

CLINICAL ALLERGY

Clinical Allergy. By French K. Hansel, M.D., M.S. (Pp. 1,005; 86 illustrations and 3 colour plates. £6 10s.) London: Henry Kimpton. 1953.

This massive volume is presented as a complete text on the subject of general allergy and has been expanded from the author's previous work on allergy of the nose and paranasal sinuses published in 1936. Some eleven chapters are largely devoted to this subject, three to hay-fever, two to bronchial asthma, and five to allergy in children. The chapter on antihistamines is rather disappointing, and of its 16 pages almost half are occupied with the effect of antihistamines on the common cold. The chapter on A.C.T.H. and cortisone gives an adequate review of the subject.

No obvious omissions were found, and the text fulfils its aim of completeness. Unfortunately, a number of methods of treatment are stressed and recommended to which few, if any, allergists in Britain would subscribe and which are not considered normal practice in other countries. Thus, the author recommends small desensitizing doses rather than the usual progressive dosage found best in hay-fever in most hands. Perhaps that is why he finds (p. 516) that "treatment has not modified . . . the skin reactions." In Britain we expect the skin reactions to be greatly diminished or to disappear after adequate specific high-dosage therapy. The author also recommends sublingual antigen therapy and lauds the non-specific use of staphylococcus toxoid in urticaria, angioneurotic oedema, and eczema. In the presence of these unorthodox recommendations, the book may be considered an excellent reference volume for the expert rather than a text for the beginner in allergy. The general format and printing are superb and no typographical errors were observed. The bibliography and index are satisfactory features of the book.

C. J. C. BRITTON.

ELEMENTARY HISTOLOGY

Elementary Pathological Histology. By W. G. Barnard, F.R.C.P. 3rd edition. (Pp. 77. 185 illustrations, including 8 in colour. 17s. 6d.) London: H. K. Lewis and Co. Ltd. 1953.

This is the third edition of Professor Barnard's book, which was designed to help students during their first course in elementary pathological histology by providing them with a strictly limited number of large photomicrographs of good quality illustrating the processes of inflammation, degeneration, and tumour formation. This subject is taught just before or early in the student's clinical training, when he needs assistance in forming a clear and permanent visual memory of a few basic pathological lesions, which he should

then be encouraged to look for as he becomes more experienced. By this means he trains himself to deduce from a complex histological picture the fundamental process responsible for it. During this period it is remarkably easy to produce irreparable confusion in the student's mind by a surfeit of illustrations. Professor Barnard's careful selection and rigid censorship have skilfully avoided this pitfall: each of his 185 illustrations justifies its inclusion, and we can safely recommend this book to students about to embark on a subject which rather too often becomes more difficult for them than it should be.

This edition is enlivened by the inclusion of some illustrations in colour. The textual alterations are few, and the short pithy descriptions are eminently suitable for what is, after all, no more than a good laboratory companion, to be used while sections are being examined under the microscope.

GEOFFREY HADFIELD.

MANUAL OF OBSTETRICS

Eden and Holland's Manual of Obstetrics. By Alan Brews, M.D., M.S., M.R.C.P., F.R.C.S., F.R.C.O.G. 10th edition. (Pp. 812; 57 plates, 12 in colour, and 378 illustrations. 52s. 6d.) London: J. and A. Churchill, 1953.

Should an undergraduate textbook provide for the bright student at the top of the class or the dullard at the bottom? Should it give only the bare essentials of a subject—enough merely to provide the average reader with a reasonable expectation of a pass in the qualifying examination, or should it aim at satisfying as well as whetting the appetite of the most intelligent and diligent of students, stimulating them to further endeavour and opening up for them new fields of thought? A wide outlook on education surely demands the latter approach. It brings material as well as spiritual benefit in that the resulting book caters not only for the surmounting of the immediate hurdle of "finals," but remains a companion and a source of reference for the years to come.

Eden and Holland's Manual of Obstetrics has always taken the large view, and in consequence has long been recognized as one of the finest textbooks on obstetrics published in this or in any other country. It is renowned not only for its subject-matter but for its style and prose, and this again can have nothing but a favourable impact on the student with a receptive mind. The confidence of the author in the reader is shown not only by the text but by the suggestions for further reading which appear at the end of each chapter.

This edition, like its immediate predecessor, is written by Mr. Alan Brews and has entailed a good deal of modification. Clear photographs and radiographs now take the place of several of the diagrams of earlier editions. Despite thorough revision the author has succeeded in retaining the original style and flavour, and this is no mean achievement.

The undergraduate looking for a sound, attractive, and complete textbook rather than a cram précis could not find a better, and after he has qualified it will be a standby in his practice and in his pursuit of higher diplomas in obstetrics.

T. N. A. JEFFCOATE.

DIABETIC NEUROPATHIES

The Diabetic Neuropathies. By Joseph I. Goodman, M.D., S. Baumof, M.D., L. Frankel, M.D., L. J. Marcus, M.D., and S. Wassermann, M.D. (Pp. 138. £1 15s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications, 1953.

This is a very good book, and, although there are bits and pieces on the subject in many large books on diabetes, it is the only book I know whose authors have put the whole subject together in a competent way. The reading behind the book has been wide and the bibliography ranges through a hundred years since the relations between diabetes and its neuropathic complications were first mentioned.

The authors emphasize the early peripheral nature of this type of complication and give a clear account of how it can creep upwards, if untreated, to the more central nervous system, with protean manifestations such as impotence, apart from malnutrition; the tabetic-like bladder; chronic relapsing diarrhoea; neuritis of the nerves in the eye, with resulting diplopia, and even retrobulbar neuritis. Mention of the rare involvement of almost any one or two peripheral nerves round the chest and the abdomen or even the phrenic seems to be omitted.

The early attack—perhaps the first manifestation of this neuropathy—on the autonomic nervous system has been pointed out. It would appear that the non-medullated nerve fibres suffer first, and their unprotected axis cylinders are the earliest to suffer degeneration. This has been shown by biopsy material by Martin since this book was written. It is tragic to realize, in the rapid progression of medical discovery, that not even this nor any book is quite up to date. However, it is really excellent and should be read by all neurologists and, shall I say, diabetologists.

R. D. LAWRENCE.

CLINICAL CARDIOLOGY

Clinical Cardiology. Edited by Franklin C. Massey, A.B., M.D. (Pp. 1,100; 250 illustrations. £5 2s. 6d.) London: Baillière, Tindall and Cox, 1953.

The reader of this book cannot help wondering whether the subject of cardiology has really become so large and diffuse that it requires the minds of 33 collaborators to produce a book upon it. It is almost inevitable that there will be repetition and overlapping. This will then lead to a disintegration of the subject, and consequently its complication instead of simplification. It is indeed a pity that the razor of William of Occam had not been used here, and the multiplication of authors and opinions beyond necessity avoided. There has, however, been a sound attempt at a fairly uniform use of technical terms, so "atrial" fibrillation and flutter it is throughout. Each chapter starts with a sort of "Who's Who," so that age, birthplace, and various particulars about its author are set out. The description of the anatomy of the heart in the first chapter is well done; in the chapter on physiology "circus movement" is accepted without comment, but not so in the chapter on arrhythmias. Here, unfortunately, the discussion of diagnosis and treatment and much other information on this subject lack orderly presentation, and the reader is left in some confusion, though the line illustrations are clear and economical. The chapter on physical diagnosis is unsatisfactory. The description of signs is weak and in places hardly accurate.

There is a chapter on the radiology of the heart. This subject should surely be joined with the various matters it helps to elucidate. The sketches are poor, artistically and practically. The surgery of the heart similarly stands alone as a chapter, instead of being discussed where this method of treatment is appropriate. The key to the study of congenital lesions is so short that it is doubtful if it opens any door of knowledge. In the description of angina pectoris on page 622 there is a piece of Latin which would have made Heberden shudder. But this is really a good chapter; unfortunately it lacks the all-important cardiograms, and for them one must turn to the chapter on electrocardiography. The chapter on arteriosclerosis needs a clear basis of pathological classification, but there is much interesting material on atheroma and some good photomicrographs. Most of the chapters give a fairly full list of references from the American literature. The paper and print are excellent, and most of the illustrations are good. The index is full. There is a vast amount of information in this book, but it suffers from having too many authors, and consequently is rather dull to read, for it lacks the individual touch and any sort of soul or personality.

TERENCE EAST.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 16 1954

THE PRESS AND THE PROFESSION

Professor Ian Aird's letter to this week's *Journal* (p. 153) draws attention to a matter of much concern both to the medical profession and to journalists—the publication in the lay press of intimate details of medical or surgical treatment which traditionally should be the concern of two parties only—the patient and his relatives and those who look after the patient. This traditional reticence, which is primarily in the interests of the patient, has never been strictly observed. For example, the illness of a public figure is rightly held to be a matter of public concern, and his medical attendants will often issue bulletins giving details of the illness and of the treatment administered. In the case of a crowned head this has indeed come to be looked on as a public duty. The editor of a newspaper may, too, consider that his obligations to his readers extend beyond this and through his special correspondents pursue inquiries of his own. *The Times*, for instance, some sixty years ago entered pertinaciously into the controversy over the illness of the Crown Prince Frederick.¹ The other kind of occasion of relaxed reticence is when some spectacular or unusual operation is performed: here it is the procedure rather than the person that is the focus of attention, and, inevitably, the surgeon who carries it out. Professor Aird's letter shows how the natural desire of a journalist to acquire news for his paper—in fact it is his duty as a journalist to do so—may embarrass the surgeon, needlessly alarm the patient's relatives, and have a harmful effect on other patients awaiting a serious operation.

An operation on Siamese twins is news. Modern medicine in the present exciting phase of its development is news. The public wants to know about these things, and any editor or journalist will therefore do what he can to give the public what it wants. How this news is gathered and presented depends upon a number of factors: the standard a paper sets itself; the competence and integrity of the paper's medical or science correspondent; the degree of intelligence and knowledge of science a newspaper's readers may be judged to have; and the extent to which the medi-

¹ See Morell Mackenzie, by R. Scott Stevenson, London, 1946.

cal profession may feel it can go in supplying the press with information. It is this last that concerns us most.

There is need for a clearer understanding by the medical profession and the press of each other's problems. Doctors have an intense dislike of publicity, quite unrelated to the fact that publicity may draw upon them the unwelcome attentions of the General Medical Council. In these days the surgeon who operates on a patient is a member of a team, and the operation he performs is more often than not the outcome of the work of others besides himself. His scientific conscience and sense of justice are therefore affronted when he sees himself singled out in the press as the hero of the occasion, and he may fear, not unnaturally, that his colleagues may suspect him of seeking such publicity, and that this will harm what is to him of supreme importance—his professional reputation—and lower him in the esteem of his colleagues; and nothing will horrify him more than to see his photograph staring at him from the front page of the *Daily X* when he opens it at his breakfast table. The journalist, however, knows that his public is interested above all in personalities; and that the only anonymity they will tolerate in a newspaper is the anonymity of the editor and, perhaps, his special correspondents. A matter of life or death, as an operation so often is, is something of intense human interest; when the operation itself is a dramatic one the interest is intensified and the public has a natural desire to know something about the person of the operator, and will tend to brush aside the conventions of the medical profession as of little account. When archbishops, bishops, deans, judges, barristers, field-m Marshals, authors, and artists submit to the publicity of the press with little demur, why, says the public, should doctors kick against the pricks? The short answer is that no other professional man has such an intimate relationship with his fellow human beings, or has to bring to bear upon them skills that may shift the balance between life and death, apart from the rarely operated skills of barrister and judge in cases of alleged murder.

In his letter Professor Aird suggests that the profession should face the fact that the press will not be content to wait for the presentation of medical facts in the medical journals before it breaks any particular news to its public, and that, this being so, such news might be given to the press through an intermediary such as a public relations officer. He hopes that in this way anonymity might be preserved and accuracy ensured. Helpful though the work of public relations officers is in meeting press inquiries, it may be doubted whether this is a solution to the problem. The press seems to be relying more than it used to do on scientific and medical

periodicals as a basis for the scientific and medical information the papers dish up for their readers; and, if we may judge from our own experience, reporters seek and welcome a closer co-operation with the editorial staffs of such periodicals in trying to ensure the accuracy of the accounts they write for their papers. Such co-operation might well be extended, and, busy though practising doctors are, they should, we suggest, do what they can to help the practising journalist when he makes a bona-fide request for information. A good journalist will always respect his informant's desire for anonymity and keep his word that any background information should be regarded as confidential. A better relationship between doctors and the press should go a long way to prevent a repetition of the harassing experiences which have provoked Professor Aird's letter, intensified as they were by the shocking behaviour of certain press photographers against whose thug-like intrusions the hospital authorities had to act by blacking out the lower halves of the windows of the wards where the Siamese twins were lodged. If any surgeon is faced with Professor Aird's dilemma in the future he would be well advised at the outset to seek the help of the public relations officer of the B.M.A. and thus make use of the facilities available in his own professional organization.

An operation on Siamese twins is as rare as the twins themselves, and such an intensive news-hunt is unlikely to be common. But our journalist colleagues of the lay press will surely remember on any such future occasion that the strain on those carrying out difficult medical or surgical procedures is heavy, and that any intrusion on them in the course of their work or in their homes can do nothing but harm. Possibly the many responsible science writers attached to newspapers would consider among themselves how best to deal with this matter of gathering and presenting medical news to their readers, if only for the reason that what they say and how they say it has a profound effect upon men and women who may at any time be in need of medical care. The medical profession has no wish to regard its art and science as an esoteric mystery, and recognizes that with a public more widely educated in science this cannot be the case. It fears, however, the ill effects of premature publicity and the dangers of the unwittingly distorting head-line. Professor Aird's letter will have served a useful purpose if it makes profession and press more conscious of each other's difficulties and makes mutual and responsible co-operation easier in the future. The doctor's first and last concern in all this is to protect the interests of his patients and their relatives.

GENERAL PRACTICE ANALYSED

In the opening pages of this issue we publish a paper by Drs. E. M. Backett, J. C. G. Evans, and Mr. J. A. Heady which reports selected results from a year's statistical study of what they call "some of the more quantitative aspects of the doctor's job." The authors of this study, which is an experimental part of a larger study of the methods which might be used to investigate general practice, examined one closely knit working-class urban practice of some 3,000 patients in charge of one principal assisted by a trainee and, occasionally, by another practitioner. Private practice is not mentioned, and presumably was non-existent. The principal and his assistants bore the main burden of record keeping—a simple basic form completed after every consultation and every six weeks members of the research team attended all consultations for one week and recorded in greater detail what went on. A consultation, the basic unit of work studied, was taken to mean any meeting between doctor and patient in which advice was given, and included telephone inquiries, visits to patients in hospital, "and the like." It is estimated that 99% of consultations were recorded.

Fry¹ and Logan² directed their studies to ascertaining the amount and kind of ill-health in particular practice communities, and Fry also reported figures illustrating the amount of work done by the doctor. In the present study the authors report only on the amount of work done and relate it to the nature of the practice population grouped by sex and age and by type of illness classified as serious or not serious, acute infective or acute non-infective, or chronic. The patients' occupations were not taken into account.

The following are some of the facts which emerge. During the year 15,788 consultations took place, which represent 72% of the practice population, or five for every registered person or seven for every person who consulted. On examination it is found that of those aged over 64 (10% of the practice) 25% of males and 32% of females consulted the doctor on 10 or more occasions. Thirty-six per cent. of the total consultations were in the patient's home, and, of this 36%, 50% were for children and the elderly. Only 12% of children aged 0-4 did not see the doctor at least once. In all age groups the percentage of males who had no contact with the doctor is greater than that of females. Half of all the work was on one-sixth of the patients (some 500), who saw the doctor 10 or more times, and 18% of the work concerned 4% (125), who consulted 20 times or more.

¹ *British Medical Journal*, 1952, 2, 249.
² *General Practitioners' Records*. General Register Office: Studies on Medical and Population Subjects, No. 7, 1953, H.M.S.O., London.

Twenty per cent. of diagnoses were of chronic disease and entailed 30% of the work. Acute infective disease accounted for 50% of diagnoses and 50% of the work, and the 10% of serious diagnoses accounted for 43% of the work. One certificate was given for every 4.5 consultations, and half of these were for National Health Insurance purposes. Reference to hospital or other agency occurred at the rate of 35 for every 100 registered persons. During 10,889 out of 15,788 consultations, one or more prescriptions were issued, and this equals at least five for every patient who consulted.

It is worth emphasizing that these facts relate to one community of people and one doctor and his assistant. They cannot be taken to be representative of general practice as a whole or even of practices of a similar kind, nor do the authors claim that they should. With this proviso in mind it may be remarked that the facts coincide in many respects with those of other observers and will confirm what has been up to now generally accepted on the evidence of experience. For instance, that old people and chronic illness should loom large in a G.P.'s work is to be expected, but perhaps the proportion of work with young children and females of all ages has not been so well realized. It is interesting that of the hard core of sick people in the practice over half were under 45 years of age and more than a quarter were children and therefore a fruitful subject for the practice of rewarding medicine. Likewise the fact that 43% of the general practitioner's work is associated with illness diagnosed as serious supports the same encouraging contention, and, as the authors say, tends to refute statements such as "the general practitioner is a specialist in the trivial."

Our correspondence columns have often borne witness to conflicting opinions on what are the aims of general practice and what are the principal needs that patients look to their family doctors to satisfy. The inquiries being carried out under the Medical Research Council and elsewhere will help to answer these questions, made the more urgent by the rapidity of technical advance in this mid-twentieth century, when the ascertainment, prevention, and treatment of disease in general practice are fast changing.

MYELOMATOSIS

Multiple myeloma is a condition which is all too often diagnosed incorrectly. A case with conspicuous bone lesions may be regarded as an example of secondary carcinoma from a latent and undiscoverable primary tumour, while sometimes the presence of bone lesions is not suspected during the life of the patient. For

reasons of this sort it is not easy to be sure of the frequency of occurrence of what is regarded by some as a very rare condition. The paper by Mr. A. Naylor and Dr. F. E. Chester-Williams which appears at page 120 of this issue of the *Journal* is therefore of interest in that it describes a series of twenty-five cases, twenty-four of which occurred in one hospital group during a period of five years.

Not only is their paper a reminder of the frequency of this condition, but the series of cases they describe emphasizes the diversity of clinical presentation associated with it. Seventeen of the twenty-five cases showed the conventional "generalized" picture with multiple bone involvement by discrete osteolytic lesions. Naylor and Chester-Williams regard this as the terminal stage of myelomatosis, and in an endeavour to institute early therapy, and to avoid confusion with other conditions, they draw attention to two other types of case which are perhaps not so generally known. In their series the first of these is a group of four cases in which a solitary lesion was initially found, and the second—also of four cases—was characterized by diffuse bone involvement without focal radiological lesions.

As to the way in which patients with multiple myeloma present clinically, it is of interest to note that in this series six of the patients with the generalized form of the disease sought medical attention because of general symptoms—particularly those related to the anaemia produced by replacement of bone marrow by myeloma tissue—and showed no clinical evidence of skeletal involvement.

Occasional examples of solitary myeloma (sometimes called solitary plasmacytoma of bone) have been reported, and have been reviewed recently by Raven and Willis¹ and by Lumb.² This type of case is rare, and in Naylor and Chester-Williams's series generalization soon occurred in each of the cases in which an initial solitary lesion had been found.

Of recent years interest has been aroused by chemical studies on the abnormal proteins present in the urine of many patients with multiple myeloma (originally noted by Bence-Jones in 1848,³ and known by his name), and in the related abnormal plasma protein constituents which are also present: studies of these proteins have been reviewed by Rundles *et al.*⁴ It has been shown by Martin⁵ and by Miller *et al.*⁶ by means of electrophoresis and ultracentrifugation that the myeloma tissue itself contains the same abnormal globulin as is present in the blood, which finding suggests that the plasma-celled tumour tissue is concerned in the synthesis of these protein molecules. This is of considerable importance in view of the increasing emphasis given by such workers as Fagraeus⁷ and Bjorneboe *et al.*⁸ to the role of plasma cells in the production of the rather similar globulin molecules of antibodies.

A NEW ORAL DIURETIC

Efficient diuretic treatment is almost as important as digitalis therapy in the management of congestive heart failure, and is of major importance in the treatment of many other oedematous states. No other diuretics compare in efficacy with the organic mercurials, and in view of their many clinical applications it is rather surprising that they are not used more often in general practice.¹ Doubtless the necessity of administering mersalyl parenterally militates against its more common use. For maintenance treatment many patients require two or three intramuscular injections a week, and, as these may have to be continued over some years, the treatment is apt to be abandoned in the course of time. These inconveniences would be obviated by the discovery of orally administered diuretics which are really effective. Recent clinical trials in America²⁻⁴ have been carried out with 3-chloro-mercuri-2-methoxy propyl-urea. Named in the U.S.A. "neohydrin," and now made available in Britain with the name "mercioran," it is an extremely effective diuretic whose potency when given orally is about one-fourth of its potency when given by intramuscular injection. No other mercurial diuretic approaches such a favourable ratio of oral to intramuscular potency. Experience suggests that a daily individual dose is more effective than the same amount given in divided doses throughout the day. As with mersalyl, the dose should be given immediately after breakfast, and its effect is potentiated by the previous administration of ammonium chloride and a low sodium intake.

Besides the two problems presented by an injected diuretic—systemic toxicity and diuretic potency—an orally administered agent presents a third problem of local gastro-intestinal irritation, and unfortunately this is very commonly produced. Clearly if the oral dose is small enough the incidence of such side-effects vanishes, but so does the diuretic action, and it appears impossible to obtain with mercioran the diuretic effect commonly produced by, say, 2 ml. of intramuscular mersalyl, without inducing a prohibitive number of unpleasant gastro-intestinal symptoms. Few patients indeed seem to be able to tolerate a dose which will give a diuretic response of more than would be expected from about 0.5 ml. of intramuscular mersalyl. Nevertheless, even if abdominal cramps, nausea, vomiting, diarrhoea, and bloody stools develop in about two-thirds of patients after effective doses of mercioran, there is the remaining one-third of patients who will tolerate it well. These can be discovered only by trial and error, but for them the inconvenience of long courses of injections can often be eliminated; in others, more sensitive to the drug, it may be possible by the use of appropriate smaller doses to prolong the interval between injections. While, therefore, the use of this preparation may be limited, it is likely to prove a useful addition to the list of new drugs.

INHALED FOREIGN BODIES

When a foreign body is aspirated into and retained in a bronchus many pathological changes may arise. Most foreign bodies irritate the bronchial mucosa, causing chronic inflammation which gives rise to a persistent cough. If the bronchus is completely occluded by the foreign body, the corresponding pulmonary segment collapses; distal infection in the collapsed segment often proceeds to bronchiectasis or lung abscess. Even when bronchial obstruction is not complete, the lung segment is liable to recurrent pneumonia, which may be complicated by pleurisy or empyema. Finally, it is possible for a foreign body to cause valvular obstruction to the bronchial lumen, so that air cannot escape during expiration and obstructive emphysema is produced. Thus the clinical features resulting from the accidental inhalation of material into the bronchus are extremely variable, and in the absence of a clear history of such an accident the underlying cause of the trouble is easily overlooked.

The hazards of inhaling foreign bodies are greater in young children, in whom the choking and gagging due to "something going the wrong way" are of commonplace occurrence. On page 125 of this issue of the *Journal* Dr. Bernard Laurance describes the cases of three children who developed serious pulmonary disease after inhaling foreign bodies. In one child, who had recurrent lung abscesses, pleural effusion, recurrent pulmonary collapse, and repeated haemoptyses, the true cause of the disease was discovered only after lobectomy showed an ear of barley within an abscess cavity in the removed lobe. Several thorough bronchoscopic examinations had failed to disclose the offending ear, although its presence had been suspected. In the other two children re-expansion of a collapsed lobe followed the successful removal of vegetable bodies by bronchoscopy, but in one case there was residual bronchiectasis. Dr. Laurance emphasizes that both lung abscess and haemoptysis are rare manifestations of bronchial foreign bodies in children. His cases also serve as a useful reminder that there is often a long latent interval between the inhalation of foreign bodies and the onset of respiratory symptoms. Indeed, it is not unknown for large bony fragments to be removed from the bronchus of patients who vehemently deny any possibility of their having been inhaled.

The diagnosis of foreign bodies in the bronchus is not always easy, but the possibility should be constantly remembered. When a history of inhalation of foreign material or choking over food is given by a parent or patient, full examination should never be neglected. Radiographs in the postero-anterior and lateral positions may assist diagnosis by showing segmental collapse, consolidation, or emphysema, but if any doubt remains bronchoscopy should be done. Even in the absence of a history of inhaling a foreign body, bronchoscopy should be done in patients with lung abscess, persistent pulmonary collapse, or prolonged or recurrent pneumonia. Such patients are often found to have underlying bronchial obstruction, and if a foreign body is found to be the cause its

removal at bronchoscopy is usually all that is required to bring about full clinical recovery.

CURRENT RESEARCH ON INFLUENZA

By the end of the last war laboratory methods for the study of influenza had been so simplified that it seemed opportune to study the disease on an international scale. The primary task of co-ordination and of promoting the exchange of scientific information was undertaken by the World Health Organization, whose latest monograph¹ gives an account of research on influenza. A principal task has been the detailed examination of virus strains from all over the world. Two main serological types of virus, A and B, have been recognized since 1940 (a third type C has been described, but its relation to epidemic disease is not yet clear). Virus A has consistently been found in association with major epidemics. A closer examination of A strains shows a definite change in antigenic character, whereas B strains are more homogeneous and less concerned with epidemic disease.² The original strain of 1933 (WS) was largely replaced about 1935 by a new type, PR8, which in turn gave way in 1947 to the current A-prime strains. There is every indication that this is a progressive change, though some doubt exists about its cause. As to further changes, time will show.

It seems clear from the behaviour of influenza in recent years that influenza-A epidemics may not only spread from country to country but may have multiple points of origin. Andrewes³ considers this to be in favour of the concept of a "hidden" or "basic" virus in the inter-epidemic period which reappears when conditions are favourable. A virus which is capable of such antigenic change will clearly be at an advantage in securing a foothold if it differs from its predecessor. In addition the influenza-A viruses appear to have developed a more flexible method of coping with the immediate problem of survival in a partially immune population. Strains have been recovered which show a marked variation in susceptibility to antibody. Isaacs considers that this biphasic change (P-Q variation) may be a more common form of variation than the appearance of a new strain.²

In the laboratory it has been found possible to create new virus types. Australian workers⁴ have shown that following infection of the chick embryo with two distinct influenza strains the resulting viruses may under appropriate conditions show a switch-over of inherent properties. Fascinating as this subject of virus recombination is, its precise relation to human disease is by no means clear. The emergence of new strains in 1947 is also reflected, not unnaturally, in antibody changes in the population⁵ and in the constitution of virus vaccines.⁶ Francis⁶ has shown that by incorporating A-prime strains into vaccines significant protection can be obtained even when the current strain is not identical

with that incorporated in the vaccine. Recent experimental work on combining adjuvants with virus vaccines has given encouraging results. Preliminary tests in man point to a much higher antibody titre with adjuvant vaccine than with aqueous vaccine.

Influenza can be a lethal disease with considerable variation in severity from one epidemic to another. In the 1918 pandemic an undue proportion of young adults were killed. In the Liverpool epidemic of 1951 most of the deaths occurred in old people. Mulder and Stuart-Harris discuss⁷ the differential diagnosis and treatment of pulmonary complications such as influenzal bronchiolitis and pneumonia. Energetic treatment with antibiotics is particularly necessary in the latter case when infection with *Staph. pyogenes* is superimposed on an epithelium denuded by virus action. This monograph should do much to help international research into a disease capable of causing world-wide havoc.

IONIZING RADIATIONS

The ionizing radiations used in industry include x rays, and the alpha, beta, and gamma radiations emitted by radium, mesothorium, and many radioactive isotopes now available from atomic energy establishments. The description of the manifold industrial applications of these sources of radiation, contained in a pamphlet¹ issued by the Factory Department of the Ministry of Labour and National Service, shows clearly how the speed, efficiency, and improvement of modern chemical and engineering processes are dependent on the facilities which radiography provides for examination and control of their products. The examination of castings, forgings, and metal articles subjected to high stress, for which x rays were until recently chiefly used, is now widely carried out by means of radioactive isotopes such as cobalt⁶⁰, tantalum¹⁸², and iridium¹⁹², since they have the advantages of mobility, relative cheapness, and automatic control. Among the many other uses of ionizing radiations are the elimination of static electricity in processes where accumulation of an electric charge may be either dangerous or highly inconvenient, measurement and control of the thickness of materials, sorting of packets passing along conveyor bands, and calibration of monitoring instruments. The chief application of radium itself or of mesothorium is its incorporation into a self-luminous compound for painting instrument and clock dials in the process known as "luminizing."

This is the only use of radioactive material in which precautions against health hazard are specially required by law (the Factories (Luminizing) Special Regulations, 1947). Other ionizing radiations are the subject of recommendations and safety codes which have been published from time to time in an attempt to minimize, on a voluntary basis, the risks to health arising from their use. Such are the recommendations drawn up by the British X-ray and Radium Protection Committee (Seventh Revised Report, 1948), and by the Sixth International Commission on Radiological Protection in 1950. The latter body agreed on the maximum permissible dosage rates, which are regarded as a proper basis for

¹ *Precautions in the Use of Ionizing Radiations in Industry*. Ministry of Labour and National Service. H.M.S.O. 2s.

protective measures and on no account to be exceeded. General precautions are directed towards minimizing the exposure of workers to powerful sources of radiation by suitable planning of equipment, so that protection may be given by distance, screening, and remote control. Other measures include the prevention of inhalation or ingestion of radioactive gases and dusts by suitable ventilation; adequate supervision by trained persons; recording of exposure by means of dosimeters or photographic films; and periodical medical examination with regular blood counts when possible and desirable. When all such precautions are carefully observed the danger of ionizing radiations has been found to be slight, but the potential hazard of overexposure through accident or carelessness must always exist. Awareness of it is particularly important at a time when the rapidly expanding use of radioactive substances entails exposure to them of an increasingly large section of the industrial population.

HYALINE MEMBRANE IN THE NEWBORN

Pulmonary hyaline membrane in the newborn is an amorphous, acidophil deposit on the walls of air spaces, chiefly respiratory bronchioles and alveolar ducts. It forms only in spaces that have received air, though similar hyaline material may occur in lumps in unexpanded alveoli. The affected air spaces become overexpanded, while the rest of the lung substance is in complete atelectasis. Rupture of overexpanded air spaces may produce interstitial emphysema and pneumothorax.

Hyaline membrane is a common condition. Potter¹ considers that it is responsible for more deaths of live-born infants in the neonatal period than any other single cause. It is seen chiefly in the premature, and is usually the only apparent cause of death. It occurs much less commonly in full-term infants, and is rare in premature babies weighing under 1,000 g. (2½ lb.). It is not found in the stillborn, and has not been observed under one hour after birth. Several observers have noted a high incidence in babies delivered by caesarean section.

In the typical clinical picture the baby breathes spontaneously and may appear well until several hours after birth, when respiratory difficulty develops, with inspiratory recession of the sternum and lower ribs, and cyanosis. Deterioration is progressive until death, which is usually within 30 hours of birth, though some live till the fourth day or longer. While this picture should suggest hyaline membrane, it can be due to other causes, and the diagnosis can be confirmed only by microscopic examination of the lungs. It is not known how often affected infants survive. Clinical observation suggests that some recover, and the recent radiological study of Donald and Steiner² supports this view.

The cause of death is atelectasis, which is constant and always severe. It is usually regarded as resorption atelectasis, developing after membrane has formed and sealed off the more distal air spaces. This opinion is supported by the study of Donald and Steiner, who

demonstrated radiological changes in the lungs indicating progression of atelectasis from alveolar to lobular or lobar extent. Histological studies, however, suggest that the atelectasis may be in part primary.

The chemical composition and the cause of the membrane are not fully understood. Because it often contains stainable lipoid, it was for long believed to be composed of vernix caseosa, inhaled together with liquor amnii; but lipoid is not constantly present. Claireaux³ recently claimed to have produced it experimentally by injection of macerated epithelial squames from liquor amnii. Blystad *et al.*⁴ suggested that it is formed from protein of the amniotic fluid concentrated after a period of air breathing. Other workers believe that the membrane is an exudate or transudate. Hyaline membrane is not peculiar to the newborn; similar membranes have been described in older subjects in various diseases, including influenzal and rheumatic pneumonia, irritant gas poisoning, and heart failure. In the newborn, some authorities have suspected oxygen as the cause, but the condition occurs in the absence of oxygen therapy. Although most affected babies who survive for 48 hours develop pneumonia, there is no evidence that the membrane is of infective origin. Failure of adaptation of the pulmonary circulation to postnatal conditions, possibly associated with persistent primary atelectasis, might be responsible.

While the cause of the condition remains uncertain, treatment and prophylaxis can only be empirical. Some workers claim success for measures directed to thorough clearing of the air passages, while others recommend oxygen and high atmospheric humidity. A comprehensive review by Tran-Dinh-De and Anderson⁵ is recommended to the interested reader.

THE ANNUAL MEETING

This year's annual meeting of the B.M.A. is to be held at Glasgow on July 19, and the provisional programme is published in the *Supplement* this week so that members may make a note of the dates and as many as possible arrange to attend. The President-Elect is Sir John McNee, who after a distinguished career in London gave lustre for seventeen years to the post of Regius Professor of Practice of Medicine in the University of Glasgow, retiring last October. A great variety of events are being prepared for the instruction and entertainment of the visitors. These include three plenary scientific sessions. The success of the plenary sessions in the last two years has encouraged the organizers to hold them again, and the themes chosen for discussion at Glasgow are "The Problem of Sleep," "Food and Disease," and "The Problem of Pulmonary Tuberculosis To-day." Seventeen scientific sections will meet on July 7-9, and there will be a scientific exhibition on the lines of those which were so successful at Dublin in 1952 and at Cardiff last year. A number of special excursions have been arranged for the ladies. Early reservation of hotel accommodation is advisable, and it is hoped that as many doctors as possible will be able to attend, even if only for a day or so, and share in the warm hospitality that is an invariable feature of the Scottish scene.

CLINICAL PATHOLOGY IN GENERAL PRACTICE EXAMINATION OF FAECES FOR INFECTION AND INFESTATION

BY

K. B. ROGERS, M.D.

Clinical Pathologist, Children's Hospital, Birmingham

When a patient has diarrhoea it is usually desirable to know the cause of the attack. The symptoms may be so mild that the doctor is inclined not to have the faeces examined, but an early investigation can provide valuable information, particularly if the disease does not clear up as quickly as expected. Also, even if the patient is only slightly ill, the same pathogenic agent could produce a severe illness in other members of the house.

The bacterial infections are those caused by the dysentery, the food-poisoning, and the *Bact. coli* groups of organisms. Bacillary dysentery is usually associated with diarrhoea, often accompanied by colic, and the organisms causing this disease belong to the genus *Shigella*. In England the commonest of these is the *Sonne bacillus*. *Salmonella* is the food-poisoning group, and one of the most often encountered in this country is *Salm. typhi-murium*. The patients usually have severe diarrhoea and often vomiting. The enteric group (typhoid and the paratyphoids) also belong to the genus *Salmonella* but are not usually included among the food-poisoning group.

During the past ten years many fulminating food-poisoning epidemics have been caused by organisms which do not belong to the salmonella group, such as the enterotoxin-producing *Staphylococcus aureus* and the heat-resistant strains of *Clostridium welchii*. The symptoms in this type of food-poisoning are caused by toxins produced in the food by these organisms, and for this reason the incubation period is a very short one of only a few hours. In this form of toxic food-poisoning it is nearly always possible to isolate the causal organisms from the faeces.

Diarrhoea can also be caused by protozoal infections. Apart from the importance of diagnosing the cause of an attack of diarrhoea, an examination of the faeces is often necessary to prove whether or not there is a worm infestation or whether there is a metabolic disorder which affects the intestinal tract.

Collection and Delivery of Specimens

Rectal Swabs.—The passage of an ordinary sterile throat swab through the anal canal is a convenient way of obtaining a specimen that will not be contaminated after it leaves the body. Apart from any aesthetic objection to this method, these specimens are very often anal and not rectal swabs. Once the swab has passed the external sphincter the cotton-wool can be caught by the loose anal mucosa, which makes it feel as if any further pressure would tear the mucosa. Anal swabs, as distinct from rectal swabs, can provide misleading false cultural results.

Sheathed Rectal Swabs.—Some laboratories surround the swab with a suitably sized glass sleeve with rounded ends. These swabs are sterilized with a small quantity of liquid paraffin at the bottom of the containing test-tube and the lower end of the glass sleeve is lubricated. This lubricated glass tube is inserted through the anus with a to-and-fro rotary movement until the internal sphincter is felt as a distinct obstruction. The tube is pushed gently through the internal sphincter and the swab is then passed up into the

rectum, after which it is withdrawn within the glass sleeve. Both are then removed and reinserted into the test-tube. In babies with acute diarrhoea this method is very convenient, as on touching the internal sphincter the whole of the glass sheath is filled with liquid faeces, which otherwise would have soaked into a nappy.

Faeces.—Care must be taken to avoid contamination of the specimen after it leaves the body. All laboratories provide sterile containers which incorporate a spatula with which faeces can be picked up. In hospitals it is relatively easy to obtain uncontaminated faeces, and there are several ways of doing this in the home. One is to pour boiling water into a chamber-pot, which is then emptied; when it is cool the motion is passed into it. Another method, which avoids using a chamber-pot, is for the patient to empty his bladder and then fill the lavatory pan with many layers of toilet paper, on to which the motion is passed. The specimen is obtained with the spatula, after which the toilet is completed. Before using the technique it is convenient to remove the nether garments, as otherwise it is awkward for the patient to turn round to obtain the specimen.

Delivery to the Laboratory.—When cultural examinations are required a delay may reduce the numbers of the viable pathogens, especially if the specimen is on a rather dry rectal swab. When the specimen is being examined to establish a diagnosis, this delay may be dangerous to both the patient and his contacts. Very often some member of the patient's household can deliver the specimen to the laboratory if it is not too far from the home. Some laboratories issue tubes containing glycerol-saline into which a specimen of faeces is placed. This helps to prevent pathogenic organisms dying in transit, and it may be convenient for the practitioner to keep a supply of these bottles in his surgery. A specimen with only an occasional pathogen present will give entirely negative results if tested when 18 hours old—that is, if posted to the laboratory. Examinations for *Entamoeba histolytica* must be made on very fresh specimens, as only the cysts will be seen in faeces which have been allowed to cool.

Information Provided

Most laboratory examinations of the faeces are carried out to exclude or confirm the presence of pathogenic organisms or parasites. Therefore normal appearances and results are not usually reported, merely whether or not abnormalities are detected.

Routine examinations should enable infections caused by salmonellae, shigellae, the specific serological types of *Bact. coli*, *E. histolytica*, and *Giardia lamblia* to be diagnosed. The presence of an infestation with ascarides (roundworms) or with rarer worms such as whipworms is usually relatively easy to determine.

Direct Wet Smears.—Many laboratories make a direct examination of the faeces, without which the presence of amoebae, amoebic cysts, and *G. lamblia* would be entirely missed. In the acute stages of a dysentery and of many salmonella infections the finding of pus and red cells in excess of mucus may indicate the need to institute barrier nursing within a very short time of the specimen having been received in the laboratory. In infants the presence of many fat globules may be the earliest indication of fibrocystic disease of the pancreas; these babies are sometimes first seen as cases of diarrhoea. In ulcerative colitis there is usually a great deal of blood and mucus as well as pus in

⁵ Tran-Dinh-De, and Anderson, G. W., *Obstet. gynec. Surv.*, 1953, 8, 1.

the faeces, but the proportion and amount of each of these are very variable. Except that there is usually more blood present, this exudate may be very like that of a dysentery and may be misleading at first.

How Soon?

Immediately

The direct examination, outlined above, allows an immediate diagnosis of amoebiasis and *G. lamblia* infestation, but it must be remembered that the latter is not uncommonly associated with Sonne dysentery, both infections having been acquired at the same time. Worm infestations will be diagnosed immediately but they are more conveniently dealt with separately.

The laboratory may also be able to suggest that dysentery is present by demonstrating an exudate in the direct smears: this could allow early segregation of the case, which might help to prevent the infection spreading.

After 18-24 Hours

The specific serological types of *Bact. coli* which cause epidemic enteritis in infants are primarily identified by slide agglutinations of 18-hour-old cultures. These results have to be confirmed by further laboratory tests, which take a day or more to complete. False-positive reactions are relatively common when a laboratory first undertakes these examinations, so the confirmatory tests are extremely important. With experience the number of false-positive results becomes much smaller, as the technician soon learns which type of reaction is a false-positive result if he is constantly checking the slide-agglutination results by tube agglutinations. Therefore laboratories which are constantly making examinations for these *Bact. coli* types can fairly safely diagnose their presence within 18 hours of the receipt of the specimen.

The Sonne bacillus gives very characteristic colonies on desoxycholate citrate plates, and slide agglutination of 18-hour-old cultures provides an answer which further laboratory tests usually confirm as correct.

The colonies of salmonellae on selective media can be examined by slide agglutination, and experienced workers will often be able to make a tentative diagnosis of a salmonella infection after one day's incubation. As the danger of a false-positive result is much greater in this type of infection than it is with Sonne dysentery, some pathologists prefer to wait another day, when confirmatory tests would be available.

After Two Days

Confirmatory biochemical and tube agglutination tests on organisms isolated on the first day will be nearly completed after 24 hours. The more specialized selective media, such as Wilson and Blair's bismuth sulphite plates for the enteric group, will be producing their first identifiable colonies. The enrichment media, such as selenite, tetrathionate, and brilliant green, will be subcultured after 24 hours, and the subcultures will be giving recognizable colonies after 48 hours.

It will thus be seen that after 18 hours a tentative diagnosis of infections due to *Sh. sonnei*, specific types of *Bact. coli*, and a few species of *Salmonella* can be made, but the confirmatory tests will take a few days longer. However, it is not unusual to isolate the pathogens by means of the enrichment techniques only, which means that the first positive results might not become available for three to four days.

Reference Laboratories.—Because of the great complexity of the antigenic structure of the members of the shigella and salmonella groups, in which there are over 250 types, reference laboratories have been established by the Medical Research Council. Laboratories are encouraged to send all salmonella and shigella cultures, except those of *Sh. sonnei*, to these reference laboratories so that the identity of the organisms can be confirmed. Therefore a provisional report naming a salmonella may be followed by a second giving an entirely different name. However, the treatment of the

condition will be the same: correct identity of the organism is of importance only to the public health authorities in their efforts to trace the origin of the cases and the connexion between them.

Infestation with Worms

If the whole worm or segments can be sent to the laboratory so that its identity could be confirmed any clean convenient container is suitable.

Threadworms (*Oxyuris vermicularis*) (Fig. 1) can occasionally be seen adhering to the surface of faecal scybala, otherwise they are rarely found in faeces. If there is any doubt about the identity of threadworms, it is advisable to send the specimens to the laboratory, as vegetable fibres can be mistaken for these small worms (about $\frac{1}{2}$ cm. long).

The ova of threadworms (Fig. 2) are never found in the faeces, as they are deposited on the perineum by the female worms. A "sellotape" slide produces a very convenient and easy method of diagnosing threadworm infestations. The slides can be prepared by placing a strip of 1-in. (2.5-cm.) sellotape on a glass slide. In the morning, before the child dresses, the mother detaches from the slide nearly the whole length of the sellotape. The sellotape is stuck on the skin near the anus and is immediately slowly

FIG. 1.—Two threadworms. (×12.)

FIG. 2.—Threadworm ova photographed through a sellotape slide. The coiled larvae can be seen within the transparent shells. (×280.)

removed. It is then stuck back flat on the glass slide and sent to the laboratory. These slides are much easier to examine than the old N.I.H. "cellophane" swabs.

Roundworms (*Ascaris lumbricoides*) can be between 3 and 8 in. (7.5 to 20 cm.) in length.

Tapeworms (*Taenia saginata* and *Taenia solium*). When mature segments (Fig. 3) are passed they measure about $\frac{1}{4}$ by $\frac{1}{2}$ in. (1.3 by 0.6 cm.), are coloured pinky grey, and may show slow movements. The type of taenia infection can be ascertained easily if one of these segments is blotted very thoroughly so that the adherent mucus is removed, dried, and then pressed firmly between two microscope slides. When held up against a bright light the number and arrangement of the uterine horns are easy to see. The commonest tapeworm in England is *T. saginata*, which has 20-30 uterine horns. If the laboratory is to look for the head of the

*All the photographs in this article were taken by Mr. J. G. Williamson, of the Children's Hospital, Birmingham.

"STATUS LYMPHATICUS," THE GROWTH OF A MYTH

BY

H. B. DODWELL, M.D.

Anaesthetist, Royal Northern Hospital, London

tapeworm (Fig. 4), all the faeces passed after the administration of the saline aperient should be sent for examination. A search is made for the head by washing the faeces through a metal 28-mesh sieve. Unless such a sieve is used the head of the worm may be lost, so no attempt should be made to concentrate the specimen before it is sent to the laboratory. Specimens should be sent to the laboratory as

FIG. 3.—*Taenia saginata*: mature segment and flattened segment showing uterus.

FIG. 4.—Head of *T. saginata*. (×25.)

soon as possible, for once the worm has been passed it tends to degenerate. It is worth remembering that tapeworm ova are very rarely found in the faeces, because they are not liberated until the mature segments degenerate.

Criteria of Cure

If any of the antibiotics, such as chloramphenicol, aureomycin, or terramycin, have been given, or one of the intestinal sulphonamides, tests of cure should not be started until about five days after the drug has been stopped.

Salmonella and Shigella.—At least three consecutive negative examinations are necessary before a cure can be established. Because salmonella organisms often localize in the gall-bladder, it is best to obtain a specimen of faeces after a saline aperient, which will act as a cholagogue.

Specific Serological Types of Bact. coli.—Before it is safe to allow a child who has been excreting these organisms to enter an uninfected community of infants at least six faeces cultures, taken on alternate days, should be negative. If the baby is living in a community in which a specific type of *Bact. coli* is endemic, then it is preferable for the clearance tests to be made when the baby is away from that community. If the infant is going to its home, and other babies are not in the house, three negative results would be sufficient.

G. lamblia.—Three daily specimens should be examined three days after the mepacrine course has finished. It must be remembered that other members of the household may be infected and in this way the patient may easily become reinfected.

Ascaris, etc.—Examination for the ova of worms is preferably made on faeces obtained following a saline aperient, and at least six negative specimens should be obtained.

E. histolytica.—At least six daily specimens obtained after saline aperients should be examined for the cysts. It is also advisable to repeat these examinations six months later.

Next article on Clinical Pathology.—"Chemical Examination of the Faeces," by Dr. W. W. Payne.

The latest edition (the sixteenth) of *Principles and Practice of Medicine*, originally edited by Osler, defines status lymphaticus as "a combination of constitutional anomalies, among which are hyperplasia of the lymphoid tissues and of the thymus gland, hypoplasia of the cardiovascular system and peculiarities of configuration, with frequent sudden death." Results of the condition are various, among them are: (1) Liability to sudden death—this may be from anaphylaxis, cerebral haemorrhage, or, in young children, pressure on the trachea by the enlarged thymus gland. (2) Increased susceptibility and decreased resistance to acute infections. (3) Increased danger in childbirth. (4) Psychical instability; these subjects forming a large proportion of cases of drug addiction and suicides.

The most circumstantial account of the condition is given by Hower (1953). According to him the findings of Kemp (1932), Campbell (1937), Moncrieff (1938), and the late Sir Bernard Spilsbury, in spite of several attempts to discredit their work, have definitely established the existence of the syndrome. It would seem that Hower bases his case that status lymphaticus exists as a clinical entity upon three claims: (1) that the condition has been recognized for some 300 years; (2) that there is a recognized clinical picture with three classical signs; and (3) that there are well-recognized post-mortem findings. I propose to show that not one of these claims is supported by the available evidence.

Attitude of the Textbooks

In contrast to the above the attitude of the textbooks of pathology is much less positive, although the writers of such works must have much greater experience of the post-mortem findings in such cases; or is it for just that reason that their attitude is one of doubt or of definite scepticism?

Thus Boyd (1947) states that "there is no proof that the thymus gland has anything to do with stoppage of the heart." Dible and Davie (1950) state: "There is no doubt that ignorance of the great variation in size to which the thymus gland is subject in health and disease has often led to an unjustifiable resort to the convenient diagnosis of status lymphaticus in cases of sudden death. . . . Many pathologists of experience are of the opinion that there does exist some abnormal constitution or condition which is associated . . . with a liability to sudden death from relatively trivial stimuli, such as excessive sensitivity to stimuli of the autonomic nervous system, but no constant anatomical or pathological abnormality." Muir (1951) quotes the findings of the Joint Committee of the Medical Research Council and of the Pathological Society of Great Britain and Ireland, its general conclusions being that the facts that have been ascertained afford no evidence that the so-called status thymo-lymphaticus has any existence as a pathological entity.

The conclusion in Muir's textbook is that "this does not imply that there is not a constitutional condition of low resistance power, with a tendency to sudden death; simply that it is not possible to relate it definitely to thymic or lymphoid hyperplasia."

Green (1949) states that there are "no manifestations of the condition during life, but violent exertion, rapid temperature change or anaesthesia may lead to sudden death," and, finally, "it has been agreed that status lymphaticus

as a pathological syndrome, based upon pure thymic dysendocrinism, does not exist."

If Dr. Hewer's story were correct we should expect to be able to follow these references to status lymphaticus back to the earliest editions of current works and further back still in the earlier editions of books now out of print but in being before Osler's *Medicine* was produced.

Ewing and the Vienna School

Actually there is no reference to the condition in Osler's first and second editions, or in any contemporary medical or pathological book I have been able to discover such as Fagge (1888, 1891), Bristowe (1890), Roberts (1873, 1890), Taylor (1890), or Coats (1895); in fact, it is not until the third edition of Osler's *Medicine*, published in 1898, that any reference is made, and then in these terms: "Much attention has been paid lately to a somewhat rare condition . . . and the reader is advised to consult an article by Ewing (1897).

Ewing in discussing the views of Paltauf (1889) begins: "There have recently been described a series of cases . . ."; he continues, "The importance of the constitutio lymphatica and its relation to some forms of sudden death, especially to fatalities under chloroform narcosis, have been recognized by the Vienna school of pathologists, but have received very scant attention elsewhere."

Six successive editions of Osler's *Medicine* carried the passage based upon Ewing's article but without his final sentence, which ran: "In conclusion, while the studies of the Vienna observers seem to have placed the existence of the constitutio lymphatica upon a firm basis in pathology, the observations yet remain far too limited fully to demonstrate the truth of an hypothesis which connects a large class of sudden deaths with simple hyperplasia of the lymphatic structures of the body."

It is surely significant that Paltauf makes no mention, in a long list of references, to any work published earlier than 1850; equally so that John Simon (1845)—although his bibliography is immense, going back as far as Galen and Rufus of Ephesus—seems entirely to have missed this historical association.

Growth of the Legend

The history of the growth of the legend of status lymphaticus can be quickly told; gradually during the first decade of the twentieth century the idea of a status lymphaticus began to spread, so that in the eighth and ninth editions of Taylor's *Practice of Medicine*, in 1908 and 1911, references begin to appear, and in 1911 for the first time a separate entry of diseases of the thymus gland makes its appearance in the annual report of the Registrar-General for England and Wales.

In 1917 Dr. Symmers, professor of pathology at the Bellevue Hospital, New York, published an original work upon status lymphaticus in which he recorded the weights of the thymus gland in 66 cases out of 249 which he had diagnosed "status lymphaticus."

The weakness of Dr. Symmers's case is that he publishes no standard for normal weights of the thymus gland, and if we compare the weights of his enlarged glands with the normal weights arrived at by Hammar (1916), or by the Medical Research Council's Joint Committee (1931), whose findings were based on a much larger published collection, we find that a preponderance of these abnormally heavy glands of Dr. Symmers's fall within these other observers' normal weights.

However, Dr. Symmers's views have gained much popularity and have formed the basis of the description of the condition in Osler's *Medicine* from the eighth edition, of 1920, to the latest, the sixteenth, published in 1947.

Platter's Observations

Felix Platter's name does not appear in connexion with status lymphaticus until 1925, although his name was brought

to the attention of American medical men some years earlier by C. G. Cumston (1912), who quoted some extracts from Platter's memoirs and from some other papers of his still preserved in the museum of his native Basle.

In 1925 Ruhrah gave a short sketch of Platter's life and the text of a short article to be found in his *Observationum in hominis affectibus*, together with an English translation (not without error). Ruhrah's own comment was: "To paediatrics we know he made one contribution of great value, the description of thymus death; like many first descriptions of disease it is contained in a few words."

Marine (1928) referred to this observation of Platter's, and in 1932 Kemp began a long original article upon status lymphaticus with Ruhrah's translation of the paragraph from the *Observationum*—error and all.

The first edition of Hewer's *Recent Advances in Anaesthesia and Analgesia* appeared earlier the same year, I presume, since there is no reference in his work to Platter's observation; but in the second edition, published in 1937, Platter's article is quoted and the legend of the 300-year-old tradition is fairly launched in British medical literature; although one tentative diagnosis at one post-mortem examination is perhaps rather scanty material. From the fourth to the latest (the seventh) edition of *Recent Advances* the date of Platter's article has been placed in 1641; one can only say what a remarkable old gentleman Felix Platter must have been to have published his three volumes of clinical reminiscences at the age of 104. However, there can be little doubt that the date of his death as given on the plaque in Basle Cathedral—July 28, 1614—is the correct one; the 1641 edition of the *Observationum*, a copy of which is to be found in the library of the Royal Society of Medicine, is really only a reprint of the work brought out a few months before the author's death in 1614.

"Classical" Signs

With regard to the "classical" clinical signs—those of Sergeant, Schridde, and Orroya—they are mentioned for the first time by Kemp (1932), who quotes no case notes to support his statements; no other writer records cases presenting these physical signs, nor that of Madan; while the three leading medical dictionaries—Dorland's, Stedman's, and Blakiston's "New Gould"—make no reference to Orroya or to Madan.

Campbell (1937) lists an impressive number of physical signs, far too numerous to be mentioned here, associated with status lymphaticus, but, like Kemp, fails to favour us with any case records.

As to Sir Bernard Spilsbury's post-mortem findings in status lymphaticus, I have been completely unsuccessful in my attempt to discover any published work in which such findings are quoted. In 1926 there was set up a Joint Committee of the Medical Research Council and of the Pathological Society of Great Britain and Ireland, which published its report in 1931; some 680 post-mortem examinations were made, and the care and detail with which these cases were analysed place this investigation in a class by itself. Hewer (1953) relegates all reference to this committee's report to a footnote, it being apparently one of "several attempts [that] have been made to discredit the existence of the condition," and prefers to base his belief upon the views of Kemp, Campbell, Spilsbury, and Moncrieff, although the last-named alone of these four quotes any case notes—those of seven children, none of whom are reported as having died but whose thymus glands are diagnosed as enlarged by x-ray photography—a somewhat unreliable basis, as the writings of Garland (1929) and of Capper and Schless (1934) have emphatically shown.

I suggest that were this account of status lymphaticus other than a fable ample material in support could have been found among the thousands of post-mortem examinations reported since 1945 by Helperm and Rabson (1945), Keith Simpson (1947), Richards, (1947), Deadman (1947), and others, or from among the odd 200 deaths reported annually by the Registrar-General for England and Wales.

Conclusion

In conclusion, until some such evidence is produced we must surely accept, as does Professor Weiss (1940), that instantaneous physiological death occurs, but is not associated with either clinical or pathological signs, that the twelve conclusions of the Joint Committee remain the considered judgment of informed opinion, and that the last sentence of their report holds good: "In the opinion of the Joint Committee the facts elicited in the present inquiry are in harmony with those of Hammar (1926, 1929), and of Greenwood and Woods (1927) in affording no evidence that so-called status thymo-lymphaticus has any existence as a pathological entity."

Nova et Vetera

"THE NAPOLEON OF SURGERY"

Medical students' notebooks written in the more leisurely days of the last century or earlier sometimes provide little-known facts about their teachers, the state of contemporary medical education, and the day-to-day events, all so valuable to the historian who comes after.

Professor Charles McNeil recently published¹ some excerpts from a notebook kept by his father, William McNeil, in the year 1861. At that time William was a student of James Syme, the Edinburgh surgeon, and the importance of the notebook is that it brings back to life some of the words and acts of Syme at the height of his achievement and influence.

Before the advent of anaesthesia Syme already had a reputation for conservatism in surgery. He was neither quick nor brilliant as a technician, but he always insisted on scrupulous cleanliness at operations. In 1829, having failed to obtain an appointment on the surgical staff of Edinburgh Royal Infirmary, he opened a small surgical

¹A Student's Notebook of James Syme's Class of Clinical Surgery in 1861-62. Kept by William McNeil, M.D. Ed. 1864: with Extracts and Comments by Charles McNeil. *Edinb. med. J.*, 1952, 59, 266.

clinic at Minto House, where he rapidly built up a reputation second to none in Europe. His lectures were always crowded, and he was received by his assistants and students like a monarch. Alexander Miles has called him "the Napoleon of surgery." His pupils included Lawson Tait and Joseph Lister, who both inherited his zeal for surgical cleanliness and who were afterwards to diverge so widely in their methods of developing it. Lister later married Agnes, Syme's daughter.

An earlier pupil (in pre-anaesthetic days) was John Brown, later to distinguish himself as an essayist. His sketch *Rab and His Friends* immortalized the little hospital at Minto House. Syme was the surgeon who operated on Ailie for a cancer of the breast, who "dressed her [wound], and spoke to her in his own short kind way, pitying her through his eyes."

Professor McNeil has included sufficient extracts from the notebook to show the setting in which a great surgeon worked 90 years ago. "Beside him are his assistants—the house-surgeon and dressers; around, on the crowded benches his students, attentive and admiring; over the head of the surgeon bending to his work the invisible but felt aura of his experience and reputation." The patients, too, are not mere cases, but become living creatures, like the little girl from Wales, aged 8, who "seemed in the very highest spirits, was carrying a large doll very gaily dressed, and laughed immoderately at the round of applause with which the students greeted her appearance." There is also the man with cancer of the scrotum who did not reply when Syme asked whether or not he would like chloroform.

"Pr. [Professor] Syme with a pair of scissors at once cut out the cancer which was situated in the most dependent part of the scrotum. The shouts of the fellow were terrific. Pr. Syme, after he had completed the tying of the vessel cut, questioned him concerning the period of its growth, and got for a reply: 'Hoo the devil can I answer any questions just noo?' This created a very hearty laugh among the students, which did not improve the temper of the patient. He left the theatre uttering imprecations on Pr. Syme and all concerned."

The callousness of surgeon and students sometimes implied by the notes is, as Professor McNeil points out, countered by the sympathy and pity for the patient so well expressed in *Rab and His Friends*: "Don't think them heartless; they are neither better nor worse than you or I: they get over their professional horrors, and into their proper work; and in them pity as an emotion, ending in itself, or at best in tears and a long-drawn breath, lessens, while pity as a motive is quickened and gains power and purpose." And again, after the operation on Ailie: "It is over; she is dressed, steps gently and decently down from the table, looks for James; then, turning to the surgeon and the students she curtsies, and in a low, clear voice, begs their pardon if she has behaved ill. The students—all of us—wept like children."

With the notebook we can picture the dramatic scene in the surgical theatre 90 years ago; on the stage the surgeon, assistants, and patients; in the audience the students, with eyes and ears directed to the stage, where Syme dominates the scene and conducts the play.

Preparations and Appliances

AUSCULTATION IN ANAESTHESIA

Dr. J. D. LAYCOCK, consultant anaesthetist at St. Thomas's Hospital, writes: During thoracic operations it is important for the anaesthetist to be able to detect with ease the presence of secretions in the bronchial tree so that he may pass a suction catheter and remove them. A large amount of secretion may be recognized by an audible rattle which is not easily missed, but smaller amounts may pass unnoticed.

If seems that the most logical way to find out what is happening in the bronchial tree and whether there are secretions there is by direct auscultation. With this object I have designed a small appliance which can be fitted over the wide-bore rubber tube that leads from the anaesthetic apparatus to the endotracheal connexion. The appliance

is a metal cuff surrounding the rubber tubing and connected to a stethoscope which can be worn by the anaesthetist. Various shapes of cuff have been tried, but the most satisfactory has been the one shown in the drawing. This is made to fit firmly over the tube, and it is essential that the fit should be airtight, to prevent extraneous sounds from entering.

The application of the cuff, of course, interferes in no way with the gases passing through the rubber tube inside it. During normal respiration breath sounds similar to those heard over normal lung in clinical examination will be heard, but the sounds are distinctly louder when respiration is controlled or assisted, as is usual in thoracic operations. Kinking of the endotracheal tube causes a characteristic change in these sounds, and the appliance is thus a ready means of detecting even a slight degree of kinking. Bronchial secretions can be heard very easily. The tone of the bronchial musculature can be studied, and the wheezing of asthma or bronchial spasm can be noticed even if very slight.

There is probably no simpler or more certain way of checking up on the state of the bronchial tree and its contents at any stage of the operation, and if bronchial secretions are present they can be recognized at once and dealt with by suction. The efficiency of the suction can be checked by listening again afterwards. The cuff may be used with advantage in general surgical operations where information regarding the tone of the bronchial tree, or secretions within it, is likely to be of value.

The appliance is manufactured by Blease Anaesthetic Equipment Ltd., 12, Hinde Street, London, W.1, and is supplied complete with a wide-bore rubber tube fitted with a universal catheter mount for connexion to the anaesthetic machine. I am grateful to Miss J. Davenport for the drawing.

A SIMPLE INDICATOR FOR EXTRADURAL ANALGESIA

Dr. G. A. JACKSON, anaesthetic registrar, Plymouth Hospitals, writes: The extradural potential space is often difficult to demonstrate with certainty, using negative pressure and other methods. I have described a syringe and method (*British Journal of Anaesthesia* 1950, 22, 150) which gave a more positive approach to the problem, it being an improvement on the Dogliotti technique. In our hands it had one disadvantage: it was not always easy to place the needle-point in the interspinous or ligamentum flavum in such a position

that the strong spring in the syringe did not sometimes force the saline indicator to leak into the tissues. This might happen before the extradural space had been demonstrated. It occurred mostly in the obese, who presumably had poor ligaments which were to some extent infiltrated with fat. When it does happen a good method is rendered useless.

The syringe to be described overcomes the difficulty completely by using a weaker spring. It is simple and costs very little. It has been used with entire success in very many cases. An extradural block is now as easy and reliable to administer as a spinal analgesic.

A 2-ml. Record-type syringe is very simply modified and acts solely as an indicator. A small compression spring is fitted on the spindle between the piston and the handle, together with a washer between the spring and the metal syringe cap. The photograph shows the assembly perhaps more clearly than words. The spring should be approximately the same length as the spindle, so that it is not compressed until the plunger is manually withdrawn. This spring should be of such a strength that it will just bring the piston gently home without any undue force. It should preferably be of a non-rusting variety.

The locking device is desirable, but not essential. It consists of a very thin piece of springy brass soldered to the syringe end cap and arranged just to touch the spindle. On extension this locks into a notch cut in the spindle as shown. It is easily released by turning the handle clockwise or anti-clockwise.

The patient is positioned and prepared in the usual way. The space chosen is infiltrated with a little local analgesic

and the skin pierced with a cutting needle. The syringe is filled with saline and locked. A fine lumbar-puncture needle is inserted in the usual fashion in the midline for about 1 in. (2.5 cm.) until it is felt to be firmly gripped by the interspinous ligament. The syringe is attached and unlocked. No saline should leak into the ligaments. The needle is very slowly advanced until the saline is automatically ejected into the extradural space. The needle-point is now just in the space, and the advancing saline tends to push the dura mater away from the advancing needle-point without damage.

The syringe is disconnected after several aspiration tests for cerebrospinal fluid. Should a small amount of saline emerge from the needle it should be felt on the back of the hand or on the wrists. It will be cold as compared with warm cerebrospinal fluid. The analgesic solution is now slowly injected.

This method has been used in Plymouth for some time now without dural puncture. In fact, latterly, test doses have been omitted with perfect safety and with a great saving of time. Lignocaine hydrochloride 1-1.5% is used in varying quantity.

The syringe will be obtainable from Medical and Industrial Equipment Ltd.

I should like to thank my senior colleagues for their most helpful criticism and advice while this technique has been devised.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Press Publicity

SIR,—In two very recent instances my name has appeared in the daily newspapers in relation to patients. The embarrassment which has attended such publicity is a private affair of mine, but there have been aspects of the contacts between my department and the press which have raised very much broader issues covering the whole field of the relationship between medicine and the press.

In the first of these instances intimate medical details have been obtained by medical correspondents of newspapers and have been published sometimes with mathematical accuracy so that an almost complete picture of the medical course of the case could be built up, and indeed has been built up, exclusively from press cuttings. The great majority of these details, and all the minor details, have been unofficially obtained.

In the second case, news of a procedure which had been developed in my department was reported in the press with the names of the doctors concerned. This information had also been obtained through what doctors would regard as irregular channels. Several inaccuracies in this report were embarrassing and I had to enlist the good offices of the Press Association to publish a short true account without mention of names of doctors or hospitals.

What we doctors do not sufficiently realize is that reporters in general believe that it is perfectly legitimate to collect medical news by any means available to them and that any method of collection is entirely legitimate and honourable. We have up to date not admitted this premise, but on the other hand have held strictly to the rule that medical information should be communicated by a doctor only through the columns of a medical or scientific journal. This ideal method of presentation of medical news is to my mind no longer attainable, and by attempting to attain it we are inviting for ourselves and for our patients all the inconvenience and even dangers which attend the uncontrolled competitive search for medical news by professional journalists. During the past few weeks we have in this medical school suffered this inconvenience in an extreme degree.

I do not wish to stress the private inconvenience which my family and I suffered. It is sufficient to say that on one evening the police had to be called to clear the precincts of my home of objectionable men who claimed to be reporters but who from their behaviour at a late hour and in the darkness may well have had more felonious intentions than the collection of news, but there may in fact, from this situation, be an actual danger to the patient. The patient himself, or his relations and friends, may be dismayed by the reports they read of an operation still to be faced and openly described in the press with an unbalanced estimate of the dangers attendant upon it. Patients awaiting treatment by new techniques may be extremely disturbed by an inaccurate lay record of its details. This is the most serious effect of inaccurate medical reporting in the public press and I have experienced how potent that effect may be. Press publicity may also affect a patient indirectly; it does not make it easier for a surgeon to decide to undertake a dangerous or novel operation in the full glare of hourly publicity. Not only the press reports but the technique for the collection of news has its effect too. The relatives of patients may be subjected to a constant degree of press interest which amounts almost to persecution. Working conditions may become almost intolerable in a hospital invaded by dozens of reporters competing for exclusive news and by crowds of press photographers who consider that they have the right to photograph almost any clinical situation, who enter wards almost indiscriminately if they can, and who, if they are refused entrance, try to take pictures through the ward

windows. Added to all this there is the effect on the morale of the staff of the hospital in these circumstances; natural professional reticence has to be replaced by an overconscious sense of the need for security, and if leakage occurs an atmosphere of suspicion may develop; leakage is almost inevitable in a community where many of the relevant medical facts are known to hundreds of people.

It would seem that with increasing newspaper appreciation of the public interest in fresh medical news the best that we can hope for is that our individual anonymity will be preserved and that any reports that are issued are accurate and unharmed. The press requirement for news can in fact be relatively easily satisfied, and once it is satisfied all persecution ceases. In one of the cases I have mentioned part of our responsibility was to a great public company. This company offered us the services of its public relations office, and as soon as we took advantage of these the whole situation improved immeasurably. All press inquiries were canalized through that public relations office. I satisfied ethical requirements by not giving any information whatever to the press directly but by giving the company concerned a report of their patient from time to time, and at their discretion they furnished what particulars they thought were suitable to the press. I believe that my hospital and I could have remained anonymous if the press had not already been in possession of my name before the arrangement with that company was made.

If a route of this sort were available for hospitals to provide the press anonymously with a certain amount of information, and if opportunities were permitted for the press to ask those questions which they consider publicly important through an intermediary, my recent experience with the press suggests that the newspapers in return would go a long way towards preserving our wishes about anonymity and about the date of publication of medical matter. —I am, etc.,

Hammersmith, W.12.

IAN AIRD.

Sensitivity to P.A.S.

SIR,—In view of the recent reports of allergy to para-aminosalicylic acid in the journals, and the widespread use of this drug in the treatment of tuberculosis, the following example of sensitivity to P.A.S. may be of some interest. The sequence of symptoms, fever, depression of the white cell count of the blood, and later urticaria, was quite definite.

A Chinese nurse, aged 24, single, was admitted to hospital on September 29, 1953, complaining of vague ill-health, loss of weight, and a bad family history of tuberculosis. Examination was negative except for tenderness deep in the right loin. Laboratory findings were: red cells, 4,370,000 per c.mm.; Hb, 11.9 g.%; white cells, 4,800; blood film, no malaria parasites seen; urine, S.G. 1017; faint trace of albumin; sugar, nil; x-ray of lungs, N.A.D. An intravenous pyelogram showed normal excretion, but the lower end of the right ureter as high as the pelvic brim appeared double. At retrograde pyelogram the ureteric catheter could not pass beyond the "double" part of the right ureter, but radio-opaque injection in this position filled both "arms" of the "double" section.

A 24-hour specimen of urine, when centrifuged, showed acid-fast bacilli resembling *M. tuberculosis* in all respects, and guinea-pigs were inoculated. This examination was repeated twice more with similar results.

On October 13, going by the excellent results obtained with this therapy in pulmonary tuberculosis here, the patient was started on P.A.S. 2 g. four-hourly, and isoniazid 50 mg. twice a day, this latter being increased to 100 mg. twice a day on October 22. On this day, in the evening her temperature rose to 100° F. (37.8° C.), to 103° F. (39.4° C.) on October 23, and again on October 24 to 103° F. (39.4° C.). All treatment was stopped on the morning of October 24 and crystalline penicillin G 80,000 units four-hourly started. White cell counts were as follows:

October 23, 4,200; October 24, 3,200; October 25, (a.m.) 3,000, (p.m.) 4,400; October 26, (a.m.) 3,800, (p.m.) 4,600; October 27, 4,600; October 29, 4,000; October 30, 5,600; November 9, 6,400 per c.mm.

All differential counts showed a normal distribution of cells, despite several repeated examinations to detect a true agranulocytosis. She was apyrexial by October 26, and the penicillin was stopped on the 28th. On November 8 a desensitizing course

of both drugs was commenced—one dose of P.A.S. 50 mg. and one of isoniazid 5 mg. being given. There was an immediate flare-up of temperature to 99.2° F. (37.3° C.) and mild urticaria. On November 9 P.A.S. 25 mg. only was given with a similar recurrence of symptoms, plus swelling of the face and a "lump in the throat." Symptoms were controlled quickly with anti-histamines and adrenaline.

On November 10 a patch-test with P.A.S. 1% aqueous solution was strongly positive after four hours (a control was used). On November 11 the girl was started on isoniazid 50 mg. twice a day without any ill effects, this later being increased to 100 mg. twice a day, as well as injections of dihydrostreptomycin.

—I am, etc.,

Sarawak.

K. F. D. SWEETMAN.

The Diploma in Public Health

SIR,—The discussion which follows Dr. Max Park's remarks on the curriculum for D.P.H. (*Journal*, October 3, 1953, p. 778) is both instructive and inspiring. An elaboration of comprehensive curriculum leading to the D.P.H. is a very responsible task, as its ultimate aim is to secure success for the diplomad, and, through this, ultimate good for the community in which he is working.

A few years ago I attended the D.P.H. course in London, and after its completion I worked in Canada and the States. The course is divided in two parts: the preliminary part, leading to C.P.H., and introducing comprehensively the basic subjects and the historical background of public health, the syllabus of the second part being based on the student's direct and very active participation in the course. His duties are not only to listen and to learn, but to observe, to report, and to share his experience with his classmates and instructors during frequent class discussions or special seminars. Elective subjects and studies were encouraged according to the student's liking. Many problems are illustrated through excellently diversified field-visits and field-work. In retrospect, I recollect that course as a splendid example of instructors' and students' co-operation, based on the promotion of better human relationships and the application of the medical and scientific achievements to public health.

It must be extremely difficult for the committee responsible for the D.P.H. curriculum to decide what subjects should be actually taught and for how long. While the main object of public health is still the same as it was in Chadwick's and Shattuck's time, yet the tools and ways for its achievements have changed almost completely. In addition to epidemiology, sanitation, medical statistics, and public health administration, the sound knowledge of paediatrics, nutrition, psychology, and psychiatry is very indispensable to the public health physician working with a progressive community. The study of human relationships seems to be of the utmost importance, and it should be included in the curriculum besides the detailed studies of the environmental and genetic factors.

The idea of elective subjects introduced some time ago at the London School of Hygiene and Tropical Medicine features also the possibility of extending knowledge in particular subjects during the D.P.H. course. This, indeed, is proving to be very useful, as many public health physicians are performing duties limited to the special fields, as in the case of school medical officers, epidemiologists, haematologists, nutritionists, public health paediatricians, public health psychiatrists, etc. This trend and need for specialization within public health medicine may support the view that the curriculum for D.P.H. should be changed appropriately, and elective subjects extended to the various "specialties" within the public health curriculum.

It may also have to be considered seriously at the same time that not only the D.P.H. curriculum but also its name and the name of the diploma should be changed; likewise the name M.O.H. should be replaced by P.H.P., or public health physician.—I am, etc.,

Boston, Mass.

L. L. KULCZYCKI.

What is Encephlo?

SIR,—I would suggest that the answer to Dr. J. Cauchi's interesting query (*Journal*, December 19, 1953, p. 1378) is "erysipelas." If the late Robert Rawlinson, C.E., took the statement quoted in Dr. Cauchi's letter from a medical report, it would, at that time, have been in manuscript and probably written in the traditional obscure handwriting of a doctor.—I am, etc.,

Pangbourne, Berks.

ERIC DONALDSON.

Post-operative Backache in Women

SIR,—As a general practitioner I welcome Dr. E. Schleyer-Saunders's memorandum on post-operative backache in women (*Journal*, January 2, p. 28).

Before the use of relaxants in anaesthesia very few of my patients suffered in this way, but during the last 6-7 years there has been a succession of such cases in my practice, nearly all following operation or examination under anaesthesia in the lithotomy position. The most difficult have been those with symptoms of sacro-iliac subluxation, which have sometimes resisted prolonged treatment or relapsed at intervals, a characteristic sequel when those joints have been disturbed.

I have assumed that the lifting or lowering of one leg at a time has produced a torsion strain on a sacro-iliac joint in the absence of any protecting muscle tone. In many cases the backache has been only moderate in degree during the few days in bed and accepted up to a point by the patient, often without saying much about it in the ward. It is on returning home that the pain and fatigue are indignantly complained of, and all the more so if the operation in question was a trivial one. This condition may in fact be more familiar to the family doctor than to the gynaecological departments, which have sometimes disclaimed any responsibility in causing it.

A change in theatre drill and organization on the lines suggested in the memorandum would probably abolish this very troublesome and increasingly frequent sequel to operations which would otherwise be followed by the briefest convalescence without discomfort or disability. I am, etc.,

London, W.2.

ANNIS GILLIE.

The Accident-prone

SIR,—In the conclusion of his illuminating study of "The Accident-prone in General Practice" (*Journal*, December 12, 1953, p. 1306) Dr. R. M. McGregor refers to the importance of parallel studies. One such study, just published, by J. M. M. Hill and E. L. Trist,¹ is unlikely to come to the attention of your readers and may be briefly summarized here.

The study was of detailed four-year work records in a large iron and steel works. In such industrial studies it is possible to relate "withdrawal from work" due to sickness to that due to accidents and to what is known as "voluntary absence." Hill and Trist (in agreement with Dr. McGregor) find a positive correlation between absence due to accident and that due to sickness; but with the aid of additional figures they have shown an even stronger correlation between accidents and "voluntary absence." The work concerned is to be continued and offers strong evidence of the need to extend current studies in this field to include the characteristics of the social relationships of the individual, both in his work situation and elsewhere.—I am, etc.,

London, W.1.

A. T. M. WILSON.

REFERENCE

- 1 "A Consideration of Industrial Accidents as a Means of Withdrawal from the Work Situation," *Hum. Relat.*, 1953, 6, 357.

SIR,—I should like to pass certain comments on the article by Dr. R. M. McGregor entitled "The Accident-prone in General Practice" (*Journal*, December 12, 1953, p. 1306).

Urban dwellers are more accident-prone than countrymen.—Dr. McGregor assumes that all accidents in his practice are reported to him. Surely he realizes that the countryman, for reasons of distance and self-sufficiency, bred in the days of necessity when medical aid was not available, does not report many of the minor accidents that the urban dweller living near his doctor does. I suggest that it is this fact that Dr. McGregor's figures prove, and not, as he deduces, that the urban people are more accident-prone than the rural.

Existence of accident-prone people.—Surely it is agreed that clumsy people meet with more accidents than do the skilful. However, Dr. McGregor's figures do not prove

this; but rather that a man who reports one accident will report another, while another man would treat both himself and report neither to the doctor.

The accident-prone are illness-prone.—The figures given do not prove the above contention, but rather confirm my view that there are doctor-conscious patients who report every bruise or cold and self-reliant patients who do not trouble the doctor over trivialities.

Sex ratio of patients.—A cardinal factor affecting the reporting of accidents is the need for a certificate. Since Dr. McGregor does not confine his figures to insured persons, and since there is a much higher proportion of men insured than women, Dr. McGregor's conclusion, regarding the sex ratio of accidents is invalidated.

Change in sex ratio of accidents over 45 years of age.—May this not be apparent rather than real? I would suggest that many women under 45 have young children, and consequently ignore their minor accidents so that they can carry on their domestic responsibilities, whereas women over 45 have reached a stage in life where their duties are less onerous and they can indulge in the luxury of a little fuss, sympathy, and a trip to the doctor.—I am, etc.,

Wantage.

D. LEIGH.

Malaria Prophylaxis

SIR,—In view of the present interest in the new anti-malarials, I am sending you a record of two families here who have been taking pyrimethamine ("daraprim") 25 mg. weekly during the malaria transmission season, which has been more severe than usual owing to exceptionally heavy rains. Malaria here is almost entirely malignant tertian variety.

One family, that of the writer, who personally supervised the administration of the drug, consists of three English adults and three children under 4 years (non-immunes) and four Sudanese servants (immunes). All the adults, including the servants, have had pyrimethamine 25 mg. regularly once a week. The children have had half a tablet (12½ mg.) once a week. Four weeks after taking pyrimethamine, W.P., aged 2½ years, English (never had malaria), became irritable and feverish, temperature 99.4° F. (37.4° C.) (axillary), blood film: positive malignant tertian malaria. Cured by taking mepacrine ("atebrin") ½ tablet twice a day for five days.

After three months of continuous pyrimethamine prophylaxis, the following also had malaria: M.P., age 30, English (never had malaria), complained of severe headache. Temperature 100° F. (37.8° C.). Blood film: positive malignant tertian malaria. Cured with mepacrine (1 tablet three times a day) for five days; S.S., age 18, English (never had malaria), complained of cold for three days and severe headache. Temperature 99.4° F. (37.4° C.). Blood film: positive malignant tertian malaria. Cured with mepacrine (one tablet three times a day) for five days; R.P., age 10 months, English (never had malaria), cross and irritable for two days. Temperature 99.6° F. (37.55° C.) (axillary). Blood film: positive malignant tertian malaria. Cured with four intramuscular injections of quinine; J.P., age 35, English (had malignant tertian malaria once before in 1946). Temperature 102° F. (38.9° C.) Headache. Blood film not taken. Cured with camoquin (three tablets on first day and two on second day); A.N., Sudanese (Nuba), age about 34. Complained of cold and headaches for two days. Temperature 99.8° F. (37.4° C.). Blood film: positive malignant tertian malaria. Cured by four intramuscular injections of quinine; K.K., Sudanese (Nuba), age about 21, complained of pain in back and chest. Temperature 101° F. (38.3° C.). Blood film: positive malignant tertian malaria. Cured by four intramuscular injections of quinine; O.I., Sudanese (Darfuri), age about 26, complained of diarrhoea for two days. Temperature 99.2° F. (37.3° C.). Blood film: positive malignant tertian malaria. Now having mepacrine (one tablet three times a day); H.W., Sudanese (Darfuri), age about 55 years, complained of fever. Temperature 100° F. (37.8° C.). Blood film: positive malignant tertian malaria. Cured by four intramuscular injections of quinine.

The other family consists of two English adults and three children under 5 years. The adults have been taking pyrimethamine 25 mg. weekly, and two of the children half a tablet (12½ mg.) weekly, since their arrival from England in July, 1953. E.H., age 34, English. Temperature 99.6° F. (37.55° C.). Com-

plained of diarrhoea. Blood film: positive malignant tertian malaria. After taking mepacrine 1 tablet three times a day for five days, a second blood film was positive. She was then given four intramuscular injections of quinine; R.H., age 38, English (has had malaria before). Temperature 99.8° F. (37.7° C.). Complained of headache and lack of concentration. Blood film: positive malignant tertian malaria. Cured with camoquin three tablets on the first day, followed by two tablets on the second day; A.H., age 5, English (never had malaria before). Cross and irritable and mild diarrhoea. Temperature 99.4° F. (37.4° C.). Blood film positive malignant tertian malaria. Cured with mepacrine ½ tablet twice a day for five days; C.H., age 3, English (never had malaria). Temperature 99.8° F. (37.7° C.). Blood film: positive malignant tertian malaria. Cured with camoquin one tablet followed by one tablet on the following day; C.H., age 9 months, English, did not take pyrimethamine until a month ago when she had malaria, which was cured with four intramuscular injections of quinine. After that she had ½ tablet weekly for two weeks. Following this she again had diarrhoea. Temperature 99.4° F. (37.4° C.) (axillary). Blood film: positive malignant tertian malaria. Cured by intramuscular quinine.

Only one person in these households has not had malaria since taking pyrimethamine: E.P., age 4 (E.P. had a typical attack of malaria four months ago before taking pyrimethamine. Temperature 102° F. (38.9° C.) (axillary) with delirium). All the attacks have been mild and all the cases ambulant. One patient (E.H.) failed to respond to mepacrine therapy and had to have quinine. The two infants had quinine as they could not take mepacrine. Three Sudanese servants expressed a preference for quinine injections. Proguanil has been used prophylactically by a few English and Greek families resident in this area during the post-war period. The number of local Sudanese families taking the drug is probably less than 1%.

Although it appears to mitigate the attack, pyrimethamine in the dosage given appears to be quite inadequate in preventing attacks of malignant tertian malaria in Dueim.—I am, etc.,

Dueim, Sudan.

MARY G. PHILLIPS.

Partial Hepatectomy

SIR,—I read the very refreshing article by Sir Heneage Ogilvie on partial hepatectomy (*Journal*, November 21, 1953, p. 1136) with great interest, and I was particularly impressed by his description of a simple but extremely effective technique which I have never seen in use nor previously heard described. Apart from the subject of biopsy little has been published about partial hepatectomy either in connexion with malignant disease or otherwise. In this connexion the following case, with whose treatment I assisted Professor Mercer several years ago, is of interest.

A man, aged 64, complained of pain, sickness, severe borborygmi, flatulence, and diarrhoea for two and a half years. On examination he demonstrated the features of subacute small bowel obstruction and visible peristalsis was noted. Barium meal examination, with follow-through, showed an incomplete hold-up at the lower end of the ileum. Laparotomy revealed an almost complete obstruction at the lower end of the ileum of the string stricture type. The tumour was solitary, there was a little free fluid, but there was a superficial nodule approximately the size of a pigeon's egg on the lower part of the anterior surface of the right lobe of the liver. Resection and anastomosis of the affected portion of the bowel and its mesentery was carried out. The pathological report stated that the tumour was a carcinoid. In view of the accessibility of the only detected metastasis it was decided to excise the nodule from the liver. This operation was accordingly successfully performed 20 days later. The tumour was excised by diathermy and the cut liver edges exposed by deep sutures. The pathologist reported malignant carcinoid. The patient was discharged 16 days later and his doctor has written to say that he remained in good health, and fit for work, for over three years. Subsequently liver enlargement became evident and he eventually died three and a half years after operation.

Although the long-term result, in this case, was unsuccessful, the patient at least enjoyed a further three years of active life, and one can only speculate that probably he would not even have enjoyed this period if the liver nodule had not been removed.—I am, etc.,

Kirkcaldy.

WM. DRUMMOND.

Studies on Pancreatitis

SIR.—I read with much interest the instructive article "Studies in Pancreatitis" (*Journal*, December 19, 1953, p. 1335), and the authors are to be congratulated on endeavouring to throw some light on the vexed problems concerning the surgery of the pancreas.

However, few would agree that in cases of acute pancreatitis "if an occasional laparotomy is needlessly performed little harm to the patient is likely to follow." The consensus of opinion is that operative interference in acute pancreatitis carries a mortality of 30%, as compared with 3% treated symptomatically, and who are mostly fulminating cases who are doomed whatever may be done. Therefore every precaution must be taken to avoid laparotomy, even in the occasional case, and a valuable physical sign in acute pancreatitis is tenderness over the left renal angle—i.e., over the tail of the pancreas.

I have for many years been interested in the difficult problem of the "post-cholecystectomy syndrome," to which I have referred in a recent article.¹ My experience agrees with those expressed by the authors, with one exception. I believe that spasm, or even fibrosis of the sphincter of Oddi, is a definite clinical entity, manifested by recurrent attacks of dyspepsia, colicky pains, and even slight jaundice. These attacks are usually relieved by pethidine, but, if they incapacitate the patient, division of the sphincter, preferably by means of a sphincterotomy, not only relieves back pressure on the liver but also provides drainage of the main pancreatic duct, and thus lessens the risk of progressive infection. I have performed this operation on 14 patients, in 10 of whom symptoms were entirely relieved, and the remaining 4 were improved sufficiently enough to be grateful. —I am, etc.,

Appendicitis in the Course of Measles

SIR.—The article by Dr. W. H. Galloway on this subject (*Journal*, December 26, 1953, p. 1412) is of interest to all who have to deal with children, and especially those who have the difficult task of deciding whether the appendix of a young child is inflamed or no. There seem to be three points of importance.

(1) It might be better to separate off a group and call it pseudo-appendicitis. In Dr. Galloway's seven cases all the appendices were removed, but two were "apparently normal," one showed "slight redness," and one was "slightly inflamed." Lacking further details one can only suggest that these four were possibly removed unnecessarily. (2) In making a diagnosis, a count of the white blood cells may be useful. Dr. Galloway does not give his figures, but it is usual to find a leucopenia in early measles. I have notes of two cases which were seen last spring. They had both been admitted to hospital with the diagnosis of acute appendicitis. One, a boy of 7, had his appendix removed, and it was found to be covered with Koplik's spots but otherwise normal. A white blood count taken next day showed 7,500 cells per c.mm., of which 81% were polymorphs. The measles rash appeared two days later. In the other child, a girl of 4, the white blood count was 4,300, with 80% polymorphs. Operation was not performed; the rash appeared next day and she made a perfect recovery. (3) The routine use of sulphonamides in measles is important in preventing respiratory complications, especially in children under 3 years of age.

Obviously there are some cases where it would be dangerous to delay and exploratory laparotomy is essential; but as often as not the situation is not so grave and a period of observation in hospital with special attention to the search for Koplik's spots in the mouth and a white blood count may solve the problem without surgical and anaesthetic intervention.—I am, etc.,

Bath.

H. R. E. WALLIS.

The College of General Practitioners

SIR.—I really cannot allow to pass unchallenged Dr. J. Inglis Cameron's remarks in the *Journal* of December 19, 1953 (p. 1376), on the future of the College of General Practitioners. While it is not my purpose to argue with his suggestion that there should be no delay in applying for a royal charter, although it would seem to me that such an honour should be conferred upon a body which has proved its worth, I am wholly against advocating a registrable diploma of general practice.

Dr. Cameron's concern for improving the standard of general practice is, of course, understandable, but I am sure that his traditional plan for attaining this end is the wrong one. The mind boggles at the thought of yet another diploma to be added to the surfeit of examinations for this and that which we have already. And the fact that it will shortly be impossible to practise medicine at all after the completion of one's house appointments without a "higher qualification" makes a mockery of the qualifying examination. If it be true, as Dr. Cameron asserts, that the equality of colleges partly depends upon whether they are also examining bodies, then I am sure that, when it becomes widely appreciated that to-day one's diploma count is more important than one's experience, the problem will cease to exist among the ensuing inevitable and widespread changes. (If the loss of a lively source of income is felt too deeply, then I for one will be glad to subscribe to an annual flag day.)

No, let us resist the temptation to foster this present impossible system of promotion by creating an examination for general practitioners, and instead allow the College of General Practitioners to prove its worth by influencing the revolution in medical education which is now spluttering into life. Let it ensure that the curriculum for the qualifying examination is designed to produce general practitioners, and not housemen. Let it then encourage a system of promotion based on experience instead of academic honours. In this way, perhaps the new College will be able to find its own feet by helping to recover the dignity of the established royal colleges, which is waning in face of this craze for collecting diplomas instead of beer-bottle tops. Until then, we are in no position to ridicule the reasoning of the patient who prefers his general practitioner to be an M.R.C.S., L.R.C.P., rather than a plain M.B., B.S. "After all, has he not eight letters as against four? He must be twice as good!" I am, etc.,

Barnstable.

G. V. BALMFOURTH

Ferrous Sulphate Poisoning

SIR.—Dr. F. G. M. Ross's article (*Journal*, November 28, 1953, p. 1200) prompts us to record a similar case of pyloric obstruction following ferrous sulphate poisoning. At the same time we wish to support the views expressed in the leading article in the same issue on "Accidental Poisoning of Children" (p. 1207). These show there are many medicines prescribed for adults which should be labelled "Poisonous for Children," and in this particular instance the manufacturers of the green sugar-coated ferrous sulphate pills should also be urged to make their preparation less like "smarties," the sugar-coated chocolate sweets beloved by all small children. Attempts along these lines made by the Paediatric Department in Oxford have been unsuccessful, and it is to be hoped that another appeal with the weight of the B.M.A. behind it may be more effective. Ferrous sulphate is extensively prescribed for mothers attending antenatal and post-natal clinics, and after the arrival of the new babe it has seemed to us that it is the toddler of 1-2 years, temporarily less well supervised, who is in danger; certainly the majority of the seven cases seen here in the last three years fall into this category.

A baby girl, aged 16 months, arrived in hospital from the country just over an hour after swallowing an unknown number of ferrous sulphate tablets, 20 of which she had vomited immediately. She was pale and restless on admission, and vomiting

blood-stained fluid; a stomach washout with sodium bicarbonate produced more fresh and altered blood, but no tablets. She continued to vomit, and at the end of 24 hours looked ill and shocked. Her haemoglobin had fallen to 55%, so she was given a small blood transfusion, followed by one of glucose saline to maintain hydration. Her condition then steadily improved and she was discharged well after 12 days, taking a light diet without vomiting, and weighing 18 lb. 10 oz. (8.38 kg.). Seen after three weeks, her appetite was said to have been poor, she had vomited occasionally, but had gained weight. Seen again four weeks later, however, she presented with symptoms of pyloric obstruction, weighing only 15 lb. 11 oz. (7.06 kg.).

Before operation.

3 1/2 months after operation.

At operation many adhesions were found between the stomach and surrounding viscera, and in particular those between stomach and liver were so tough as to necessitate sharp dissection for their separation. The distal half of the stomach was thickened, rigid and fibrotic, the proximal half was hypertrophied and dilated, but was otherwise normal, as was the duodenum. The fibrotic portion of stomach was resected, a Billroth I type of partial gastrectomy being performed. The post-operative course was satisfactory, and a rapid gain of 4 lb. (1.8 kg.) in the first four weeks occurred. Subsequent progress during the past two years has continued to be good.

The pathologist's report on the portion of stomach removed stated: "The gastric wall almost up to the upper limit of resection was grossly fibrotic and 0.75 cm. in thickness. The mucosal surface had a granular brownish appearance, and the lumen of the whole pyloric antrum and pylorus was narrowed to about 0.1 cm. diameter. Histology: Over part of the specimen gastric mucosa remains, while elsewhere this is replaced by a granulation tissue layer in areas of ulceration, or by squamous epithelium which is presumably due to metaplasia. The mucosa shows slight irregularity of pattern, with scattered small cysts lined by flattened epithelium, and exaggerated mucus secretion. The squamous epithelium is regular with no invasive tendency. The submucosa and granulation tissue are congested and oedematous, with a very dense inflammatory exudate including polymorphonuclear leucocytes, plasma cells, and lymphocytes. The muscularis and subserosa are also congested, with interstitial haemorrhage, but here the most obvious change is a diffuse fibroblastic proliferation. Inflammatory infiltration similar to that in the submucosa extends down into these layers, chiefly around vessels, and iron-containing histiocytes are present in large aggregates. The mucosal cells give only a weak staining reaction for iron, and the histiocytic accumulations may be due to interstitial haemorrhage, but their extreme frequency makes this unlikely. A thin fibrinous layer covers the serosa. The appearances as a whole are in keeping with a corrosive poison, and the intra-epithelial iron is a strong indication that the poison was or included an iron compound."

It is evident that "pyloric obstruction" does not adequately describe the pathological lesion, which is in fact an extensive fibrosis affecting all coats of the distal half of the stomach and leading to a near obliteration of its lumen.

In these cases of poisoning it appears that the children swallow the tablets whole, and it is only after the sugar coating dissolves that the caustic action of the ferrous sulphate occurs. The oesophagus, therefore, escapes completely, and it follows that the maximum damage is done to the pyloric end of the stomach. This is borne out in Ross's case, where the x-ray several days before operation showed obstruction to barium in the distal half of the stomach. The appropriate treatment must be, therefore, to relieve the gastric obstruction by a gastro-enterostomy or gastrectomy.—We are, etc.,

A. ELLIOT-SMITH.

Tales of a Pomander

SIR.—Professor Charles Singer (*Journal*, December 19, 1953, p. 1373) is surely wrong in stating that Richard Mead made no important contribution to medical science. In 1748 Mead first described the occurrence of fatty liver in a case of diabetes mellitus, and held the view that the liver was in some way concerned in the aetiology of the disease. This was quite revolutionary in an age when medical opinion was divided between those who believed diabetes mellitus to be due to a "disordered assimilation," by the intestines and those who supported the theory of a "morbid affliction" of the kidneys, and, of course, antedated Claude Bernard's important discoveries by a hundred years. The wonder is that any man with Mead's reputation as a practising physician could have found the time to indulge in medical research.—I am, etc.,

London, S.E.1.

A. PATON.

Medical Needs in the Gold Coast

SIR.—Dr. D. B. Scott's letter (*Journal*, December 19, 1953, p. 1377) is very interesting. First, let me say that I was in the Gold Coast Medical Service until June, 1953—not years ago. Next, it is certain that the Government would eagerly offer permanent pensionable posts to specialists if they could be found. The response to advertisements has been uniformly poor, so, rightly or wrongly, they seem to think that if they offered contract terms a few highly qualified men could be found by a form of secondment. For instance, a consultant could go to the Gold Coast to do, say, two tours with full assurance that only strictly temporary locums would assist his group in his absence. After his contract he would then be able to return to his former job invigorated, having also given new vitality to the Colony. This scheme is clearly capable of development and diversification. In the interest of avoiding waste of professional men, could the B.M.A. not usefully press for S.H.M.O. posts for ex-colonial specialists and for similar measures?

Finally, a vague air of dissatisfaction surrounds Dr. Scott's letter, and the reason for it is not quite clear. There are at least two fellow Cambridge men in the Gold Coast Medical Service, recently employed, who show every sign of enjoying their work.—I am, etc.,

Manchester.

K. A. TAYLOR.

Distinguishing a Psychopath

SIR.—The exchange of views between eminent legal and psychiatric experts on the definition of a psychopath (*Journal*, November 28, 1953, p. 1224) serves to show how difficult it is for lawyers and alienists to attain mutual understanding. The crux of the problem appears to lie in the fact that lawyers, accustomed to dealing in tangibles, are for ever pressing the psychiatrist to confine himself to nice definitions. Although the diagnostic term "psychopathic personality" is widely recognized among psychiatrists, nobody has succeeded in defining it in a universally acceptable or succinct manner. The definition given by Dr. Denis Hill to the Royal Commission on Capital Punishment stresses

the violent propensities of the aggressive psychopath, but psychopaths are not necessarily aggressive or impulsive. Indeed, the inadequate psychopath may be totally lacking in these qualities. The definition of psychopaths (used by Mr. Christmas Humphreys) as "those persons who do not suffer from a disease of the mind, but suffer from some form of character deficiency or emotional instability which makes it impossible for them to enter into normal contact with society," is much broader than that attributed to Dr. Hill. However, it must be as difficult to define "normal contact with society" as to define "normal behaviour." The latter definition might perhaps be strengthened if the words "from a disease of the mind" were altered to read "from one of the well recognized diseases of the mind," and the words "normal contact with society" changed to "harmonious contact with society." Dr. A. Shepherd's definition (*Journal*, December 19, 1953, p. 1379) lacks the virtue of brevity, yet it fails to cover the cardinal features of all types of psychopath.

Criticism of the above definitions has been made to support a belief that a psychopathic personality defies precise definition. The term psychopathic personality has been frequently stretched to include not only personalities displaying immaturity with volcanic aggressiveness, but chronic liars, spongers, swindlers, vagrants, perverts, and addicts. Clearly, it is impossible to adopt a Procrustean attitude towards such a motley group of social misfits. Nevertheless, it would make medico-legal practice easier if lawyers and psychiatrists could agree on some broad, working "definition" of a psychopath (like that quoted by Mr. Humphreys) leaving the interpretation of such expressions as "abnormal behaviour" and "normal contact with society" to the common sense of judge, jury, and counsel.—I am, etc.,

Littlemore, Oxford.

J. TODD.

SIR,—The definition by Dr. Denis Hill (*Journal*, November 28, 1953, p. 1224), as is the case of all other definitions, invites criticism. The most obvious weakness lies in the word "abnormal," which is repeated three times. Mr. Justice Hilbery did not hesitate to pounce upon this, and sought definitions of "abnormal" and "normal" behaviour—which of course were not forthcoming. I doubt whether it is possible to define these terms accurately, any more than it is possible to define insanity and sanity; and similarly I do not believe it is possible to define clearly what constitutes "psychopathic behaviour." The only definition of psychopathic personality that I like at all is the quotation given at the beginning of a paper by Drs. Curran and Mallinson: "I can't define an elephant; but I know one when I see one." Unfortunately this can be readily criticized as having the flaw of a variable, personal bias.

The other observation I would make is that positive types of abnormal behaviour are referred to, but not negative types. Violent outbursts of temper can certainly be pathological, but a poverty of emotional reactivity is surely just as pathological. There are passive, relatively unemotional psychopaths who fall into criminality through such negative constitutional failings, often being the tools of aggressive psychopaths; and if we are to claim some measure of diminished responsibility for the latter we should logically also demand a similar privilege for the former.

Finally, I would point out that Dr. Hill's definition can be descriptive of some cases of cyclothymic illness, and is therefore not exclusive.—I am, etc.,

I. ATKIN.

Treatment of Blood Disorders with A.C.T.H. and Cortisone

SIR,—The M.R.C. Haematology Panel has again published a report to the Medical Research Council (*Journal*, December 26, 1953, p. 1400); and it is difficult to imagine how it can be of use to the practising physician, even although it may quite possibly be what the Council requires. The first

report made the task of the haematological physician much more difficult than it need have been, because competent general practitioners, who had read that "A.C.T.H. and cortisone, as at present used, are not likely to have an important part to play in the treatment of disorders of the blood" were not keen on co-operating with those of us who, aware of the work of Dameshek,¹ wanted to treat cases of acquired haemolytic jaundice with these hormones. The second report is not likely to be quite such a nuisance, but it will certainly not be a help. Thus there is the veiled suggestion that if A.C.T.H. in adequate dosage fails, as it did in two of the Panel's cases, cortisone will be equally useless. And this suggestion seems to be based on failure in the only case in which cortisone was given—in inadequate amounts. My own (inevitably small) experience has clearly shown that there are cases in which A.C.T.H. fails to arrest the haemolytic process, whereas cortisone will do so. And I am not alone in this experience: Aitchison² has demonstrated the fact quite clearly.

This letter is not intended to record my experiences in the treatment of acquired haemolytic jaundice with A.C.T.H. and cortisone, but to pose the question whether such reports as the present one should not remain in the archives of the M.R.C., because in my opinion they can be no use to the practitioners for whom they are intended, and can, indeed, do great harm by discouraging physicians who have little experience in clinical haematology.—I am, etc.,

London, W.1.

SIR,—The second report to the M.R.C. (*Journal*, December 26, 1953, p. 1400) records a more favourable impression of the value of A.C.T.H. and cortisone in the treatment of acquired haemolytic anaemia and thrombocytopenic purpura. In deciding to concentrate in future on the long-term treatment of these two conditions the advisory panel of haematologists may discourage the use of cortisone in the non-thrombocytopenic purpuras, notably Schönlein-Henoch disease. The value of any treatment is difficult to assess where spontaneous remission is the rule rather than the exception, and not unnaturally opinions differ.

Professor L. S. P. Davidson *et al.* (*Journal*, November 15, 1952, p. 1059) recorded no beneficial results from hormonal treatment of four cases of non-thrombocytopenic purpura (allergic). Dr. M. G. Philpott refers (*Journal*, October 24, 1953, p. 937) to nine children who did not respond although severe constitutional disturbances might have been alleviated as in one of Davidson's cases. Dr. M. Stephanini (*Lancet*, September 19, 1953, p. 620) in a similar series of nine children believed that A.C.T.H. was of great value even if it might not modify the pathogenetic mechanism of the disease. Unlike Philpott he thought that the improvement in cases which did respond was "too prompt to be exclusively due to spontaneous recovery." Dr. D. G. Adamson *et al.* (*Journal*, September 19, 1953, p. 656) obtained an apparently conclusive response in a girl of 13 years. From personal experience I know that cortisone promptly controlled the abdominal features of Schönlein-Henoch purpura which had increased in severity for three weeks during which time all other treatment had been tried by my most skilled and attentive colleagues. The associated joint pains also responded, but the purpuric spots persisted for long after the cessation of cortisone treatment (28 days).

So long as the existence of purpura and positive capillary tests applied to the skin are regarded as the criteria of non-success then such cases must be recorded as failures of hormonal therapy despite the dramatic and possibly life-saving effect of cortisone or A.C.T.H. on the visceral lesions in certain cases. Purpura of the skin may be produced by minimal disturbances and accentuated by mechanical considerations. It may be illogical to associate its pathogenesis directly with that of the viscera despite the

fact that the only abnormality in the classical Schönlein-Henoch syndrome is diminished capillary resistance. It is likewise generally accepted that the syndrome is an allergic phenomenon despite the fact that the allergen is rarely, if ever, found and no response is elicited by antihistamine drugs.

So little is known of its pathogenesis, or for that matter of the action of cortisone or A.C.T.H., that one cannot say with any certainty that hormone treatment is either useless or specific. At the same time there would appear to be enough justification to administer cortisone or A.C.T.H. in full doses to every case of Schönlein-Henoch purpura, bearing in mind that spontaneous remission, in this admittedly rare disease, is not the foregone conclusion that some present-day clinicians might have us believe.—I am, etc.,

A Cosmetic Amputation

SIR,—What Sir Heneage Ogilvie said in his letter (*Journal*, December 12, 1953, p. 1322) appealed to me so much that I wrote and told him so. I am consequently bound to express a little surprise that Mr. Ian Lawson Dick (*Journal*, January 2, p. 45) differs so markedly. It may be that in time his views will change.

Some years ago I also was impressed and attracted by this "cosmetic" operation—"nobody notices that there are only three fingers," "the 'knob' does not catch on openings of pockets or bags," and so on. But with the passage of time I have come to the conclusion that on balance the cosmetic gain does not by any means justify the functional loss. With the head of the metacarpal many manual assets including the "hollow of the hand" disappeared, but, what is more important, the control of which the hand is capable is seriously impaired. I say that the operation should never be performed on manual workers, and that even for other patients it should be used only after the most careful consideration and explanation. I am, in fact, inclined now to advise such patients for whom the metacarpal amputation appears to be justified by diminution of disfigurement and of convenience to wait and see how much inconvenience the metacarpal knob really causes before they have it removed. "Two bites at a cherry"—I know, and quite right too.—I am, etc.,

BRYAN MCFARLAND.

Whither Anaesthesia?

SIR,—In Dr. C. Langton Hewer's letter (*Journal*, January 2, p. 42) he poses the question "Whither Anaesthesia?" and criticizes the new approach to anaesthetic problems. It is, of course, impossible to hazard a guess as to where physiological and pharmacological research may lead us in the near future. It appears to us that if we are to fulfil our duty to our patients we must take advantage of every means by which they may be protected from the effects of surgical aggression.

Anaesthetic techniques in general use to-day, however skilfully employed, and with the aid of supportive measures, have well recognized limitations. In fact the term "anaesthetic shock" is still in current use. The precise physiological mechanism by which surgical shock is induced is not completely understood; but the factors which lead to the onset of shock in surgical procedures are well known. These have been admirably classified by Dr. Langton Hewer himself.¹ By the use of the artificial hibernation technique, reaction to all but one of these causes is removed or diminished. As we have already stated (*Journal*, December 5, 1953, p. 1247), the circulating blood volume must be maintained. In the beginning we employed this technique only in those cases where operation could not otherwise have been contemplated. Our experience of what must necessarily be a small series of this type was so encouraging that we felt that an exchange of views with other workers in this field would be an advantage. We hope soon to publish a much larger series of results.

In answer to Dr. Hewer's charges that the technique is complicated and uses a multiplicity of drugs, we would point out that it is extremely simple, and, in fact, fewer drugs are used than in many methods in current use. We have in the past used these drugs, pethidine, promethazine, and chlorpromazine, as adjuvants to normal anaesthesia. We found this line of research impractical, as the results were equivocal and any improvement could not be definitely attributed to the drug under investigation. It is also suggested that paralytic ileus and pulmonary complications are more frequent. This is certainly not so where hibernation alone is employed. Physical cooling introduces additional hazards and has not been employed by us.

Dr. Langton Hewer is concerned about the term "artificial hibernation." We have taken pains to point out that it is not a truly comparable state to that found in the hibernant mammal, but is a term we have used to avoid confusion with methods employing active physical cooling. We await another Oliver Wendell Holmes to improve on it.—We are, etc.,

ANGUS SMITH.

Management of Ulcerative Colitis

SIR,—May we comment upon the annotation on the management of ulcerative colitis (*Journal*, December 19, 1953, p. 1364) and challenge the traditional view that patients with this disease are primarily "inadequate and dependent sufferers"—a belief that leads many to regard it as a disorder of psychogenic origin? Wittkower did, indeed, find that in many patients psychological abnormalities were present before the colitis began; but he also found the same in patients suffering from pulmonary tuberculosis.¹

We would again raise the *post hoc propter hoc* argument and submit that the personality features of those with ulcerative colitis, such as lack of aggressiveness, timidity, reliance on others, undue resentment of the disease, and "immaturity," are the result of months or years of diarrhoea—the most humiliating and incapacitating of symptoms. No one has, or is ever likely, to study the personalities of the patients before the complaint begins. Now, however, many have been restored to a normal active life by surgery and an efficient ileostomy bag; the observation of these is far more important than any psychiatric assessments made during the course of the illness. This group of patients that have been "cured" seem to us to be a remarkably normal cross-section of the community. There are 70 cases who regularly attend this centre for follow-up review; all except three have by now returned to a full-time job. The women have had no difficulty in adjusting themselves to family life, socially and from the sexual aspect; the complete range from labourer to teaching and high executive posts with heavy responsibilities is represented by jobs now undertaken by our male patients. As individuals they appear to be as capable of enjoying life as their more fortunate fellows who have not been afflicted with this disease. Many have been seen regularly over five years or more and are strikingly free from neurotic traits or induced symptoms. They have not been submitted to psychiatric assessment; yet it may be that our personal and intimate knowledge of them over a period of time is as valuable as an interview with a psychiatrist.

Psychological factors are important in every case of diarrhoea, whether this be due to ulcerative colitis, steatorrhoea, or Crohn's disease, for the influence of the mind on the alimentary tract is great. We ourselves believe that any of these diseases will produce the same type of personality if the diarrhoea is sufficiently prolonged, but that this will disappear when it is relieved.—We are, etc.,

Obituary

LORD GEDDES, P.C., G.C.M.G., K.C.B., M.D.

The career of Lord Geddes, who died in hospital at Chichester on January 8, furnishes another instance of a man who turned from medicine to serve the State in many high capacities, including that of Ambassador to the United States.

Auckland Campbell Geddes was born on June 21, 1879, in London, and was educated at George Watson's College and at Edinburgh University. His studies were interrupted by the South African war, in which he served as lieutenant with the third Highland Light

(Elliot & Fry, Ltd., London)

Infantry. Returning to Edinburgh for his medical studies—he was one of Sir William Turner's pupils—he graduated M.B., Ch.B., with honours, in 1903. He took a prominent part in university life and played in the first Rugby football fifteen. After postgraduate study on the Continent he won the gold medal for his M.D. thesis in 1908. His first appointment was that of demonstrator and assistant professor of anatomy at Edinburgh, and later he became professor of

anatomy of the Royal College of Surgeons in Ireland. In 1910 he was secretary of the Section of Anatomy at the B.M.A. Annual Meeting, and in 1912 vice-president of the same Section.

His next appointment was to the chair of anatomy at McGill University, Montreal, but when war broke out in 1914 he obtained extended leave and recrossed the Atlantic, serving first with the Northumberland Fusiliers on the east coast of England and in 1915 and 1916 in France, where he was promoted brevet lieutenant-colonel for gallant and distinguished conduct in the field. He served for a time with great success as Deputy Assistant Adjutant General and came to the notice of the war leaders. The Prime Minister at that time, Mr. Lloyd George, had a great opinion of the abilities of Auckland Geddes and of his brother Eric, and Auckland was made Director of Recruiting at the War Office in 1916. In the following year he became Minister of National Service at a time when Britain was being fitted into the unfamiliar and uneasy battle-dress of conscription. He entered Parliament for Basingstoke and Andover in 1917, and his first task was to introduce a Military Service Bill.

In 1918 Sir Auckland Geddes, as he had now become, was made President of the Local Government Board, while retaining his position as Minister of National Service. The days of the Local Government Board were numbered, for the Ministry of Health was in the offing. *This Journal*, in acclaiming the appointment of a medical man to this position, said that no doubt the state of the physical fitness of the nation, which had been brought home to the Minister of National Service as a result of the recruiting figures, would influence the

advice he gave to his Cabinet colleagues on the establishment of the Ministry of Health. Geddes, however, was not destined to be the first Minister of Health; that post, by a coincidence, was for another anatomist, Dr. Christopher (later Lord) Addison. Geddes continued as Minister of National Service, a Ministry which, with the end of the war, had left the active for the passive stage, and to this was added the Ministry of Reconstruction, which really meant that he shouldered a principal responsibility for demobilization. Later in 1919 for a brief period he followed Lord Ashfield as President of the Board of Trade.

In 1919 an invitation came to him to return to McGill, this time as Principal, his duties to begin in the autumn of that year. He had no sooner accepted the appointment than he had to resign it, for early in 1920 he was appointed British Ambassador in Washington. In spite of some expectation to the contrary he did well in this post and added to his already great reputation. Unfortunately serious eye trouble forced him to resign in 1924. Later he forsook both the academic world and the world of politics and diplomacy and became immersed in big business, being chairman of the Rio Tinto Company and interested in other corporations.

Early in 1939 the imminence of war again brought him into public prominence. He was appointed regional commissioner for the south-eastern district of England, with headquarters at Tunbridge Wells, to direct civil defence. He resigned this post in September, 1941, for he had to undergo an operation for cataract, resulting from a burn of the right eye (he had lost the sight of his left eye while serving in Washington). His recovery was a good one, and in December, 1941, he was made regional commissioner for the north-western region, but owing to impairment of his general health he was compelled to resign this appointment also. For the last few years of his life he had been totally blind.

In the New Year's honours in 1942 he was raised to the peerage as Baron Geddes of Rolvenden, where he had a country house in Kent. He had been created K.C.B. in 1917 and G.C.M.G. in 1922. Lord Geddes married in 1906 Isabella Gamble, the daughter of W. A. Ross, of New York, and had four sons and one daughter.

CYRIL LEWIS, M.D.

Dr. Cyril Lewis, one of the oldest and most respected physicians in South Wales, died peacefully at his home at Cardiff on December 30, 1953, in his 85th year. His death severs a link with bygone medicine. His father, a doctor, born in the year of Waterloo, was apprenticed to a Dr. Watkins, and was educated at University College Hospital, London, where he was gold medallist in surgery. He qualified in 1838 and later took the M.D. and the M.R.C.P. After holding resident appointments at University College Hospital for two years, he returned to his native Carmarthen, where he practised for many years and was physician to the Carmarthen-shire Infirmary. He was a justice of the peace and lived to the age of 87.

Born in 1869, Cyril Lewis was educated at Carmarthen Grammar School, at Bedford School, and at Edinburgh University, where he graduated M.B., Ch.B., in 1891. He proceeded to the M.D. six years later, receiving a commendation for his thesis. After graduation he acted as assistant medical officer to the Mental

Hospital at Carmarthen for three months, and in 1892 became resident medical officer at the Royal National Hospital for Diseases of the Chest, Ventnor, "at a salary of £100 a year," which after 18 months was increased to £120 and later to £150. After six and a half years at Ventnor he went to the Metropolitan Hospital, London, as senior house-physician "at a salary at the rate of £40 a year with board, washing, and lodging." In 1899 he became house-physician to Birmingham General Hospital, and was there for two years. In 1902 he settled in practice at Cardiff, being elected honorary anaesthetist to Cardiff Royal Infirmary later in the same year. Early in 1906 he was appointed honorary assistant physician to the Royal Infirmary, and in 1913 was promoted to the senior staff as honorary physician, which post he held until he reached the age of retirement in 1934. Throughout the 1914-18 war he served as a major on the staff of the Third Western General Hospital, and in the last war he gave his services to the Military Hospital at Whitechurch and the Prince of Wales Hospital, Cardiff.

A knowledgeable physician who enjoyed the practice of medicine, Dr. Lewis visited his wards almost daily and would never fail to call to see every emergency admitted to them. Always willing and eager to try new remedies, he never forgot that his patients were human beings with individual personalities and physiques, and he took both into account when considering diagnosis and treatment. For many years he gave the lectures in medicine to the nurses at the Royal Infirmary, and on the establishment of the Welsh National School of Medicine in 1931 he became a recognized clinical teacher. He took a keen personal interest in his students and in the welfare of his old house-physicians, and was not averse to dropping hints to them on "suitable young ladies." He himself married a trained nurse and held the firm view that nurses made the best of wives.

As a man Dr. Lewis was completely unselfish, self-effacing to a degree, full of sympathetic understanding, kindness, and never-failing courtesy. He treated all alike, from the junior probationer to the senior surgeon. He was a good amateur carpenter and mechanic, and at his home had a fitted workshop where he loved to pass his spare time making all sorts of things. Failing health obliged him to give up active work in 1946, and, although confined to the house for the 12 months preceding his death, he was alert mentally to the end and ever interested in all that was going on. Out of the fullness of years his reminiscences of men and affairs were always most informing:

"His head was silvered o'er with age,
And long experience made him sage."

In his younger days Dr. Lewis was extremely versatile. While at Edinburgh he served in the volunteer medical staff corps and attained the rank of staff sergeant. He was a great cyclist, and is known to have cycled on a "penny-farthing" machine from Edinburgh to his home in Carmarthen for his holidays. He was a good tennis player and had played in amateur tournaments. Having a knowledge of music and a good voice, he was active in organizing and taking part in entertainments for patients when he was a resident medical officer. At Ventnor, in particular, he did much to help in the amusement of the patients. He took part in concerts and amateur theatricals not only at the hospital but also at the local assembly rooms, and, being an excellent

performer, often gave solos on the flute. When he left Ventnor a most successful farewell concert was arranged in his honour, and a clock and an illuminated address were presented to him. On leaving the hospital the patients and staff lined the drive and cheered him on his way. Thus in his young days, as in his old, he was sincerely loved by all. A member of the British Medical Association for 61 years, he was one of the two honorary secretaries of the Cardiff Division from 1907 to 1912, and in 1928, when the Association held its Annual Meeting at Cardiff, he served as a vice-president of the Section of Medicine. The funeral service was held at St. Andrew's Church, Cardiff, where he had been a churchwarden for 35 years. He is survived by his widow and two sons, one of whom is a member of the medical profession in practice at Hove.—A.M.K.

Dr. JAMES WARNOCK, who died at Oxford on December 4, 1953, at the age of 74, was for 40 years a well-known general practitioner in Leeds. As a student he had a distinguished career at Queen's College, Galway, and at Belfast. He took the B.A. of the Royal University of Ireland in 1901, gaining first place and first-class honours, and when he proceeded to the M.A. two years later he obtained first-class honours in mathematics and was awarded a special prize. He then entered the faculty of medicine and graduated M.B., B.Ch., B.A.O. in 1906, gaining first-class honours. He rounded off his scholastic record by winning a gold medal when he proceeded to the M.D. in 1908. In the following year he settled in general practice at Leeds, where he remained until he retired to live at Abingdon, Berkshire, in 1949. He served with distinction in the first world war, being mentioned in dispatches, and in 1919 he was appointed O.B.E. On returning to civilian life he built up an extensive family practice, while as certifying factory surgeon he took a special interest in industrial medicine long before it became a vogue. A shrewd and sound clinician, he was a family doctor of the old school, enjoying to the full the confidence and affection of his patients, notwithstanding his absolute frankness, for he had no time for any humbug or window dressing. Of a somewhat shy and diffident nature, he took little part in public affairs, although he was prevailed upon to serve on the executive of the Leeds Division of the B.M.A. for a time and was chairman of the Division in 1934-5. Dr. Warnock was a man of considerable culture and erudition. The study of higher mathematics remained an engaging passion to the end of his life; it was not uncommon to find him after his afternoon surgery deeply engrossed in some problem of the calculus. His other hobbies showed the same love of refined detail and scrupulous exactitude, although in a more practical form. He made furniture of a very high order of craftsmanship, while his inlaid trays and mirrors were especially attractive. In his latter years he took up bookbinding with the same enthusiasm and attention to detail. All these additional accomplishments made him an arresting personality and a rather unique type of family doctor. His passing is a great loss to his many friends and medical colleagues. Dr. Warnock is survived by his wife, a married daughter, and a son, Mr. G. J. Warnock, who is a Fellow and tutor of philosophy of Magdalen College, Oxford.—W. MACA.

Dr. HANS SCHAEFER, a well-known general practitioner at Enfield, Middlesex, died in a London nursing-home on December 14, 1953, after a short illness. He was born on February 15, 1888, and was educated in Berlin. After qualifying, he worked as a surgeon in several hospitals there, and in 1923 became assistant in Professor Borchardt's surgical department. Later Dr. Schaefer established his own general practice, while still retaining his keen interest in orthopaedic and plastic surgery. In 1934 he

came to England, and after re-qualifying in Scotland in 1936 he settled again in general practice in the Enfield area, where he soon acquired an excellent reputation among his patients, to whom he became not only a medical adviser but a good friend. His chief interest outside his professional life was sculpture, and he was himself an artist of exceptional ability. To all his friends he was a man of eternal youth and of unfailing charm and kindness; in spite of his brilliant attributes he remained always humble. Our deep sympathy is extended to his widow.—E. G.

The death occurred on December 27, 1953, of Dr. JAMES GILCHRIST in a nursing-home at Sydenham, where he had been in general practice for nearly half a century. He was 76 years of age. James Gilchrist was born in Aberdeenshire on July 4, 1877, and from the local grammar school he entered Aberdeen University in 1894, graduating M.A. in 1898, and taking the degrees of M.B., Ch.B. three years later. After five years spent chiefly in private practice he proceeded to the M.D. in 1906, and then settled in general practice in Sydenham. From 1918 to 1930 he was honorary surgeon to the South-eastern Hospital for Children at Sydenham, and for many years was medical officer to the Passmore Edwards Teachers' Home, district medical officer to the Post Office, and medical referee to assurance companies. A member of the British Medical Association for 40 years, he was chairman of the Lewisham Division in 1923-4, and represented the division at the Annual Representative Meeting held at Glasgow in 1922. From 1928 to 1950 he was treasurer of the Sydenham District Medical Society, which he joined in 1909, and proved himself a prudent adviser. He had also been president of the society. His great sense of humour was very much appreciated by his fellow members, to whom he would relate anecdotes in a way that was all his own. "Gilly," as he was known to his many friends, was a pattern of the old kind of family doctor; a good physician and surgeon, he devoted his life to the relief of suffering in others, and was well loved by his patients. He is survived by his widow, who was a most devoted helpmeet in his practice, and two sons, both members of the medical profession, the elder being a wing commander in the Royal Air Force and the younger a member of the Colonial Medical Service.—F. M. B.

Dr. BERNARD RIVIERE died at his home at Salhouse, near Norwich, on December 27, 1953, at the age of 73. He retired from general and surgical practice in Norwich nearly thirty years ago, and this enabled him to give more time to ornithology, on which he was a well-known authority. Bernard Beryl Riviere was born in London on April 13, 1880, the son of Briton Riviere, a Royal Academician, from whom he inherited some of his artistic talent. Educated at St. Paul's School, London, and at St. Andrews University, he received his clinical training at St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P. in 1904. Two years later he obtained the diploma of F.R.C.S. After qualification he held the appointments of house-surgeon at Bart's, clinical assistant at the East London Hospital for Children, and house-physician at Birmingham General Hospital. Then, in 1908, he joined a partnership in Norwich, where he also became honorary surgeon to the Jenny Lind Hospital. In 1914, for health reasons, he was obliged to leave Norwich, and for the next two years lived in Switzerland and South Africa. On his return to England he resumed his medical work at Norwich until the mid-twenties, when increasing anxiety about his health forced him to retire. Eventually he made a good recovery, and in 1929 he was appointed to the board of the Norwich Union Insurance Societies. He took an increasingly important part in the business and for a short time during the last war he was vice-president of the Norwich Union Life Society. He was also a trustee of the East Anglian Trustee Savings Bank. Always a keen naturalist, Dr. Riviere had been a

member of the Norfolk and Norwich Naturalist Society for 45 years, serving a term as president, and he was also treasurer of the Norfolk Naturalists' Trust. In 1930 he published *A History of the Birds of Norfolk*, the best work on the subject there is. He was also the author of many pleasantly written articles on the habits of individual birds. In 1927 he was co-opted a member of the Norwich Museums Committee, his knowledge of natural history and art proving of great value in the work of the committee. As an artist he had a number of small works of sculpture to his credit, and he was a member of the Norfolk and Norwich Art Circle. He is survived by a widow, formerly Miss Veronica Mack, and three sons.

Dr. MONTAGUE WAY, a member of a well-known Portsmouth family, died at his home at Southsea on December 30, 1953, at the age of 78. Montague Harold Way was a medical student at Guy's Hospital, where he held the post of house-surgeon after qualifying in 1897. After a short period of service in India as a plague medical officer he returned to England and went into practice in Portsmouth, where he had been senior house-surgeon at the Royal Portsmouth Hospital. In addition to devoting himself to his steadily growing practice, Dr. Way took a great interest in public affairs and was a member of the Portsmouth City Council for eight years. He was also a past chairman of the Portsmouth Conservative and Unionist Association. In 1926 he was appointed a justice of the peace. For 13 years he was a member of the old Portsmouth Insurance Committee and its chairman in 1930-1; he was also a member of the local panel committee and for a number of years attended the annual Panel Conference. During the first world war he served as a captain in the R.A.M.C. at the 5th Southern General Hospital and in Salonika. A member of the British Medical Association for 56 years, he was chairman of the Portsmouth Division in 1924-5. He retired from practice as long ago as 1932. Seven years later he was appointed O.B.E. in recognition of his political and public services.

M. A. K. writes: The death of Dr. Montague Way has removed from the ranks of general practitioners in Portsmouth a notable member. His father was a well-known Portsmouth solicitor, and his uncle was equally well known as a doctor in Portsmouth before him so that he inherited a name already well respected and appreciated in the city. Municipal and magisterial honours followed in due course and were combined with much activity in politics, horticulture, and other interests. He was a frequent attendee at B.M.A. meetings almost to the end of his life. But it is in the hearts of his patients that a family doctor's memory may be enshrined, and this can be said of Dr. Montague Way. He leaves two sons, Dr. John Way, of Hordle, and Mr. Paul Way, of London, by his first wife. He afterwards married Miss Scott Foster, a daughter of Sir Scott Foster, a previous Lord Mayor of Portsmouth. To his widow and sons we offer our deep sympathy.

The sudden death of Miss B. E. NESBITT, the well-known ear, nose, and throat surgeon, in Edinburgh on December 30, 1953, at the age of 55, leaves a gap that will be hard to fill. Born at Galway on July 7, 1898, Belinda Elizabeth Nesbitt was educated at the Methodist College and at Queen's University, Belfast, where she graduated M.B., B.Ch. in 1924. She then held house-surgeon posts at the Royal Ear Hospital (now the ear, nose, and throat department of University College Hospital, London), the King Edward VII Hospital, Windsor, and the Birmingham and Midland Ear and Throat Hospital. After further extensive postgraduate study in London and Vienna she became a Fellow of the Royal College of Surgeons of Edinburgh in 1931 and immediately set up in consultant practice. Later she became ear, nose, and throat surgeon to the Bruntsfield Hospital and the Eye, Ear, and Throat Infirmary, Edinburgh, the Redlands Hospital for Women, and the Dunfermline and West Fife Hospital. Always a hard worker, she built up a wide and

busy practice and took infinite pains with all her patients. Her bright and happy disposition never failed to bring comfort to all who came under her care. Miss Nesbitt was a skilled pianist, but her chief recreation was golf, a game she took up after the war, and to it she devoted the same keenness and enthusiasm which characterized her work. She won the trophy of the City of Edinburgh Branch of the British Medical Association on two occasions and the Notts Ladies' Challenge Cup at the Annual Meetings of the B.M.A. in 1949 and 1950. Her husband, Mr. C. R. Duncan Leeds, won the Treasurer's Cup in the latter year, and this was possibly a unique event in the history of these competitions. To Mr. Duncan Leeds, who is an ophthalmic surgeon in Edinburgh, we offer our sincere sympathy in his loss.

Medico-Legal

DIABETIC MOTORIST ACQUITTED

Salford's stipendiary magistrate, Mr. Leslie Walsh, gave his reserved judgment on January 8 in the case of Robert Geoffrey Healey, 28, of Heywood, Lancs, who had pleaded not guilty to driving his car under the influence of a drug and dangerous driving.

The alleged offences occurred, said the Stipendiary, when Healey's car was involved in an accident in Bury New Road, Salford, on November 7, 1953. Police said that Healey's car ran backwards into a bus and then shot forward and collided with a van. The magistrate said that Healey suffered from diabetes and was treated with insulin. On the day of the accident he attended a diabetic clinic in Manchester and was seen by a doctor. He left the clinic and was later involved in the accident in circumstances which prima facie showed dangerous driving. Medical evidence was given, which was not contradicted, that his condition—hypoglycaemia—could occur without the defendant knowing about it.

"It is clear from the medical evidence," he continued, "that hypoglycaemia could arise without premonitory symptoms, and I am satisfied that Healey had no warning of the attack. In these circumstances the issue on dangerous driving is covered by a High Court ruling on motorists suddenly attacked by an illness which incapacitates them. I find that he was not guilty of dangerous driving. As for the charge of driving under the influence of a drug, I think that this section of the Act was never intended to cover such cases. The condition of hypoglycaemia could be caused in a diabetic by other factors than insulin, such as extra exertion, worry, or exasperation. As I am satisfied that Healey took only his normal dose of insulin on the day in question, and had never previously suffered ill effects as the result of that dose, I am not satisfied that he was under the influence of insulin at the time of this accident. Before the accident he was seen by a doctor, when his condition was normal. The charge will therefore be dismissed."

Universities and Colleges

UNIVERSITY OF OXFORD

The Theodore Williams Scholarship in Pathology for 1953 has been awarded to Antony Babington Herring.

UNIVERSITY OF CAMBRIDGE

Dr. W. E. Hick has been appointed Reader in Experimental Psychology from October 1, 1953.

The following degrees were conferred on November 28, 1953: M.D.—M. G. Thorne, J. K. Wagstaff. Sc.D.—Kenneth Bailey, Ph.D., F.R.S.

The Raymond Horton-Smith Prize for 1952-3 has been awarded to Dr. John Perrin and Dr. Ernest Keith Westlake (equal).

UNIVERSITY OF LONDON

The degrees of M.B., B.S. were awarded to D. D. J. Rees on October 21, 1953, the date to be inscribed on the diploma to be June 25, 1952.

The following candidates at the Institute of Psychiatry have been approved at the examinations indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN PSYCHOLOGICAL MEDICINE.—G. F. Vaughan, Lorna Wheelan. Part I: R. H. Gosling, W. A. Kennedy, J. Pisani, N. H. Rathod.

UNIVERSITY OF MANCHESTER

The following candidates have been approved at the examination indicated:

FINAL M.B., Ch.B.—Sheila Berry, J. K. Bleasdale, C. Booth, Margaret A. Broughton, J. W. Chamberlain, G. H. H. Dwyer, Pauline R. Dyckhoff, G. Gold, L. Goldie, A. Greenbaum, Mabel L. Haigh, Daphne J. Hall, F. Heyworth, J. Johnson, J. B. Jones, L. K. Levens, J. S. Lord, F. G. Lucas, Jean McCracken, C. Mawdsley, V. B. Maxwell, P. W. Murphy, W. C. Newport, J. Parkin, L. Reece, Eve M. Roper, J. G. B. Russell, Ruth M. Sellars, Joan E. Singleton, J. N. Standing, A. O. F. Stuart, A. T. Thompson, S. T. Whitehead.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus ———, the figures for 1953 thus ———. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

The usual fall in the number of notifications of infectious diseases that occurs during Christmas week was reported in England and Wales during the week ending December 26. The decreases in the number of notifications included 880 for whooping-cough, from 2,304 to 1,424; 335 for scarlet fever, from 1,284 to 949; 194 for dysentery, from 503 to 309; 167 for measles, from 778 to 611; and 162 for acute pneumonia, from 692 to 530.

The largest falls in the notifications of whooping-cough were 80 in Lancashire, from 220 to 140; 59 in Derbyshire, from 85 to 26; 56 in Southampton County, from 110 to 54; 47 in Kent, from 109 to 62; 46 in Essex, from 115 to 69; 45 in London, from 101 to 56; 44 in Glamorganshire, from 83 to 39; 44 in Yorkshire West Riding, from 177 to 133; 40 in Durham, from 69 to 29; 39 in Hertfordshire, from 61 to 22; and 36 in Middlesex, from 79 to 43. The largest fall in the local returns of scarlet fever was 37 in Essex, from 83 to 46. 15 cases of diphtheria were notified, being 1 fewer than in the preceding week. The chief features of the returns of diphtheria were a fall from 5 to 0 in Durham and a rise from 1 to 5 in Lancashire. The only large decline in measles was 43 in Lancashire, from 177 to 134.

29 cases of acute poliomyelitis were notified during the week. These were 20 fewer for paralytic and 2 fewer for non-paralytic cases than in the preceding week. The largest returns were London 4, Kent 3, and Lancashire 3.

The largest returns for dysentery were London 52 (Islington 19), Yorkshire West Riding 39 (Sowerby Bridge U.D. 15, Bradford C.B. 9), Lancashire 35 (Bolton C.B. 12), Leicestershire 23 (Leicester C.B. 20), Middlesex 21 (Enfield U.D. 11), Norfolk 21 (Norwich C.B. 20), and Kent 20 (Cranbrook R.D. 13).

Week Ending January 2

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,111, whooping-cough 2,284, diphtheria 29, measles 1,327, dysentery 340, acute poliomyelitis 53, paratyphoid fever 0, and typhoid fever 1.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending December 26 (No. 51) and corresponding week 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Pharmaceutical Research.—The cost of research in the British pharmaceutical industry is now between £2,000,000 and £2,500,000 a year, according to Mr. S. M. Lennox, president of the Chemists' Federation. He was speaking at a dinner given by the National Pharmaceutical Union to the Chemists' Federation and the Council of the Pharmaceutical Society on January 6. He added that the industry now employed over 50,000 people and produced pharmaceutical products to the value of over £90,000,000 a year.

Scottish Hospital Endowments Research Trust.—The Secretary of State, Mr. James Stuart, has now appointed the trustees. The chairman is Sir John Erskine, formerly general manager of the Commercial Bank of Scotland, and the members are Lieutenant-Colonel Donald Cameron of Lochiel, Mr. J. T. Dowling, Mr. R. L. Gwilt, Dr. James Lawson, Bailie James A. Mackie, and Mr. Iain Maxwell Stewart. The Trust's general funds, which will provide an income of up to £120,000 a year, will be built up from a proportion of the endowments of the former voluntary hospitals in Scotland, and also from gifts and legacies from private individuals. The Trust is charged with the duty of assisting medical research in Scotland, and will be advised by the Advisory Committee on Medical Research in Scotland, of which Sir Edward Appleton is chairman.

Diploma in Health Education.—The University of London Institute of Education has arranged a year's full-time course in health education (fee £62 10s.) leading to a diploma. It is intended for those wishing to train for work in this field and is open to lecturers in training colleges and departments of education, qualified teachers, doctors, nurses, health visitors, sanitary inspectors, and others. The London School of Hygiene and Tropical Medicine and the Central Council for Health Education have agreed to give some help with the course, which will comprise lectures, seminars and discussions, and field work. The syllabus includes the following subjects: principles of education; principles of social and preventive medicine; history and administration of public health and education; scientific bases of health and human behaviour; and principles, methods, and media of health education. Behind this new move by London University is the recognition that the best use of the nation's health services demands an instructed public. Improvements in the public health depend largely on the individual layman taking the trouble to observe the elementary rules of hygiene. Further details about the course may be obtained from the secretary, University of London Institute of Education, Malet Street, London, W.C.1.

Deaf Children.—One of the most urgent problems for the parent of a deaf child is what to do about his child's education. To help with this, the National Institute for the Deaf has published a booklet, "The Education of Deaf Children," prepared with the help of the National College of Teachers of the Deaf, which answers many of the questions such a parent would want to ask. The booklet contains a number of articles on teaching deaf children by leading British authorities and a full list of the schools for the deaf and partially deaf in the British Isles. The booklet costs 1s. 3d., and may be obtained from the National Institute for the Deaf, 105, Gower Street, London, W.C.1.

The Cost of Private Treatment.—The London Association for Hospital Services, controlled by a council of management whose members are nominated by the B.M.A., the Royal Colleges, and the King Edward's Hospital Fund for London, offers a comprehensive insurance scheme to those who wish to provide in this way for the costs of private medical treatment. Lately the London Association has been able to improve its benefits and conditions. One

scheme is intended specially for doctors. It covers the expenses of private in-patient treatment at any hospital or recognized nursing-home, including monetary gifts to professional colleagues. The latter are sent direct by the London Association as a present from the doctor who has received treatment. Full details of this and other schemes may be obtained from the London Association for Hospital Services, Tavistock House South, Tavistock Square, London, W.C.1.

Dispensing Opticians.—The Board of Registration of Medical Auxiliaries has issued a "Register of Dispensing Opticians." It contains the names of 352 dispensing opticians whose applications for registration were received and approved by the Board up to the end of last November. The names are classified geographically and alphabetically. In each case place of employment, private address, telephone number, and qualification are given. If an artificial eye service or contact lens service is provided this is also indicated. Copies of the Register may be obtained, free, on application to the Secretary and Registrar, Board of Registration of Medical Auxiliaries, B.M.A. House, Tavistock Square, London, W.C.1.

Sir Ewen Maclean's Will.—After various substantial legacies, which included £1,000 each to the Welsh National School of Medicine (to augment the Ewen Maclean Research Scholarship) and the Cardiff Royal Infirmary and £500 to the B.M.A. Charities Fund, Sir Ewen Maclean left one-third of his residuary estate to the Welsh National School of Medicine and another third to the Royal College of Obstetricians and Gynaecologists, of which he was president from 1935 to 1938. Sir Ewen Maclean was president of the B.M.A. in 1928 when the annual meeting was held in Cardiff, and previously he had been chairman of the Representative Body.

President of British Association.—At a ceremony at Burlington House on January 8 Dr. E. D. Adrian, O.M., president of the Royal Society, was inducted as the 116th president of the British Association by the retiring president, Sir Edward Appleton.

Editorship of "Brain."—Sir Russell Brain, F.R.C.P., has assumed the editorship of *Brain* in place of Sir Francis Walshe.

Sir Andrew Davidson, Chief Medical Officer of the Department of Health for Scotland, is to retire on March 31. He was appointed in 1941.

Lord Horder.—In honour of his 83rd birthday Lord Horder's former house-physicians entertained him to dinner on January 7 at the Royal Society of Medicine. Dr. A. C. Roxburgh was in the chair.

Mr. R. Scott Stevenson, who has left London to live in Gibraltar, was presented with a gift in recognition of his services as chairman of the National Institute for the Deaf from 1945 to 1954 at a dinner held on January 7 with Lord St. Audries in the chair.

Professor W. O. Reinhardt, of the department of anatomy, University of California, is coming to Bristol for a year next September to work with Professor J. M. Yoffey on the reaction of the bone marrow to anoxia. Professor Reinhardt has been given a grant by the United States Public Health Service for this purpose.

COMING EVENTS

Oxford Graduates' Medical Club.—The winter dinner will be held at the Royal College of Surgeons, Lincoln's Inn Fields, on Friday, January 29, at 7 for 7.30 p.m. Sir Russell Brain will be in the chair. Tickets (price 38s.) may be obtained from Mr. Selwyn Taylor, 3, Roedean Crescent, London, S.W.15.

Contraceptive Technique.—A lecture and demonstration will be given by Marie Stopes, Ph.D., at the Mothers' Clinic,

108, Whitfield Street, London, W.1, on Thursday, February 4, at 2.30 p.m. Admission free, but tickets must be obtained in advance.

Fifth International Congress on Mental Health.—The congress will be held in Toronto from August 14 to 21, and the theme will be "Mental Health in Public Affairs." Further information may be obtained from 111, St. George Street, The Congress Office, Toronto, Canada.

NEW ISSUES

Annals of the Rheumatic Diseases.—The next issue (Vol. 12, No. 4, December, 1953) will be available in a week's time. The contents include:

ARTHRITIS. Philip Ellman and F. Parkes Weber. **PULMONARY LESIONS OF DISSEMINATED LUPUS ERYTHEMATOSUS.** S. I. Rapoport, L. Meisner, F. M. Steele, and S. R. Caniglia. **PRODUCTION OF ARTHRITIS IN THYROIDECTOMIZED RAT BY INJECTIONS OF DEOXYCORTONE ACETATE.** R. G. Harrison and T. J. Barnett. **FINGER CONTRACTURES DUE TO TENDON LESIONS AS A MODE OF PRESENTATION OF RHEUMATOID ARTHRITIS.** B. M. Ansell and E. O. L. Bywaters. **RESTORATION OF KNEE JOINT FUNCTION IN CHRONIC RHEUMATOID ARTHRITIS.** Robert L. Preston. **EFFECT OF ACTH AND SODIUM SALICYLATE ON THE URINARY URIC ACID: CREATININE RATIO, AND CIRCULATORY EOSINOPHILS IN MAN.** F. O. W. Marston. **COLLAGEN DISEASE COMPLICATING MALIGNANCY.** John Lambury. **RHEUMATIC DISEASES IN DENMARK.** K. Kalbak. **EPIDEMIOLOGY OF RHEUMATIC FEVER IN A RURAL DISTRICT IN ITALY.** A. Poppi, G. Labo, G. Lenzi, and L. Rossi. **INCIDENCE OF REFLEX SYMPATHETIC DYSTROPHY OF THE UPPER EXTREMITY.** Velkko A. I. Laine.

Issued quarterly; annual subscription £2 2s., single copy 12s. 6d. Available from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, January 18

HUNTERIAN SOCIETY.—At the Mansion House, 8.30 p.m., Hunterian Lecture by Dr. George Crile (Cleveland, Ohio): Under Southern Seas. **ROYAL EYE HOSPITAL.**—5.15 p.m., Dr. T. H. Whittington: Care and Treatment of the Squinting Child.

Tuesday, January 19

BRITISH POSTGRADUATE MEDICAL FEDERATION. At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor G. R. Cameron, F.R.S.; Tissue Repair. **INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. W. N. Goldsmith: Vegetating Dermatoses. **LONDON UNIVERSITY.**—At Meyerstein Theatre, Westminster Medical School, 5.30 p.m., special university lecture in medicine by Dr. George Crile (Cleveland, Ohio): Medical Treatment of Hyperthyroidism and Thyroiditis. **ROYAL EYE HOSPITAL.**—5.30 p.m., Dr. B. S. Cardell: Pathology of the Ocular Melanoma. **ST. MARY'S HOSPITAL MEDICAL SCHOOL.**—5 p.m., Professor W. I. C. Morris: Complete Perineal Test. **SOCIETY FOR THE STUDY OF ADDICTION.**—At 11, Chandos Street, Cavendish Square, W., 8 p.m., Dr. J. H. Gould: Biochemical Detoxication in the Treatment of Alcoholism; Lady Frankau: Vitamins Plus Subconvulsive Therapy in the Treatment of Long-standing Alcoholism. **SOUTH-WEST LONDON MEDICAL SOCIETY.**—At Bellinghame Hospital, Wandsworth Common, 8.30 p.m., Dr. W. D. W. Brooks: Aetiology and Treatment of Bronchitis (illustrated by lantern slides).

Wednesday, January 20

BURGESS SOCIETY.—At Burlington House, Piccadilly, W., 5.30 p.m., Dr. J. Spencer, Ph.D.: Delinquent Behaviour: Some Unanswered Questions. **HARVEIAN SOCIETY OF LONDON.**—8.15 p.m., Presidential Address by Dr. Tom Hare: The Tudor Ancestors of Dr. William Harvey. **INSTITUTE OF DERMATOLOGY.**—5.30 p.m., Dr. H. Haber: Clefts, Vesicles, and Bullae. **INSTITUTE OF UROLOGY.**—4.30 for 5 p.m., Mr. R. Ogier Ward: Stone in the Ureter. **LONDON UNIVERSITY.** DEPARTMENT OF EXTRA-MURAL STUDIES AND ATOMIC SCIENTISTS' ASSOCIATION.—At Beveridge Hall, Senate House, 7 p.m., Sir John D. Cockcroft, F.R.S.: Atomic Research at Harwell. **MIDDLESEX COUNTY MEDICAL SOCIETY.**—At Edgware General Hospital, 3 p.m., clinical meeting, Dr. G. S. C. Sowry: The Inheritance of Essential Hypertension; coloured film by Dr. G. Riddell Royston: A Case of Scurvy. **MIDLAND MEDICAL SOCIETY.**—At Birmingham Medical Institute, 8.15 p.m., joint meeting with Junior Legal Club, Birmingham Law Society. **PHYSIOTHERAPISTS ASSOCIATION, LTD.**—At Bonnington Hotel, Southampton Row, W.C., 7 p.m., Mr. R. Rowden Foote: Varicose Veins (with coloured film). **ROYAL COLLEGE OF SURGEONS OF ENGLAND.**—5 p.m., Mynihan Lecture by Dr. George Crile (Cleveland, Ohio): Treatment of Diseases of the Thyroid Gland. **ROYAL EYE HOSPITAL.**—5.30 p.m., Mr. L. H. Savin: Ophthalmic Operations and Their Indications (4). **SOCIETY FOR ANALYTICAL CHEMISTRY.**—At Institution of Electrical Engineers, 6 p.m., joint meeting with Royal Institute of Chemistry. Subject: Determination of Alcohol in Blood and Urine. Paper by Dr. D. W. Kent-Jones, Ph.D., F.R.I.C., and Mr. G. Taylor, F.R.I.C. **SOCIETY OF PUBLIC ANALYSTS.**—At Institution of Electrical Engineers, 6 p.m., joint meeting with Royal Institute of Chemistry. Subject: Determination of Alcohol in Blood and Urine. Paper by Dr. D. W. Kent-Jones, Ph.D., F.R.I.C., and Mr. G. Taylor, F.R.I.C.

Thursday, January 21

BRITISH POSTGRADUATE MEDICAL FEDERATION. At London School of Hygiene and Tropical Medicine, 5.30 p.m., Dr. D. D. Reid: Design of Clinical Experiments. **EDINBURGH CLINICAL CLUB.** At 7, Drumshugh Gardens, 8 p.m., Dr. E. H. Cameron: Ophthalmology in General Practice. **GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.**—At Glasgow University Union, 7.30 p.m., Honorary Presidential Address by Professor R. A. Lennie. **INSTITUTE OF CHILD HEALTH.** 5.30 p.m., Miss B. C. Marshall: Handling of the Family in Mental Deficiency. **LIVERPOOL MEDICAL INSTITUTION.** 8 p.m., demonstration of cases of pathological interest. **LONDON JEWISH MEDICAL SOCIETY.** At Medical Society of London, 8.30 p.m., films: (1) Early Diagnosis of Acute Anterior Poliomyelitis; (2) Industrial Dermatitis; (3) Venomous Snakes—Medical Aspects. **ROYAL COLLEGE OF SURGEONS OF ENGLAND.** 5 p.m., Ophthalmology Lecture by Professor Arnold Sorsby: Abiotrophy. **ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.** 7.30 p.m., Lieutenant-Colonel A. K. Brown, R.A.M.C., and Dr. A. Knudsen: Acute Haemorrhagic Fever—Clinical and Pathological Aspects. A discussion will follow. **ST. ANDREWS UNIVERSITY.** At Physiology Department, Dundee, 5 p.m., Dr. Macdonald Critchley: Parietal Symptomatology. **ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.** 5 p.m., psychiatry demonstration by Dr. M. Partidge.

Friday, January 22

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. W. N. Goldsmith: Vegetating Dermatoses. **LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.**—7.30 p.m., pathological meeting. **POSTGRADUATE MEDICAL SCHOOL OF LONDON.** 2 p.m., Professor Henry Barcroft, F.R.S.: Sympathetic Control of Human Blood Vessels. **ROYAL MEDICAL SOCIETY, Edinburgh.** 8 p.m., Professor J. W. Crofton: Tuberculosis: Scotland's Problem. **ROYAL SANITARY INSTITUTE.** At Town Hall, Slough, 10 a.m., Symposium on Industrial Health. Miss F. Schofield: Factory Law and Health; Dr. A. A. Banger: Slough Industrial Health Service and Area Services; Dr. M. E. M. Herford: The Appointed Factory Doctor: Possible Developments; Dr. E. Hughes: The View of a Medical Officer of Health.

Saturday, January 23

BRITISH ASSOCIATION OF ALLERGISTS. At Royal Society of Medicine, 11 a.m., Professor G. Payling Wright: Fate of Injected Soluble Antigens; 11.40 a.m., Dr. J. H. Humphrey: Participation of Formed Elements of the Blood in Experimental Allergic Reactions; 2.40 p.m., Dr. J. O. Cunningham: The Actions of Ethylenediamine Tartrate in Industry; 3 p.m., Dr. H. Wiles: Some Unusual Industrial Sensitivities; 3.30 p.m., Dr. P. B. S. Fowler: Printers' Asthma.

APPOINTMENTS

CURRAN, A. P., M.B., Ch.B., D.P.H., Deputy Medical Officer of Health and Deputy School Medical Officer, County Borough of West Ham. **GRAY, DAVID KEMPSON, M.B., B.S.,** Resident Aural Registrar, The Hospital for Sick Children, Great Ormond Street, London, W.C. **LIVERPOOL REGIONAL HOSPITAL BOARD.** R. D. Holston, M.B., Ch.B., M.R.C.P., Part-time Consultant Physician to Hospitals in North Wirral Area; P. M. O'Flanagan, I.R.C.P.S.I., D.P.M., Whole-time Consultant Psychiatrist to Winwick Hospital; A. H. Bruce, FR.P.S., M.M.S.A., D.A., Part-time Consultant Anaesthetist to Central Wirral and Chester Areas. **STARR, VIDA I. McE., M.D., D.P.H.,** Senior Medical Officer (Maternity and Child Welfare), Liverpool Public Health Department. **YOUNG, WILLIAM C., M.B., Ch.B., D.P.H., D.P.A.,** Medical Officer of Health, Borough of Motherwell and Wishaw.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Crane. On January 1, 1954, at Dr. Nest Crane (formerly Llewellyn), wife of Dr. J. E. Crane, Carmarthen, a son David Llewellyn. **Fox.** On October 14, 1953, to Rosemary (formerly Wilson), M.B., B.S., D.P.H., wife of Percy Francis Fox, of Melchester, Southern Rhodesia, twin daughters, Annabelle and Philippa, and on December 27, 1953, a son Timothy. **Smith.** On December 1, 1953, at Leeds, Yorks, to Kathleen (formerly Turner), M.B., B.S., wife of Irvine Smith, F.R.C.S., a daughter—Dorothy Battinson.

DEATHS

Butler. On December 16, 1953, at 2, Whybourne Crescent, Tunbridge Wells, Kent, George Guy Butler, M.B.E., M.D. **Dargatzis.** On December 14, 1953, at his home, Inglebrook, Upper Clarendon Road, St. Heller, Jersey, Patrick Arthur Dargatzis, M.R.C.S., I.R.C.P., Lieutenant-Colonel, I.M.S., retired, aged 69. **Dew.** On December 15, 1953, at Colindale, Wimblesbury Road, Horeham, Sussex, John Wescott Dew, M.C., M.B., B.Ch., aged 66. **Fothergill.** On December 17, 1953, at 65, Bromley Road, Beckenham, Kent, Arthur Fothergill, M.D. **Heller.** On December 6, 1953, at 1, Ivywell Road, Bristol, Joseph Heller, M.D., aged 79. **Higgins.** On December 11, 1953, at his home, Nazareth Cottage, Monkstown, Co. Cork, Eire, John Higgins, M.R.C.S., I.R.C.P., late R.A.M.C., retired. **Joan.** On December 11, 1953, at Wilkesborough Hospital, Ashford, Kent, Murray Parry Jones, M.R.C., I.R.C.P., Surgeon Captain, R.N., retired, of Wye, Kent, aged 81. **Kelly.** On December 20, 1953, at Harman's Cross, Swansea, Dorset, Harry Beatty Kelly, O.S.O., M.B., B.Ch., Colonel, late R.A.M.C., retired. **Stephen.** On December 12, 1953, Karin Stephen, M.R.C.S., I.R.C.P., of 1, Upper Harley Street, London, N.W., aged 64. **Welch.** On December 12, 1953, at Daleford, Hartley, Longfield, Kent, Frederick Day Welch, M.R.C.S., I.R.C.P., aged 75.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Hot Syringes and Vaccines

Q.—To what extent are vaccines damaged by being aspirated into a hot syringe? Does the vaccine cool the syringe sufficiently quickly for loss of inoculating material to be unimportant?

A.—Although some bacterial vaccines might not be damaged appreciably by brief contact with a hot syringe, the undue haste in inoculation technique implied by the question is undesirable. Moreover, a technique begun with apparent safety for a certain bacterial vaccine might lead to disaster if used for a relatively unstable product like yellow fever vaccine or for a therapeutic serum which is readily coagulable by heat. It is unnecessary to discuss the high specific heat of water or to define a "hot syringe," but a practical working rule might be that, if a syringe has cooled sufficiently to enable it to be held comfortably in the hand, it is not too hot for use.

Penicillin Lozenges

Q.—What is the place of the penicillin lozenge in therapy?

A.—Penicillin lozenges are not intended to provide an adequate concentration in the blood: they are used solely for their local effect.

The originators of this method of treatment, McGregor and Long, used a pastille with a gelatin base. In this, with its fairly high water content, penicillin was unstable, and when such a product came to be manufactured stability was ensured by giving it in the form of a dry tablet with a lactose base. This is the product which has caused soreness of the mouth, owing at least in part to the merely mechanical action of granules of the excipient. There may be other factors: prolonged use leads to overgrowth of a penicillin-resistant flora, and it is possible that the lactose itself affords a pabulum for bacterial growth. The position has changed again with the commercial production of stable gelatin pastilles and chewing gums; these are to be preferred to tablets.

Treatment of this kind is of little use unless continuous: a pastille should remain in the buccal sulcus until dissolved and then be replaced by another, this being continued throughout the day. It is indicated for Vincent's gingivitis and for mild haemolytic streptococcal throat infections. Whether other forms of sore throat will respond depends on their aetiology and the sensitivity to penicillin of the causative organism. Indiscriminate use will inevitably lead to many disappointments. The treatment is naturally less effective than penicillin given by injection, and whether this should replace local treatment or perhaps be given in addition to it is a matter for individual judgment.

Central Heating and Colds

Q.—An intelligent headmaster tells me that he always postpones the central heating in his school as long as possible, regardless of the discomfort to himself, the teaching staff, and the boys, because he finds that a really troublesome epidemic of colds always follows the first use of central heating. Is this proper hoc pro merito post hoc?

A.—The only answer that could be supported by enough facts to satisfy the intellectual integrity of the headmaster is, "We do not know." Nevertheless, it has been claimed by some, e.g., van Loghem,¹ that periods of cold weather are commonly followed by a high incidence of colds, and this may support the questioner's post hoc interpretation. I know of no adequate study in which the effect of the use

of central heating, or of its commencement in the autumn, has been related to the incidence of colds.

Tetanus and Sport

Q.—In games played on grass, such as football, hockey, lacrosse, etc., in which there is a risk of open wounds, is there any evidence of a raised incidence of tetanus amongst the players? Where the playing fields are used for grazing cows and horses, or if manure is spread over the ground, is there any evidence that there is an even greater risk of tetanus? Is it advisable to inoculate schoolchildren and adults who play games under these circumstances?

A.—While nothing is known of the existence of any series of figures showing a greater incidence of tetanus in those who play games on grass, it is relevant that the tetanus bacillus is more numerous in places where horses and cows have been grazed or where their manure has been thrown. Thus the risk of contracting tetanus would appear to be greater in playing fields where such manuring is done, or in back gardens, than in the streets of modern cities where there are relatively few horses. The largest number of cases of tetanus in peacetime occurs between the ages of 5 and 14 years, when children are very active and presumably more prone to slight septic wounds and whitlows. As might be expected, males develop tetanus much more often than females.

Since tetanus antitoxin cannot be administered prophylactically after every injury or scratch, active prophylaxis with tetanus toxoid is being used increasingly, particularly in the United States. Schoolchildren and adults, playing games on grass, could certainly be protected. Moreover, the use of a diphtheria-pertussis-tetanus prophylactic is worth considering for infant immunization.

Inheritance of Eye Colour

Q.—How is the colour of the eyes inherited? What are the chances that two brown-eyed parents will have a child with blue eyes, and vice versa?

A.—It used to be thought that brown versus blue eyes depended on a single gene difference, brown eyes being dominant. If this were true, brown-eyed parents could have children with brown or with blue eyes, whereas two blue-eyed parents could have only blue-eyed children. It is now known, however, that this view is oversimplified, though it may be accepted, perhaps, as a rough approximation. Probably all that can be said at present is that it would be very unusual for two blue-eyed parents to have a brown-eyed child. Some studies have, however, shown instances of this, but it is difficult at present to express an opinion as to how many may be real, how many due to faulty observation, and how many to the difficulties of classifying eye-colour.

Sunlight and Neoplastic Changes

Q.—Is there any evidence that undue exposure to sunlight predisposes to neoplastic changes?

A.—Reference to any standard textbook will give much information on the effects commonly resulting from undue exposure to sunlight, including neoplastic changes. They are seen more particularly in the white-skinned races, on exposed parts, in the elderly, outdoor workers, sailors, and in those who live in hot climates. Such changes are very commonly seen in Australia. There is great individual variation which to some extent goes with the degree of pigmentation, the fair and red-haired being more susceptible. In cattle, epithelioma may arise only on white patches of hide.

There is a rare congenital condition, xeroderma pigmentosum, where the susceptibility is so extreme that minimal exposure produces grave effects, and before puberty the patient may have developed numerous epitheliomata.

There is no convincing evidence that artificial sunlight therapy as ordinarily employed provokes such changes, even

when used intensively over the course of some years as was usual in the treatment of lupus vulgaris until recent years.

Growth and its Control

Q.—What is the driving force which causes growth?

A.—The term "driving force" is not clearly defined. Growth can be regarded as the result of the increase in size of cells and in some instances an increase in their total number. The deposition of structural material in the cell, and the processes which lead to cellular fission, are influenced by enzyme systems which in turn are influenced by genes present in the cell nucleus. The congenital absence of nuclear factors may lead to improper growth of the tissue concerned. In the more complex organisms the endocrine glands also influence growth. Hormones which affect growth include the growth hormone of the anterior pituitary gland, thyroxine or triiodothyronine from the thyroid gland, androgens from the sex glands and adrenal cortex, and adrenal-cortical hormones from the adrenal cortex. In general the adrenal-cortical hormones appear to antagonize the growth-stimulating action of pituitary growth hormone, although where adrenal insufficiency exists the administration of small doses of suitable adrenal steroids may stimulate growth. Pituitary growth hormone, as its name implies, is of particular importance in the stimulation of growth, though its mechanism of action is not known, and many physiological actions other than that of stimulating growth are ascribed to growth hormone. One view that has been put forward is that growth hormone facilitates the entry of amino-acids into the cells in order to provide for growth, but there is no certain evidence on this point. There is some evidence that insulin may exert an action similar to that of growth hormone under some conditions. Hormones which stimulate growth usually stimulate the appetite also, and the food intake and the search for food must obviously be important factors in the driving force which causes growth. But how the hormones stimulate the appetite, why the hormones which stimulate growth do not continue to do so indefinitely throughout life in higher animals, and why an organ, in the absence of a derangement of growth such as that caused by cancer, is controlled with respect to growth in relation to other organs of the body, are still matters for investigation.

Vitamin K and Dental Haemorrhage

Q.—In what conditions is vitamin K indicated as a prophylactic against dental haemorrhages? What preparation is advised, when should it be given, and in what dosage?

A.—Vitamin K is only indicated when the prothrombin activity has been diminished by liver damage, obstructive jaundice, malabsorption (in some cases), anticoagulant therapy with coumarin derivatives, and long-continued salicylate therapy. It is naturally of no value in dental haemorrhage due to other causes, such as scurvy or purpura. If there is no urgency it can be given orally as acetomenaphthone, 20 mg. daily, for two or three days before the extraction. Should there be any urgency, however, it should be given parenterally; intramuscular injection is painful, so 20 mg. of a water-soluble preparation should be given intravenously.

Disinfectants in the Lavatory Pan

Q.—To what extent is it safe to use bleaching agents and disinfectants in a lavatory pan which drains into a cess-pit?

A.—It is not clear what is meant by a "cess-pit." If this is a cesspool, a mere receptacle for the retention of sewage without any attempt at purification the admission of disinfectants or bleaching agents is of no importance.

If, however, the "cess-pit" is a septic tank, the bacterial process will be discouraged by the introduction of disinfectants, which should not be used. A bleaching agent, however, would normally be diluted by bath water, etc., to such an extent as to render its presence unimportant.

NOTES AND COMMENTS

"Stripping" for Varicose Veins.—MR. HAROLD DODD (London, W.1) writes: Your contributor's reply to the question, "What place has the operation of 'stripping' in the treatment of varicose veins?" damns the method by faint praise ("Any Questions?" December 12, 1953, p. 1334). Actually this procedure, preceded by an efficient sapheno-femoral or sapheno-popliteal ligation, is the operation of choice for varicose veins. We are indebted to Myer for an efficient stripper. I started stripping the saphenous trunks in 1951, and since January 1, 1953, have used it exclusively on 170 legs. Before this, I did a five year series of over 700 operations for varicose veins, which consisted in "top" ties followed by internal abrasion and fractional sclerosing injections of the saphenous trunk. This gave over a 90% "cure" or "much improved" rate in patients followed-up for over two to five years. The stripping procedure promises equally good results without the need for so many subsequent sclerosing injections. For instance, in my out-patients, before using stripping, it was usual to give 25-30 sclerosing injections per session; it is now down to four to six, during which time 30-40 patients with varicose veins will be seen. As your contributor says, the method tears off the tributaries, which afterwards thrombose; there is also subcutaneous bruising and staining for a fortnight or so, but neither are of temporary or remote disadvantage; in fact the after-progress is singularly trouble-free considering that the method is a comparatively crude one. After stripping, as in all operations below the diaphragm in adults, there is the need for constant movement and early ambulation, and further, on the slightest pain in the calf, suggesting deep thrombosis, anticoagulants must be given, an elastic bandage applied, and exercises steadily maintained, sedatives being administered to enable patients to do so. In the hands of those interested in varicose veins, stripping is now established and it has placed in the hands of general surgeons an effective remedy for varicosis which when done with the same care that is usual for a hernia is as free from risk and as effective. I think that shortly stripping of varicose veins will appear on the operating lists of general surgeons with the same regularity that a radical cure of a hernia or appendicectomy does, and that out-patient operations for varicose veins will be shortly abandoned and given the same sort of disapproval as is now given to out-patient tonsillectomies, although it is only ten years or so since they were fairly general practice.

OUR EXPERT replies: The questioner asked what place the operation of "stripping" had in the treatment of varicose veins, and the first sentence of the reply was as follows: "It is difficult to say exactly what place the operation of 'stripping' has in the treatment of varicose veins, but it is certain that at the present time this type of operation is carried out by only few surgeons." This surely represents a cautious attitude of mind towards the reintroduction of a technique which had once been abandoned. Many of the objections to this blind type of surgery, which tears across veins, including deep communicating ones, must remain, and Mr. Dodd's experience of the method is still fairly recent. One pertinent question that must be asked is, how often does deep thrombosis actually occur with the present method of stripping? In any case the variety of clinical pictures presented by varicose veins makes it unlikely that any one type of operation or procedure will meet all requirements. It is certainly premature to suggest that the stripping operation can be compared with the radical cure of a hernia or with an appendicectomy.

"Any Questions?" Book. The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

PROBLEMS OF MALARIA CONTROL IN TROPICAL AFRICA

BY

LEONARD J. BRUCE-CHWATT, O.B.E., M.D., M.P.H., D.T.M.&H.

(Malaria Service, Medical Department, Nigeria, British West Africa)

Three years ago the introductory sentence of an excellent world-wide review of modern methods of malaria control read as follows: "Into Africa—perhaps the most malaria-ridden of all continents—modern methods of control by residual insecticides were introduced at a late date and on a small scale" (Pampana, 1951). It will be only fair to admit that during the past few years there has been no radical improvement of the situation in tropical Africa. Although there are to-day many signs of forthcoming changes, it might be of value to outline the main reasons for the hitherto slow progress of malaria control in Africa south of the Sahara.

Two years ago one of our greatest living malariologists, at the end of his extensive journey through East and Central Africa, said: "There is nothing mysterious about African malaria; it is only the size of the problem that is different." This is true, but the quantitative difference is so great that it imparts to African malaria several exceptional characteristics.

The speed with which we can reach the objective of achieving and maintaining better standards of public health depends in the first place on the knowledge of the causes and conditions that favour the spread of communicable diseases. Secondly, there must be the will, the means, and the favourable environment to apply the existing knowledge in order to promote health.

We know that malaria can be eliminated either by attacking the parasite or by dealing with the insect vector. A nearly perfect degree of malaria control can be achieved by chemotherapy and chemoprophylaxis in organized communities or under supervision. A similar degree of malaria control in ordinary communities in tropical areas has never been attained, mainly because of practical difficulties in regular drug administration. It seems, however, that the new anti-malarials (chloroquine, pyrimethamine) may open new possibilities of chemotherapeutic control of malaria. An interesting example of this new trend is the mass-administration in Brazil (Pinotti, 1953) of chloroquine incorporated into common salt distributed by a government agency. Nevertheless, the general consensus of opinion is still overwhelmingly in favour of malaria control by attacking the anopheline vector, preferably by the use of residual insecticides.

The following factors are of importance in considering malaria control by residual insecticides in tropical Africa: (1) Knowledge of the amount and distribution of malaria and of the importance of this disease from the point of view of public health; (2) knowledge of the

natural history of the disease, particularly with reference to its insect vector; (3) technical knowledge of the action and methods of application of residual insecticides, particularly in rural areas; (4) economic possibility of carrying out a large-scale malaria control on a long-term basis, first as a special project, but as soon as possible within a framework of general health services of the country; and (5) sociological background for malaria control and its possible future implications. An analysis of each of these factors, with reference to tropical Africa generally but on a basis of personal experience mainly in West Africa, gives the following results.

1. Malaria in Tropical Africa

Our knowledge of the amount and distribution of malaria in tropical Africa is still woefully inadequate. The blame for the lack of general information on morbidity and mortality due to malaria is often ascribed to medical administrators, but the conditions in tropical Africa are particularly difficult. With an average of one qualified medical practitioner to 90,000 inhabitants and one hospital bed to 3,000 inhabitants, only a small proportion of the African population has the benefit of medical attention. But even when the medical officer is available the malaria morbidity records are far from adequate, since the diagnosis of this disease in Africa leaves a wide margin for personal interpretation of clinical symptoms and of laboratory data.

Some striking differences between two successive annual rates of malaria in the same locality could be traced to a change of medical officers who had different ideas on the diagnosis of this disease.

It is only recently that investigations carried out in Nigeria estimated that the age-specific malaria mortality figures expressed per 1,000 Africans exposed to risk were as high as 12.5 in infants, 7 in small children, and much lower (about 0.5) in older children, adolescents, and adults. If these malaria mortalities hold good for the rest of tropical Africa, with its 150 million inhabitants, it means that in this part of the world at least 175,000 children below the age of 15 die every year from the direct effects of the disease. The amount of morbidity due to malaria is so imperfectly known that even an approximate estimate of it would be merely a guess. In the absence of reliable biostatistical records the classical malariometrical indices provide a guide, but some of these indices, based mainly on experience in other parts of the world (India), can be misleading if applied uncritically to African conditions, and might have to be amended.

Any comprehensive malaria-control project must therefore be provided with a yardstick by means of which the efficacy of adopted methods can be assessed. Since clinical morbidity statistics are not available and biostatistical records cannot be compared with previous data, which do not exist,

the only thing that remains is a constant and critical checking of malariometrical indices by an ancillary survey organization initially forming a part of the control project and later remaining as a permanent feature of a mobile field unit dealing with rural public health. Wherever impressions are substituted for facts they are usually favourably biased in projects which are expensive and regarding which there is an understandable and perhaps subconscious desire to show good results for expended money.

The results reported from Mauritius (Dowling, 1953) have shown that moderately endemic malaria can be eliminated within a relatively short time by a residual spraying campaign. Similar though not so convincing results were reported from other African areas with epidemic or hyper-endemic malaria. The results of the Ilaro scheme in Nigeria are interesting. There, a continuous though not quite complete control of two main vectors within a small holo-endemic area changed in three years the picture of the local malaria to a surprising degree. If such results can be achieved in a small area, supersaturated with malaria, surrounded by a dense tropical forest, with a long period of transmission, then there is little doubt that equally good or better results could be expected from larger and more sustained projects (Bruce-Chwatt *et al.*, 1953).

The imperfect knowledge of the true parasite-host relationship in African malaria is the root of the controversial problem whether it is advisable to control malaria in holo-endemic and hyperendemic areas where the community has achieved a high degree of tolerance to the parasite at a cost of considerable mortality of its youngest members. We still do not know what part the acquired defence mechanism plays in the group tolerance to superinfection and how far it must be considered in conditions when eradication of the vector species without a chance of reimportation or a permanent malaria control over a wide area cannot be guaranteed (Macgrath, 1950).

Are we justified in concentrating on localized malaria control for the benefit of those continuously protected but who run a risk of their reinfections becoming more serious should they become accidentally exposed to it? Would it be wise to embark lightly in holoendemic areas of tropical Africa upon unrestricted measures of malaria control? What would happen if the control over a large area broke down because of a financial slump, difficulty in obtaining supplies of insecticide, or political unrest? Would the vector sweep the country and cause outbreaks of malaria, with a high fatality rate in the younger generations (Wilson, Garnham, and Swellengrebel, 1950)?

Our present state of knowledge is still inadequate to answer those haunting questions. It must be realized, however, that the possibilities of detrimental effects of incomplete malaria control are somewhat theoretical, and not confirmed by any reliable observations. The problem will not be decided until we have more basic data to work upon instead of arguments often derived from the personal philosophy of their proponents.

Whatever the future solution, it seems to-day that as a result of recommendations of the Kampala Conference (W.H.O., 1951) there is throughout tropical Africa a welcome and growing awareness of the need for pilot malaria control, whatever the original degree of endemicity.

2. The Anopheline Vectors of Malaria in Tropical Africa

Of the 30 species and varieties of Ethiopian anophelini only 11 can be regarded as vectors of human malaria. Seven of these (*A. brunnipes*, *A. hancocki*, *A. hargreavesi*, *A. moucheti*, *A. nili*, *A. pharoensis*, *A. rufipes*) are of some local importance in areas where and when the main vectors are rare. The part played by the secondary vectors is, however, insignificant in comparison with the continent-wide amount of transmission of malaria by *A. funestus* and *A. gambiae* (including *A. gambiae melas*). There is little doubt, therefore, that with some local exceptions the con-

trol of malaria by residual insecticides must be concentrated on the two main vectors, which are both characterized (though not to the same degree) by their wide distribution, predominantly house-haunting (endophilic) and man-biting (anthropophilic) habits, and high infective potential. All these factors comprise what Gabaldon (1953) calls the "vectorial power."

A. funestus has always been regarded as essentially endophilic and anthropophilic with a relatively stable breeding potential and fixed habits. It was therefore anticipated that residual insecticides would be highly successful in the control of this mosquito. The results did not deceive the expectations. Reports available from Madagascar, from Mauritius, from the Belgian Congo, and from Nigeria are particularly striking in their similarity. Whatever residual insecticide was used the density of *A. funestus* in these areas decreased with a spectacular speed and bordered on eradication, with a concomitant decrease of malaria transmission. These results would not have been achieved if the species concerned could either change its habits or produce any number of bionomically varying strains.

In contradistinction to the experience with *A. funestus*, the results recorded with *A. gambiae* in similar malaria-control schemes in tropical Africa varied most unpredictably. Methods that eliminated *A. funestus* from Mauritius and Madagascar have not succeeded in doing so to *A. gambiae* in these two islands, though the species concerned was reduced to small numbers and has apparently ceased to invade the human habitations and to transmit malaria. In a small-scale experimental scheme in Nigeria the density of *A. gambiae* decreased very greatly, but a certain amount of malaria transmission was still occurring. In the Belgian Congo, Ruanda-Urundi, and Southern Rhodesia the density of this mosquito decreased so much that the transmission was cut down to a very low level, but there was no evidence of the change of habits of the species. In Freetown the use of residual insecticides to improve still further the good results of a larvicidal scheme reduced *A. gambiae* density to extremely low levels but did not eliminate it entirely. On the other hand, in an experimental area in East Africa (Kasanje) and in Swaziland there was relatively little difference between the results of surveys carried out before and after the application of residual insecticides for over two years. In Transvaal, in a sparsely inhabited large rural area, a well-organized control by residual insecticides was very effective for six years, during which the rainfall was not unduly heavy, but one exceptionally rainy year proved the imagocidal control to be insufficient and led to a considerable influx of *A. gambiae*, which had to be dealt with by additional larvicidal measures (Annecke, 1953).

The inconsistency of results reported from various parts of tropical Africa cannot be fully explained by the differences in the size of the area, climatic conditions, type of the insecticide, method of its application, etc. It seems that at least some of the divergencies are due to our ignorance of the bionomics of *A. gambiae*, and particularly of the subtle interplay between the habits of this mosquito, its longevity, and macroclimatic and microclimatic conditions of the environment.

Habits of *A. gambiae*

A. gambiae was known to be the most man-linked malaria vector in tropical Africa, and yet it has been shown that it can be found in great numbers in dense, uninhabited forests of East and West Africa, that it might feed in nature on various animals as well as on man, that it can be induced to do so in a laboratory colony, that it might feed indoors and out of doors, that it can use for a shelter not only human or animal dwellings but also natural haunts, and that its infectivity may vary greatly from season to season in one area or from one area to another during the same season.

It might be that *A. gambiae* is either a species with a most remarkable plasticity which undermines the present concept of physiological races or perhaps it is really a

species complex with at least two cryptic subspecies (Holstein, 1952) and many varieties with bionomical differences, particularly with regard to their preferential feeding habits. These differences, however, will have an epidemiological significance only when confirmed by similar differences of the infectivity of the subspecies concerned.

The apparent differences in feeding habits of *A. gambiae* might, on the other hand, be explained in a simpler way, as suggested by Muirhead-Thomson (1951). It has been shown that in this species some of the females may rest in houses after the blood-meal, while a proportion will leave the house at this stage and rest out of doors. The less suitable the feeding site as a daytime resting place the higher the number of mosquitoes which will leave after feeding. While many human dwellings provide suitable daytime shelters, many domestic animals are kept in exposed structures, so that mosquitoes feeding there at night seek daytime shelters elsewhere. Thus precipitin tests on the blood found in the stomachs of anopheles collected out of doors will reveal a high proportion of animal bloods, even though the bulk of the mosquito population feeds preferentially on man.

All these obvious gaps in our knowledge of the habits of the main malaria vector in Africa prevent the rational and systematic application of available techniques of control by residual insecticides. This knowledge might be ultimately more important for the future of malaria control than many data on the physical and chemical properties of insecticides.

3. Residual Insecticides in Tropical Africa

In spite of the fact that large-scale use of D.D.T. for malaria control dates from 1944, our present knowledge of technical problems associated with the choice of the residual insecticide, its adequate dosage, best formulation, duration of adequate toxicity to mosquitoes, and any danger to man and his animals is in a state of flux which makes any large-scale planning of malaria control rather difficult.

It is a matter of regret that the published reports of laboratory and field investigations show a disconcerting lack of agreement on the significance of their results. This indicates perhaps the importance of some unknown or insufficiently corrected variables in their design.

The often-neglected practical aspect of any malaria control scheme—namely, the consideration of the ratio of the size of the mosquito-breeding area to the size of the toxic area (represented by the total surface of sprayed walls and ceilings)—has led to some disappointments. In one case at least (in the Gambia) this was recognized at an early date and recommendations were made accordingly, substituting a plan for swamp drainage in preference to a residual control of a small area by insecticides.

It seems that in some parts of Africa too much reliance has been placed on the possibilities opened up by the residual insecticides. This has led to their uncritical or perhaps inexperienced use, and was often accompanied by a neglect of simple laws of environmental sanitation or by a rejection of the time-honoured, cheap, and logical methods of prevention of mosquito-breeding.

The results obtained in Ilaro (Nigeria) have shown clearly that the success of a malaria-control scheme by residual insecticides depends in Africa, as elsewhere (Gabaldon, 1953), on the size of the controlled area. It is possible to decrease but not to eliminate the malaria transmission from a relatively small area surrounded by a vast uncontrolled territory. Two factors will constantly upset the results: the influx of infected mosquitoes from the outside and the usually underestimated mobility of the indigenous population, liable to acquire new infections when leaving temporarily the narrow limits of the controlled area.

The discovery of the irritant effect of D.D.T., the knowledge of the relationship between its particle size and the toxicity to mosquitoes, the crystallization effect from oil solutions, the absorptive and chemical effect of some mud

surfaces, the fumigant and particulate effect, the importance of suspensibility of water-dispersible powders, the nature and proportion of the diluent, the effect of tropical storage, and many technical aspects of the spraying routine such as blockage and erosion of nozzles, uniformity of coverage, ratio of absorbent to non-absorbent components of the wall surface, etc., all these slowly emerging factors have not ceased to emphasize the fact that residual spraying needs a careful planning, thorough execution, and constant supervision—postulates not easy to follow in tropical Africa with its chronic shortage of trained personnel.

Reports on some large malaria-control schemes in Africa were somehow conflicting. D.D.T. was claimed to have been very successful in the Belgian Congo, Ruanda-Urundi, Transvaal, Mauritius, and Reunion, less satisfactory in Swaziland, and disappointing in Uganda (Kasanje).

The arrival of B.H.C., with its high initial toxicity at very low dosage, its relative lack of irritant effects on the mosquito, the absence of the factor of critical particle size, and, last but not least, its low cost, aroused great hopes and seemed to point to it as the ideal insecticide for malaria control in tropical Africa. In most of the schemes in which B.H.C. was used (particularly in Southern Rhodesia, according to Alves and Blair (1953), and partly in Nigeria) it gave good results, but it was found unsuitable in Mauritius.

During the last two years evidence began to accumulate that, applied at the initially advocated low dosage of 0.11 g. gamma isomer per m.² B.H.C. has a satisfactory residual effect shorter than the expected three months, and there is now in tropical Africa a growing tendency to use much higher doses, up to 0.4 g. gamma isomer per m.² (Alves and Blair, 1953) to prolong the duration of the residual action.

"Dieldrin"—the latest arrival on the field of residual insecticides—is extremely promising because of its high initial and long residual toxicity to mosquitoes even at a very low dosage, because of its effect on culicines as well as on anopheles, and because of the economy in its use. Its higher toxicity to man and his animals might be less important than expected, and does not prevent its use on a large scale, as shown in Venezuela. It is possible that dieldrin will prove to be the most suitable insecticide for tropical Africa.

Long Residual Action

The object of malaria control by residual insecticides is to create artificial conditions in which the reproduction rate of malaria is consistently kept below 1.0 (Macdonald, 1952). In rural areas of tropical Africa the density of *A. gambiae* is often so high that even when the man-biting index is below the conventional figure of 0.5 the reproduction rate of the disease cannot be maintained at its target figure below 1.0 unless the persistent anopheles mortality is at least 70% (Macdonald and Davidson, 1953). Thus for the purpose of malaria control in these areas a steady level of toxicity of sprayed indoor surfaces is more important than a short high initial kill. An insecticide combining a small effective dosage with a long residual action is particularly necessary in rural tropical Africa with its low population density, shortage of trained labour, and poor communications.

The advantages of an insecticide with a long residual action lies not only in its saving of costs of labour and transport. Problems of malaria control in underdeveloped areas have their ethnological and sociological implications, which must not be forgotten. In the almost mediaeval, closed, Moslem societies of West and Central Africa, with their strict customs, seclusion of women, and distrust of strangers, any invasion of the privacy of the compound is resented and will be tolerated only when absolutely necessary. Here again if we want to preserve the good will and gain the co-operation of the local people the residual spraying must be restricted to one or at most two cycles per annum.

Resistance of mosquitoes to insecticides, reported from other parts of the world, has not been recorded from tropical Africa, where attempts at control by contact insecticides have been few. Nevertheless, the possibility of its happening must not be overlooked, and it can safely be predicted that should it ever happen it would concern *A. gambiae*. The use of a highly toxic insecticide with a long residual action is less likely to produce any resistant strains.

4. Economic Aspects of Malaria Control in Tropical Africa

The problem of costs of malaria control is the leitmotiv of many conflicts not only between the public health officer and the administrator, but also between the malariologist and the public health officer. And it is the economic possibility of malaria control within the general framework of medical and health services that presents one of the challenging dilemmas in Africa. In some malaria-control projects carried out in tropical Africa the assessment of costs is often made very casually if reported at all, and the lack of standards for uniform appraisal of costs in widely varying conditions makes any comparisons between them very difficult, to say the least. The new W.H.O. proposals for standard assessment of costs of malaria control will improve the situation considerably.

Calculating the cost of malaria control by residual insecticides from some African projects, and expressing it in a convenient consolidated figure per head of the protected population per annum, we arrive at figures varying between 1s. 6d. (25 U.S.A. cents) and 5s. (70 U.S.A. cents), with a median cost of 3s. (42 U.S.A. cents).

It is interesting to note how the proportion of separate items of the cost of malaria control varies according to the type of the area, type of the insecticide used, number of spraying cycles, labour wages, and transport problems. Averaging the differences and oversimplifying the overall picture, one can say that in a large-scale project in rural African areas the cost of the insecticide constitutes about 30-50% of the total expenditure, the cost of labour and supervision between 25 and 40%, the cost of transport between 10 and 40%, and the cost of spraying apparatus and contingencies between 2 and 5%.

The cost of labour and transport is an important item in any large-scale malaria-control scheme in Africa, and this more than anything else will irresistibly increase the demand for an insecticide with a long residual action. It is in this field particularly that the competition between the relatively cheap B.H.C. and the relatively expensive dieldrin will become acute.

It was of interest to calculate the costs per head per annum of a pilot malaria-control project in Northern Nigeria and assess them separately for three main insecticides (D.D.T., B.H.C., and dieldrin) at generally accepted dosages and spraying cycles.*

Relative Costs

This calculation shows that, taking into account only the insecticide, labour, and supervision, the cost of a D.D.T. project amounts to 3s. per head per annum, the cost of a B.H.C. project to 2s. 3d., and the cost of a dieldrin project to 2s. 4d. (42, 32, and 33 U.S.A. cents respectively). If we add, however, the costs of transport over a large area with primitive roads and the high cost of fuel, lubricants, and repairs, then the differences between the above figures become even more pronounced, and are: 3s. 3d. for D.D.T., 2s. 9d. for B.H.C., and 2s. 7d. for dieldrin (46, 39, and 37 U.S.A. cents respectively).

The above costs of residual spraying of rural areas of tropical Africa are calculated at frequencies of spraying as

*D.D.T. at 2 g. para-para per m.² twice per annum. B.H.C. at 0.15 g. gamma isomer per m.² four times per annum. Dieldrin at 0.25 g. per m.² twice per annum. All as water-dispersible powders, of 50% concentration for D.D.T. and dieldrin, and of 6.5% concentration of B.H.C.

adopted by the Kampala Conference (1951). It is possible or even probable that in parts of tropical Africa, where climatic conditions are sharply seasonal and the malaria transmission period short, a reduction by half of the frequency of spraying might be adequate to intercept the infection.

In that case the total cost of malaria control by residual insecticides might decrease to something between 1s. 4d. and 1s. 9d. a head per annum, equivalent to 21-25 U.S.A. cents. This is the lowest possible cost of adequate malaria control in semi-rural or rural areas of tropical Africa, in the present circumstances, and with the barest amount of supervision.

The sum of 1s. 4d. to 1s. 9d. (21-25 U.S.A. cents), readily acceptable in many parts of the world and perhaps also in some more developed parts of Africa, is, however, seen in a different perspective when one recalls that over most of tropical Africa the total expenditure on all medical and health services amounts to something between 1s. 6d. and 3s. (21-42 U.S.A. cents) a head per annum.

It is here that the malariologist comes to an argument with the medical administrator and the medical officer of health. How can we hope to extend malaria control over wide rural African areas if our lowest estimates of costs represent in the best case 50%, and in the worst case 120% of the total medical and health budget per head?

Administrative Point of View

We know that in the African tropics malaria is an insidious, ever-present enemy, killing infants and young children, sapping the energy and strength of the people, interfering with education, decreasing the labour output, and preventing or slowing down the economic development. And yet, because of the absence of epidemic malaria, this steady wastage of life and human assets is not dramatic. The medical administrator who has to balance his financial estimates between general hospital care, sanitation, malnutrition, and such spectacular social diseases as leprosy, sleeping sickness, yaws, tuberculosis, smallpox, schistosomiasis, yellow fever, and so on, has often little patience with our, to him, one-sided and expensive argument.

From another point of view malaria-control schemes find little favour with the administrative authorities. Unlike a vaccination campaign or the checking of an outbreak of cerebrospinal meningitis, a malaria-control project is a long commitment without a prospect of rapid and dramatic result even if it is successful. In the latter case, as pointed out by Covell (1953), it is often difficult to maintain the control, because the administration is reluctant to provide further funds when malaria is no longer serious for the community.

It seems that at the present time an efficient country-wide malaria-control programme can hardly be undertaken and be integrated into the general framework of public health services in underdeveloped areas in tropical Africa. This does not mean, however, that we must wait patiently for some future changes in economic conditions. On the contrary, we must make every possible effort to start and to carry out malaria control pilot schemes in varying environmental conditions and using different methods. These projects when properly supervised, assessed, and reported will produce series of basic data which, when interchanged between different African territories, will bring us much closer to the ultimate solution of the problem of expanding malaria control as efficiently and as economically as possible, and of fitting it permanently into the standard public health activities in tropical Africa.

The need for such projects is vital, and the fact that no fewer than five of them (in Liberia, French West and Equatorial Africa, British East and West Africa) are already in their early stage and that they have the active co-operation and help of such powerful bodies as W.H.O. and Unicef is a good augury for the future.

5. Sociological Environment in Tropical Africa

The problem of uncontrollable population pressure is often quoted as an argument against the "premature promotion of malaria control in tropical Africa." The example of the Far East has shown that large-scale public health programmes improve human welfare in an immediate sense, but may defeat their own aim by leading to a rapid growth of population, which more than offsets the benefits that might otherwise have been enjoyed by a steady improvement in economic conditions. How does this situation, so well studied in the Far East and giving rise to so much concern, apply to tropical Africa, with its inherently high reproductive potential?

The population of tropical Africa—estimated in 1935-6 at 96 million (Hailey, 1938)—is estimated to-day at about 150 millions, with an average density of 17 per square mile. Such average figures are apt to be misleading, however, since we must exclude from the calculation the land not suited for human occupation. Variations in the average population density of tropical Africa will become apparent when it is realized that area densities of the population are from 1 per square mile in Bechuanaland, through 5 in the Sudan and Northern Rhodesia, 12 in Belgian Congo, 40 in Uganda, Nyasaland, and the Gold Coast, 67 in Sierra Leone and Nigeria, to over 150 per square mile in South-eastern Nigeria and in Ruanda-Urundi. This uneven distribution of the population is due to an uneven distribution of land suitable for continuous human occupation.

The population of tropical Africa, stationary or perhaps even declining during the eighteenth and nineteenth centuries, because of epidemics, wars, and the infamy of the slave trade, is now increasing at a rate on which the demographers cannot quite agree. Notenstein (1949) estimates that the most probable annual rate of the present population increase in tropical Africa is about 1.5%, and that this rate of growth will continue until 1970. Thus within the span of a man's life tropical Africa will double its population if the present rate of growth is maintained.

This may not be entirely due to the imperfect and, until now, only half-hearted methods of improving the health of the population, but it would be reasonable to assume that these methods have contributed a great deal and that they are gathering momentum. The increase of population in Africa is mainly due to an increased rate of survival.

Farming and Population Problems

The greatest part of tropical Africa is favourable to pastoral rather than to agricultural economy, but an enormous proportion of the potential cattle country is infested by the tsetse fly, which makes cattle rearing impossible. Most of the arable land not already in use is marginal and needs a great amount of work, fertilizers, and agricultural pesticides to give reasonable returns. Those who think that modern methods of mechanized agriculture will help in developing marginal lands forget that in Africa much of the unused land is very short of water.

There are possibilities of temporary nature such as improvement of present farming methods by mixed farming and fertilizing with animal manure. Unfortunately such advances have been in many instances offset by deforestation and by the general worsening of soil erosion. A more balanced approach could be achieved only by collective scientific farming instead of the primitive and wasteful small-farming methods. But this needs a heavy capital outlay, skilled technique, and, above all, a revolutionary change of old social traditions of land tenure. This change must be voluntary, since any coercive methods are out of the question from the point of view of the present administrative policy.

There is no agreement among the demographers and social scientists about the actual existence of the problem of

population pressure over tropical Africa. Macmillan (1949) goes so far as saying that "the population of Africa as a whole is positively inadequate. Many hands are needed even to clear the minimum of land at present under cultivation and then to keep it effectively occupied. The people are really all too few." On the other hand, most experienced colonial administrators agree that there is undoubtedly serious overcrowding in many areas and land hunger with all its attendant evils.

At the present time the problem of overpopulation of tropical Africa as a whole is not yet acute, and there is still some margin of safety. But this margin is narrowing every year, more slowly in some parts, faster in other parts, and the stage is set for future problems as difficult as those that mankind is facing now in Asia, if not more so. It is unlikely that in its present stage of economic development tropical Africa could withstand any considerable population pressure.

That successful malaria-control projects in Africa may have similar effects on the demographic curve as they have had in India, Ceylon, and British Guiana can be seen from the example of Mauritius and Madagascar, where the infant mortality has decreased spectacularly within the last few years. Small wonder that some people view our efforts with concern and refer to us as "sorcerer's apprentices," unable to control the primaevial forces that we might unleash. A rapid improvement of economic conditions is therefore necessary to provide for the growing population and to create all the essentials important for the well-being of modern States.

But the standard of health and education both influences and is influenced by the economic status. African standards of health and education cannot rise unless more wealth can be produced to provide for them; on the other hand, higher standards of health and education are equally necessary to increase economic production, since ill-health and ignorance are powerful factors in keeping people poor. Poor health conditions and backwardness are the main barriers to an economic development based on the increased food production per head so as to support the growing population with greater efficiency (Batten, 1949). It is my deep conviction that better health and better education are basic conditions for greater receptivity of modern trends in improvement of the economic environment in tropical Africa.

It is true, as Davey (1950) points out, that in countries of the Western Hemisphere diseases were not originally controlled as a result of a sudden medical intervention but by a steady improvement in standards of living, by a process compared to a biological growth, the speed of which depended on the technological level, and above all on the general education and active co-operation of the population. To-day we are trying to reverse this process—a method which has not yet been tested by long-term results, and which, although imposed from without, is generally followed by spectacular immediate successes in bringing down the high morbidity and mortality of underdeveloped areas.

It is clear that an attempt to solve the immensely complicated problem of overpopulation should be made not only in those countries where it already exists but also in those where it is looming in the distance, since in the latter case it may be easier to introduce the stabilizing processes. These stabilizing processes are a balanced and simultaneous development along educational, economic, medical, and social lines, with special attention to raising the status of women, and to a gradual stabilization of the population by birth control. Problems related to voluntary limitation of the size of the family are notoriously difficult to put into practice because of the religious and moral principles involved. But "the social ethic, like the law, is mutable . . . and will have to be adjusted to the circumstances of a world in which the major quest is for social amelioration" (Crew, 1953).

The difficult problem of population growth will never be solved by neglecting public health. And withholding

the resources of modern public health methods, of which malaria control is one of the most brilliant achievements, will certainly not create an environment suitable for a balanced development. As Russell (1952) says: "Pooled intelligence is required, not passive dependence on those capricious forces of nature which indiscriminately sacrifice human lives and cultural institutions."

Discussion

This is the background against which the medical and health policies in tropical Africa should be framed and must be judged. The health situation needs attacking from many angles: prevention of disease, treatment, health education, nutrition, and control of population increase. The difficult point is to decide on the order of priority of these goals, not only in relation to their respective importance but also with regard to the economic possibilities of rural areas which are providers of food and foci of disease.

Seeing that the rapidity of results achieved by modern public health measures and particularly by the control of insect-borne diseases always outstrips other aspects of harmonious socio-economic development, the administrator, the social scientist, and the agricultural officer would like us to keep pace with them, to adjust our methods to their stride, and to take part in a "co-ordinated" programme of development. But experience has already shown that the speed of such a co-ordinated programme will have to be adjusted to the speed of its lowest component. Can we slow down for the sake of keeping in line? Have we any choice?

It seems that, even had we desired it, we cannot impede the march of events for the sake of theoretical considerations: primarily because we have been taught by experience that even for a co-ordinated programme it is a better policy to emphasize at first one or two fields—either health or education, or both. Later, when the first field is established, the comprehensive programme can be developed, and will be speeded up by the example and success of one part of it.

We often hear the argument that a single-purpose project is bound to fail, and examples of such failures are often quoted. But the truth is that nearly all of these failures are due to careless planning. It will be pertinent to outline here the five points of sound planning of any programme of technical aid in underdeveloped areas quoted after Marshall Balfour (1952).

1. Objectives of the plan must be clear and definite, and they should have prospects of realization.
2. The personnel needed for it must be competent, qualified, and, above all, available.
3. The environment of the plan must be favourable for its realization. In other words, a need for the plan must be either felt by the population concerned or it must be created.
4. Sufficient time must be allowed for the job and there must not be too much pressure for immediate results.
5. There must be adequate funds to carry out the plan, remembering that long-term projects have considerable financial implications.

The other reason why we cannot possibly slow down the progress of modern public health to keep it in line with the gradual development of all spheres of social and economic activity is the demand for faster improvement of health standards in tropical Africa. This demand comes primarily from the growing national political movement, which desires the African (and quite rightly so) to have his share in the progress of mankind.

Intelligent nationalism can be a strong unifying factor wherever the people are not unified on the basis of common culture. There is no doubt that the days of crude colonialism have gone, and the new national political trends are most obvious in British West Africa, where the idea of trusteeship has originated and where no attempt has been made to suppress the indigenous culture or to model it according to some pattern. However, there are forms of extreme

and destructive nationalism which create a distrust and antagonism towards all things that are foreign, and which will jeopardize any honest attempt to help the underdeveloped areas. To prevent these extreme forms of nationalism, and to create the collective African effort which will be the basis for social and economic development, we must have genuine African leaders on our side. And so we come back in a circle to politics again in its widest application.

As Huxley (1948) says: "There is no problem in tropical Africa that it not part of some other problem. All are intertwined; nothing can be treated in isolation." How, then, to provide adequate medical care and how to control the numerous prevalent communicable diseases over a huge area inhabited by a large and varied African population, the majority of whom are at a low stage of social and economic level, live under unsanitary environmental conditions, suffer from malnutrition, have a very high infant mortality rate, and yet continually increase in numbers? How to make the necessary progress when this population is as yet unable to contribute substantially toward the financing and staffing of a tolerably adequate medical service and has to rely almost entirely on help from the outside? How to extend the social services in spite of the acute shortage of trained staff, and how to minimize the time lag between rapidly growing needs of the people and much slower economic development, hampered at times by the social confusion and political tensions of a culture in an acutely transitional stage? A tall order, indeed!

For centuries the rhythm of Africa remained unchanged. In the enormous, brooding, hot silence of this cruel and beautiful continent, man's activities were moulded by the environment. But, to-day, Africa is different. It is a continent in spasmodic transition, in ominous ferment, launched on an irreversible social revolution, and it would be unthinkable and dangerous to try to withhold from it any fruit of human progress.

My thanks are due to Dr. S. I. A. Manuwa, Inspector-General of Medical Services, Nigeria, for permission to publish this paper.

CLINICAL AND CHEMICAL STUDIES IN HUMAN LACTATION

BY

F. E. HYTEN, M.B., B.S.

Midwifery Department, University of Aberdeen

I. COLLECTION OF MILK SAMPLES

The greatest single difficulty in the study of human lactation has always been the collection of milk, and if the study is to be of practical physiological significance the milk collected for analysis must be at least all that the infant would have taken by suckling both in quantity and in composition. Further—and this will be demonstrated in later papers—a true estimate of the quality of lactation at any stage must be based on an analysis of milk representing the whole of every feeding for 24 hours.

To satisfy these conditions the infant must be replaced at each feeding by some mechanism which will remove milk without disturbing the course of lactation. It can probably never be known to what extent this is possible, because the suckling of a baby has, for the mother, emotional overtones beyond the mere local stimulation of the nipple and areola; and the mechanical replacement of this local stimulus, however ingenious, cannot hope to be an entirely effective substitute for the baby.

The shortcomings of artificial milking methods have been controlled in the past, so far as may be, firstly, by the use of methods which are reputed to be effective and to cause little or no discomfort; and, secondly, by the choice of subjects who are interested and willing to take part in the study. The advantages of having co-operative subjects are obvious, but restriction of a study to volunteers tends to select those with higher milk yields, as, for example, those donating a surplus to a milk bank.

Methods of Milk Expression

Most authors in the past have found hand expression more satisfactory than the mechanical pump, and one such manual method, used by Macy in her extensive studies, is described in detail by Davies (1945). It was used in the study by Roderick *et al.* (1946a, 1946b), and a progressive rise in milk yield during five-day sampling periods found by these authors has been illustrated by Morrison (1952). The level of milk production prior to the sampling periods is not shown, so there is no evidence that the method of sampling revealed the true yield. Morrison interprets the rise as a return towards normality from an initial depression. Deem (1931), who described a similar method, found that an infant put to one breast obtained more milk from it than could be obtained from the other breast by manual expression, but no cross-over experiments were made to eliminate the possibility of unequal breast capacity. She also found manual expression to be unsatisfactory when applied to the "large flat muscular type of breast," and excluded such cases from her study.

Personal experience in the use of both manual expression and the standard types of mechanical breast pumps has shown them to have many drawbacks. Both are uncomfortable, and the pumps often cause oedema and cracking of the nipple. Although skilled manual expression can probably empty a breast, it is time-consuming, and the use of a single operator to maintain a standardized technique throughout a 24-hour period is impracticable. The mechanical pumps are, on the whole, less effective than manual expression in emptying the breast.

*Described in the *British Medical Journal*, 1951, 2, 234.

The most recent work in man and animals stresses the importance of the milk ejection reflex in assisting milk removal, and it has been shown that injections of pitocin may replace or amplify the mechanism. Newton and Newton (1948), who used a mechanical breast pump, found that more milk was obtained from one breast when the other was simultaneously suckled and even more if pitocin was given first. These results do not suggest that the yield induced by pitocin is necessarily that which most closely represents the normal yield to the infant. It is also probable that the prospect of five intramuscular injections in one day will upset many subjects and thus have the effect of diminishing the milk yield. It would be better, therefore, to try to find a mechanical method which would imitate suckling to the extent of inducing the milk ejection reflex in the normal manner.

In the present studies, a recently devised breast pump, the "humalactor,"* has been used. This apparatus mechanically mimics the mouth action of the baby. It is much more comfortable than manual expression and seems to evoke milk ejection in each case where this has been experienced in suckling the baby. So far as can be judged, it is slightly more effective than expert hand expression in emptying a breast, since it is rarely (and only in some apprehensive subjects) that milk can be forced from the breast by hand when the humalactor has finished, whereas the humalactor can, in many cases, remove a little milk from a breast which has already been stripped by hand.

The humalactor has additional advantages. Firstly, the technique is standardized and there is no dependence on skilled operators; secondly, a great deal of time is saved for the nursing staff; and, thirdly, more patients are willing to undergo a subsequent 24-hour sampling when the initial sampling has been easy and comfortable.

Results

Data by which the two methods can be compared are presented in Tables I and II.

TABLE I.—Milk Yield

Table I shows a series of 83 subjects in a study made in 1948-9. Milk yield on the sixth day was computed from test weighing of the infant at each feed, with the addition of any residual milk manually expressed after each feed. Milk yield on the seventh day represents the result of manual expression of the whole of every feeding by an experienced and skilful nurse.

In Table II a series of 85 subjects from a current study, the sixth-day yield is again computed from test weighings and measured strippings, but the seventh-day yield was removed entirely by the humalactor.

In neither table, therefore, are the yields on the sixth and seventh days strictly comparable, since only the seventh-day yields are measured accurately. At this stage of lactation the yield is generally increasing, although many factors affect the day-to-day output, but in two series as large as these some increase in the mean from the sixth to the seventh day would be expected, whatever individual fluctuations there might be.

In the first series the mean seventh-day yield was 379.6 ml. and the sixth-day yield 441.3 ml. The reduction of 61.7 ml. is statistically significant at the 5% level.

In the second series the seventh-day yield averaged 445 ml. and exceeded that of the sixth day, 419.8 ml., by 25.2 ml., a difference which, while not statistically significant, is nevertheless an increase, and in line with the expected trend.

It is well known that a progressive rise in fat content occurs during a feeding, so that milk from completely emptied breasts would be expected to have a higher average fat content than milk from breasts which have been only partially emptied. There is no significant difference between the fat contents of the seventh-day milk in the two series; nor is any difference found if the mean fat content of milks which have decreased from the sixth to the seventh day is compared with that of milks which show an increased yield on the seventh day.

This suggests that both methods of milking can probably empty a given breast at any time in most subjects, but that manual expression, either from its discomfort or because of its lack of natural stimulation, at the time or in anticipation, causes a decreased amount of milk to be secreted.

Summary

The collection of a complete 24-hour milk output involves more than the mere emptying of the breasts at the usual feeding-times. The mechanism for milk removal should be such that not only is all the milk taken from the breast but also normal milk production is undisturbed.

This is probably not possible in all subjects, especially the more excitable, but the use of the humalactor breast pump gives encouragingly better results than manual expression.

I am grateful to Professor Dugald Baird and to the staffs of the Midwifery Department and the Aberdeen Maternity Hospital for invaluable help; to Dr. I. Leitch, of the Commonwealth Bureau of Animal Nutrition, Bucksburn, for criticism and advice; and to Mr. W. Billewicz, of the Social Medicine Research Unit of the Medical Research Council, for statistical assistance.

II. VARIATION IN MAJOR CONSTITUENTS DURING A FEEDING

The change in milk composition during the course of a feeding has been discussed in medical writings since Bartholomeus Metlinger (1473) advised that "... the wet nurse should first milk the breast so that the watery part runs from it, and then give the child to suck." During the past 50 years there have been frequent descriptions of the variations, both in man and in animals.

Morrison (1952) has made a comprehensive review of the literature on human milk, and it would be profitless to duplicate this. He quotes few exceptions to the general finding that the fat content increases from the beginning to the end of a feeding. However, Waller (1943) and Newton (1952) found a variable pattern, and Lucignani (1934) observed that the fat increased to a maximum in ten minutes and thereafter declined slightly.

There have been comparatively few observations of the variation of the other major constituents. Novellis di Coarazze (1936) described a diminution in lactose content, followed by a later recovery, in 15 out of 20 cases, but other workers have found no significant variation. A number of investigators describe no significant change in the total nitrogen content, but Macy *et al.* (1931), who examined milk from the first and last halves of the feeding, found a small but highly significant rise. The variation of nitrogen has been studied in more detail by Waisman and Petazze (1947), who found that the casein nitrogen rose and the non-casein nitrogen (including the non-protein nitrogen) fell as the feeding progressed.

Most previous observations have been made on only two or three samples from the feeding. The usual method has been to remove a sample from the breast

by hand before the infant is fed and another by stripping the breast when it is finished. One sample, or sometimes two samples, may be removed after interrupting the infant during the course of the feeding. Macy *et al.* (1931) had the entire feeding expressed by hand, but were content to divide it into first and last halves. Thus, in the human, the pattern of change in the constituents of milk throughout a feeding has not been observed in any great detail.

Method

Collection of Samples.—In the present study a number of small samples have been taken during the emptying of a breast by the "humalactor," a machine whose efficiency has been shown in Part I of this paper. The humalactor was applied to the breast in the usual way, using, instead of a collecting-bottle, a test-tube marked to contain 12 ml. When this tube was filled it was replaced by another without stopping the machine. In this way a consecutive series of 12-ml. samples was obtained until the breast was emptied.

Methods of Analysis.—Fat was estimated by the Gerber method, lactose by a modification of the chloramine-T method of Hinton and Macara (1927), and nitrogen by a modification of the micro-Kjeldahl method described by Steel (1946) for plasma protein. Casein was precipitated by acetic acid at 40° C. (Rowland, 1938) and total protein by dialysed iron. When all these constituents were estimated it was necessary to mix adjacent samples to give the necessary volume of milk. This had the effect of halving the number of samples in these cases.

Results

In any one case the breasts seldom produced equal volumes of milk unless both had been emptied completely at the previous feeding. The breast which gave the larger

FIG. 1.—Case 18, fourth post-partum day, showing the progressive rise in fat content of the milk during emptying of the breasts.

FIG. 2.—Case 16, seventh post-partum day, showing the degree of irregularity which can occur in the usually progressive rise in the fat content of milk during emptying of the breasts.

volume was usually the one at which the infant had suckled last and which had been left with more residual milk than the other.

The changes during a feeding in fat, lactose, and nitrogen found in this investigation are shown in Tables I, II, and III. The experiments are numbered so that when more than one constituent was estimated the values of all constituents can be compared together.

Fat.—A rise in fat concentration always occurred, but there was considerable variation in both the regularity of the rise and its degree (Table I). Fig. 1 demonstrates the most commonly found shape of curve, showing a flat, somewhat irregular start and an increasingly rapid terminal rise. The curve from the

right breast represents the maximum percentage rise found in the series: from 0.45 g. to 6.25 g. per 100 ml. Fig. 2 shows a more irregular rise that was sometimes found. The abrupt changes of direction seen in the curve from the right breast are discussed later. Fig. 3 shows, in the curve from the right breast, the smooth uninterrupted curve which was seen on only three occasions.

Lactose.—The lactose content shows an inverse relationship to the fat, falling from a maximum in the first sample to a minimum at the end of the feed (Table II). This is to

	8								

be expected, since, in a given quantity of milk, the volume of water is dependent on the volume of fat present, so that a rise in fat will cause, by displacement, a lower volume of water, and therefore less water-soluble constituents. The overall change in lactose was usually small, and the maximum fall, from 6.60 g. to 5.65 g. per 100 ml., was associated with an increase in fat content from 2.20 g. to 10.05 g. per 100 ml.

Nitrogen.—The total nitrogen gave a variable pattern, but the changes were in any case usually very small (Table III). In milk of the first three or four days of lactation the total nitrogen falls from beginning to end of the feeding, but after the fifth day there is usually a slight increase.

85	6	47	38	40	34	30		

The inconsistency may be explained if the protein is recognized as two fractions differing in behaviour. Casein, which may be partially adsorbed to the fat, either rises slightly at the end of the feed or remains at an almost constant level, but the soluble protein falls as less water per unit volume is available. The pattern for total nitrogen will depend, therefore, on the relative proportion of its fractions, and in the very early milk the fall is due to the characteristic preponderance of globulin. Non-protein nitrogen showed a haphazard variation in most cases, although changes were small. There was a decrease in a few cases.

Mechanism

A number of theories have been advanced to explain the mechanism of the rise in fat concentration. The belief has been expressed by earlier workers that the fat globules are arrested mechanically by the finer ducts in the breast and are squeezed out finally only by the pressure of milking, but Petersen (1929), who studied the distribution of fat in the bovine udder histologically, denied this. Lowenfeld *et al.* (1927) and von Sydow (1944) have suggested that the magnitude of increase in fat is dependent on the method of extraction, a more forcible process causing a higher final fat content; and Götz (1940), who attributed the increase to a difference in viscosity between fat and the other solids, believed the increase to become apparent only with inept evacuation. Johannson *et al.* (1952), who supported the theory of mechanical arrest of the fat globules, were able to obliterate the rise in fat content, in the cow, by vigorous massage of the udder before milking.

The steep terminal rise found in many of the present experiments is suggestive of fat being adherent to the alveolar and duct surfaces of the breast, probably by adsorption; if this is so, it should be possible to duplicate the phenomenon by exposing milk to a large and suitably arranged surface for a few hours. A rubber sponge was chosen to test this. This type of sponge has finer spaces than others available, and it is thus more nearly comparable to the breast in structure. There are, however, no spaces fine enough to hinder the passage of any fat globule. Rubber has no specific affinity for fat in globules. The sponge, cut to fit a porcelain filter funnel (Fig. 4), was filled with milk and allowed to remain immersed in it for four

FIG. 4. Apparatus used in demonstrating the adsorption of milk fat to the surface of a sponge.

TABLE IV

Sample	Fat (g./100 ml.)		
	Time of Immersion		
	3 Hours	4 Hours	12 Hours
1	2.30	2.65	0.70
2	2.30	2.85	1.15
3	2.85	3.35	2.00
4	4.00	5.25	4.45
5	6.60	7.75	9.80

hours. At the end of that time it was removed from the milk and the excess not held within it was allowed to drain. It was then placed in the filter funnel and compressed by a plunger until empty. In a number of experiments the sponge was inverted in the filter funnel so that any effect of "creaming" within the spaces could be eliminated. The milk was collected as successive 15-ml. samples, and the fat contents of these samples invariably gave a curve similar to Fig. 5. The steepness of the fat rise varied with the time allowed for adsorption, and Table IV shows the fat contents of samples obtained from a sponge immersed in milk for 3, 4, and 12 hours. This is in accord with the behaviour of the breasts, the gradient for fat being steeper on the side which has been left the longer.

FIG. 5.—The progressive rise in fat content which occurs when a sponge soaked in breast milk is emptied by compression. Curve I is from a sponge after four hours' immersion in milk, and curve II from a sponge after 12 hours' immersion.

In most cases the second breast to be sampled was, as in the usual breast-feeding practice, the breast first suckled at the previous feed. It may therefore have had an hour longer than the other breast for adsorption. This effect has also been demonstrated in the cow, a steeper gradient occurring after the long night interval than after the shorter daytime intervals (Johannson *et al.*, 1952). A breast which has been incompletely emptied at the previous feed will show a higher initial fat content than one which has been stripped completely, since its residual milk, to which the subsequent secretion is added, is of high fat content.

FIG. 6.—The effect of refilling with milk a sponge which has been only partially emptied. Curve I is from a sponge partially emptied after four hours' immersion in milk, and curve II from the same partially emptied sponge after a further four hours' immersion in more of the same milk.

Fig. 6 shows the effect produced when the sponge, after four hours' immersion, is partially emptied of milk and then re-immersed in more of the same milk for a further four hours before it is squeezed empty.

It is not surprising that the breast seldom shows in its output of fat the smooth curve of Fig. 5, since it consists not of a simple unit like the sponge but of up to 20 separately drained lobules. Only if all the lobules act in unison can such a curve be expected. Clinically, this is observed infrequently, and if the collecting-bottle of the breast pump is watched the steady trickles of milk can often be seen to be joined by an additional jet as a new lobule comes into action. In this way the rising fat concentration may be suddenly reduced by the dilute first milk of the new lobule (Fig. 2). This may explain the occasional reverse changes found by some workers, and particularly the terminal drop described by Lucignani. The findings of Lowenfeld *et al.* and of von Sydow also might be explained by the theory of physical adsorption, since the removal of the fat closely adherent to the walls of the ducts would require considerable mechanical force.

The other major constituents behaved in the sponge as they do in the breast. This would confirm that the fall in the water-soluble constituents is due to simple displacement by the fat.

Summary

During the course of a feeding there is a progressive and usually large increase in the concentration of fat, associated with a small decrease in the concentration of lactose. The total nitrogen falls from the beginning to the end of a feeding during the first few days of lactation, but as the milk matures there is usually a small increase due to a relative rise in the casein concentration.

It is suggested that the behaviour of the fat is due to the mechanical phenomenon of adsorption of the fat globules to the large secretory and duct surface of the breast, and the changes in the other constituents are secondary to this.

The entire picture has been duplicated by soaking a rubber sponge in breast milk and emptying it by mechanical compression.

I am grateful to Professor Dugald Baird and to the staffs of the Midwifery Department and the Aberdeen Maternity Hospital for invaluable help, and to Dr. I. Leitch, of the Commonwealth Bureau of Animal Nutrition, Bucksburn, for criticism and advice.

III. DIURNAL VARIATION IN MAJOR CONSTITUENTS OF MILK

The more recent literature on human milk has paid particular attention to the diurnal variation of both yield and composition, since most of the earlier work done on milk from a single feeding gave widely divergent results and little indication of the sort of milk which would be available for the whole 24 hours.

Most workers have examined the output of milk at the conventional feeding-times of 6 a.m., 10 a.m., 2 p.m., 6 p.m., and 10 p.m., with an eight-hour interval between 10 p.m. and 6 a.m., and there is general agreement that the volume is maximal at the 6 a.m. feeding and decreases during the rest of the day. Macy *et al.* (1930), however, made an analysis of milk drawn off every four hours during the day and night, including one sample at 2 a.m., and found no such early morning peak. Apart from this unusual sampling method, their results are in any case not strictly comparable with other studies, since their subjects were quite exceptionally large milk producers whose lactation had been artificially maintained and prolonged by manual expression.

Deem (1931) studied the output of a single breast in 27 cases and was able to demonstrate a mean yield dropping from 150 ml. at 6 a.m. to a level of approximately 75 ml. for all other feeds. That the yield following an eight-hour interval was double the yield after a four-hour interval strongly suggests a constant hourly secretion rate for the whole 24 hours, but no other studies have been able to confirm this, and Morrison (1952), who reviewed this literature in some detail, believes there is insufficient evidence that the yield varies only with the interval between milkings.

There is more general agreement about the very considerable variation in the fat content, the agreed pattern showing a minimum value at 6 a.m., rising steeply to a maximum at 10 a.m., and falling off during the following three feeds.

No systematic change in any of the nitrogen fractions or in lactose has been described, although for both there may be substantial differences from feed to feed in the same individual.

The collection of the entire milk output for 24 hours presents considerable difficulties, particularly without the convenience of a hospital, and it would be much more practicable to collect merely the total output of one feeding. The following study was partly undertaken, therefore, to discover to what extent any single feed is representative of the whole day.

Method

Altogether, 49 24-hour samples were collected from 42 subjects. The 24-hour sample comprised the whole output of both breasts collected by the "humalactor" at the usual feeding-times of 6 a.m., 10 a.m., 2 p.m., 6 p.m., and 10 p.m. To ensure that no residual milk from the previous 24 hours was included, the breasts were completely emptied by the humalactor after the last feed prior to the sampling period. Samples from the first week of lactation were obtained from patients in the Aberdeen Maternity Hospital, and the more mature samples from patients in the mother and baby unit of the Royal Aberdeen Hospital for Sick Children and from unmarried mothers in the Aberdeen Mother and Baby Home. The methods of chemical analysis used have been outlined in Part II of this paper.

Results

All estimations of yield and of fat, lactose, and nitrogen content are shown in Tables I-V. When any relationship has been tested statistically the level of significance is shown in parentheses.

in milk from the first week of lactation the decreasing nitrogen content characteristic of this period is so rapid that it is obvious even from feed to feed, and a progressive drop throughout the day can be seen (Table IV). In this small series the drop is not, however, statistically significant. Non-protein nitrogen, in general, remains almost constant through the day, although there are quite large variations in some cases (Table V). The differences between feeds are not statistically significant, and the slightly lower mean value at 10 a.m. is due to a few cases in which the value was much lower than the average. This may have occurred because the 10 a.m. specimen was usually analysed within one hour of its removal from the breast, whereas the other specimens were stored in a refrigerator for periods up to 20 hours, and some protein breakdown may have occurred.

Apart from the milk volume, which can be estimated with reasonable accuracy by test-weighing the infant, fat is the only variable of any practical consequence, and the results were examined to determine whether any particular feed had a fat content similar to the overall fat content of the whole 24-hour output. The fat contents were considered to be similar if they were within 0.1 g. per 100 ml. of each other. In 26 cases there was no one feed similar to the average for the 24 hours, and in 23 cases one feed was similar—the 6 a.m. in four cases, the 10 a.m. in five cases, the 2 p.m. in three cases, the 6 p.m. in five cases, and the 10 p.m. in six cases.

Discussion

The difficulties of obtaining milk samples which represent the normal yield have been stressed in Part I of this paper, and for this reason the average values, by ironing out such sampling irregularities as occur in the individual case, may have more real meaning. With the exception of the low 10 p.m. volume found in the earlier milk, the graphs in Fig. 1 show a levelling off during the day similar to those published by Deem; but although the volumes of the 10 a.m., 2 p.m., 6 p.m., and 10 p.m. feeds are almost constant, the volumes at 6 a.m. do not support her evidence of a constant hourly secretion rate in either the early or the more mature milk. There are, in fact, only three cases out of the 49 in which the 6 a.m. yield is double the yields of the other feeds. This does not, in itself, nullify the hypothesis, since the breast must have a limited capacity for milk storage, so that although most breasts can probably store four hours' full secretion, only a few may be able to accommodate twice that volume. A more detailed discussion of breast size and capacity will be presented in a later publication, but a striking illustration of this limiting effect is shown by Case 74. This woman had particularly small breasts, and her output at the five feedings of 114, 113, 117, 99, and 117 ml., strongly suggests a ceiling of milk storage.

The low fat content at 6 a.m. rising steeply to a maximum value at 10 a.m. and falling off during the rest of the day confirms previous results, although there have been no published descriptions of the variation in early milk and of the changing pattern as the milk matures. There is no evidence to support Ruzicic's (1936) belief that the variation is merely a reflection of meal-times, since all the subjects supplying early milk, and many of those giving mature samples, showed widely different patterns while living on an institutional diet which was uniform in composition and eaten at strictly regulated times. Nor does it seem to be an individual characteristic, since the same subject was able to produce different patterns on different days. For example, Case 35 on the twenty-first day had fat contents of 2.95, 4.15, 4.65, 3.65, and 3.30 g. per 100 ml., but on the thirty-seventh day produced 2.15, 5.30, 3.35, 3.35, and 2.75 g. per 100 ml. at the five feeding times. The pattern of variation was apparently unaffected by the level of total daily fat secretion, and two extreme cases—No. 41 with an overall fat content of 4.80 g./100 ml., and No. 115 with 1.45 g./100 ml.—both produced the characteristic changes throughout the day.

Bartlett (1929) found that the fat content of morning milk was particularly low in cows with small udders. He believed that the increased tension caused resorption of

milk, but this would imply that the fat was selectively resorbed, which seems unlikely. In these series the low fat content at 6 a.m. occurred even when the breast was in no way distended or even apparently full.

Kon and Mawson (1950) found that the fat content tended to be high in samples taken within four hours of the last feed and low in samples taken after six hours. This result could be explained if the breasts had not been fully emptied, as is possible with manual expression, since the first milk of a breast left longer will contain less fat than that from a breast left only a short time (Part II of this paper).

It might seem at first sight that there is some interdependence of fat concentration and milk volume, so that the rising fat and the falling milk yield would combine to produce a constant amount of fat for each feed (Fig. 3).

Fig. 3. Mean diurnal variation in the output of fat in milk from the 21st day of lactation or later.

shows the mean quantities of fat at each feeding, in mature milk, and it can be seen that almost half the daily fat output is available in the first two feeds. There is no obvious physiological advantage to the infant in this arrangement.

It is clear from the above data that the total daily output of fat cannot be assessed accurately from the analysis of any single feed.

Summary

There is a very marked diurnal variation in both the volume and the fat content of human milk, but the other major constituents show no systematic change. The variation, particularly in fat content, is very irregular in milk from the first week of lactation, but it tends to conform to a pattern in the more mature milk.

The volume of milk obtained at a feeding may be due to a combination of two factors—the length of time since the last milking and the storage capacity of the breast—but no clear conclusion can be reached from the data presented.

The reason for the very substantial variation in the fat content remains obscure.

I am grateful to Professor Dugald Baird and to the staffs of the Midwifery Department, the Aberdeen Maternity Hospital, and the Royal Aberdeen Hospital for Sick Children for invaluable help; to Dr. I. Leitch, of the Commonwealth Bureau of Animal Nutrition, Bucksburn, for criticism and advice; and to Mr. W. Billewicz for statistical assistance.

FURTHER STUDIES ON THE REDUCTION OF GASTRIC ACIDITY

BY

A. H. DOUTHWAITE, M.D., F.R.C.P.

Physician, Guy's Hospital

AND

M. G. THORNE, M.D., M.R.C.P.

Senior Medical Registrar, Guy's Hospital

The gastric acidity of patients with duodenal ulcers is more effectively reduced by the continuous sucking of alkaline tablets* than it is by the intermittent administration of antacids (Douthwaite and Batty Shaw, 1952). The above trials were made during the course of the digestive period of gruel test meals, and subsequently by drawing samples from the stomachs of fasting patients. Criticism that results based on a relatively inert gruel meal were of little value must be in part accepted. However, this type of meal has been extensively used in studies of gastric acidity over the past thirty years, and it was therefore chosen as a basis for comparison.

In the above paper were reported experiments made on the gastric pH of fasting patients exhibiting the characteristically low pH of duodenal ulceration. It is probable that this high acidity of the inter-prandial periods is responsible for maintaining duodenal ulceration. The alkaline tablets were shown to raise the pH from figures of 1.5 to 8 during the period of sucking. When food was brought into the ward a fall of pH was often noted, presumably as a result of psychic stimulation. It was therefore decided to carry out a similar series of investigations on patients with peptic ulcer taking ordinary meals, except that solid food was minced. Patients 1 and 12, however, were eating ordinary food, unminced.

Choice of Patients.—Twelve patients were chosen who were suffering from chronic ulceration—one in the stomach, eleven in the duodenum. They gave a typical history and showed the clinical and radiological signs of the disease. Those in the wards were ambulant and were eating a mixed diet, as stated above.

Method

The patients were deprived of all drugs for 18 hours before the tests. Within an hour of their usual ward or home breakfast, or lunch, they came to the laboratory and 2-ml. samples

*Subsequently given the trade name of "Nulacin."

were drawn from the gastric contents every 15 minutes. During the first hour no medicaments were given, but in the subsequent two hours the patients sucked either alkaline tablets or dummy tablets without alkali. The tests were made on two successive days; in some instances the dummy tablets were given on the first day and in some on the second. A comparison of the gastric acidity during the first-hour periods shows the degree to which the measurements are reproducible on successive days. Where the acidity on the test day is reasonably similar to that on the control day it seems legitimate to attribute differences between the two following periods to the difference in composition of the tablets. Immediately after each experiment was completed the pH of each sample was measured electrometrically.

The composition of the alkaline tablets is:

Solids from whole-milk, combined with dextrins and maltose	40 gr. (2.6 g.)
Magnesium trisilicate	3½ gr. (0.23 g.)
Magnesium oxide	2 gr. (0.13 g.)
Calcium carbonate	2 gr. (0.13 g.)
Magnesium carbonate	½ gr. (0.03 g.)
Ol. menth. pip.	q.s.

This tablet, if lodged between gum and cheek, was found to take 20 to 30 minutes to dissolve. Its food value was approximately 11 calories.

Results

The results of the tests in the order of their performance are shown in the accompanying graphs. It may be seen that in every case the alkaline tablets produced an appreci-

Acidity of gastric contents plotted against time. ← → Shows the period of tablet-sucking and the number of tablets taken. ●—●—●=Alkaline tablets. O—O—O=Dummy tablets.

certainly to a mild or moderate attack. It was found, however, that under cortisone these attacks were either extremely mild or completely absent. This encouraged us to increase the inhalation period under large doses of cortisone to double and later to treble the period which had previously caused a mild attack. Without cortisone protection such an abrupt increase must invariably be expected to cause a most violent reaction. A second exposure of the same duration was carried out when the patient had decreased his daily cortisone intake to 75 or 50 mg., a third a few days after the end of the cortisone course, and a fourth about two weeks later.

In the later experiments the second or third exposure was omitted and only three exposures were made, one under large, one under small cortisone doses, and one after the cortisone influence had ceased. Skin tests were carried out before, during, and after the course, and the blood pressure, weight, and subjective impressions of the patients recorded. No changes of blood pressure or weight were found. There was no oedema of the ankles. In one case there was slight "mooning," and in several cases the patients reported increased appetite, or nycturia, or a mild degree of sleeplessness, particularly towards the morning.

Recently two patients* were found in whom, contrary to previous experience, cortisone neither suppressed nor modified the response to a 30-33% increase of antigen dosage. It was thought inadvisable to double or treble the antigen dosage in these patients, and they are not included in the results.

Results

The results of the 18 experiments are included in the Table. Two of the experiments could not be completed because of intercurrent febrile infections. In the attacks before cortisone medication the reduction of the vital capacity was between 160 and 830 c.cm., and it occurred within 5 to 10 minutes. Under high cortisone dosage, when the period of exposure was doubled or trebled, the reduction was between 0 and 785 c.cm., and it occurred within 4 to 15 minutes. After omission of the cortisone the reduction was between 0 and 640 c.cm., and it occurred within 7 and 15 minutes. It is noteworthy that in eight experiments carried out during or after cortisone it took longer than 10 minutes to reach a significant reduction of the vital capacity. These figures show that in the immediate reactors the exposure to very large amounts of allergen was followed under cortisone by the same mild reaction which had been demonstrated after much smaller amounts of allergen without cortisone. In some cases the attacks under cortisone were even milder than those seen before, and this persisted when cortisone was omitted. In our experience this was evidence that tolerance to double or treble the amount of inhaled allergen (hyposensitivity) had been established. If this was correct we should have been able, in consequence, to increase the inhalation period further in the way which had become the routine without cortisone protection. We were able to do this in all cases.

The seven experiments with the "late reactors" differed from the others in so far that no reactions occurred under full cortisone, under reduced cortisone, and immediately after its omission. After the effect of cortisone had disappeared, mild attacks occurred in three experiments. When the exposure was repeated these attacks disappeared. It is interesting to note that this phenomenon occurred in one experiment with the subject (Case 7) who underwent two similar experiments. In the first the inhalation period was doubled and no reaction occurred after the cortisone effect had disappeared. In the second it was trebled, and a mild attack occurred after cortisone protection had ceased.

*In one of these patients the reason for this failure has now been discovered. The lowest amount of allergen capable of inducing a mild attack had not been determined accurately enough, and the experiment had been started with too large an amount of allergen as a basic value. It has now been repeated, with a satisfactory result.

Among the immediate reactors there was one exception (Case 3) from the general experience. In this experiment the attack under reduced cortisone dosage was more severe than under high dosage. It was feared that without cortisone the reaction might become too severe, and the inhalation period was therefore accordingly reduced the next time. When the whole experiment was repeated with the same subject two months later no severe reaction occurred after any of the exposures.

The skin tests did not show any decisive changes under cortisone influence. The immediate weal and flare were not suppressed in any of the cases. In two of the immediate reactors we had the impression that the skin reaction was not as intensive under cortisone as it was before. In these two cases there had been a considerable area of redness and oedema secondary to the local weal and flare. In four of the patients late positive skin reactions occurred, consisting of a local area of redness and slight swelling. These reactions were not influenced by cortisone, although suppression of the late tuberculin reaction by cortisone has been reported frequently.

The size of the weal and flare areas showed some variation on repeated testing, and sometimes an allergen showed a positive result, whereas it had been negative before or was negative afterwards. These variations were quite irregular and could not be attributed to the cortisone influence.

Discussion

An obvious possible objection to these experiments is the absence of controls. I am unable to fill this gap except from previous experience. We know what happens if a patient is exposed to an overdose of his allergen. In every case a violent attack with more or less serious consequences (hypersensitization) has followed, whether the overexposure occurred from ignorance (as in the first experiments) or by a technical error. Moreover, we have seen that attempts to increase the dosage by more than 33 to 40% above the previous exposure regularly produced too violent a reaction; since then every precaution has been taken to avoid even such minor overexposures; to double the exposure time without cortisone protection merely in order to provide a control experiment can hardly be justified.

It must be regarded as certain that without cortisone protection violent attacks would have occurred in both immediate and late reactors. It would have been expected that cortisone, so efficient in severe chronic asthma, would suppress every sign of an induced severe attack. The attacks were, however, not completely suppressed. In some of the late reactors a mild attack reappeared after the cortisone action had ceased, and in the immediate reactors the violent attack was modified into a harmless and transient wheeze. Cortisone therefore does not abolish the immediate acute attack, and it must be remembered that it does not abolish the immediate skin reaction either. There is a definite difference between the cortisone effect in the immediate and late reactors, but I cannot explain this difference.

The facts suggest that under cortisone protection an overdose of antigen has not the violent effect it otherwise would have. The after-effect is also different: no hypersensitization follows. On the contrary, the same overdose may be repeated under small cortisone doses, and later without it, without any stronger reaction than before. We see, therefore, that the mild attacks caused by a sudden twofold or threefold increase in antigen dosage (overdose) under cortisone have the same effect as the mild attacks caused by an increase of 20 to 25% without cortisone protection—that is, the development of tolerance to the higher dose (hyposensitization). The difference is that under cortisone protection a higher level of tolerance is quickly reached. This might be explained by supposing that hyposensitization is effected by the formation of a larger amount of circulating antibody in the blood, and that the more antigen is supplied the more antibody is formed. Normally, a sudden large supply of antigen leads to a violent reaction and to a condition in which the body remains more sensitive than

before—that is, hypersensitive. The mechanism of this is not understood, but it seems that cortisone suppresses it and, at the same time, allows hyposensitization to proceed undisturbed and on a larger scale than would otherwise be possible.

This action of cortisone is very different from that of sympathomimetics and antihistamines. These substances are capable of protecting against or suppressing minor and even major attacks caused by overdoses of antigen; but as soon as their effect has faded the violent reaction to the overdose becomes apparent and requires a new dose of sympathomimetic; it seems that hypersensitization as a secondary effect cannot be avoided, although this can be deduced only from general experience. Evidence from experiments is still lacking.

Our experiments have so far been done on patients with mild or moderate asthma who were either in an asthma-free interval or had chronic asthma of moderate intensity kept under control by small amounts of drugs. Whether the same effect can be achieved with severe cases of asthma remains to be seen. We know from clinical experience that the continuous severe asthmatic reaction to the allergen can be suppressed by cortisone, and that it continues to be absent for a short time after the omission of the cortisone. Gradually, however, the asthma returns. One might think that in these cases the hyposensitizing effect which may develop under cortisone is soon replaced by the hypersensitizing mechanism which has been present before.

We shall not be able to understand these observations until the action of the cortisone is more fully understood. It may be concluded, however, that in certain types of asthma hyposensitization is greatly facilitated by cortisone.

One practical conclusion follows. It will be possible to shorten the cumbersome process of hyposensitization by proceeding in bolder steps under cortisone protection. So far the therapeutic success of hyposensitization has been poor, in spite of the sometimes enthusiastic statements in many textbooks of allergy (see also Rackemann, 1932; Unger and Wolf, 1943). Hurst (1943) has expressed strong doubts of the efficacy of hyposensitization, and Herxheimer and Prior (1952) have shown that objective success is rare and can probably be achieved in only 2.5 to 4% of all asthmatics. With the help of cortisone it may be possible to by-pass some of the otherwise unavoidable setbacks, and to extend the procedure to patients with polyvalent allergy in whom this treatment so far has been less successful.

Summary

In 18 experiments on 11 asthmatic patients the amount of inhaled allergen causing a mild attack was determined. The patients were given cortisone, and when under its full influence were exposed to double or treble the amount of the same allergen. This exposure was repeated when cortisone dosage had been reduced and again after the cortisone influence had ceased.

The doubling or trebling of the amount of inhaled allergen, which normally would have caused a violent and severe attack, caused under cortisone influence either a very mild and transient attack or, in the late reactors, no attack at all. The same overexposure under reduced cortisone dosage had the same result, and this did not change after the omission of cortisone. In the immediate reactors the asthma attack tended to become still milder towards the end of the experiment, until it finally disappeared when the exposure was repeated a second or a third time after omission of the cortisone. In two other patients* cortisone did not influence a mild induced attack, and these patients were therefore not exposed to double or treble the antigen dosage.

*See note at foot of page 186.

It is concluded that, in most moderate and mild cases of asthma, cortisone protects the patients from the violent attacks through overexposure. Moreover, it prevents the otherwise unavoidable hypersensitization and permits hyposensitization to develop in spite of over-dosage.

Cortisone can therefore be used to speed up the process of hyposensitization.

I am indebted to the Medical Research Council for a personal grant and to the Asthma Research Council for a grant for technical assistance. I am also obliged to Messrs. Aerosols Ltd. for the loan of a pressure pump.

FATAL BRONCHIAL ASTHMA

A REVIEW OF 18 CASES

BY

C. KELMAN ROBERTSON, M.D., F.R.C.P.Ed.
D.P.H.

Assistant Physician, the Royal Infirmary, Edinburgh

AND

KENNETH SINCLAIR, M.B., M.R.C.P.Ed.

Registrar, the Royal Infirmary, Edinburgh

The serious results of repeated attacks of bronchial asthma are well recognized, the usual sequence of events being that emphysema gradually develops, giving rise so often to "pulmonary failure" (Fulton, 1953) and ultimately to death. The asthmatic attack itself, however, although regarded as an annoying interlude in a patient's life, causing domestic and social upset, rarely ends fatally.

The first full pathological review of a case of asthma was given by Leyden in 1886, but during the ensuing 35 years only 15 further case reports, giving both macroscopic and microscopical details, seem to have been published. Huber and Koessler (1922) summarized those 15 cases together with six of their own. Since then at least six outstanding articles (Lamson and Butt, 1937; Thieme and Sheldon, 1938; Craige, 1941; Rackemann, 1944; Unger, 1945; Walton *et al.*, 1951) have appeared, dealing with conjoint clinical and necropsy findings, the most recent of which stresses the low number of recorded cases and gives the opinion that this could be due to lack of recognition of the condition at necropsy.

The distressing consequences of this disease, both immediate and remote, have been recorded by various authors. Lamson and Butt considered that approximately 40% of cases may survive not more than four years of symptoms. In a review for insurance purposes Old (1933) estimated that the ratio of actual to expected deaths in 274 asthmatic subjects was 121% $\pm$ 5%. In differentiating between extrinsic and intrinsic asthma,

Cecil and Loeb (1951) believe that extrinsic cases do not die of the disease alone unless in very exceptional circumstances, whereas the death rate for the intrinsic group is 7.6%. The possible causes of death—hypoxaemia, dehydration, peripheral vascular collapse, drug intoxication, etc.—are fully dealt with by Segal (1950). Herxheimer (1952) reminds us that the course of bronchial asthma is always unpredictable and that even the psychologically induced attack may end fatally.

It is impossible to obtain accurate figures of death directly attributable to asthma; nevertheless reference has been made to the Statistical Review of the Registrar-General for England and Wales (1940-8) and to the Annual Reports of the Registrar-General for Scotland (1940-8), bearing in mind possible errors of certification due to diagnostic difficulties. From these reports it would seem that the average annual death rate is 3,268 for England, Wales, and Scotland. It is significant that by far the greatest number of deaths in England and Wales were recorded during 1940 (4,167), a time of particular stress in the life of the nation, which no doubt affected the asthmatic personality as adversely as those prone to perforation of gastric and duodenal ulcers (Illingworth *et al.*, 1944).

The possibility of a serious outcome from any asthmatic attack should always be borne in mind, however mild it may appear to be in the beginning. Because of the small number of reviews dealing with combined clinical and pathological findings, it has been decided to record a series of cases which fulfil all the recognized criteria of asthma.

Investigation

The following consists of a review of 18 cases, all of which were treated as in-patients in the Royal Infirmary and associated hospitals in Edinburgh between the years 1939 and 1952.

Post-mortem examination, including a careful microscopic study of the lungs and bronchi, was carried out in all cases. The clinical features of each patient were consistent with a diagnosis of bronchial asthma. In some, although other factors contributed to death (as noted in Table III), the main immediate cause was always asthma.

TABLE I

Case No.	Sex	Age	Known Duration of Asthma	Date of Death
1	F	54	Many years	24/9/39
2	F	46	4 days	5/10/45
3	M	57	9 months	7/12/47
4	M	42	35 years	16/1/48
5	F	65	Unknown	20/9/49
6	M	14	5 years	26/9/49
7	F	47	42 "	17/10/49
8	F	49	9 "	18/6/50
9	M	48	3 months	18/7/50
10	F	66	6 years	6/10/50
11	M	45	10 "	19/10/50
12	F	50	1 year	26/10/50
13	M	67	21 years	31/10/50
14	F	59	10 "	24/2/51
15	F	47	1 1/2 "	17/9/51
16	M	46	22 "	24/4/52
17	F	41	8 "	17/7/52
18	F	47	4 "	2/10/52

The sex incidence, 11 females to 7 males, in such a small review, cannot be regarded as significant. The majority died between the ages of 40 and 50 years. The variable duration of the disease (Table I) suggests that this factor cannot be related to a fatal outcome in the present series. The seasonal distribution of deaths—11 out of 18 in the months of September and October—corresponds with previous findings (Williams, 1952), the incidence having been related to respiratory infections.

For the purpose of aetiological classification three groups were recognized: psychological, allergic, and infective. It

was realized, however, that more than one of these factors could be operative in the same patient at the same time, as is evident in Table II, in which the predominant factor is placed first. A psychological background was present as either a primary or secondary factor in 12 cases. Two

TABLE II

Sex:	P		P and A		P and I		A		A and I		I		I and P	
	F	M	F	M	F	M	F	M	F	M	F	M	F	M
No. of cases	4	1	3	—	1	1	—	1	1	2	—	2	2	—
	5		3		2		1		3		2		2	

modes of death were apparent: sudden and unexpected in 13, and progressive exhaustion and terminal coma in 5. The duration of the fatal attack varied from a few minutes to 12 days.

The pathological criteria accepted were: *Macroscopic*: (1) Voluminous lungs which did not collapse when the thorax was opened. (2) Mucous plugs in the large and small bronchi. *Microscopic*: (1) The presence of mucous plugs in the bronchi associated with excessive mucus production by the bronchial glands. (2) Hyaline thickening of the basement membrane of the medium-sized bronchi. (3) Hypertrophy of the muscle of the medium-sized bronchi. (4) Eosinophilic infiltration, especially in the bronchial walls.

These features were looked for and recorded in each case. All were not constantly found, but no case was included unless the pathologist discovered unequivocal evidence of asthma. Eight cases fulfilled all criteria. All cases showed

18	+	+	+	+	+	+	

mucous plugs in the bronchi with active glands. Eosinophilia was present in all but one. The right ventricle was hypertrophied in seven. Records of Cases 3 and 15 are given below.

Case 3

A miner aged 57 was admitted on November 26, 1947. He had felt well until nine months before admission, when he first developed attacks of sneezing in the mornings, soon to be followed by attacks of breathlessness in bed at night. No precipitating cause for this could be found. The attacks at first lasted 30-60 minutes but became more severe and of longer duration, and eventually occurred nearly every night.

He also had occasional milder attacks during the day. Oral ephedrine gave slight relief. A severe attack developed in the early hours of the day of admission and adrenaline subcutaneously gave only temporary relief. He had a cough with slight mucoid sputum. His previous and family history showed nothing relevant.

On examination he was seen to be a hardy well-built man, distressed, dyspnoeic, and slightly cyanosed. His temperature was 98° F. (36.7° C.), pulse 100, and respirations 32. There was no finger-clubbing. Wheezing was audible in both phases of respiration. The chest was emphysematous. Auscultation revealed rhonchi, mainly expiratory, all over the chest. There were no crepitations. Cardiovascular system: the blood pressure was 130/80; pulse 100; no oedema; heart sounds were of poor quality. There was slight tenderness over the right antrum. On November 27 the E.S.R. was 8 mm. in the first hour; W.B.C., 9,000; Hb, 100%; a few organisms were found in the sputum. On November 28 an x-ray film of the chest showed slight emphysema, and an x-ray film of the sinuses showed some opacity in the right antrum. The E.C.G. was normal on December 2.

The patient responded initially to intensive adrenaline therapy and slept well after taking paraldehyde. He was maintained on oral ephedrine and stramonium mixture, frequently supplemented by adrenaline, "adrenutol," theophylline with ethylenediamine by injection, also phenobarbitone, amylobarbitone sodium, phenobarbitone sodium, and on one occasion pethidine, 50 mg. intravenously. He was very nervous and tense, and "sat waiting for his next injection." On December 6 all drugs except phenobarbitone were stopped, some 40 minims (2.4 ml.) of and adrenaline were given during the day. The bronchospasm subsided and he was much better. He then collapsed and died suddenly and unexpectedly at 1.30 a.m. on December 7.

Necropsy showed only bronchial asthma with marked plugging of the bronchi.

Case 15

A married woman aged 47 had suffered from a winter cough of only mild severity for many years and was not incapacitated. Eighteen months before admission she became breathless and wheezy one morning. She was in bed for 14 days, relieved by isoprenaline and theophylline with ethylenediamine. Since then she had had several relapses. The attacks were usually worse at night and were best relieved by isoprenaline. She was able to go about, apart from occasional spells of a few days in bed. There was some tension regarding her employment, and at the time of admission she was apprehensive and in bronchospasm of moderate severity. She had had an acute anxiety state when her husband died of cerebral tumour in 1933. Since then she had been very nervous and easily upset. She had had an artificial menopause induced in 1939.

On examination she was pale, thin, and anxious, but not cyanosed. Her temperature was 98° F. (36.7° C.), pulse 90, and respiratory rate 22; no finger-clubbing. There was slight emphysema; rhonchi, mainly expiratory, were heard all over both lungs. There were no crepitations. Cardiovascular system: the pulse was 102, regular; blood pressure, 110/70; heart not enlarged—sounds normal and no oedema. Endocrine system: palms were warm and moist, there was slight tremor. There was no thyroid enlargement, and no bruit was heard over the gland. On September 3 the sputum contained the usual respiratory organisms. The an x-ray film of the chest showed possible slight emphysema, and an x-ray film of the sinuses was negative.

Bronchospasm of moderate degree was present on admission. She responded to sedation with phenobarbitone sodium and oral theophylline with ethylenediamine, plus sodium and oral theophylline with ethylenediamine, plus phenobarbitone. Isoprenaline sulphate was also used on occasion. As it was thought there might be a thyrotoxic state, thiouracil was begun on September 7 with slight effect. The patient was reasonably well at 12 noon on September 17,

with slight bronchospasm. She collapsed suddenly at 1.30 p.m. and died in a few minutes.

Necropsy revealed asthma and emphysema, with marked plugging of the bronchi with tenacious mucus.

Discussion

It is generally thought that most cases of asthma react to treatment. A fatal issue can, however, be tragically sudden and unexpected. The possibility of error in an unduly optimistic attitude is emphasized by the fact that 18 such deaths have been available for review (3 in 1949, 6 in 1950, 2 in 1951, 3 in 1952, along with 4 earlier ones) from four general hospitals in this area. Analysis of the aetiology, age, and duration of disease has shown that these factors are unreliable aids to prognosis in any single attack.

The treatment carried out in all cases consisted of the usual measures employed in hospital. The drugs used included bronchodilators, expectorant mixtures, sedatives, anti-histamine drugs, and antibiotics. Oxygen and oxygen-helium mixture were often used. Bronchoscopy was performed in some cases. Cortisone was available for the most recent case.

No new pathological feature was observed, but ample confirmation of the importance of plugging of the bronchi with tenacious mucus was apparent.

The immediate cause of death in bronchial asthma has not yet been clearly defined. From the nature of the condition it would seem probable that several factors can be responsible. It is proposed to review a few which have emerged from this investigation.

As previously noted, two modes of death were observed. It is reasonably easy to account for exhaustion and ultimate death from a prolonged severe resistant attack of bronchospasm which has lasted several days without remission. Progressive anoxia and failure of the right heart are responsible. Although it may be significant that a psychological element existed in 12 cases, the reason for the failure of response to therapy cannot be related to any constant clinical or pathological pattern.

The sudden death of an asthmatic patient who was relatively well until within a few minutes of death is more difficult to explain. At the present time we can only offer the following suggestions for consideration.

In a very severe acute attack progressive rise in the intra-alveolar pressure must quickly overcome the pulmonary capillary blood pressure of 10 mm. Hg. This would lead to occlusion, as when the pressure in the cuff of a sphygmomanometer approximates to that in the brachial artery. The much-increased resistance of the pulmonary vascular bed thus cannot be overcome by the right ventricle, which fails, with consequent cyanosis, collapse, and death.

It must be regarded as significant that mucous plugging was invariable in this series. The possibility of mechanical asphyxiation by this means has been previously noted in the literature. This may be explained by tenacity of mucus, bronchial spasm, and oedema, along with the fact that the mucus is sucked deeper and deeper down into the bronchial tree until it becomes impacted. The effect of this is inadequate alveolar gaseous interchange, with sudden death due to suffocation. Such can occur in a relatively well asthmatic subject with much mucus in the large bronchi who inspires deeply because of emotional or physical stress—for example, excitement, or, as happened in one of our cases, straining at stool on a bedpan.

The importance of an adequate initial clinical assessment and subsequent management of the asthmatic patient between attacks is already recognized. In view of the varied therapeutic measures used in the cases under review, it is thought that suggestions outlining a programme of treatment for the acute attack, rationally based on clinical and pathological findings, might be of interest.

The patient in an acute attack who shows signs of increasing cyanosis, dyspnoea, and distress within a few hours, in spite of attempted control, should be transferred to

hospital. This decision would be hastened by a history of previous resistant attacks. On admission attention must first be directed towards relief of bronchial spasm.

Adrenaline when used "in adequate dosage" must still be considered the most effective bronchodilator. It should be stressed that many allegedly resistant cases have been shown to be due to too small a dose. In the absence of obvious cardiovascular contraindications we would recommend the immediate injection of 20 minims (1.2 ml.) of 1:1,000 adrenaline hydrochloride as advised by Herxheimer, and used by one of us (C. K. R.) Where contraindications exist 0.25 g. of theophylline with ethylenediamine may be given intravenously.

For the severe, acute, cyanosed asthmatic sufferer from anoxic anoxaemia the early use of oxygen/carbon-dioxide mixture 95.5% is obviously indicated at a rate of 6 litres a minute. This mixture is used in preference to pure oxygen as the carbon dioxide helps to prevent the onset of apnoea and has an expectorant action (Basch *et al.*, 1941).

While one cannot condemn the use of morphine in status asthmaticus too strongly, because of its central depressant action on a respiration already barely adequate, these patients are as a rule fatigued and apprehensive, and benefit from the safe sedation produced by phenobarbitone sodium, 3 gr. (0.2 g.) intramuscularly.

Mucous plugging has been stressed throughout this paper, as it has apparently often contributed to the death of the patient. Potassium iodide renders sputum less viscid and thus easier to expectorate. It should therefore be given as soon as possible, in the form of Lugol's solution, 10 minims (0.6 ml.) three times a day.

Cortisone and A.C.T.H. are accepted as powerful anti-allergic agents and can be used in attacks resistant to the scheme of treatment outlined above. These drugs encourage fluid retention, however, and this should be borne in mind if there is any sign of cardiac failure.

In the asthmatic patient with an infective sputum penicillin should be given in anticipation of bacteriological results.

Summary

The relevant literature on bronchial asthma is briefly reviewed. Eighteen cases of fatal asthma are recorded, with clinical and pathological findings. Thirteen deaths were sudden and unexpected.

Possible immediate causes of death are discussed.

Treatment is considered.

We wish to thank Dr. Robertson Ogilvie and the staff of the Pathology Department of the University of Edinburgh for valuable co-operation. We are indebted to the physicians of the Royal Infirmary, Edinburgh, and associated hospitals for access to case records.

CHRONIC BRONCHITIS IN GENERAL PRACTICE

BY

JOHN FRY, M.B., F.R.C.S.

General Practitioner

Diseases which are commonly encountered in hospital practice are not necessarily the most important from the point of view of national health and personal suffering. In considering disease from these aspects we must have regard to (a) its total incidence; (b) its average duration; (c) the types of persons affected and the period of life at which it produces its effects—thus a disease during the working years is of more national economic significance than one affecting the retired age groups; (d) the loss of time from work which it causes; (e) its mortality; (f) its preventability; and, above all, (g) the suffering which the victim undergoes. The most important national diseases, with regard to these factors, are the infections of the upper and lower respiratory tracts, the nervous and mental disorders, acute and chronic rheumatic manifestations, tuberculosis, and disorders of the digestive and cardiovascular systems.

As a distinct clinical entity, chronic bronchitis is one of the most important of diseases in this group—both numerically and socially. It is only in general practice that it is seen in all its stages and in all the effects it produces on the individual and the family group. In hospitals the condition is encountered only when the patient is referred there by the general practitioner, and this is usually only for diagnostic purposes—x-ray examination and sputum analysis—during an acute exacerbation and during the late stages with cor pulmonale.

Chronic bronchitis is in some degree responsible for over 30,000 deaths annually in Great Britain. It has been estimated to account for the loss of some 16½ million working days a year (Report of Ministry of National Insurance, 1950), and this does not include the condition as it affects the housewives, who, although an important and essential working group, do not receive insurance benefits. In general practice it accounts for a large volume of work. In my own practice in S.E. London it was in 1952 responsible for some 8% of all attendances, while Pemberton (1949), in Sheffield, estimated that it accounted for some 11% of all attendances. Proportions are probably higher still in some north-west areas of England.

The condition produces serious disablement. The Disabled Persons Register (*Ministry of Labour Gazette*, May, 1950) lists 7.9% of its total as being disabled on account of "non-tuberculous disease" of the lungs, of which chronic bronchitis constituted the largest proportion. The Treasury Deputy Medical Adviser's Report for the G.P.O. for 1951 shows that chronic bronchitis was responsible for 15% of all retirements on health grounds.

Other factors which make the disease one of such major national importance are its long duration, often causing trouble for 25 to 30 years, and the fact that each winter it causes a considerable loss of worktime. In addition, it affects principally middle-aged men in their most active and able years, which makes the absence from work of even greater significance. The fact that it is probably largely a preventable condition adds to its

importance and introduces an urgent and imperative need for further researches and actions in this field.

What is "Chronic Bronchitis"?

Having glibly talked of "chronic bronchitis," implying it to be a specific and distinct clinical entity, I must attempt to define the condition before proceeding further. Almost certainly what we now know, or think we know, as "chronic bronchitis" consists of a number of separate but allied conditions, and it is necessary to separate these clinically and to seek out their different causes before we can proceed to its rational and satisfactory management.

For the purposes of this paper the term has been used to depict a chronic condition as seen in patients who have been under my care for some years and in whom the chief features are an irritating and recurring productive cough with variable amounts of sputum, to which some degree of dyspnoea is usually superadded. These patients have at some time during the course of the illness had their chests x-rayed to exclude such conditions as tuberculosis, neoplasms, pneumoconiosis, etc. Cases of asthma and bronchiectasis have been excluded from this series.

A survey is made of a series of 127 cases of chronic bronchitis, using the term in a broad sense, seen in my practice. It is most important to stress this, for the results and observations can by no means be taken to represent the state of affairs in the country as a whole, but perhaps it might show the need for, and the possibilities of, a nationwide investigation.

The Condition as Seen in General Practice

Before discussing the disease it is essential to know something of the population at risk and the area in which they live. The practice is situated on the south-eastern outskirts of London and is typically suburban. The patients, numbering 4,500, are principally in social classes 3 and 4, being employed either in local light industry or in clerical and administrative duties in London, which is some 10 miles distant. The age distribution includes the usual proportions of all ages (Table I). The climate is that common to the

TABLE I.—Numbers at Risk in Age Groups

Age	0-9	10-19	20-29	30-39	40-49	50-59	60-69	70+
No.	663	466	670	790	780	550	370	208

British Isles. This area has its share of temperature changes in winter and summer, and is also liable to have severe winter and autumnal fogs. Atmospheric pollution is probably not excessive, but, while there are no large industrial concerns, each house—and these are all of the simple semi-detached three-bedroom variety—burns at least one fire almost continually during the winter.

For the purposes of this survey a note has been kept over the past few years of all patients thought to be suffering from chronic bronchitis; the report is a retrospective one covering in detail the year 1952, which in some ways was an abnormal one, as it included a severe and persistent fog.

In September, 1952, there were 127 chronic bronchitics in the practice, five of whom died during the following 12 months. This gives an incidence of 28 per 1,000. On these figures there might be some 1½ million such patients in the British Isles at the present time.

Sex Distribution.—There were 71 males and 56 females. Although there is a slight male preponderance, it is not nearly so marked as that quoted by Oswald *et al.* (1953) and Goodman *et al.* (1953). The former had an 8:1 male predominance and the latter had a mortality from chronic bronchitis of four males to one female. The actual numbers in the different age groups and the rates per 1,000 of the practice's population are given in Table II. The incidence

TABLE II.—Age Distribution of Chronic Bronchitis and Rates Per 1,000

Sex	Under 40		40-49		50-59		60-69		70+	
	No.	%/100	No.	%/100	No.	%/100	No.	%/100	No.	%/100
Males	7	7	12	30	20	67	27	142	12	125
Females	7	7	19	30	13	52	16	90	13	127

is seen to rise with age, especially when the true rates per 1,000 are studied, and here, too, can be seen the definite male preponderance, except in the under 40 and the 70+ groups, but this may be peculiar to the practice.

Social Classes.—As already stated, the practice consists principally of social classes 3 and 4, and the chronic bronchitics show roughly the following distribution:

Social Class:	1	2	3	4	5
Males	..	..	..	35	30
Females	..	..	1	30	20

Goodman *et al.* (1953) showed that the mortality from chronic bronchitis increased inversely with the social groups, but their figures were for 1931. Oswald *et al.* (1953), however, found that the distribution of chronic bronchitis was parallel to that of the controls. It cannot be concluded, therefore, that the condition is one of the lower social groups.

The duration of the condition is shown in Table III.

TABLE III.—Duration of Condition (Years)

	Less than 5	5-9	10-19	20+
Males	6	13	30	22
Females	9	12	17	18

The age of onset was usually between 30 and 60 (Table IV).

TABLE IV.—Age of Onset

	Under 20	20-29	30-39	40-49	50-59	60-69	70+
Males	1	5	16	16	28	5	—
Females	2	9	9	19	12	5	—

The personal habits of the patients may possibly have a bearing on the condition, and some attempt has been made to examine these. Most of them had always resided in London and its environs.

Tobacco smoking has recently been prominent as a possible cause of carcinoma of the bronchus, and it must also be considered in chronic bronchitis. No real differences were found between the smoking habits of the chronic bronchitics and those in a series of controls of similar age and sex distribution (Table V). Oswald *et al.* (1953), on the

TABLE V.—Smoking Habits of Chronic Bronchitics Compared With a Series of Controls

		Consumption of Tobacco		
		Non-smokers	Under 20 Cigarettes a Day	20+ Cigarettes a Day
Males	Chronic bronchitic	10	36	25
	Control	11	38	22
Females	Chronic bronchitic	22	19	15
	Control	30	21	5

other hand, found a significant difference: 9% of non-smokers among the chronic bronchitics and 20% among the controls.

There was no evidence of alcohol being a causal factor, nor were there any significant occupational hazards.

A family history of chest disease was rather difficult to ascertain accurately, but it was thought to be significant in some 47 instances (25 men and 22 women).

Extent of Morbidity

Some 25% of all attendances in general practice are for conditions of the respiratory tract. Most of these are on account of minor upper respiratory affections such as the common cold and its complications. In 1952, in my practice, this group of upper respiratory infections accounted for some 60% of attendances for respiratory conditions. Chronic bronchitis was responsible for 25% of the total respiratory attendances (over 1,000), representing 8% of all the attendances during the whole year.

These attendances for chronic bronchitis showed a rise with age corresponding to the age incidence of the condition, and again there was little difference in the sexes. As would be expected, there was a marked seasonal variation, the attendances for chronic bronchitis being six times more in December than in August. Almost a third of these patients had to have more than one month away from work during the year, and the majority of them were men (Table VI). It is common knowledge that the housewife cannot afford as much time for illness as her husband.

TABLE VI.—Duration of Sickness in Chronic Bronchitis Over One Year

	Incapacity Time		
	Nil	Less than 1 Month	More than 1 Month
Male	26	15	30
Female	30	16	10

Clinical Features

Difficulties in connexion with the diagnosis and conception of the disease are partly due to the fact that a number of other conditions have very similar clinical features which require differentiation.

Asthma, as a diagnosis, should be reserved for cases which are characterized by sudden and limited bouts of dyspnoea with signs of bronchospasm and in which, at least in the early stages, cough and sputum are not prominent. The late stages of asthma, on the other hand, can present a picture identical to that of chronic bronchitis, with severe productive cough, dyspnoea, and the barrel-chest deformity and heart failure. **Pulmonary tuberculosis**, especially in elderly men, can present clinical features like those of chronic bronchitis, and can be excluded only by chest x-ray examination and sputum analysis for tubercle bacilli; these investigations should therefore be carried out in all chronic bronchitics. The various types of **fibrosis of the lungs**, both occupational and others, can also present similar features, and here again radiological differentiation is necessary. **Congestive heart failure** at times presents difficulty when a productive cough is a prominent symptom.

Clinically, chronic bronchitis is a condition with few symptoms and signs. It is characterized by a productive cough—at first present only in the winter months and usually worse in the morning and evening—and dyspnoea, which varies both in degree and in duration. The course of the condition is often punctuated by acute exacerbations with severe local and systemic disturbances. The signs are merely those resulting from the presence of secretions in, and obstruction of, the bronchial tubes—namely, rhonchi and rales. In the later stages non-specific structural changes take place and produce the barrel chest and emphysema.

There are no specific diagnostic tests. Chest radiography shows little abnormality in the early stages and only features of non-specific emphysema later, but it should be carried out to exclude other conditions already mentioned. Sputum analyses have not been found of any real value in either diagnosis or treatment.

Closer study of any large group of chronic bronchitics will reveal certain grades of severity, and it is of value to define and describe them.

The onset itself is variable; usually it is slow and insidious, with a productive winter cough, increasing in severity year by year; but in some, particularly the more elderly patients, it may be sudden, often following a pneumonia; in others there may be no apparent cause.

Case History.—A fit groundsman aged 58 had never suffered from a cough until the influenza epidemic in 1951, when he contracted pneumonia, which was complicated by severe bilateral lobar pneumonia. Since then he has had a persistent cough with much sputum and dyspnoea. The chest skiagram is not abnormal and bronchography reveals no bronchiectasis.

Grading

It must be realized that the following grading does not necessarily imply that the condition is a progressive one from one grade to the next. It can remain stationary at one level without any deterioration. The distribution is shown in Table VII.

TABLE VII.—Distribution of Different Grades of Chronic Bronchitis in the Two Sexes

	Males		Females		Total	
	No.	%	No.	%	No.	%
1. Winter cough	26	36	15	27	41	33
2. Winter cough and acute exacerbations	13	19	17	30	30	25
3. Symptoms all year round	20	28	19	34	39	30
4. Complete invalid	12	17	5	9	17	12
	71	100	56	100	127	100

1. **Winter Cough.**—The least troublesome form of chronic bronchitis is that which is characterized merely by a recurrent winter cough. There are usually no abnormal physical signs. The sputum varies in quantity and appearance, most often being mucopurulent. The symptoms usually begin in October or November, following a cold which "goes to the chest," and persist until about April. In the present series this form represented 33% of the total, being slightly more common in males.

2. **Winter Cough and Acute Exacerbations.**—The next group is those patients with the winter cough who, in addition, are liable to have acute exacerbations. This complication occurs as a sudden deterioration in the chronic state with urgent dyspnoea and severe systemic upset—but there are various degrees of severity. Some cyanosis is usually apparent and there is a distressed wheezing respiration. The pulse is rapid and full, and the temperature may vary from subnormal to a high fever. Examination of the chest most commonly reveals restricted movements and suppressed breath sounds with added rhonchi and rales. There is no evidence of any consolidation, either clinically or radiologically. The exact cause of this serious and common complication is unknown, but it seems to be the result of an acute superadded condition affecting the bronchial and bronchiolar mucosa in a subject with an already defective respiratory apparatus. It is suggested that the infection in some way disturbs the distribution of the pulmonary blood flow (*Lancet*, 1953). This condition was particularly common during the severe fog of December, 1952.

3. **Symptoms All the Year Round.**—Patients with these symptoms constitute the next group. By the time this stage is reached—and it accounts for some 30% of all the cases—the patient is becoming increasingly dyspnoeic and disabled. Although the productive cough is present all the year the symptoms are worse in the winter, and at this time, too, the course is apt to be complicated by the acute exacerbation already discussed. Each such attack leaves the victim more disabled, and the condition eventually merges into the next grade.

4. **Complete Invalidism.**—This group, which fortunately accounted for only some 12% of the total, presents a distressing and pathetic picture. It is more common in men and is the stage of respiratory and cardiac failure. Dyspnoea is severe; the cough is extremely irritating and

disturbing, and is associated with the expectoration of a large volume of purulent and mucopurulent sputum. There is a profound accompanying general systemic upset with loss of weight and appetite, lack of sleep, headaches, nausea and vomiting; and eventually death occurs, either from cor pulmonale or during an acute exacerbation.

Management

It is the general practitioner who has the task of caring for these patients in all their stages. For they are seen in hospital practice only when the diagnosis is being considered and when some special forms of treatment and special nursing are necessary. At all other times the G.P. is responsible for the physical and moral care of these cases, and it should be stressed that the latter aspect of treatment is a most important one. "Sympathetic encouragement" is an absolute essential in management. It should be stressed that treatment cannot be applied rationally, but only empirically, on account of our lack of knowledge of the causes, but these empirical measures can help our patients considerably.

General advice on the best type of occupation and on ways of improving living conditions and the removal or correction of any aggravating factors can be of great value. Breathing exercises are important in maintaining good respiratory movements.

Relief of the cough is a most difficult problem. Although the scientific value of expectorants and linctuses is doubted, our patients invariably tell us what relief they have had from our favourite mixtures. Postural drainage should be encouraged night and morning, and is often of much value.

Bronchospasm and dyspnoea are sometimes helped by antispasmodics such as ephedrine, isoprenaline, and others—either by mouth or as sprays. It is important that the acute exacerbations be treated energetically, with antibiotics and oxygen, when necessary, in order to prevent any deterioration in the already poor pulmonary reserves.

It is wrong to pretend that we can influence the natural course of the condition, with the exception of the acute exacerbations, and it is much more important to endeavour to devise methods of preventing it rather than to seek new forms of therapy for the established state.

Discussion

Before we can prevent the disease we must know more of its causes. In order that we may be able to do this it is essential to study more carefully and thoroughly what is known about the disease and its natural history. We should seek reasons to explain differences in age and sex incidence, and the differing mortality and morbidity rates in the different countries of the world. We must study the possible influences of smoking, climate, atmospheric pollution, and any other factors which may present themselves.

Global Incidence

It is difficult to compare vital statistics from different countries, particularly when they relate to an indefinite condition such as chronic bronchitis. Nevertheless, interesting and useful information is obtainable (W.H.O., 1952). The death rates for "bronchitis" for many countries of the world are given and can be presented as rates per 100,000 of the population.

A difficulty is that this term includes both acute and chronic forms, but this can to a certain extent be overcome by excluding countries where the death rates from bronchitis are greatest in children. This will leave us with figures which, although not necessarily representing the true incidence of deaths from chronic bronchitis, will give roughly comparable figures. Table VIII shows that the death rate is 100,000 in various countries. It shows that the death rate is highest in England and Wales, and the term "English disease" might well be transferred to chronic bronchitis, which alike appears to be a typical product of English weather and murky towns" (*British Medical Journal*, 1953).

TABLE VIII.—Showing Death Rates Per 100,000 from Bronchitis in Different Countries of the World in 1950

England & Wales	65	S. Africa (White)	15	Chile	7
N. Ireland	47	Italy	15	France	6
Scotland	43	New Zealand	14	Uruguay	6
Spain	35	Australia	12	Sweden	4
Japan	30	Netherlands	11	Canada	4
Belgium	28	Germany	10	Israel	2
Portugal	25	Austria	10	U.S.A.	2
Switzerland	20	Puerto Rico	10	Finland	2
Ceylon	16	Norway	7	Denmark	1

Although these figures require more investigation and confirmation, it can be seen at once that great differences exist between countries with similar degrees of social and economic development. Thus the death rate for England and Wales is 30 times greater than that for U.S.A. and more than twice as much as for more industrialized and more thickly populated Belgium.

Lewis-Fanning (1940) compared the seasonal variation in mortality rates between Great Britain and the U.S.A., and found that, whereas the total rates do not differ much over the year, the mortality rates from chronic bronchitis were over 12 times greater in Great Britain during the winter and more than six times greater in the summer.

There are also differences in the rates for different areas in the same country. In this country the death rates are highest in the regions of Newcastle-upon-Tyne, West Riding of Yorkshire, Liverpool, S.E. Lancashire, Birmingham, and South Wales, and there is a definitely increased rate in the urban areas as compared with the rural areas (Goodman, Lane, and Rampling, 1953). Lewis-Fanning (1940), however, in his survey of New England, U.S.A., found that the death rate from chronic bronchitis was greatest in the rural areas.

Climate and Atmospheric Pollution

We have only to look back to the fog of December, 1952, to see the effects which cold and atmospheric pollution exert on the mortality from respiratory disease. During this period some 4,500 deaths were directly attributable to this cause. Almost all these deaths occurred in chronic bronchitics over 45. Similar effects were observed in Glasgow in 1925, in the Meuse Valley in 1933, and in Donora, U.S.A., in 1948. In my own practice that fog produced severe effects on some 35% of these chronic bronchitics (Fry, 1953). There is therefore no doubt that atmospheric pollution, as fog, produces serious effects in the chronic bronchitic. It is another matter, however, to deduce that chronic bronchitis is caused directly by atmospheric pollution, but there is strong evidence for this point of view.

The effects of the climate have received all too little attention. Woods (1928) showed that the most extraordinary relationship exists between the fall in temperature and deaths from respiratory disease. Further attention should be paid to the physiological and pathological effects of climate on the respiratory tract.

Conclusions

Chronic bronchitis, accounting as it does for 30,000 deaths annually and for 16½ million days lost from work every year, is indeed a national wasting disease.

It is extraordinary that, whereas the mortality rate from pulmonary tuberculosis has decreased sevenfold in the past 100 years (3.11 per 1,000 in 1847 and 0.47 per 1,000 in 1947), the rate for chronic bronchitis has not altered conspicuously (0.96 per 1,000 in 1847 and 0.75 per 1,000 in 1947) (Daley, 1951). What are the reasons for the mortality remaining at this high level? It may be that the condition is merely a degenerative state which now reflects our ageing population. It may result from an increase in our atmospheric pollution, which, acting in conjunction with our cruel climatic conditions, produces inflammatory changes in the bronchi. It may be the aftermath of certain acute infective conditions such as influenza. It may be connected with our changed smoking habits—although in this series no appreciable difference was noted in chronic bronchitics and controls. All these factors need further inquiry.

We must also explain the differences in mortality rates from chronic bronchitis in the different countries of the world. Why should our mortality rate from this condition be almost 30 times greater than in the U.S.A.? And why should it be more than twice as much as that of Belgium? Obviously there is a great need for further research and inquiry into the causation of and variation in the disease.

This research should be carried out at a number of levels, one of which should be in general practice, for it is here that the true incidence and course can be observed. That this is possible has been proved, and perhaps it should be the first step in a national and possibly world-wide investigation and effort. It is considered by many to be a preventable disease (Lewis-Fanning, 1940; Pemberton, 1952; Joules, 1953a, 1953b). If this is borne out then vigorous steps at the highest levels should be taken to implement the findings.

Summary

The toll from chronic bronchitis includes 30,000 deaths and 16½ million lost days from work annually. In the G.P.O. 15% of all medical retirements are due to this cause. Around 10% of all attendances in general practice are for chronic bronchitis.

It is an indefinite clinical entity, which probably includes a number of separate and distinct clinical conditions.

In a study of a single S.E. London practice 127 chronic bronchitics were diagnosed (incidence of 28 per 1,000) during one year. Males numbered 71 and females 56. The incidence rises with age. No social predisposition was noted. It is indeed a chronic condition. In more than half the cases it had already been present for over 10 years. The commonest age of onset was between 30 and 60. In this particular series there was no difference between the smoking habits of those with chronic bronchitis and controls. A third of the patients were incapacitated from their usual occupation for more than a month during the year.

An attempt has been made to grade the disease into four groups of severity.

At present we have to rely almost entirely on palliative measures in the management of cases. Until its causes are defined and rational steps taken to prevent the condition, little progress can be made.

The most helpful lines of research may be closer studies of the natural course and distribution of the disease. The mortality rate from chronic bronchitis in England and Wales is far and away the highest in the world. It is some 30 times that in the U.S.A. These differences must be more closely examined.

There is a definite relationship between climate and atmospheric pollution and the disease. We have only to note that 4,500 deaths in December, 1952, were directly attributed to fog.

A nation-wide effort is necessary if we are to reduce the wasteful, and possibly unnecessary, effects of the disease.

It is a pleasure to acknowledge the help received from Mrs. K. Sabel and Mr. A. A. Cushion in the preparation of this paper.

SALMONELLA DUBLIN OSTEOMYELITIS OF THE SPINE

REPORT OF A FATAL CASE

BY

A. A. MILLER, M.D., D.P.H.

(From the Group Laboratory, Royal Infirmary, Preston)

Bone and joint infections due to the food-poisoning salmonellae have been recorded much less often than have typhoid and paratyphoid infections. Ramon Guerra (1940), in his review of the literature on this subject, found 15 authentic cases of salmonella bone or joint infections during the period 1926–38. Thirteen of these were due to *Salm. suispestifer* and two to *Salm. breslau* (one of the two was a mixed infection with *Streptococcus haemolyticus*). Reports of *Salm. typhimurium* osteomyelitis were published by Stevenson (1938) and Krauss (1947). Vinke and Downing (1947), in their report of a case of *Salm. montevideo* infection of the knee-joint in an infant aged 6 months, state that in the 17 known outbreaks of *Salm. montevideo* infection in the U.S.A. this was the only reported instance of knee-joint involvement.

Salm. dublin, although well known as an intestinal pathogen, has seldom been isolated from bone or joint lesions. Lawrie (1952) described a chronic *Salm. dublin* osteomyelitis of the femur in a man aged 29 in which *Staphylococcus aureus* was found in association with *Salm. dublin*. Purnell (1952) reported a case of a woman aged 71 with a purulent prepatellar bursitis due to *Salm. dublin*.

The following case is reported because of the unusual localization of the *Salm. dublin* infection to the lumbar vertebrae. It was a post-mortem finding.

Clinical History

A man aged 77 who had enjoyed good health until the latter part of July, 1951, began to complain of lethargy. After a holiday in Scotland he had a shivering attack on August 11, and two days later was confined to bed with a temperature. He complained of increasing lethargy, headache, frequency of micturition, and pain in the left renal angle. Acute pyelitis was diagnosed. He was unsuccessfully treated with citrates and later with courses of penicillin and chloramphenicol. On August 28 he was admitted to the Lytham Hospital for investigation and was discharged in about a week. For the four and a half months until his death, treatment was continued in hospital and at his home. The earlier complaints persisted with increased severity and the patient suffered a long illness, characterized by rigors, high temperatures, and constant backache. Courses of chloramphenicol and aureomycin had surprisingly little effect, although the aureomycin controlled the temperature better than did the chloramphenicol. He died on January 13, 1952, the illness having lasted about five months.

Laboratory Investigations.—The bacteriological findings can be summarized as follows. *Salm. dublin* was isolated from two blood cultures, one early and one late in the illness, and from each of two specimens of urine and faeces, about midway in the disease. Many faecal specimens enriched by tetrathionate broth and selenite F medium failed to grow *Salm. dublin* except on two occasions, on October 8 and 20, 1951. It is noteworthy that before the initial isolation of *Salm. dublin* from the faeces five consecutive specimens of faeces were negative for salmonellae. The same negative results were obtained on examination of five consecutive specimens of faeces after the second isolation of *Salm. dublin*. This illustrates the difficulty which may be

experienced in isolating the organism in atypical cases of *Salm. dublin* infection. By the *in vitro* sensitivity tests the *Salm. dublin* strain was sensitive to chloramphenicol and aureomycin in the concentrations used in the disk method.

The results of agglutination tests with the patient's serum early and midway through the disease were as follows:

	September 13		October 31	
	H	O	H	O
<i>Salm. typhi</i>	Nil	Nil	1:25	1:25
<i>Salm. paratyphi B</i>	1:25	1:125	1:25	1:25
<i>Salm. enteritidis</i>	—	—	1:2,500	—

Radiographic examination of the abdomen on August 31 showed considerable osteoarthritic changes in the lower dorsal and lumbar spines.

Necropsy

Examination 20 hours after death showed an extensive haemorrhagic rash on the neck and upper part of the trunk, together with purpuric patches on the outer aspect of the left thigh and on the left great and second toes. The left thigh was very swollen, tense, and fluctuant. The mucous membranes were blanched. Basal bronchopneumonia and membranes were present. Both ventricles were oedema of both lungs were present. The myocardium was flaccid and moderately dilated, and the mucosa was slightly toneless. The whole of the small intestine was slightly dilated and the lower part of the ileum contained abundant mucus, while the mucosa itself was engorged. In the lower abdomen, the most striking feature was a large tumour mass in the retroperitoneal tissues which projected into the root of the mesentery of the small intestine and filled the left iliac fossa. It consisted partly of a saccular arteriosclerotic aneurysm of the posterior wall of the lower abdominal aorta, about 3 cm. above its bifurcation. It was a relatively large sac, the entrance measuring 4.5 by 3 cm., and the large sac, the entrance measuring 4.5 by 3 cm., and the walls were lined with thick layers of organized blood clot. It had burrowed posteriorly and to the left, and by means of its increasing size had pushed forward the lower part of the aorta. Behind the sac was a large psoas abscess which extended from the upper lumbar bodies along the psoas muscle to the mid-thigh. The bodies of the second and third lumbar vertebrae were partly destroyed and the residual portions were soft, necrotic, and oozing with pus, suggesting an acute pyogenic osteomyelitis with psoas abscess formation, associated with an aneurysm of the lower abdominal aorta. The kidneys showed chronic interstitial nephritis and at the necropsy the blood urea was 130 mg. per 100 ml.

The anatomical diagnosis was osteomyelitis of the lumbar vertebrae, *Salm. dublin* septicaemia, uraemia, basal bronchopneumonia, and cardiac dilatation.

Post-mortem radiographic examination of the lower spine revealed marked destruction of the bodies, the intervertebral disks, and of both contiguous and articular surfaces of the second and third lumbar vertebrae.

Histological examination of the affected lumbar bodies showed marked bone necrosis with polymorphonuclear response around the lesions, the pathological picture of acute pyogenic osteomyelitis.

Pure cultures of *Salm. dublin* were isolated from post-mortem specimens of blood (approximately 45 organisms per ml.) and of pus from the psoas and the thigh abscesses, and mixed cultures, including *Salm. dublin*, from the small intestine and the lung.

Discussion

The overall clinical picture was that of a typical *Salm. dublin* septicaemia characterized by rigors with high temperature and continued fever. The osteomyelitis with psoas abscess, clinically obscured by the lack of localizing symptoms and by the marked constitutional disturbance, was the main factor responsible for the continued and progressive severity of the illness, the blood stream having presumably been repeatedly infected from this source.

Bacteriological examination of post-mortem material from the lumbar and psoas abscesses showed that the progressive osteomyelitis was caused by a single salmonella type and not by a mixed infection. The histological appearances of the affected lumbar bodies, closely resembling the well-known picture of acute pyogenic osteomyelitis, serve to demonstrate that salmonella osteomyelitis may be similar to or identical with bone infections produced by other pyogenic organisms and that the diagnosis must always be made by the isolation of the actual organism from the lesion.

The localization of the disease to the lumbar spine could be explained as a metastatic lesion or as a haematogenous osteomyelitis. According to the literature, the latter is a relatively rare or infrequent finding. Weaver and Sherwood (1935) state that haematogenous osteomyelitis due to *Salm. suispestifer* apparently occurs only in infants.

A more likely explanation lies in the association of the lesion with the aneurysm of the lower abdominal aorta. The repeated and continued erosion of the lumbar bodies by a large aneurysm would provide a locus minoris resistentiae with localization of the organism and the production of acute osteomyelitis. Most authors agree that in the production of typhoid and paratyphoid osteitis and osteomyelitis injury is an important localizing factor. This association has also been observed and recorded in the food-poisoning salmonellae infections, although much less often than in the typhoid lesions. Steuer (1937), in his case of *Salm. breslau* infection in a boy of 12 years, states that a bicyclist accident eight days before the onset of the illness precipitated osteomyelitis of the sacro-iliac joint. The same article mentions the case of a young woman in whom obstetric manipulation was followed by fatal *Salm. suispestifer* infection. Purnell (1952), in his case of atypical *Salm. dublin* infection, states that a fortnight before the onset of the prepatellar bursitis the patient fell and injured her knee.

Although the psoas abscess could have caused the aneurysm of the lower abdominal aorta, the degree of aortic atheroma strongly favours the presence of an aneurysm long before the abscess developed.

The mode of infection could not be traced. Food-poisoning during the patient's visit to Scotland was the most likely explanation. Potential domestic sources of infection were explored. No history of infection was obtained from the only two surviving members of his family. Single faecal and urinary specimens from one of them failed to reveal salmonellae. Samples of the household milk, which came from four different sources, were examined for salmonellae, with negative results.

Summary

A fatal case of bacteriologically verified *Salm. dublin* osteomyelitis of the spine is recorded and the relevant literature is reviewed.

The localization of the osteomyelitic lesion was probably associated with a large arteriosclerotic aneurysm of the lower abdominal aorta.

There is no specific histological or radiological picture in salmonella osteomyelitis. The diagnosis rests upon the isolation of the organism from the lesion itself.

I am indebted to Dr. D. M. Anderson and Dr. J. Glynn for the clinical history, and to Dr. Joan Taylor for identifying the organism.

p-OXYPROPIOPHENONE IN TREATMENT OF MENOPAUSAL DISORDERS

A STUDY FROM GENERAL PRACTICE

BY

ALBERT W. BAUER, M.D., M.R.C.S., F.I.C.S.

No reliable agent for provoking the secretion of anterior pituitary follicle-stimulating hormone (F.S.H.) has yet been discovered. To inhibit its secretion, however, we can use oestrogens and androgens; these substances will act as a brake on the anterior pituitary, but they have unwanted and even dangerous effects on the genital organs. For a long time, therefore, a search has been made for a substance which would inhibit pituitary activity without exerting a peripheral stimulating action. Buu-Hoi *et al.* (1950) and Lacassagne *et al.* (1950) succeeded in modifying the chemical structure of synthetic oestrogens in such a way that they lose their peripheral oestrogenic action. The new compound, which they have called 4-hydroxy-propio-phénone, represents chemically one-half of the diethylstilboestrol molecule:

Perrault (1950) introduced this substance into therapy. Several authors (Perrault and Vignalou, 1949; Perrault *et al.*, 1949; Gennes *et al.*, 1950; Husslein, 1951) have reported that, in men, *p*-oxypropiofenone ("popp") tends to inhibit the gonadotrophic secretion of the anterior pituitary, although its oestrogenic activity is less than 1/10,000 to 1/1,000 of that of stilboestrol (Hohlweg, 1949). The potential value of the compound was quickly recognized. Perrault, de Gennes *et al.*, and Husslein used it clinically in conditions in which they suspected excessive anterior pituitary activity, especially where this was associated with hyperfolliculinaemia. They claimed that symptoms could be controlled without undesirable side-effects.

Clinical Trial

It seemed of interest, therefore, to try the compound in cases in which peripheral oestrogenic activity could be readily assessed, control of anterior lobe function seemed

Some Details About the 34 Patients Treated

Age Groups:	45-50	51-55
Last period 2 years ago	10	4
" " 3 or more years ago	12	8
Flashes up to 15 or more daily	16	8
" " 5 a day maximum	6	4
Vaginal smears, cornification present	20	7
" " semi-atrophic condition	4	3
Weight normal	11	5
" above normal	7	4
" under	4	3
" after treatment normal	15 (+4)	6 (+1)
" " above normal	3 (-2)	3 (-1)
" " under	3 (-1)	2 (-1)

desirable, and the symptoms could not be ascribed entirely or primarily to deficiency of oestrogens. The substance was therefore submitted to clinical test in 34 women complaining of post-menopausal disturbances, in particular of flashes (see Table). Most of these women had previously received treatment with oestrogens for periods of at least six months without improvement, and they could therefore be regarded as refractory. Before treatment with "popp" (four weeks or more after the last administration of oestrogens) vaginal smears were examined. In 27 cases vaginal cornification was still in evidence, whereas in the remaining seven cases the epithelium showed the typical semi-atrophic appearance with prominent basal and transitional cells. Eleven of these women were overweight, seven were somewhat below normal weight, and none of them showed any complicating systemic disorder. The group as a whole was thus highly selective, being composed of women with varying oestrogen levels but with the common characteristics of frequent flashes refractory to oestrogen medication.

After the initial vaginal smear, treatment was begun. Following Husslein's procedure 0.5 g. of "popp" was given twice daily by mouth and this dosage was maintained until the frequency of flashes was significantly reduced; the dose was then gradually lowered to a maintenance dose of 0.1 g. twice daily for two to three months, after which treatment was stopped. In the cases which did not respond the maintenance dose of 0.1 g. twice daily was also stopped after three months. During treatment vaginal smears were examined periodically.

Results

Effect upon Flashes.—In 31 out of the 34 patients the symptoms were readily controlled by treatment. For instance, in a woman aged 55 who had had no period for two years and had experienced up to 15 flashes daily the attacks were reduced after 11 days' treatment to one or two flashes daily. Continuation of the treatment at the reduced dosage level resulted in reducing their occurrence to one every third or fourth day, and ultimately to one weekly, and this only in the presence of some exciting factor such as agitation. The symptoms did not recur after stopping treatment, and the patient has remained free of symptoms (duration of observation one year). Similar striking results were observed in 30 other patients. In three there was no definite effect. They were sophisticated women who had already seen many physicians and had demanded hormones for their rejuvenating effect (which effect I failed to observe in them).

Effect upon Vaginal Smears.—Cornification persisted throughout treatment in 19 of the 27 women in whom it was present before treatment, nor did cornification appear to be reduced after treatment (six weeks after its termination). In the seven women in whom the smears had shown a more or less atrophic condition of the epithelium, cornification was not restored with the doses used; however, it must be stressed that the smears were taken after the dose had been reduced to 0.1 g. twice daily (equivalent to less than 1/1,000 to 1/100 mg. of stilboestrol).

Toxic Effects.—No toxic effects were observed, and the only side-effect was slight indigestion, which responded rapidly to sodium bicarbonate. Three overweight patients lost some weight. There was no vaginal bleeding either during treatment or after its termination, and no other pelvic changes were noted.

Discussion

The results indicate that in a high proportion of women with menopausal flashes refractory to oestrogens control may be achieved by "popp." (I have lately used "popp" indiscriminately in all cases of menopausal flashes with satisfactory results.) The response can safely be ascribed to medication rather than to any psychological reaction to treatment, since all the women had received treatment "with tablets" before the present course without reporting any response.

It is unlikely that the drug acted by virtue of its peripheral oestrogenic action, not only because animal tests have shown this to be low but also because the doses used failed to evoke vaginal cornification. The drug's apparent efficacy is of particular interest as its use may obviate two dangers which occur in oestrogen therapy. Oestrogens may advance precarcinomatous conditions; in addition, they may give rise to an "unphysiological state." In the natural climacteric oestrogens are gradually eliminated from the endocrine concert, and any artificial increase in their level, besides placing an additional burden upon the mechanism of sterol inactivation, tends to aggravate the state of disbalance now recognized to be present in many menopausal disorders (*British Medical Journal*).

In the present series absence of irregular vaginal bleeding was particularly noticeable, as bleeding is a common occurrence in patients receiving oestrogens and is worrying to both patient and physician alike.

While it is clear that the clinical effect of "popp" can hardly be ascribed to its minute oestrogenic action, it is difficult to provide a satisfactory alternative explanation. The control of anterior pituitary secretion which Lacassagne and others claimed for "popp" has not been observed by and others experimenting on animals (Guillemin, 1951; Money *et al.*, 1951; Paulsen *et al.*, 1951; Schaffenburg *et al.*, 1951). It is of course possible that the substance is sufficiently potent to regulate anterior lobe function during the labile menopausal state. Further clinical experiments, involving the study of the gonadotrophic titre of the urine, are now being planned.

Summary

Thirty-four women with post-menopausal flashes uncontrolled by oestrogens were treated with *p*-oxypropiofenone ("popp"). This drug is related to stilboestrol and is claimed to inhibit pituitary gonadotrophic activity without exerting a peripheral oestrogenic effect.

Of the 34 patients, 31 were completely relieved of their symptoms. There were no toxic effects and no vaginal bleeding such as may be encountered during oestrogen therapy.

Smears taken during and after treatment showed no evidence of vaginal cornification in seven patients with evidence of vaginal cornification in seven patients with evidence of vaginal cornification. This is interpreted as indicating that "popp" does not exert any appreciable oestrogenic effect.

The mode of action of the drug is discussed.

I am indebted to Messrs. Metochem, of Vienna, VI, Austria, for supplying tablets of "inphysen" (*p*-oxypropiofenone) and to Messrs. Arthur H. Cox & Co., Brighton, for making up such tablets. I am also indebted to Dr. Erica Wachtel for cytological information concerning vaginal smears.

THE WINTER VOMITING DISEASE

A REPORT FROM GENERAL PRACTICE

BY

JOHN F. GOODALL, M.D.

Skipton, Yorkshire

About the end of January, 1953, we began to see a number of patients whose main complaint was sudden and severe vomiting. Measles and the usual feverish colds were prevalent, chickenpox was ending after a mild visitation, influenza due to virus A had just arrived from the South, and there were a surprising number of cases of true lobar pneumonia.

The typical story was of a person going to bed "as right as rain" and waking up in the early hours to vomit energetically, repeatedly, and copiously. This was preceded by brief nausea, accompanied by epigastric pain and some collapse, and followed by a few loose pale stools. The appetite was poor and nausea persisted for a day or two, after which recovery was complete and the patient was ready to accept the diagnosis of "gastric flu" from either his doctor or his friends.

This diagnosis was not confirmed by serological tests from nine patients. No change was found in complement-fixation titre to virus A or B of influenza, as between sera taken early in the disease and after recovery.

Faeces from six patients were not found to contain pathogenic organisms. E.S.R. and white-cell counts were done for four patients seen in the acute stage, and were normal.

It was decided to make a more detailed study, and it soon became apparent from patients whom we examined that friends and relatives had suffered from this disease but had not consulted a doctor. Of 46 patients 11 neither called nor consulted us for their attack of vomiting. It was obvious that the epidemic was far larger than we ever knew.

We were not impressed with the infectivity of the disease, for of our 46 patients 35 were the only sufferers in the household. Frequently there was another member of the family who had had a cold, but this was thought to be coincidental. Only five of our patients had an upper respiratory infection at the time of their attack.

The illness was brief, usually less than two days, though those patients whom we had previously treated for functional dyspepsias took longer to recover. There were six such patients, and their illness lasted six days on an average.

Only one patient had a relapse. Two patients who never vomited are included in the series. Both were seized with diarrhoea at dawn, for no obvious reason, and both lost their appetite for a day or two. One such attack was followed the next day by the typical illness in another member of the household.

It seemed to be impressive that only two patients ascribed their illness to food. Why food, which is blamed for hypertension, rheumatism, and the failing strength of old age, should escape incrimination for a gastro-intestinal upset is a mystery which was not solved. One man ascribed his attack to having just felt the first movement of his first child in his wife's abdomen.

The typical attack is easy to recognize in an epidemic; the less typical or the isolated attack has to be distinguished

Incidence of the Disease

4 to 8 p.m. ..	3	4 to 8 a.m. ..	11
8 p.m. to midnight ..	6	8 a.m. to noon ..	4

Two patients did not vomit.

from food-poisoning, Sonne dysentery, infective hepatitis, appendicitis, and the beginning of an upper respiratory infection in children, especially measles. Laboratory tests help to exclude some of these. Positive help in establishing the diagnosis is not yet available.

The disease has previously been described under the name "winter vomiting disease" or hyperemesis hiemis, and reports of a few epidemics have been published.

The epidemic here described appears to conform; and the belief that there is no such disease as "gastric flu" seems to be strengthened.

I am grateful to my partners, who took the trouble to investigate thoroughly what was really a trivial disease, and to Dr. H. T. Findlay, of the Public Health Laboratory, Wakefield, for his advice and for the assistance given by his laboratory.

Medical Memorandum

Dysgerminoma of the Ovary

Dysgerminoma of the ovary is not a very common tumour, and when it does occur often presents before the age of 20. A case is described of such a tumour in a child of 8, the tumour itself having undergone torsion. So far as I can ascertain from the literature this is the first case in which this has been recorded. Novak (1941) reports a case in a child of 6, but this tumour had not undergone torsion.

CASE HISTORY

A girl aged 8 was admitted on March 4, 1951. She had been in good health until five days before admission, when she suddenly developed colicky pain in the mid-abdomen just below the umbilicus and vomited shortly afterwards. The pain had been present on and off ever since, but lately had become more constant. Vomiting had persisted since the onset. There had been normal daily bowel actions until the morning of admission. On this day she had had several loose motions. There were no urinary symptoms.

She was an ill-looking child with a temperature of 102.8° F. (39.3° C.) and pulse of 100. There were no abnormal findings other than those in the abdomen. Here an obvious swelling was visible in the lower part in the mid-line. It was hard and extremely tender, with a well-defined edge, and seemed to arise from the pelvis. There was no rigidity in the abdomen but some guarding; rectal

examination revealed a firm tender mass in the pouch of Douglas. A catheter produced a few drops of urine. The abdomen was then re-examined, the findings being exactly the same. Urine examination was normal, and the white cells numbered 19,000 per c.mm. An exact pre-operative diagnosis was not made.

It was decided to perform a laparotomy. The abdomen was explored through a right lower paramedian incision, and some free blood-stained fluid was seen. A solid ovarian tumour which had undergone torsion was found. This tumour had replaced the right ovary. The left ovary looked normal, and the uterus was the usual size for a child of 8. Rapid exploration of the abdomen did not reveal any evidence of disease elsewhere. The tumour was removed easily and convalescence was uneventful. The pathological report, for which I am indebted to Dr. A. G. Marshall, was as follows:

"The specimen consists of an ovarian tumour which is ovoid in shape, measures 10 by 7 by 6 cm., and weighs 147 g. Its surface is lobulated and one half is engorged. The cut surface shows this half to be heavily infiltrated with blood, but the rest consists of a white tumour; it is soft and has no definite structure, but there is a suggestion of cyst formation in it. It is very mucoid. Section shows the tumour to be composed of large cells having a fairly abundant cytoplasm and a large oval nucleus. They lie packed together in clumps, giving them a polygonal appearance. There are large numbers of mitotic figures. Between the clumps there are fibrous trabeculae, which in this case are not infiltrated by lymphocytes. While the capsule at this point is intact, there is infiltration of it by the tumour cells. An unusual feature is one alveolus made up of columnar cells. It might be an example of metaplasia, it might represent a residual embryonic structure, or it might suggest an origin in an embryoma. The appearance is that of a dysgerminoma of the ovary. Novak states that a fairly high proportion are malignant, but, of course, this case was operated on before there was evidence of local spread. It appears that radiotherapy is often useful. It is noted that there is no sexual abnormality. I should be interested to know whether there is an abnormality of the urinary tract, as so often occurs."

The Hogben test was negative.

On receipt of the pathological report the child was examined particularly for signs of pseudohermaphroditism, but no signs were found. A chest radiograph was quite normal. In view of Dr. Marshall's question about the urinary tract an intravenous pyelogram was performed, but this also was normal.

COMMENT

Dysgerminomas are not common tumours. Novak (1941) reports what appears to be the youngest case, that of a child of 6. Pick (cited by Matsner, 1923) records a case in a child of 9. Rösle (1912) records a bilateral dysgerminoma with metastasis in a child of 12. This case therefore appears to be the second youngest recorded in the literature and the first case of torsion of such a tumour. Willis (1948) states that three-quarters of the subjects are under 30 years of age and quotes Meyer's (1951) original review, in which 27 out of 48 cases were associated with pseudohermaphroditism. However, the proportion of subsequently recorded cases of dysgerminoma associated with pseudohermaphroditism has been much lower. The tumours are essentially malignant and capable of metastasis. Klasten (1933) refers to metastasis in the lymph nodes and peritoneum, and Kirshbaum and Newman (1943) performed a necropsy three years after removal of the ovarian growth and showed that there were deposits in the lungs, liver, kidneys, and peritoneum.

I am indebted to Mr. J. C. Newbold for permission to deal with this case and to Dr. A. G. Marshall for the pathological report and Hogben test.

THE MEGALOBlastic ANAEMIAS

The Megaloblastic Anaemias. By Professor L. J. Davis, M.D., F.R.C.P., F.R.C.P.Ed., F.R.F.P.S.G., F.R.S.Ed., and Alexander Brown, M.D., F.R.C.P.Ed., F.R.F.P.S.G. (Pp. 113. 21s.) Oxford: Blackwell Scientific Publications. 1953.

A few years ago a critic attacked clinical scientists for working on problems which were esoteric and unimportant. So far as the study of the symptomatology of advanced disease is concerned this is fair criticism, but he then went on to cite pernicious anaemia as a case in point. Few examples could have been worse chosen. Pernicious anaemia is a relatively uncommon disease, but it is one of a group of megaloblastic anaemias some of which cause much sickness and many deaths in the Tropics. The true answer, however, is that the study of pernicious anaemia has given us two new and important vitamins, folic acid and vitamin B₁₂, and has opened up a large number of problems of great physiological and pathological interest. To mention only a few, there are the significance of the gastric secretion, the aetiology of simple atrophy and cancer of the stomach, the ology of intestinal absorption, and the maintenance of mechanism of the long tracts of the postero-lateral columns of the spinal cord. This is the story that Davis and Brown have sat down to tell, and they have done it in small compass and with great skill. They discuss the whole range of pass and with great skill. They discuss the whole range of megaloblastic anaemias, which are clearly defined and catalogued. Haematological controversies and minutiae are logued. Haematological controversies and minutiae are skillfully avoided and the relevant facts are presented in their right perspective. Indeed, the skill with which they have outlined the numerous problems which are exercising and exciting research workers in this field is remarkable: to give but one example, the chapter on the aetiology of the megaloblastic anaemias is a model of exposition of a difficult subject. Where possible the approach is historical, and in this connexion the authors pay a deserved tribute to a brilliant essay on the history of pernicious anaemia by a Robb-Smith which is too little known. This book is a monograph which any physician will be able to read with interest and profit. It is delightfully produced, and it reflects much credit both on the publishers and on the Scottish school of haematology.

BRITISH MEDICAL MEN

British Medical Science and Practice. An anthology arranged and edited by G. F. Petrie, M.D. (Pp. 172; illustrated. 15s.) London: Longmans, Green & Co. 1953.

The British Contribution to Medicine. By Dr. Jaime Jaramillo-Arango. Foreword by Sir Arthur MacNalty, K.C.B., M.D., F.R.C.P. (Pp. 220; 45 plates. 25s.) London: E. and S. Livingstone Ltd. 1953.

British Medical Science and Practice is an anthology which was begun by the British Council during the second world war with the object of allowing doctors practising abroad to follow the development of British medicine. The book is in three parts. In the first part 10 medical pioneers are chosen and to each is allowed a chapter of pages of quotations selected from their own writings and from their biographies, and thus Dr. Petrie builds up an attractive portrait of his subjects' personality and achievement. This is an ingenious and successful method and there will be few readers who are not stimulated by some observation unknown or forgotten. The chosen 10 are Harvey, John Hunter, Jenner, Charles Bell, Bright, Addison, Simpson, Florence Nightingale, Lister, and Manson; the last of the list was born in 1844 and the first in 1578. Their greatness is undisputed, and in no alternative selection could rival them in achievement, in universality, or in personality. The third section is composed of 98 extracts from the writings of modern masters. Here the intention is to give a picture of the British contribution to medicine and its related sciences during the last

25 years. While the names of these stars cannot rival the Great Ten, it is inspiring to remember that they include Lewis, Barcroft, Sherrington, Hopkins, Dale, Harington, Almroth Wright, Ronald Fisher, Fleming, and Dodds. The quotations vary in significance and importance, but many of them record discoveries and advances which are landmarks in modern medicine. There is included a brilliant description by Sherrington of the activities of the "roof-brain" during sleep, a dramatic personal account of the effects of salt deficiency by McCance, and a physician's discussion by Christie of the physical signs of emphysema. Although the second part, which is devoted to selected aphorisms, does not equal in interest the other part of the book, it is yet pleasant to find here one modern—Geoffrey Keynes, our great surgeon-bibliographer—undismayed by his departed and distinguished company. Dr. Petrie has constructed an admirable book, well suited to occasional reading.

Dr. Jaime Jaramillo-Arango during the recent war was the ambassador of the Republic of Colombia to Great Britain and has written this tribute to British medicine. It is said to be a historical survey of six medical advances in which British workers have played a predominant part: antityphoid inoculation coupled, as the toastmasters say, with the name of Almroth Wright; penicillin and Sir Alexander Fleming; the mosquito in malaria and Ronald Ross; paludrine and F. H. Curd, D. G. Davey, and F. L. Rose; vitamins and Gowland Hopkins; stilboestrol and Sir Robert Robinson and E. C. Dodds. Although the toast is the British Contribution to Medicine, the book, like many excellent after-dinner speeches, strays from its subject. Its greater part deals historically with antibiotics, malaria, nutrition, and cancer. Medicine is universal and indivisible, and to have included only the British contribution to these world-wide investigations would have excluded too much. It would be churlish, however, to refuse a compliment from a surgeon-ambassador, and we can in reply congratulate Dr. Jaramillo-Arango on his erudition and his eloquence.

D. V. HUBBLE.

THE NEW PSYCHOLOGY

Progress in Clinical Psychology. Edited by Daniel Brower, Ph.D., and Lawrence E. Abt, Ph.D. Volume 1, Sections 1 and 2. (Section 1: Pp. 328. 37s. 6d. Section 2: Pp. 235. 43s.) New York: Grune and Stratton. London: George Allen and Unwin. 1953.

Since the second world war there has been rapid development in the application of psychological techniques, and in the clinical field in the U.S.A. this has received great encouragement from the policy of the Veterans Administration of making use of the highly trained non-medical worker in assessment, treatment, and rehabilitation. In America, industry and its administration, education, child care, psychiatry, criminology, and the armed Forces have made use of the graduate psychologist and are making an increasing demand on the universities for larger training programmes and for more specialized postgraduate training in this field. As defined in these books, the clinical psychologist is no mere medical auxiliary, and his clinic may be the school, the workshop, the personnel department, the court, or the advertising conference. The psychological consultant is now prepared to take charge of such problems as stammering, discontent in the factory, personal maladjustment, and vocational guidance, which have for long been thrown at the doctor as a sort of general sage, in spite of the fact that he has had no more preparation for it than any other intelligent citizen. Clinical psychology can now claim that it has no more seers and mountebanks in its ranks than psychiatry, and that there is so much to do that there is plenty of room for both clinical and medical psychologists. As a logical step it now seeks to establish a synthetic code of ethics, consonant with its non-traditional development, and this is roughly the position in the English-speaking countries at the moment.

The editors have undertaken the large task of selecting and summarizing the more important contributions to the

literature of the subject in the last seven years. They have also indicated more general trends and their place in the development of the subject as a whole. The first section is mainly devoted to developments in method, while the second deals with psychology as applied in a variety of fields, and its relation to the contributory sciences such as cultural anthropology, statistics, and sociology. The whole approach is American, as is by far the greater part of the literature quoted. Since psychology has manufactured its own jargon in the course of a rapid development, the terms used are often rather surprising. Dr. Abt, who is director of research in a department of biomechanics, is as concerned as we are at the irreconcilability of the psychologists, whose approach is too rigidly scientific, and of those who are by nature intuitive and "psychodynamic." In fact, he says that "there is a nomothetic-idiographic dichotomy in clinical psychology that demands resolution." On the idiographic side American psychology seems still to be tied very closely to the psycho-analytic approach and to the "client-centred" therapy in which it is applied.

There is no doubt that in spite of the variations in quality inseparable from multiple authorship this book is a most valuable conspectus and source-book of recent psychological literature in the field of human relations and human maladjustment. The sections on the development of children and the mental hygiene of the family give an indication of the amount of conflicting testimony in this field. In fact, from the work quoted a very sound case could be made for the thesis that the greatest danger to a child's successful adjustment to society is a consciousness on the part of his parents that he has any psychology at all.

It is intended to publish further volumes every second or third year, and as judged by the first two sections the book should find its place as a valuable work of reference.

ALEXANDER KENNEDY.

CLINICAL ELECTROCARDIOGRAPHY

Clinical Electrocardiography. By David Scherf, M.D., F.A.C.P., and L. J. Boyd, M.D., F.A.C.P. Fourth revised edition. (Pp. 490; 292 figures. 42s.) London: William Heinemann, 1953.

The authors begin by describing the standard bipolar leads. This is soundly done in the old-fashioned way. The description of the chest leads might well be clearer, and the unipolar limb leads come somewhat later. One feels that the large mass of information which the beginner must absorb in those sections might have been simplified considerably if approached in a more modern way. Sometimes also CR leads are referred to as well as V leads. There appears to be no guiding principle in all this, and mental confusion must result. The effect of the position of the heart on the electrocardiogram needs further exposition, particularly for readers who are going to use the old standard bipolar leads. The difficulties which arise in lead III are not made easy. The little section on artifacts is good; it is a pity these also appear in some of the illustrations; not a few are blurred and indistinct and are below the level one expects in a book from the U.S.A. The illustrations throughout are the three standard leads and sometimes a fourth; but what that may be is never indicated. When we look for more modern topics we find a remarkably clear account of the ventricular gradient; this is well done in two pages. The last chapter, on vector cardiography, is very good too, as clear an exposition as we have read anywhere.

There is a great deal of information in this edition, much more than in the second, while the book is very little longer, which is a matter for congratulation. But it does not seem that the now apparently complex subject of electrocardiography is made any easier by reading it. Most of the difficulties that baffle the beginner come from the standard bipolar leads. They do not muddle the more experienced, but for the neophyte a new approach is easier by way of the unipolar (so-called) leads. This has been done nowadays with much success and encouragement.

TERENCE EAST.

TEXTBOOK OF THERAPEUTICS

Therapeutics in Internal Medicine. By 84 Authorities. Edited by Franklin A. Kyser, M.D., F.A.C.P. Second edition, completely revised and reset. (Pp. 830. £5 10s.) London: Cassell and Co. 1953.

This is the fourth book on the therapeutics of internal medicine compiled in America which we have reviewed in the last year and a half. As this volume, like the others, is large and not inexpensive, it is a testimony to the wide spread interest in therapeutics which exists in that continent. Like the others also, this is a composite work written by a group of outstanding men whose investigations and teaching experience in certain phases of internal medicine qualify them to make authoritative statements. There are 84 of them, 66 of whom are professors, emeritus professors, associate professors, assistant professors, or directors of large units. As each of the other three volumes could field a team roughly comparable in size and distinction, and as there was practically no overlapping between them, they exemplify the number and diversity of the medical pundits of America.

This book covers much the same ground as the other four and gives much the same therapeutic advice. Indeed, in up-to-date teaching centres throughout America, in Britain, Canada, Australia, New Zealand, Scandinavia, and Holland, it is remarkable what general agreement there is on therapeutic principles, though the same cannot be said of other European countries. This volume is planned to present material related only to treatment, and discussions of physiology, aetiology, pathology, and clinical descriptions of disease are reduced to a minimum. In this respect it differs from at least one of its competitors, which is really a textbook of scientific medicine with an emphasis on treatment. It differs from another in that its information is conveyed in ordinary descriptive paragraphs and not in a notational or tabular form nor in the imperative mood. An extensive random sampling of the contents of this second edition leaves no doubt of its excellence. Likewise the printing and production are admirable.

D. M. DUNLOP.

In preparing the recently issued seventh edition of their now classic textbook *Disorders of the Blood*, Whitby and Britton have added a new chapter on cytochemistry and biochemistry, and have extensively revised the chapters on haemopoietic metabolism, therapeutics, coagulation, and the purpuric and haemorrhagic diseases. This is the third edition of the book to be issued since the end of the war, and though it bears the date 1953 the authors have attempted to bring it up to date to the middle of that year. It is published by J. & A. Churchill Ltd. for 63s.

Common Diseases of the Ear, Nose, and Throat by Philip Reading has appeared in a second edition. The book is intended for medical students and newly qualified doctors, and description of operative techniques is confined chiefly to those minor operations which a house-man might perform. It is published by J. & A. Churchill Ltd. for 22s. 6d.

Professor A. D. Gardner has revised his *Bacteriology for Medical Students and Practitioners* for the fourth edition (Oxford Medical Publications, 12s. 6d.), paying special attention to the rapidly growing specialty of virology.

Professor C. F. V. Smout and Dr. F. Jacoby have revised their textbook, called in its last edition *Gynaecological and Obstetrical Anatomy*, and have added to the title the words *And Functional Histology* so as to "indicate quite clearly the inclusion in it of the dynamic histology of the female reproductive system and its endocrine control." A new section has been included under the title "Milestones in Midwifery." The book is published by Edward Arnold & Co. for 35s.

Rawling's Landmarks and Surface Markings of the Human Body has been revised for its ninth edition by Mr. J. O. Robinson. Only a few minor alterations to the text have been found necessary, but the section on ossification and epiphyses of the skeleton has been extended. It is published by H. K. Lewis for 12s. 6d.

The Treasury of Human Inheritance, Volume 5, Part 2, is *On Syndactyly and its Association with Polydactyly*. It is by Dr. Julia Bell and Dr. L. S. Penrose, and in accordance with the usual plan includes a discussion on the subject, case histories, and pedigrees. The book is published by the Cambridge University Press for 10s. 6d.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 23 1954

TORONTO MEETING OF THE B.M.A. 1955

The Annual Meeting of the B.M.A. in 1955 will be held in Toronto, jointly with the Canadian Medical Association. Plans for this are already far advanced and every effort is being made on both sides of the Atlantic to provide an outstanding scientific programme. Our Canadian colleagues are determined to make this, the fourth meeting of the Association to be held in Canada, an event which will long remain in the memories of those fortunate enough to attend it. The ties that unite Britain with the Commonwealth are perhaps now stronger than ever. In keeping them strong the professions in the various Commonwealth countries and in Britain have a vital part to play, and this is especially true of the medical profession. There is a steady two-way traffic of medical men and ideas between Britain and the Commonwealth which, moreover, affords an unrivalled opportunity for seeing and hearing doctors of two countries confer on those matters which are fundamental to the science and art of medicine.

The meeting in Toronto in 1955 will be particularly notable because Dr. T. Clarence Routley, now the General Secretary of the Canadian Medical Association, will be installed as President of the B.M.A. for 1955-6. Dr. Routley, a graduate of the University of Toronto, got to know many of his British colleagues during his four years' service in the war of 1914-18, and his many visits have since then ripened acquaintances into friends. During recent years he has played an outstanding part in the development of its Council Medical Association, being Chairman of its Council in its first five formative years. The letter from him in its first five formative years. The letter from him we print in this week's correspondence columns is typical of the open-handed generosity we have come to expect from our Canadian colleagues. Knowing the difficulty so many in Britain will have in obtaining dollars for the Toronto meeting, Dr. Routley tells us that "Toronto doctors and their wives are opening their homes to those members who indicate to the Secretary of the B.M.A. that they would be prepared to accept private hospitality during the week

of the meeting." Many distinguished members of our profession have already signified their intention to attend the 1955 Annual Meeting in Canada. It is hoped that those who have so far not made up their minds will take advantage of the Toronto doctors' generous offer of hospitality and write to the Secretary of the B.M.A. about it. Though the Bank of England will, in allotting dollars, take into account the desirability of the visit, a limitation of numbers is inevitable. Plans must be laid well ahead of the event. We would urge all those who can go to go, so that the British medical profession may be worthily represented on what will be a great occasion.

MALARIA IN AFRICA

It is a curious feature of a certain attitude to the most malarious of the continents that there alone men demand to know not only whether we can control malaria but also whether we are entitled to do so, postulating possible damage to the people from the well-intentioned act. The doubt was raised twenty years or so ago, particularly by Wilson,^{1,2} when it was academic only because man's inability to control malaria in Africa on any considerable scale then seemed certain. As the ability seemed to improve there was an increasing demand that action should be postponed until the long-term effects could be shown to be desirable, and the case against positive prevention was put more forcibly.^{3,4} The grounds of doubt lay in the undeniably common acquisition of a firm resistance by the African adult and the less well established belief that the child and even the young infant suffered little or no ill effect. In the extreme view the African found the malaria parasite a harmless commensal; in a less extreme view the infant suffered no more than moderately, but gained thereby an immunity which was a passport to safe travel in the most malarious circumstances and an insurance against the risks of a local recrudescence of the disease. If the extremists were right control was pointless; if those holding the less extreme view were right control would deprive the adult of an immunity worth more than the price paid for it. Controversy arising out of these opinions led the World Health Organization to assemble the Kampala Conference,⁵ at which it was agreed that control should never be withheld on the grounds of its undesirability. Since then, however, inaction has been advocated by Davey,⁶ Macgregair,⁷ and others for another reason—the effect of disease control in increasing pressure of populations. It may be noted that this reason is in direct opposition to the previous ones, according to which control should not have materially affected the death rate.

Meantime confidence in the ability to control malaria in equatorial Africa has been growing. There were initial disappointments in the effect of D.D.T. on African malaria, and work by Muirhead-Thomson⁸ led to the belief that the most potent vector, *Anopheles gambiae*, might not be poisoned by this insecticide. His work has been continued and much elaborated, notably by Davidson,⁹ and it is now known that that mosquito is fully susceptible, the reasons for Muirhead-Thomson's finding lying in the insecticide rather than in the mosquito. The point has been established by the successful control measures with either D.D.T. or benzene hexachloride in Rhodesia, the Transvaal, Mauritius, Madagascar, the Belgian Congo, and elsewhere. Analysis of the reasons for the early failures shows that insecticidal regimes which may be effective elsewhere might well prove insufficient to stop the intense transmission typical of Africa, but Davidson and Draper¹⁰ have shown the standards of efficiency needed. In the opening pages of this issue Dr. L. J. Bruce-Chwatt describes a pilot trial in an area of Nigeria selected on account of the difficulty of control; he shows that a particular method of benzene hexachloride dosage can virtually control the disease, and there is little doubt that a modified method could do so completely.

The story of failure is now becoming rare, though positive evidence of success is still lacking in some places, particularly in those parts of East Africa where the doubts have been greatest. It is reasonable to assert that African malaria at its worst can be controlled, but there is no doubt that prevention will be more expensive there than elsewhere because bigger doses of insecticide applied more often will be needed. So now the next doubt arises: Can Africa afford to control malaria? Bruce-Chwatt reviews all these questions as they affect Nigeria, and concludes that malaria can and ought to be prevented in so far as the country can afford it and provide the necessary administration and practical support. He might go further than he does. Britain's justification for authority abroad lies largely in adherence to a principle that the survival of the individual, and his freedom from fear, want, or disease, must not be sacrificed in the interests of the community save in the most pressing and evident danger to the latter. The entitlement of the public health authority to

prevent the transmission of disease has been put beyond question in our own country. Practice takes no account of loss of immunity or the fact that survivors might be a burden on the community, but rests solely on the harm done to the individual, on the practicability of preventive measures, and on the willingness of the public to pay for them. If our diminishing authority abroad is to have any justification we must actively support this attitude to the prevention of disease. But campaigns against disease must always be integrated with other work towards economic and social advancement and may often have to be sacrificed in the interests of temporarily better causes or of urgent need for economy. No harm is done thereby so long as a positive attitude is adopted that disease should be controlled unless good cause is shown why it should not be, instead of the negative one that action should be withheld until all avenues have been explored for any possible detriment to the community resulting from action benefiting the individual.

Among the fundamental weaknesses of Africa are lack of a traditional money economy, infertility of soil, land tenure and farming systems which diminish fertility, and ill-health. Further analysis and research is needed before remedies can be found for the first two; remedy of the third demands both analysis and disturbance of the social structure; but improvement in the last does not await technical knowledge, though of course more is desirable. The real problem is the full integration of all forms of progress: the justifiable fears are those of imbalance. Sanitary advance, which some think has been too long delayed, could be mounted on a scale which the countries could not support, and thereby lead to its own ruin. The aim is to achieve a rate of advance which is financially practicable and which will not weight the scale against other equally desirable forms of progress.

PULMONARY EMBOLISM

Considerable interest has been taken in venous thrombosis and pulmonary embolism during the last few years and the treatment of them has changed. Doctors are more "thrombosis-minded" and are becoming especially aware of the protean, and sometimes slight, manifestations of serious thrombo-embolic disease. But there is no room for complacency and far too many cases are still missed or misdiagnosed. Although many clinicians are quick to turn to anticoagulant therapy and the occasional strategic use of vein ligation, there are still some who prefer to adopt a relatively casual attitude to thrombo-embolism. Statistics on this subject are notoriously difficult to assess, and some rather dubious figures have been advanced in support of

different methods of treatment. Even so, there is good reason to believe that progress has been made in reducing the morbidity from these conditions. That less striking success has been achieved in the prevention of fatal pulmonary embolism may be partly due to the fact that often this catastrophe strikes like a bolt from the blue.

It is likely that pulmonary embolism and infarction are among the commonest acute lung conditions encountered in hospital. This was born out by Short's review¹ of his experience in a large general hospital, and there are many similar reports. Some of the problems in diagnosis of pulmonary embolism have recently been discussed in this *Journal*,² and reference has also been made to various outstanding problems in aetiology and treatment.^{3,4} We have also stressed the need for constant and critical review of our existing knowledge, and in this connexion there are several recent publications which warrant discussion.

It was not so long ago that many surgeons taught that pulmonary emboli following laparotomy arose from the veins in the abdominal wall. During the last decade most of us have come to accept the view that pulmonary emboli come from the veins of the lower limbs or, less commonly, from those of the pelvis. Cummine and Lyons,⁵ however, challenged this view when they suggested that primary pulmonary arterial thrombosis is a more common condition than is generally believed. Professor Harold Dew,⁶ of Sydney, speaking from his experience in the same hospital as Cummine and Lyons, supports this view and even goes so far as to say that large pulmonary emboli are rare. An examination of the available evidence would suggest that the Sydney school have overstated the case for pulmonary thrombosis and unduly minimized the incidence of embolism. But there is no doubt that primary pulmonary thrombosis does occasionally occur, and it is good to be reminded that not every pulmonary artery thrombus comes from the legs or pelvis.

An awareness of the frequency with which venous thrombosis and pulmonary embolism occur, the proper appreciation of the significance of unexplained pyrexia and minor leg symptoms, the recognition of minimal signs in lungs and legs, and the accurate interpretation of x-ray films of the chest will all contribute to earlier and more accurate diagnosis. The earlier specific treatment is instituted, the shorter is the time for which it is needed and the better the results obtained. To assist and fortify the clinician in making an early diagnosis various workers have tried to predict a prethrombotic state. Of the many laboratory tests devised, one of the simplest and most widely publicized is daily estimation of the clotting time. Cummine and Lyons keenly advo-

cate the use of daily clotting-time estimations, combined with a test for fibrinogen B, in detecting a prethrombotic state; but most other workers have failed, either partly or wholly, to confirm the value of these tests.⁷⁻¹¹ McCleery,¹² using a silicone-tube method, found the coagulation time to be shortened only in established thrombosis. It is curious that so many other investigators have failed to confirm the contention of Cummine and Lyons about the prognostic value of daily clotting times, and it is true to say that clinical sagacity is more useful than laboratory technique in predicting a thrombosis.

Many and varied have been the methods recommended in the prevention of pulmonary embolism, and a recent one of some interest is the routine use of elastic stockings by all patients confined to bed. Wilkins *et al.*¹³ published a preliminary report on this subject last year, and they have recently put forward further evidence in support of this policy.¹⁴ It has been shown that an even, concentric pressure on the leg, not exceeding 15 mm. Hg, causes marked increase in the linear velocity of the venous flow,¹⁵ and there is therefore experimental support for the recommended use of elastic stockings. There are practical difficulties in the routine use of stockings, but the clinician may well consider advising their use in selected cases. The wearing of elastic stockings may be of value to several groups of patients confined to bed, including those with a previous history of deep thrombosis, those considered to be especially at risk for thrombosis, and those with varicose veins. As with many other methods practised in the hope of preventing pulmonary embolism, dramatic results are not to be expected, but each contribution represents one more nail in the coffin of this common and sometimes fatal complication.

DEATH FROM ASTHMA

One of the perplexing facts about bronchial asthma is that some patients with severe asthma are like old soldiers and never die, whereas others succumb during comparatively trivial attacks. Death during attacks of asthma is not very uncommon. Williams,¹ from a study of the Registrar-General's reports, deduced that about 3,000 people die each year from asthma in England and Wales, and it is therefore important for the general practitioner to know how to detect the potentially dangerous case, to understand the reasons why death takes place, and to assess the value and pitfalls of the therapeutic measures in treating such patients. Some help in these problems has emerged from recent analyses of the clinical features of patients dying from asthma. In reviewing 41 personal cases together with those from the medical literature, Williams concluded that the risk of death was greatest in the chronic asthmatics over the age of 30 who were liable to status asthmaticus. Similarly Earle² found that whereas death in early adult life was rare there was a definite risk in patients aged

between 40 and 65 years. Houston, de Navasquez, and Trounce² also suggested that death from status asthmaticus occurred particularly in adult life in those patients whose illness began late in life. Elsewhere in this issue of the *Journal* Drs. C. Kelman Robertson and Kenneth Sinclair describe the clinical and pathological features of 18 cases of fatal asthma. The majority of the patients were between the ages of 40 and 50 years. The fact that about two-thirds died in the autumn suggested that added respiratory infection played a part in the fatal outcome. Death in most patients was sudden and unexpected, the aetiology and duration of the disease giving no reliable guide to prognosis.

The mode of death in fatal asthma is often not obvious from clinical observation alone. Right heart failure may supervene in the chronic asthmatic, and death may sometimes occur from such complications as spontaneous pneumothorax. More often, however, death is apparently due to asphyxia, and at post-mortem examination widespread obliteration of the smaller bronchi by sticky mucous plugs is usually found. There seems little doubt that mucous plugging and desquamation of the ciliated bronchial epithelium play a greater part in the fatal issue than does bronchospasm. Although it has not been proved that infection plays any part in producing the viscid mucous secretion, there is some evidence that added bronchial infection is a contributory cause of death. These observations have some practical application to the management of patients with status asthmaticus. In the treatment of the adult patient the possibility of a fatal outcome must always be considered even though the initial symptoms are not severe, and the aim should be to achieve relief by energetic treatment as soon as possible. In addition to the administration of antispasmodics such as adrenaline and aminophylline in effective dosage, antibiotics can help those patients who have bronchial infection. Respiratory depressants may encourage the retention of mucous secretions and should be avoided: it has long been known that the use of morphine in status asthmaticus can precipitate death. However desirable it might seem to allay the anxiety and distress of the severely afflicted asthmatic, sedatives should be used with the utmost caution and morphine not at all. Active rather than passive measures should be the keynote of treatment. A possible new approach to the treatment of severe asthma lies in the use of purified crystalline trypsin.^{4,5} This substance has been given by aerosol inhalation as a mucinolytic agent, and there is good evidence that it can effectively help in removing the sticky bronchial secretions which constitute such a real danger to life in the asthmatic patient.

SKIN CANCER AND BURNS

The essential cause of epithelioma of the skin is unknown, but much has been learnt about it from observations on men as well as mice. The carcinogenic role of external and internal irritants in the aetiology of skin cancer has interested observers since Percival Pott described carcinoma of the scrotum in

chimney sweeps who as boys worked naked in hot chimneys. From one point of view the human being with cancer of the skin may be regarded as an experimental animal in whom the growth and character of the lesion can be observed, even though the factors responsible for its appearance cannot be controlled and cannot always be determined.

From observations on tar workers, mule spinners, and workers in contact with shale oil it has been established that certain tar products and various types of oil are carcinogens. The by-products obtained from an extraction process and also catalytically from petroleum have proved to be strongly carcinogenic.¹ Cutting oils used with machine tools probably have the same property.² Although the agent causing cancer may be recognized, there are so many factors playing a part—heredity, race, age, sex, and others such as hormones and arsenic—that any consideration of the aetiology becomes a complex matter.

In 1828 Marjolin³ described the development of epithelioma in scars and ulcers, and though nowadays those associated with radiotherapy are particularly important carcinoma may arise at the site of scarring from many causes. It has long been appreciated that a skin infection such as lupus vulgaris, which persists for many years and heals with scarring, may lead to carcinoma, though it is more common when radiotherapy has previously been administered. The common leg ulcer has been under suspicion, but there is some doubt because carcinoma associated with it is so very rare.⁴

Cancer of the skin after years of exposure to actinic rays is common in such countries as Australia, where it is found that European settlers are most susceptible. Heat, whether moderate and applied over a long period or intense and causing a burn, may lead to carcinoma. The natives of Kashmir are liable to cancer of the abdomen and thighs from burns caused by the kangri, or warming-pan, they carry under their clothing in cold weather, and Laycock⁵ has described "kang cancer" arising in the skin over the great trochanter in Chinese who sleep on heated brick beds. Carcinoma of the lips of clay-pipe smokers may have been the result of contact with the hot stems for long periods.

Some years after the skin has been severely burnt on a single occasion carcinoma may appear in the scar, usually when it has been ulcerated for some time. This is the commonest cause of Marjolin's ulceration. The scar following a burn has a poor blood supply, and its inelasticity causes it to be more readily injured than normal skin. Ulceration is likely to occur, and the repeated stimulation to growth of the marginal epithelium was thought by Treves and Pack⁶ to lead to carcinoma. The same authors suggested that tissue toxins released by autolysis and heterolysis from the burnt area might act as carcinogenic agents. According

to Hueper⁷ substances having such a quality may be produced by the destruction of organic matter by heat.

In carcinoma arising in the scars of thermal burns Lawrence⁸ has made a particular study of the influence of the age when the burn occurred and the length of the period before the diagnosis of carcinoma was established. He found that this period was inversely proportional to the age when the individual was burnt. He also found that carcinoma is less likely to occur when the burnt area has been grafted, and he believes that this provides evidence that carcinoma results not from carcinogenic agents embedded in the scar tissue, which should also cause cancer in an overlying graft, but solely from factors affecting the surface. Among these he includes an abnormal vascular supply, repeated trauma, and contact with environmental carcinogens. More work requires to be done on this subject, but from it much should be learnt about carcinogenesis.

MILLI-EQUIVALENTS

For many medical men who qualified more than a decade ago milli-equivalents share some of the mystery that irrational numbers hold for the non-mathematical. But, simple units of measurement that they are, they have largely replaced such traditional though flexible units as mg. per 100 ml. to record concentrations of ions. While readily convertible to metric units, their special features make them preferable to use in the estimation of the electrolytes of the plasma, which is becoming a commonplace laboratory investigation, essential for carrying out rational replacement or maintenance therapy of patients suffering from electrolyte depletion.

Milli-equivalents are units of measurement no less than are the other more familiar terms of metric weight; but they are units with this difference, that instead of being related arithmetically to other units of weight or volume within the metric system they imply a chemical relationship between the various ions under consideration. Thus, one milligram of sodium is not related to one milligram of potassium or one milligram of chloride one milligram of potassium or one milligram of chloride one milli-equivalent of sodium is chemically equivalent to one milli-equivalent of potassium and to one milli-equivalent of chloride and to one milli-equivalent of any bicarbonate, and in fact to one milli-equivalent of any substance, although the actual weights of these amounts are not the same when expressed in milligrams. The equivalent weight of a substance is a chemical term defining that weight of the substance which will combine with or displace one gramme-atom of hydrogen. A milli-equivalent weight of a substance is its equivalent weight divided by 1,000—that is, the weight of the substance which will combine with or displace one milligram-atom of hydrogen. Adapting an old axiom, things

¹ Example of calculation:
Sodium concentration = 340 mg. per 100 ml.
Sodium concentration = 340 / 10 = 3,400 mg. per litre.

23 mg. is the weight of 1 milli-equivalent of sodium.

Therefore 3,400 mg. is the weight of 3,400 milli-equivalents which are in one litre.

Therefore sodium concentration = 147.8 milli-equivalents per litre.

which are equivalent to the same thing (in this case hydrogen) must be equivalent to one another, and it is this which justifies the use of the term milli-equivalent in clinical chemistry to-day. Expressed in these terms, fluctuations in concentrations of electrolytes—not only in plasma but also in urine and gastro-intestinal contents—come to have some meaning in relation to one another. Calculation of concentrations expressed in milli-equivalents per litre from those in milligrams per 100 ml. is done by multiplying the milligrams per 100 ml. by ten to bring the concentration to milligrams per litre, and then dividing by the equivalent weight of the ion in question.¹ The equivalent weight of the monovalent ions sodium, potassium, and chloride is equal to the atomic weight—namely, 23, 39, and 35.5 respectively. Some laboratories report the concentration of chloride in the form of sodium chloride, in which case the concentration in milligrams per 1,000 ml. must be divided by 58.5 and not by 35.5. Special factors have been calculated for the conversion of bicarbonate from volumes per cent. and protein from grammes per cent. to milli-equivalents per litre.

ADMINISTRATIVE ACTION IN BLACKBURN

The closing on January 8 with less than 24 hours' warning of the 20 G.P. obstetric beds in the Springfield Maternity Home, Blackburn (see *Supplement*, p. 22), marks a further stage in an unhappy business. As already reported in the *Supplement* last December,² the Blackburn and District Hospital Management Committee decided to close these beds on the grounds of redundancy and the urgent claims on them of other users. The resentment of the local general practitioners against a decision which would take away the only institutional midwifery beds in the town available to them and their patients was aggravated by the failure of the hospital authority first to consult those who would be most affected. As a result, the Blackburn Executive Council passed a resolution of protest and asked that no action be taken until there had been an opportunity for discussion. This resolution was apparently ineffective.

Hospital authorities must, of course, carry out their function with proper regard to the many claimants on their all too few beds. The ultimate decision in these matters must be theirs. Nevertheless it would seem on the face of it that the Blackburn Hospital Management Committee, while sticking to the letter of its duties, has been singularly inept in failing to perform them in that spirit of co-operation which is essential if there is to be any smoothness at all in the working of the Health Service. It is an example of how not to do things.

But most disturbing of all is the report that the evacuation of the Springfield Home was carried out on the orders of a lay official at short notice and without any opportunity for the doctors concerned to decide upon the fitness or otherwise of their patients to be moved. If this is true it represents an interference with a doctor's clinical responsibility which is quite beyond the right of any administrative authority.

² *British Medical Journal Supplement*, 1953, 2, 234.

tion leading to gross reduction of bile will also produce failure of fat absorption without any evidence of other digestive errors.

Digestive disturbances attributed to fat by the sufferer are often met with. In those who do not respond to the usual common-sense remedies it would be worth while to seek by examination of the stool for evidence of a real abnormality.

Ferments

Some information can be obtained by searching for digestive ferments, a procedure complicated by the instability of digestive ferments and by the presence of active bacterial ferments. In practice the estimation of tryptic activity is the most reliable method. This must be done on a freshly passed specimen not more than four hours old. The value of the results depends somewhat on the technique used, the simple film method (see Appendix) being less in agreement with the clinical findings than the test-tube method. If there is digestion at a dilution of 1 in 100 or more it is probable that adequate pancreatic juice is being secreted. The converse, that if no digestion occurs at a dilution of 1 in 50 or less it suggests absence of pancreatic secretion, does not hold except in infants.

Appendix: Simple Chemical Tests

Blood: Benzidine Test.—Take a piece of stool about the size of a pea and emulsify with about 2 in. (5 cm.) of water in a test-tube. Boil and cool. Take a knife-point of benzidine and dissolve it in $\frac{1}{2}$ in. (1.25 cm.) of glacial acetic acid

Spectrographic appearance of (1) stercobilin in acid alcohol; (2) chlorophyll, weak; (3) chlorophyll, strong; (4) acid porphyrin; (5) acid porphyrin, weak solution; (6) acid haematin in diluted hydrochloric acid.

acid alcohol (1 ml. concentrated hydrochloric acid into 100 ml. absolute alcohol or industrial methylated spirit). Mix. Stand overnight. Filter. Examine with a hand spectroscope. The bands to be seen are shown in the Figure.

Blue.—Make a thin emulsion of the stool and mix with increasing amounts of Fouchet's reagent (trichloroacetic acid, 25 g.; distilled water, 100 ml.; 10% ferric chloride solution, 10 ml.)—not more than equal parts—either on a white tile or in a test-tube. A green or blue colour indicates bile.

Trypsin.—Make an emulsion of the stool with 1% crystalline sodium carbonate solution, about 1 in 10 dilution. Place one drop of the emulsion and one drop (as control) of the sodium carbonate solution on a dry radiographic film or photographic plate. Incubate 30 minutes at 37° C. (Keep moist by placing a sheet of wet filter paper just above the film.) Wash under the cold-water tap. If trypsin is present the coating of the film will be dissolved and a clean round spot will be seen. The control will

only be slightly swollen up. Serial dilutions of the faeces can be made with the sodium carbonate solution and a semi-quantitative result obtained.

Next article on Clinical Pathology.—"The Laboratory Diagnosis of Pulmonary Tuberculosis," by Dr. J. W. Clegg.

Refresher Course Book.—The first collection of articles in the Refresher Course for General Practitioners (fully revised) are available as a book containing 55 chapters, price 25s. Copies can be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

RECRUITMENT OF MENTAL NURSES

A three-day conference on mental nursing, arranged by the Royal College of Nursing, opened on January 12. The subject taken in the first session was "Staffing: a Survey of the Present Position."

Dame ENID RUSSELL-SMITH, Under-Secretary, Ministry of Health, in an opening address, said that this was one of the most difficult problems in the National Health Service. Mental nursing had been caught up, though in greater degree than most, in the difficulties that beset every profession. Perhaps for the first time in our history we were running short of man- and woman-power, and this was hitting us particularly at the professional level. Nearly all occupations were becoming more difficult and more technical, less manual and more professional, and therefore making ever bigger demands on a comparatively limited age group. The matter for immediate concern was the inadequate number of those offering themselves as students for mental nursing. The problem was not so much how to attract all and sundry to mental nursing: it was how to attract more student nurses of the right calibre.

The High Wastage

In the Report of the Working Party on the Recruitment and Training of Nurses, Dame Enid continued, it was calculated that the rate of wastage among mental nurses was about 80%. Another later calculation on a different set of facts gave a wastage rate nearer to 65%. She thought the latter figure was more likely now to be true, because the former was calculated during the disturbance of the immediate post-war period. A good deal was known about the causes of wastage. Some of these, of course, were inevitable, but others were susceptible of remedy. First came family reasons, including marriage, but some married women nurses, as in other professions, returned to work after their children began to grow up. There was also wastage owing to some people who had originally shown promise turning out to be unsuitable. A third reason was bound up with questions of pay, but as an arbitration was pending that question could not be discussed profitably on this occasion. Other reasons related to conditions of work and to the teaching and training itself. If the training was too difficult a student was naturally discouraged, as also if it was too elementary. Careful selection of students must be made, but if this were done there must inevitably be, at least temporarily, a drop in numbers. The question was how to fill the gap until the training was rendered more attractive. The National Advisory Council of the Ministry of Labour believed that enrolled assistant nurses should be trained and employed in mental hospitals, but the Minister's Standing Mental Health Advisory Committee was against the employment of enrolled assistant nurses and favoured the continued employment of nursing assistants, possibly for many years to come, while recommending that such assistants should be systematically instructed in the tasks they were called upon to perform. The Confederation of Health Service Employees held that the only type of nurses employed in the mental nursing service should be qualified nurses and student nurses, but

that to meet the present situation a proportion of students who failed to pass the final examination at the second attempt should be retained as nursing assistants.

Case for Nursing Assistants

Dame Enid said that the reasons which in the opinion of her Department counted against assistant nurses were the small number now in the Service, which offered no foundation on which to build, and the difficulties in the way of establishing training schools. As the law now stood it was not possible for the General Nursing Council to approve an assistant nurses training school based wholly on a mental hospital. Of nursing assistants there were more than 10,000 already in the Service, and the Ministry held the view that this number should be increased rather than that the difficult course be embarked upon of training a large number of assistant nurses for the Roll. The training given to registered mental nurses should be adequate to fit the nurse to hold the highest post in mental nursing without the need to go outside and get a double qualification, but the Department was also anxious to see an increase in schemes of combined training which gave the double qualification after four years.

Dr. J. CARSE, medical superintendent of Graylingwell Hospital, Chichester, said that on a conservative estimate 75% of the resident population of a mental hospital such as his own were long-stay patients; about two-thirds of these—that is, one-half the resident population—were able-bodied patients who were accommodated mostly in open wards and were engaged in various activities during the day in the grounds and other parts of the hospital, and the other third were patients senile on admission, a proportion which in some hospitals was rapidly increasing. The remaining 25% of the resident population were short-stay patients, who came in mostly for from four to eight weeks and responded well to treatment. In this small section there was an enormous turnover. With a total resident population of 1,150 in the hospital, they had approaching 1,100 admissions in a year.

Was it to be said, asked Dr. Carse, that 100% trained staff was needed in such a hospital? Even if they could get them they were not necessary. He thought that in mental hospitals they could do with quite a good proportion of nursing assistants. A sister or charge nurse should be in charge of every ward, but the wards could properly be otherwise staffed by nursing assistants. The difficulty about this grade was that they had no salary scales such as the staff nurse enjoyed, and had little prospect of promotion or improved salary. No one would deny that the time had arrived when nurses, whether State-registered or student, nursing assistants should spend their time in nursing duties and that a higher proportion of ward domestics should be employed and more labour-saving devices introduced. In recruiting he believed that local effort was likely to be more successful than a national campaign. The mental hospital was nothing to be ashamed of, and yet it was the Cinderella of medicine.

The other speaker in the session was Miss P. LOE, matron of St. James Hospital for Mental and Nervous Disease, Portsmouth, who said that her hospital had its full establishment of staff, about one nurse to five patients, but they could still really do with more than this. One of the chief reasons for the shortage was that mental nursing was not a job that appealed to many people; also some of those who joined the Service gave it up after a short time for a variety of reasons, chiefly marriage. Good relations between of reasons, chiefly marriage. Good relations between whole and its surrounding neighbourhood, were important factors in encouraging young people to offer themselves for service and to remain throughout their training and afterwards. She mentioned that when she started mental nursing the salaries of nurses in mental hospitals were 70% higher in most instances than in general hospitals, and the working time eight hours a week shorter. Now the salaries were about 5% higher and the working hours were the same.

After these addresses the members of the Conference split up into groups for discussion.

Nova et Vetera

THE MYSTERY MAN OF PHYSIOLOGY

Michael Servetus: A Translation of his Geographical, Medical, and Astrological Writings with Introductions and Notes. By Professor Charles Donald O'Malley. (Pp. 208. £1 1s.) Philadelphia: American Philosophical Society. London: Lloyd-Luke (Medical Books). 1953.

Before Harvey's book on the circulation (1628) stands, as has been long known, a clear statement of the lesser circulation by the Spaniard, Michael Servetus. It was made in a book entitled *Restitutio Christianismi*, "Christianity Restored," published in 1553 at the small town of Vienne, not far from Lyons. The book was highly heretical and Servetus was therefore "wanted" by both Catholic and Protestant authorities. The Catholics got him first, but he escaped from prison in France to Calvinist Geneva. There he was promptly captured, tried, condemned and, on October 27, 1553, burned at the stake. A note by Dr. Edwin Clarke in these columns recently (October 24, 1953, p. 934) was a reminder of the four-hundredth anniversary of this dreadful event, and it was accompanied by a picture of the expiatory monument raised by the citizens of Geneva in 1903.

There are many obscure points in the life history and opinions of Servetus, some of which have now been clarified in this little book by Professor O'Malley. The author has long been known for his great skill, penetration, and industry in translating and interpreting scientific works written in Renaissance Latin and not least those of Vesalius. This is an extremely useful service, especially since very few men of science can now read such difficult Latin.

Servetus, Professor O'Malley shows, was basically a restless, argumentative, offensively opinionated literalist who sought to interpret biblical doctrine in an exact verbal sense. He had considerable learning, but his medical training was inadequate, even on contemporary standards, and his course at Paris was not completed, so that his medical status somewhat resembled that of an unregistered practitioner of a few decades ago. Both Servetus and Vesalius had acted as dissectors for Guenther of Andernach, but not at the same time, and they probably did not meet. Servetus claimed to be introducing an idea not present in Galen's works. Professor O'Malley, however, points out that Galen had presented all the necessary information required for the description of the lesser circulation given by Servetus, of which he provides a translation. For Galen proclaimed the presence of blood in both veins and arteries, described the action of the semilunar valves, and indicated that there was "anastomosis" between veins and arteries. The meaning that Galen attached to the word *anastomosis* would take a special article to explain. But Galen had further suggested that something passes into the lungs by the pulmonary artery and from the lungs by the pulmonary vein, though the something was not blood but *pneuma* or "spirit."

Professor O'Malley provides us for the first time with translations of several others of the works of Servetus which are not generally accessible. These are necessary to enable the reader to form any proper estimate of the general physiological and intellectual climate in which the man lived.

Servetus had had a correspondence with Calvin in which he had been peculiarly offensive. After his flight from prison, on reaching Geneva he felt compelled to attend divine service. He was recognized and arrested. Calvin, the virtual dictator of Geneva, "was determined to have his victim though legally he had no grounds for a case. Personal vindictiveness, intolerance, and disregard of the law, though Calvin had been trained in it, brought about the execution of Servetus."

Professor O'Malley has filled a real literary gap. The idea of a lesser circulation was "in the air"—or should we say "in the *pneuma*"?—at the time, and Servetus enunciated it in the course of an exercise of ratiocination. He was no man of science and he had no experimental bias, but he was a virulent theologian, and though he was a martyr neither he nor Calvin emerges from the story as other

than unamiable characters. Our final reflection on Professor O'Malley's excellent book is that the calamities and quarrels of authors do not make edifying reading and that, since the pen is mightier than the sword, it is well that the law should be mightier yet. "Pray for the law," said one of the old rabbis, "for were it not for it, men would swallow one another alive."

CHARLES SINGER.

Reports of Societies

THE PSYCHOPATH

On January 12 the Section of Psychiatry of the Royal Society of Medicine held a symposium on "Psychopathy." Dr. E. B. Strauss, president of the Section, was in the chair.

In opening the symposium, Professor ALEXANDER KENNEDY said that the condition so often expressed itself as a disorder of citizenship as well as one of personal adjustment that medicine and the social sciences had a shared responsibility. The clinical psychopathic syndromes were the product of defects in brain structure, of the effects of these on the development of mind, and of the way in which the patient dealt with the sense of inferiority these defects engendered. The defect often showed itself in the monitoring mechanisms by which an individual checked his conduct against that of his fellow-men and foresaw its effects. These mechanisms were comparable to the way in which speech was controlled, and parallels could be drawn with disorders of the speech mechanism.

Importance of Physical Defects

Experience in early life also played its part in the laying down of personal attitudes and codes of conduct, but, if the physical means of doing this were lacking, developments must inevitably be abnormal. The natural experiment of the epidemic of encephalitis lethargica had shown that neural damage could produce similar effects. The speaker's own studies showed that, if this occurred while the sense of social responsibility was developing, the latter failed to develop and the patient showed the antisocial trends of a psychopath.

The advance of therapeutics was leaving us with many survivors of conditions formerly fatal whose lives had been spared at the cost of brain damage. The period from conception to maturity was fraught with opportunities for harm to the nervous system. Prematurity, birth injury, kernicterus, post-febrile encephalitis, tuberculous meningitis, and anoxia due to heart operations or anaesthesia with controlled hypotension all presented this danger of interference with normal brain development and of producing people who lacked the physical means of being morally aware and of exercising foresight in their personal affairs. Recent studies showed that inheritance also played an important part in psychopathic character-traits.

Alteration of the environment of the psychopath must be arranged in the interests of both patient (or prisoner) and society. With increasing complexity of civilization there were more people for whom science had no remedy and society no place. Segregation in productive communities with suspension of responsibility as citizens was kinder than prison and more realistic than certification. It could be tried first with the grosser criminal psychopaths before the principle was extended.

Institutional Therapy

Dr. MAXWELL JONES described an experiment in trying to improve the social adjustment of the psychopath through residence in a therapeutic community. The 100-bed unit for both sexes associated with Belmont Hospital, Sutton, had been in existence for seven years. Patients stayed up to a year, and the arrangements differed markedly from those of a hospital. The sister in charge did not wear

uniform, while her staff consisted of social therapists not medically trained. The doctors shed their professional status in their relationships with the patients, and one of the difficulties in running the unit had been to find doctors who were willing and able to do so.

In the therapeutic activities the patients were divided into groups (12 or under) and communities (over 12), and all problems and incidents were referred to the group and community meetings for discussion, criticism, and advice. Suicidal attempts, for example, were discussed at the group meetings, and antisocial conduct such as repeatedly disturbing the ward by coming back drunk was dealt with as a group problem. Discussion modified the patient's attitudes and prejudices and gave insight into those of others. A member of the patient's family was sometimes enrolled into the group. When an individual's behaviour was so grossly disordered as to threaten to disrupt the community life he might be asked to leave, but usually the anxiety threshold of the doctor was reached before the group sanctions came into operation.

Psychopathology and Prognosis

Dr. EDWARD GLOVER proposed, on the descriptive level, a division of psychopathy into benign and malignant (criminal) types. Criminal types could be roughly subdivided into violent and non-aggressive types—for example, the swindler—and the aggressive group again into those whose aggression found a predominantly sexual or a predominantly social outlet. All these could be further subdivided in accordance with the nature of the offence. But a classification according to the aetiological factors was more useful both in understanding psychopathic behaviour and in treatment. It was not possible as yet to put forward a wholly satisfactory classification on this basis, but Dr. Glover gave the following examples of an aetiological classification: (1) according to the form of the underlying instinctual aberration or stress, either sexual or destructive; (2) according to the nature of the defect in ego development, in particular in the formation of the super-ego; (3) according to the kind of defect in reality sense found to be present. He felt that the diagnosis of psychopathy should be narrowed down and a great many individuals, often included under the heading, placed elsewhere—for example, most alcoholics, nearly all suicidal individuals, and neurotic and paranoid characters. Sexual pervers should also be excluded, provided there was no accompanying ego-disorder.

Dr. Glover pointed out that the psychopathic behaviour of our time was the normal behaviour of other epochs. Even now, for instance in war, homicidal psychopathic behaviour was regarded as normal. From the practical point of view in treatment it was important to remember that spontaneous cure of psychopathy is common, especially after the age of 40, while any plan of psychiatric treatment must take into account the constitutional, predisposing, and precipitating factors, the characteristic constitutional factors being a demand for the immediate satisfaction of primitive needs and the inability to endure frustration. The reduction of past and present stresses was therefore essential. In psychopathic as well as in normal development the first five years were the most important, and a greater understanding of psychopathy together with more effective treatment would come through studying the interrelations of different types of environment and different types of emotional response during these years. Through the study of psychopathy, a greater knowledge of the mental development of children would also be obtained.

Dr. E. B. STRAUSS, the chairman, in thanking the three speakers, said that, in attempting the impossible task of adjusting to an impossible world, we all break down either into psychosis, neurosis, delinquency, psychopathic behaviour, or alternatively into "normalcy." We were ill-fitted to live in the kind of society we had made, and he looked forward to a symposium on the psychopathology of normalcy in a mad world.

Preparations and Appliances

SIMPLE APPARATUS FOR CONTINUOUS GASTRIC SUCTION

Dr. EUSTACE J. SEQUEIRA, honorary assistant medical officer, Antenatal Department, B.Y.L. Nair Charitable Hospital, Bombay, writes: The apparatus described originally by Wangenstein, though inexpensive and simple enough to use, is somewhat cumbersome. Electrical appliances marketed for gastric suction are undoubtedly efficient but expensive. Therefore an attempt was made to devise an apparatus which is inexpensive, simple, and yet efficient. The apparatus described below, I believe, meets these requirements.

The suction pump used is a 24-volt anti-icer aircraft pump (de-icer pump) obtained from surplus war stock and used in conjunction with a suitable transformer. Equally suitable would be an aeration pump as used by aquarists and obtainable from any fish-fancier's store. As the negative pressure required is small, a powerful pump is unnecessary. The sure required is small, a powerful pump is unnecessary. The gastric tube would, of course, be connected not to the pressure but to the suction nozzle of the pump.

A difficulty was encountered, in that the gastric mucosa was often sucked up against the orifice of the Ryle tube so that drainage stopped and more and more negative pressure

Diagrammatic representation of the apparatus as used for continuous gastric suction.

sure kept developing in the appliance. This put a strain upon the pump and made drainage still more difficult. A simple release valve was therefore introduced which overcame this difficulty and made it possible to maintain trouble-free gastric suction indefinitely at a predetermined negative pressure.

The apparatus consists of the suction pump (A), the nozzle of which is connected to a T-tube (see Diagram). One arm of this tube is connected by means of a rubber connexion to the bottle (B)—fitted with an airtight rubber bung—which is in turn connected to a Ryle tube. Another bottle (C) is filled with fluid up to a level acts as a release valve. It has an airtight rubber bung through which pass two tubes—a longer one (D) that reaches down to 6 in. (15 cm.) of the bottom of the bottle, and a shorter one (E), whose lower end is clear of the surface of the fluid. This shorter tube is connected by means of a rubber connexion to the other arm of the T-tube.

The whole apparatus is placed on the floor at the patient's bedside so that the stomach is at a higher level than the collecting-bottle. When the pump is started negative pressure is created in the collecting-bottle B, and this, aided by siphon action plus the positive pressure within the stomach itself, causes the gastric contents to be aspirated into the bottle. If the gastric mucosa happens to be sucked into the bottle, air is drawn into bottle C through tube D, bubbles through the fluid and up through tube E and the T-tube to neutralize the negative pressure within the bottle B (and within the Ryle tube), and thus releases the mucosa which has been occluding the orifice of the latter. By this means steady uninterrupted drainage of the stomach is maintained. Once the stomach is empty air

is sucked in through bottle C, so that at no time is a strain placed upon the pump or trauma caused to the gastric mucosa. When fluid again collects in the stomach drainage restarts automatically. If the gastric contents are thick or if mucus obstructs the Ryle tube, it is a simple matter to close tube D so as to allow the desired level of negative pressure to be built up in order to clear it.

It should be noted that no expensive gauges or valves are necessary. Standard empty saline bottles are used both for the release valve and for the collection of gastric contents. The bore of the two tubes for bottle C is $\frac{1}{8}$ in. (5 mm.), and this is adequate for the pump used by us, which has a suction rate of about 1,000 ml. in about nine minutes. Under these circumstances the negative pressure developed by the apparatus will depend entirely upon the level and the nature of the fluid in bottle C. It follows also that variations in the performance of the pump owing to fluctuations in voltages in the mains will not cause any change in the amount of suction applied to the stomach. It must be emphasized, however, that if a much more powerful pump is employed the bore of tubes D and E must be much larger—as large as possible.

In order to find out the degree of negative pressure obtainable when some common fluids are used in the valve bottle, water, castor oil, and pure glycerin were used in turn. In each case the level of fluid was kept at 6 in. (15 cm.). The collecting-bottle (B) was connected to a mercury manometer and the negative pressure measured, the following values being obtained: water, 20 mm. Hg; castor oil, 22 mm. Hg; and pure glycerin, 28 mm. Hg. When the apparatus was used for gastric suction, with the patient in Fowler's position in a bed of normal height, the most suitable fluid was found to be pure glycerin at a level of 6 in. (15 cm.), the negative pressure obtained being 28 mm. Hg.

The apparatus may also be found of use in other situations—for example, drainage of an empyema cavity, or drainage of the urinary bladder in suitable cases. The desired degree of negative pressure could be maintained by simply increasing or decreasing the height of the fluid in the valve bottle.

The apparatus could be easily adapted for irrigation at a constant pressure and rate. When used for this purpose the T-tube is connected to the pressure nozzle of the pump instead of the suction nozzle, and one arm of the T-tube is connected to the short tube (G) of bottle B, which now contains the irrigating fluid. The outlet tube (F) from this bottle must be long enough to reach the bottom. The other arm of the T-tube is connected to tube D of the valve bottle instead of to tube E. By this means the irrigating fluid will be forced out from bottle B at a pressure dependent upon the level and nature of the fluid in the valve bottle. The positive pressures obtained with a 6-in. (15-cm.) column of fluid in this bottle were as follows: water, 20 mm. Hg; castor oil, 22 mm. Hg; and pure glycerin, 28 mm. Hg. Further variations of pressure could be obtained by increasing or decreasing the heights of these fluid columns. It should be noted that the apparatus when used for irrigation should be placed at the same height as the cavity to be irrigated.

I wish to thank Dr. F. J. Sequeira and Dr. E. J. D'Souza for their help, guidance, and suggestions in devising the apparatus and in preparing this article.

Tonic water as a cause of cinchonism is discussed in a recent letter to the *Journal of the American Medical Association* (December 5, 1953, p. 1304). These drinks are popular on both sides of the Atlantic and many of them contain a small quantity of quinine, commonly half a grain to the pint (56 mg. to the litre). Clearly a normal person would have to consume an enormous quantity of tonic water to suffer ill effects from it, but one who has an idiosyncrasy to quinine might begin to experience tinnitus, deafness, and other symptoms after drinking much smaller amounts. The author of the letter reports a case of cinchonism in a man aged 43 due to long-continued drinking of tonic water.

Correspondence

B.M.A. Toronto Meeting, 1955

SIR,—Greetings and good wishes for 1954. You have very kindly granted me space in this issue of the *Journal* to remind members of the British Medical Association of the One Hundred and Twenty-third Annual Meeting of the British Medical Association to be held in conjunction with the Eighty-eighth Annual Meeting of the Canadian Medical Association and the Seventy-fifth Annual Meeting of its Ontario Division, in Toronto, Canada, during the week of June 20, 1955.

This will be the fourth time during its long and illustrious history that the British Medical Association has met in Canada—in 1897, in Montreal, in 1906, in Toronto, in 1930, in Winnipeg—and we in Canada are looking forward with the keenest of interest and pleasure to the fourth meeting. Many members of the B.M.A. have visited Canada on previous occasions, and we hope their impressions were such as to impel them to return. They may be sure that a most cordial reception awaits them. To those who have never honoured us with a visit, may I say that this part of the New World, which is proud of its place in the British Commonwealth of Nations, will be delighted to welcome its kinsmen most heartily.

A number of committees are already busily engaged in preparing a programme which we are confident will be scientifically and socially acceptable. Outstanding members of the profession on both sides of the Atlantic Ocean have already indicated their willingness to participate in the programme. Work and play will be well blended. Plans are already near completion for an excursion to the famous Niagara Falls—a sight once to be seen, never to be forgotten. Altogether, the week promises to be an interesting one.

Conscious of the currency restrictions in the British Isles which will limit the purchase of dollars, we are happy to report that Toronto doctors and their wives are opening their homes to those members who indicate to the Secretary of the B.M.A. that they would be prepared to accept private hospitality during the week of the meeting. It is our understanding that members may purchase all of their transportation from home to Canada and return in sterling, so the dollar situation need not interfere with their plans. One realizes that June, 1955, seems a long way off, but remote dates have a way of catching up with us surprisingly quickly. We hope that members and their wives will make up their minds now that they are going to be among those present when the "Get Acquainted" Party is held in Toronto's famous Royal York Hotel on Sunday, June 19, 1955.

We confidently anticipate the joy of welcoming a large contingent from the British Isles, but I would like to think also that this joy would be considerably increased and augmented in welcoming many members from many other parts of the Commonwealth. B.M.A. members should, please, remember that this is their Association, and the Toronto meeting is their meeting. Their colleagues in Canada wish to join with me in extending to all a most sincere and cordial invitation to join with us in making the One Hundred and Twenty-third Annual Meeting of the British Medical Association one of the most interesting and memorable in the Association's history.—I am, etc.,

T. CLARENCE ROUTLEY,
President-elect of the British Medical Association
for the Toronto Meeting.

Lumbar Puncture

SIR,—I should like to make a few comments on the interesting criticisms and questions in recent letters about my article on lumbar puncture (*Journal*, November 7, 1953, p. 1069). In such an article it is difficult to cover all the points, and I attempted to supply only a working routine for

the relatively inexperienced or those who had not done a lumbar puncture for some while.

I agree with Mr. Norman Duggan (*Journal*, November 21, 1953, p. 1161) that the position of the operator is important. In particular, a comfortable position on a stool or seat greatly helps in providing stability and avoiding strain. Personally, I think local skin analgesia essential, except perhaps in cases of chronic meningitis where daily punctures are necessary. Patients understand the reason for numbing the operation site in much the same way as one does oneself at the dentist's. It is not so much the question of one or two pricks as the feeling of security. From long experience I do not believe it possible to guarantee a straightforward and successful puncture every time, and I have often been glad of a painless skin to work on.

With regard to the lateral approach mentioned by Dr. Rex Binning (*Journal*, December 5, 1953, p. 1271), it is not, in my opinion, to be used until considerable experience has been gained. Without the use of the nearer guide of the inter-spinous space, it is easy to have the point of the needle much too far to one or other side in the deep tissues.

Dr. W. A. Ball (*Journal*, December 5, 1953, p. 1271) asks if a puncture should ever be done in the home, and, if so, when. I have not myself ever done one in the home and I feel that if a patient really needs a puncture he needs to be in hospital. I can conceive of circumstances when a puncture at home might be done, but they are quite exceptional and somewhat fanciful. If the patient needing puncture refuses to go to hospital but consents to a puncture at home, the procedure would be advisable. In very unusual circumstances, such as a great epidemic, earthquake, snow, or flood, one might be forced into doing a puncture on the spot. In this country such circumstances are rarely or never found, but abroad it might be very different.

The final decision must always be a matter, not of rule, but of judgment.—I am, etc.,

London, W.C.1.

WILLIAM GOODY.

Controlled Hypothermia

SIR,—It is with diffidence that I venture to reply to an authority like Dr. C. Langton Hewer (*Journal*, January 2, p. 42). To begin with, it must be conceded that the complexity of the continental "cocktail" is to be deplored, as also the terminology, which, if not inexact, is certainly confused. Equally to be deplored is the outright condemnation of a method just because it is new. If the debut of curare had been received in this manner, anaesthesia would have stood still. The "considerable time to recover from these varied assaults" which Dr. Langton Hewer has noticed is surprising, for in my small series (26 cases) every patient has obeyed the golden rule of anaesthesia—a rapid return to normal physiology. Often the airway is resented on leaving the theatre, and the body temperature is rising to become normal in about two hours post-operatively.

The question of complexity, however, is clearer, for chemical hypothermia (or if I may add to the terminology "controlled metabolism") can be simplified considerably. Premedication is given as usual one and a half hours pre-operatively, but promethazine and pethidine is substituted for "omnopon," scopolamine, or atropine. The drip of chlorpromazine, promethazine, and pethidine given half an hour pre-operatively is an additional complication, but offset by the minute dose of thiopentone and the ridiculously small maintenance anaesthesia. What is lost on the roundabouts is made up on the swings.

As regards nursing, no difference is made whatever whether the patient has had a standard anaesthetic or hypothermia. The case is returned to a warm bed and adequately covered by blankets. No concession is made to the post-operative maintenance of hypothermia. Placing a potentially shocked patient in a warm bed is, I know, offending the rules of treatment of the collapsed. If we are to believe that the very defence mechanism of peripheral constriction initiates a vicious circle and finally kills the organism, then it is logical to aid peripheral vasodilatation by warmth. In the theatre these cases have stood up to major surgery better than those cases done under standard anaesthesia. In addition, either chlorpromazine or promethazine, or both, appear to have a "respiratory drive," and at the closure of the peritoneum additional cyclopropane is necessary to damp

down epigastric movement, although relaxation is adequate. The need for reversal of residual myoneural block by neostigmine (a cause of post-operative paralytic ileus) is not necessary. Finally, the use of hypothermia on every possible occasion will discredit this method as surely as was done with the methonium compounds. If the method is used on carefully selected cases, and not given to arteriosclerotics, hypertensives, and the aged with a subnormal B.M.R., it can prove a useful adjunct to anaesthesia.

The march of anaesthetic events is so rapid that it may well be that Dr. Langton Hewer's letter is a timely warning. If the reverse is the case, the shock protective factor of chemical hypothermia is well worth the slight extra complexity.—I am, etc.,

Edgware.

DAVID RECKLESS.

SIR,—In your annotation (*Journal*, January 9, p. 89) we are pleased to see that you have taken note of the work of Courvoisier and her colleagues' on chlorpromazine. This has been known and made use of for more than a year in clinical practice. We must reaffirm our belief that this drug has a central action, particularly at the level of the hypothalamus, depressing the reaction of the autonomic nervous system to stress, as well as depressing the temperature regulating mechanism. It is, of course, well known that many other drugs cause a fall in body temperature, but they do not have as great an effect on the physiological reaction to stress. In the "artificial hibernation" technique a fall in body temperature is only incidental to the more important action of this drug in modifying the stress reaction. In the poor-risk patient this may be life-saving.—We are, etc.,

Suxamethonium Chloride and Muscle Pains

SIR,—I was rather surprised to read in Dr. H. C. Churchill-Davidson's article (*Journal*, January 9, p. 74) that he considers suxamethonium unsuitable for use in out-patient procedures because "it is followed next day in a large proportion of cases by muscle pains and stiffness, the severity of which is out of proportion to that of the minor operation." Suxamethonium has been in routine use at many psychiatric out-patient departments for some time now, apart from its daily use throughout the country for in-patients who are not afterwards confined to bed. The proportion of patients who complain is very small, and the reactions which are as severe as Dr. Churchill-Davidson suggests occur only rarely.

In arriving at his conclusions we are not told how the severity of the pains was established, as apart from a similarity and duration inquiry there is no special part of the questionnaire which could determine this. Obviously, with varying individual responses to pain, it is important to eliminate neurotic elaboration. It is unfortunate, therefore, that two at least of the three cases selected as examples should have a "psychological element" present. Having presented these cases to illustrate the severity and quoted the three descriptive phrases couched in anecdotal terms, the conclusion quoted above is reached. Surely this is one of the age-old fallacies in argument—e.g., that of deducing a general statement from particular cases. The value of suxamethonium, in psychiatry at least, outweighs any minor after-effects of the severity generally encountered.—I am, etc.,

Essex.

DAVID J. ADDERLEY.

Radiology and Lumbar Disks

SIR,—I was most interested in Sir Max Page's letter on the diagnosis and treatment of lumbar disk lesions (*Journal*, January 9, p. 97), but it is extremely disconcerting to learn that, since the diagnosis and treatment of this particular lesion became more precise, the period of disability has increased rather than diminished.

It cannot be denied that at the present time there is a tendency to attribute every case of low back pain, whether acute or chronic, to a lumbar disk lesion. This is a fallacy, for other factors are obviously involved. In our enthusiasm

for the disk we have forgotten the other components of the intervertebral joint. It behoves us to remember the posterior joints with their synovial membranes and capsules, and the intervertebral ligaments. All these structures, together or separately, can give rise to acute or chronic pain in the back or leg. Moreover, derangements of the posterior joints can give rise to a clinical picture indistinguishable from that of a disk lesion. However, the dramatic manner in which lesions involving these joints respond to traction serves to distinguish them from lesions of the actual disk. It becomes more and more apparent to me that many so-called disk lesions are nothing of the sort, and that the symptoms are capsular or ligamentous in origin.

I have always found it difficult to understand how a forced manipulation can reduce, and keep reduced, a large posterior annular protrusion. Conversely, thinking in terms of the posterior joints, it becomes perfectly clear how manipulation or traction can so quickly relieve symptoms due to a nipped synovial fringe. This does not imply that traction is inadvisable for the genuine disk protrusion, for it is a most rational procedure and should almost always be tried. However, results are seldom dramatic, and it is usually necessary to repeat the procedure in a number of occasions to obtain complete relief. I can assure Sir Max that there is still a place for the plaster jacket. A not inconsiderable number of disk lesions fail to respond to either rest or traction, and in such cases a plaster jacket often acts like a charm. Though the plaster jacket has admittedly been overdone in the past, it is my impression that cases adequately treated by this method seldom relapse. Thus, though the period of disability may be increased in the first place, it pays in the long run.

In conclusion, I would ask that we drop that dreadful term, "slipped disk," and substitute in its place, "deranged intervertebral joint." To borrow a phrase from the late Professor Joad: "It all depends on what you mean by a disk lesion."—I am, etc.,

London, W.1.

E. J. CRISP.

SIR,—For some years lumbar disk lesions have been the source of a never-failing spate of papers, leading articles, and correspondence in every medical journal. The views expressed vary widely, particularly in regard to treatment, and usually pass unchallenged. Yet there is no real difference of informed opinion regarding the pathological cycle and basic principles of treatment of these lesions. The more bizarre suggestions so often put forward provoke no reply only because the medical profession is, by and large, a busy one.

Mr. D. W. C. Northfield (*Journal*, January 9, p. 97) has already dealt faithfully with your leading article "Radiology and Lumbar Disks" (*Journal*, December 19, 1953, p. 1363), and it is reassuring to learn from so authoritative a source that some neurosurgeons share that "prejudice" against myelography attributed particularly to orthopaedic surgeons. It cannot be too widely appreciated that this procedure is by no means without its dangers and is of very limited value in the diagnosis of lumbar disk lesions.

In the same issue, however, Sir Max Page submits (p. 97) that though the aetiology of "sciatica and the like" may be established the resultant form of treatment has done more harm than good. Such a statement from a surgeon of Sir Max's stature should not be allowed to pass unchallenged. Sir Max's view, apparently based on his experience with the Metropolitan Police, appears to be that two factors retard recovery. The first is "premature" diagnosis—it seems that a policeman recovers more quickly from "lumbago" or "fibrositis" than from a disk lesion. It is not clear, however, whether Sir Max believes that these conditions actually exist or are meaningless terms hallowed by use. The second retarding factor is the prolonged immobilization of the lumbar spine in plaster or in a corset, and Sir Max suggests "limited rest, traction, and exercise" as alternative measures. In all "fairly severe" disk lesions as nuclear degeneration and fragmentation takes place, often accompanied by annular rupture with displacement of

nuclear substance. Healing is by fibrous tissue formation, and a satisfactory result is a firm fibrous ankylosis of the damaged joint. Favourable conditions for such healing can only be established by avoidance of mechanical strains on and movement of the lumbar spine. In other words, rest and immobilization of this region are the corner stones of conservative treatment, and it is difficult to see how any other measures could speed up, or even affect other than adversely, natural healing. For obvious reasons the figures compiled by insurance companies are not necessarily the most reliable guides to true disability periods, nor is there any real reason why a Metropolitan policeman should not carry out his duties wearing a lumbar corset with incorporated Goldthwait steels.—I am, etc.,

London, W.1.

J. R. ARMSTRONG.

Medical Needs in the Gold Coast

SIR,—Many letters both private and in the correspondence columns of the *British Medical Journal* in reply to my article (*Journal*, October 31, 1953, p. 987) show the keen interest that this subject has aroused.

Recruitment is slow and publicity is lacking. The difficulty rather than the opportunities seem to be stressed. The short-term service is a poor policy. The young man cannot have the Colony his main interest, but rather what he is going to do later. The candidate is young in experience, in administration, in prestige; if married, is young in wife. I have been written to by several people who by regulation of the National Health Service are forced to retire in the United Kingdom at the age of 65. The use of people of this age has not been considered before, and yet there is much to be said for it. They are senior in knowledge, worldly wisdom, administration, and by then the family may be able to spare them. At that age they cannot expect security of tenure, or a pension, and would be glad to accept an interesting job with good pay for some years. This might also suit the Gold Coast. I know of one or two from London teaching hospitals who would be an asset. Their age would carry prestige. This is being done to my knowledge in other departments in West Africa—e.g., the banks.

There seems to be no regular picture of the medical establishment that the Colony requires, and, even if there was an establishment, it must change from year to year. The presence of a 500-bedded hospital with its specialist departments and the probable medical school in the future all change the established figure that has stood with so little alteration through the years.

A conference of the four interested parties—the Minister of Health of the Gold Coast, the Colonial Secretary, the Chief Medical Officer of the Colonial Office, and the British Medical Association—could publish a statement which would clarify the position.

Remuneration both for the active medical officer, and when on pension, at one time was considered to be more generous for the Gold Coast than other Colonies—"danger money." With the increased health of the area the latter does not arise, and to meet Europeans who have been there 25 years and never ill, or perhaps one attack of malaria, dispels the old fear. However, the price of living both there and at home has now gone up so much that the present salary and pension is quite inadequate. It is cheaper to pay a man well and get good service with experience rather than pay him poorly so that he retires early and is on pension for a long period. The post must be made attractive to the officer of 10-20-30 years' service to retain him.

Security of tenure cannot be given in the Gold Coast or the United Kingdom or anywhere, but with a published programme of expansion and establishment the candidate can guess at the possibilities and not be dependent for the future on nebulous promises.

Africanization will come, but to be good and permanent it must come slowly. The Gold Coast must be selective and African highly trained and expert in the specialty and should be (and I feel will be) appointed. A Colony such as this would do well when fully organized to link itself up with a university and medical school. Possibly a

provincial school would be best as the medical schools of London are so decentralized and not therefore a good example for a small country. The home university would fill the original vacancies and train the African later to take over these posts. The medical officer from the United Kingdom taking up a teaching career would gladly do one year abroad, and the African would have a permanent base where he could come on his study leave for refresher courses for his higher degrees. As the Colony gets further advanced and requires a neurosurgeon, a plastic surgeon, a cardiac surgeon—these trainee Africans can come for the necessary instruction. The nursing staff for their specialist branches can all be trained in the same way under the same teachers, and so, till the Colony is self-supporting, a gradual overlap and a slow build-up can take place from this parent body.

The immediate needs are (1) a conference with the heads of the Ministry of Health of the Gold Coast together with the interested bodies in the United Kingdom. (2) The publication of the proposed expansion and the views of the Colony. (3) An increase in salary. (4) A link-up with a suitable university would be better than the haphazard training of individual African students here and there throughout Great Britain. (5) Full consideration should be given to the employment on short or on indefinite service of the senior specialist or consultant from the United Kingdom, who would accept service without asking for security of service or a pension.—I am, etc.,

Belfast.

IAN FRASER.

The Feeble-minded

SIR,—With reference to the article, "A Survey of Patients in Twelve Mental Deficiency Institutions," by Drs. N. O'Connor and J. Tizard (*Journal*, January 2, p. 16), it appears that "sampling" was done in twelve hospitals with a population of 11,850. The sample consisted of 592 patients, of whom 49 were actually tested by the authors at the time of the survey. The percentage of sample to population was therefore 8.27% and the percentage tested to population was 0.41%. Five hundred and forty-three patients were assessed by reference to the clinical diagnosis of presumably at least twelve different medical officers, and it is not stated how many of these patients had been tested previously, or by what method.

It should be noted that the application of progressive matrices to mental defectives is by no means universally accepted. If the authors' figures are correct, that over 50% of these 11,850 patients are considered to have intelligence quotients of 70 plus, then it is no wonder that a certain Sunday newspaper claims that many of these people should not be under orders of detention, but should be attempting to earn their living in the world at large. Upon such figures as are given certain conclusions may in the future be drawn in reference to important matters such as nurse/patient ratios, building requirements, workshop equipment, etc., and it is necessary that such figures should be accurate and so avoid incorrect conclusions.

I am able to compare the figures given with those already completed as part of a somewhat similar inquiry now proceeding in my own hospital, and these figures show, after careful individual testing of each of 1,011 patients, a percentage of gradings as follows:

	Idiot	Imbecile	Feeble-minded Person
O'Connor and Tizard	5.9	41.7	52.1
Prudhoe and Monkton Hospital	24.3	50.3	25.1

The percentage of patients with intelligence quotients of 70 plus to total patients in this hospital is 3.6.

Your annotation (*Journal*, January 2, p. 35) states that "to those familiar with the problem it will not come as a surprise to learn that over half the patients in mental deficiency hospitals are classed as feeble-minded or that the average intelligence quotient in young adults confined in these institutions is above 70." I am not concerned with hospitals other than my own, but it should be known

that the figures you quote are not the only figures available, and that conclusions drawn from "sampling" may possibly be incorrect.—I am, etc.,

Prudhoe-on-Tyne.

G. MCCOULL.

SIR,—The survey by Drs. N. O'Connor and J. Tizard (*Journal*, January 2, p. 16) is welcome for many of the reasons stated in your annotation (p. 35), but may we hope to see an early end to this revival of the quaint old custom of measuring I.Q.s and drawing conclusions from them irrespective of clinical findings in individual cases? It becomes particularly serious when we find your leading article discussing the reason for "detaining for an indefinite period" those with I.Q.s above 70. Surely the reason for their need of prolonged treatment is a temperamental disability which is not reflected in the I.Q. and which does not become apparent in the sheltered environment of the hospital, and yet has caused difficulties in the larger community.

None would quarrel with the statement that "a high proportion of patients in mental deficiency institutions are potentially employable in building, in factories, or in agriculture," but few would not wish to add that employability in a social group is of little value unless accompanied by the ability to live within that group.

However, the shortage of accommodation in our hospitals has led some of us to attempt a more rapid social rehabilitation for many of our patients than has been the usual practice. The results are doubtful but not easy to judge when numbers are small, so the survey you suggest on this aspect of the problem would be very welcome.—I am, etc.,

Morpeith.

C. GUY MILLMAN.

Rheumatic Heart Disease Complicating Pregnancy

SIR,—I would like to congratulate Drs. M. I. Drury, M. K. O'Driscoll, T. D. Hanratty, and A. P. Barry on their interesting and stimulating contribution (*Journal*, January 9, p. 70) to the already extensive literature concerning rheumatic heart disease and pregnancy. It does seem apparent that the treatment and their conclusions are based almost entirely on the physical state of women with this cardiac lesion from the time of conception until approximately six weeks post-partum. The authors refer, for example, to five women who died more than one year after delivery, death in each case being due to heart failure. "They had reached the end phase of their disease. The fact that they survived their latest pregnancy by more than one year suggests that pregnancy did not contribute to these deaths." Of course they had reached the end phase of their disease, but did they reach such a phase earlier than they would have done had they not experienced at least one pregnancy and labour some time more than one year previously? To suggest that pregnancy did not contribute to their early demise is surely more wishful than logical thinking.

The conclusion that there is no place for sterilization or therapeutic abortion is based, it seems, also on the immediate effects of pregnancy and labour (religious reasons excepted). I would agree that the increasing employment of valvotomy in suitable cases will appreciably reduce the numbers of patients hitherto recommended for such measures. There is, however, no mention in this article of the social side of the problem—the care of the child of the patient, and the decreasing amount of time borne by the patient, and the decreasing amount of time available for the rest she needs. Does not this also affect the prognosis for the patient? How often have we heard the dyspnoic pregnant woman voice her fears about her ability or inability to adequately care for this coming child "along with the others"? In conclusion, Sir, the fault of this otherwise excellent article is summarized in its title, "Rheumatic Heart Disease Complicating Pregnancy."—I am, etc.,

London, W.1.

FRANK DENNY.

SIR,—The conclusions reached by Dr. M. I. Drury and his colleagues in their paper "Rheumatic Heart Disease Complicating Pregnancy" (*Journal*, January 9, p. 70) that "it is

considered that there is no place for therapeutic abortion or sterilization," and their condemnation of contraceptives, must be taken as an expression of belief rather than as a deduction from their facts.

Their survey is concerned with "250 pregnancies in 175 patients with rheumatic heart disease" over a limited period of four years. Their patients are drawn from "underprivileged groups, with poor home conditions and no home help, who are fertile to a degree which workers in other countries rarely see." The average rate of birth for the group was "a pregnancy every two years," and so we may conclude that the mothers studied in the survey will continue their "uninhibited child-bearing" until death or the menopause intervene.

However much good antenatal care can minimize the direct risk of pregnancy and child-bearing, it will not ease the life of the under-privileged mother living in poor home conditions with increasing family responsibilities and diminishing cardiac reserves. As scientists we must weigh up the risks of a life of this sort against those of contraception and sterilization, and place these alternatives before the patient. If we wish to condemn these procedures, we should make it clear that our condemnation has a religious or emotional basis only.—I am, etc.,

London, N.W.5

ANTHONY RYLE.

A.P.T. and Poliomyelitis

SIR,—That recent inoculation against diphtheria and whooping-cough predisposes to poliomyelitis seems, to judge from your annotation (*Journal*, September 19, 1953, p. 669), to be a view that is now coming to be accepted. Yet a recent discovery that might cause us to modify this view appears to be escaping attention.

In Oxford, Anne McLaren¹ found that the susceptibility of mice to the virus of encephalomyelitis, when injected intramuscularly, was increased tenfold after they had been similarly inoculated with freshly obtained diphtheria A.P.T. and pertussis vaccine. But repeating the experiment on a fresh group of animals when the vaccine mixture was a month older failed to reproduce the same effect. A later experiment on mice inoculated with the vaccine after it had been stored for seven months at low temperatures disclosed the striking fact that its effect on the animals' susceptibility was reversed. This time, it actually increased ten times their resistance to the disease. In short, the effect of the vaccine, in one direction or the other, seems to depend on its age.

For obvious reasons, it does not necessarily follow that injecting a child with A.P.T. will protect it against poliomyelitis. But the principle brought to light by McLaren—that the influence of certain immunizing agents on an animal's susceptibility to a neurotropic virus depends on the age of the inocula—may possibly be a fundamental one. If so, it is important to ascertain if that principle has a clinical application.

The answer may already lie in the records of those authors who have demonstrated a relationship between inoculation and the occurrence of poliomyelitis. If not, the Medical Research Council could provide one of the requisite sets of statistics by arranging for future inoculations to be performed with prophylactically valid material of different ages. Meanwhile, the World Health Organization may be able to clarify the issue by collecting details of the dates of manufacture of immunizing agents that have been used in previous large inoculation schemes. From such data it may be possible to relate the age of the inoculum to the incidence of subsequent poliomyelitis infection among those inoculated.—I am, etc.,

London, E.C.4.

Infection and Poliomyelitis

SIR,—I was interested to read your leading article (*Journal*, December 5, 1953, p. 1258) on infection and poliomyelitis, and Dr. J. H. C. Clarke's letter (*Journal*, January 9, p. 99).

In this practice, a rural one in Yorkshire, there was a small outbreak of acute poliomyelitis last autumn, eight cases in all. Being a relatively closed area, it was possible to assess the spread of the infection with regard to contact. Three of the cases were direct contacts with three earlier cases. The most interesting case arose in a different dale: there the family had kept away from the epidemic area completely. But one of the children developed poliomyelitis (confirmed, non-paralytic). The only feasible source of infection was from a visitor, a little girl who had been a direct contact of a confirmed paralytic case. The dates of interest are: (1) contact between carrier and first case October 4, 1953, (2) diagnosis of first case October 6, (3) carrier visited second case October 17-20, (4) diagnosis of second case November 2.

This small epidemic confirms that the mode of spread is by direct contact, and, in the last case, spread by a healthy carrier. Localization of an outbreak can be helped by more thorough isolation of contacts.—I am, etc.,

Hawes, Yorks.

J. D. McDONALD.

A Cosmetic Amputation

SIR,—The only difference between Mr. Ian Lawson Dick (*Journal*, January 2, p. 45) and myself is that he speaks of his own results while I speak of the results of operations done by Tom, Dick, and Harry. Dick's results may be grand, but Tom's and Harry's are lousy.—I am, etc.,

London, N.W.8.

HENRAGE OGILVIE.

Valvotomy in Mitral Stenosis

SIR,—The excellent operative results recorded by Mr. T. Holmes Sellors and Drs. D. Evan Bedford and Walter Somerville (*Journal*, November 14, 1953, p. 1059) in selected cases with a mobile and pliant valve tempt me to ask them to reconsider the situation in a large group of patients who are excluded from surgical help by their present criteria—that is, in those with extreme narrowing of a rigid orifice. There are theoretical considerations in favour of a minimal digital dilatation in such cases, with acceptance of the consequent increase in the regurgitation, and of giving, in fact, limited but essential help in cases where a perfect result is clearly unobtainable.

It is known that with a fluid of high internal friction flowing in a laminar manner through an orifice, the frictional loss of energy is inversely proportional to as much as the fourth power of the linear dimension of the opening.¹ Roughly, therefore, for a given differential head of pressure, the flow would be doubled by a linear increase of 2 mm. in an orifice of 1 cm. diameter, or by a dilatation of less than 1 mm. in an opening of half this size. Clearly, with filling pressures in the usual range a critical point exists below which a small contraction will produce an insuperable barrier and where, conversely, a modest dilatation would give disproportionate relief.

Further, Rodbard and Saiki² have demonstrated a probably different critical level below which occurs a rapid alternation of energy conversion between kinetic energy of flow and static pressure on the orificial walls, with a chattering effect producing a harsh sound and an abrupt fall of the flow/pressure ratio.

The diagnosis of mitral narrowing to the region of such critical levels may be thought to call for minimal dilatation beyond them where surgically possible. To go further than this must necessarily be disastrous, and it may be that it is through attempts to achieve a functioning valve in such cases that this important group of cardiac invalids has become surgically disreputable.

The prognosis in a patient so left with a rigid valve depends largely on the myocardial state and need not be wholly black. All interested in the subject must see many who live to a considerable age in some comfort, and Lenel, Strauss, and Schlichter³ demonstrated severe valvular deformities in patients over 50, 18% of whom were free from symptoms. Many patients with insistent symptoms in their late 30's

would be glad to accept an imperfect result if, for example, their chance of living to see their children settled was thereby increased.

I have many reasons to be grateful for the judgment and skill of the authors of this article, and my respect for them makes me open this topic with genuine diffidence. I was encouraged, however, by their mention of "unexpected clinical improvement" in some of the few cases of this type that found their way into the series.—I am, etc.,

London, N.19.

Press Publicity

SIR,—As a journalist, may I thank you for your leading article (*Journal*, January 16, p. 141) on the difficult subject of relations between the press and doctors? As you point out, "an operation on Siamese twins is news." It was my duty to obtain this news for my newspaper, which is not sensational, but will go to any legitimate length in serving a growing body of readers.

Do you, Sir, or does Professor Ian Aird, consider it fitting and conducive to the dignity of the art and science of medicine that for news of the first operation in this country for the separation of Siamese twins the press should be dependent on information supplied by a commercial company, however great and even though it was footing the bill, including transporting the children and their mother to London? Surely if a public relations officer was to be used the B.M.A.'s own John Pringle was the man. I do not for a moment defend any bad behaviour there may have been, but opportunity for this may not have occurred if Professor Aird had enlarged his sessions with the company's P.R.O. to include a few responsible journalists.

It was my lot recently, too, to write about the magnificent history of war surgery published by the Stationery Office. One could not help referring to such authors and subjects as Sir Heneage Ogilvie, Sir Gordon Gordon-Taylor (his chapter on abdominal injuries is a wonderful piece of writing), and, again, Professor Aird and his adventures among the Germans in the Libyan desert. What possible objection can there be to such publicity?

I submit that doctors and the B.M.A. should think again, and deeply, on this whole business, with your leading article as text. And, if I may so far presume, I would urge them to trust the journalist more.—I am, etc.,

London, E.C.4.

JOHN PRINGLE.

SIR,—The letter of Mr. John Prince (*Journal*, January 2, p. 43) under the title "Press Publicity" deals with a subject which everybody knows has been a sore one for many years. It is so difficult to explain to journalists the reasons why the medical profession dislikes publicity. It is equally difficult to show editors the dangers of cutting copy to leave a misleading half-truth in medical matters.

It is for these reasons that the Central Council for Health Education are helping reporters on non-professional publications by giving them accurate factual information and assisting them to present these facts effectively. The council have always been ready to assist the press in these matters, and receive many requests for help of this kind.—I am, etc.,

London, W.C.1.

JOHN BURTON.

Appendicitis in the Course of Measles

SIR,—Dr. W. H. Galloway's series of seven cases (*Journal*, December 26, 1952, p. 1412) is most instructive, but his conclusion that "during the course of measles, symptoms of acute appendicitis warrant immediate operation" requires qualification. Abdominal symptoms associated with measles may be met with as (a) an initial manifestation in which there is transient iliac discomfort; (b) a prodromal appendicular colic which Mayerhofer¹ refers to as pseudo-appendicitis; (c) the suppurative condition which occurs after the

rash has appeared; and (d) a fortuitous association of measles with acute appendicitis.

The first is not exclusive to measles, since it can be encountered at the outset of other infections—e.g., typhoid, smallpox, and poliomyelitis. Appendicular colic is occasioned by the virus of measles, and is not uncommon. "Several times we have observed typical appendicular symptoms in the early stage of measles which caused the attending physician to send the patient to the surgical unit" (von Gröber²). Since Finkeldey³ described the histological appearances in the tonsils and pharyngeal mucosa, many writers have recorded cases presenting a similar picture in the appendix. The case of Schultze⁴ is noteworthy because sections of the removed appendix reminded him of Finkeldey's tonsillar illustrations and suggested a diagnosis of a typical eruption, confirmed by the later appearance of a typical rash. I am surprised that Dr. Galloway could not find "any report on this matter in a British journal," as in 1936 I recorded instances of appendicular symptoms in the infectious fevers⁵; the section dealing with measles was annotated in the *Lancet*.⁶ The importance of examining the buccal mucosa was stressed because, like the prodromal laryngitis which was also given rise to difficulty in its management, the natural tendency is for the acute symptoms to abate when the fourth-day rash appears. Recognition of Koplik's spots will usually clarify the issue and help to limit the spread of infection if the patient is being treated in a surgical unit.

With regard to the surgical aspect, operation in the first category is unlikely to show the elongated pinkish appendix which is seen in the second group. Banks⁷ says: "It is surprising how often appendectomy is unnecessarily performed in the prodromal stage of the exanthemata," but he goes on to remark that true appendicitis does occur in persons with an exanthematous rash in much the same proportions as in other people." When Dr. Galloway states that he feels "that the occurrence of the two together is not fortuitous," I would agree in so far as his remarks apply to the eruptive phase of measles. Here the position may be akin to the pyogenic complications (otitis media, etc.) occasioned by the action of a second organism for which the virus has prepared the way. His two cases with abscess formation were in the eruptive stage. That has also been my experience. Until 1953, when I saw two examples, I had not met with suppurative appendicitis in prodromal cases which did not require operative interference. Should the symptoms in the eruptive stage be equivocal, a white-cell count is valuable; instead of the customary leucopenia, it will show a leucocytosis if the patient has a true appendicitis.

Everyone will agree with his statement that cases should be operated on when a definite diagnosis of appendicitis has been established. A fortuitous association of measles with acute appendicitis can, of course, occur in any stage. Fortunately, such cases are not common.—I am, etc.,

Medicinal Teaspoons

SIR,—The dose of one fluid drachm has for many years been interpreted as one teaspoonful. This practice was given more formal expression by the issue of British Standard 1348, 1949, which defined a medicinal teaspoon with a capacity of one fluid drachm as 3.5 ml.

It is regrettable, therefore, that recently some pharmaceutical manufacturers have adopted and, in at least one case, are issuing, a 5-ml. teaspoon, the use of which for other preparations can only result in overdosage and considerable waste, amounting to some 40%.—I am, etc.,

L. CARLYLE LYON.

Basing, W.5.

Obituary

WILLIAM GRIFFITH, M.B., M.R.C.P.

Dr. William Griffith, who was for many years physician to St. John's Hospital for Diseases of the Skin in London, died on December 28, 1953, in the Westminster Hospital at the age of 85.

William Griffith was born at Sebonig, Dyffryn, North Wales, on March 13, 1868, and was educated at Christ College, Brecon—where there was another scholar who later made his mark in London, Mr. John Howell Evans, the well-known surgeon—and at Owens College, Manchester. He graduated M.B., Ch.B. from the Victoria University, Manchester, in 1891, and then held resident appointments at the Manchester Southern Hospital, Denbighshire Infirmary, and the London Temperance Hospital. He continued his postgraduate studies at University College and at the Middlesex Hospitals, and in 1901 he worked as a medical referee for the London County Council and the St. Pancras Borough Council during the smallpox epidemic of that time. Having decided to specialize in skin disorders, he obtained the M.R.C.P. in 1909, and then became successively registrar, assistant physician, and finally physician to St. John's Hospital for Diseases of the Skin. From 1914 to 1919 he served as a specialist in the R.A.M.C. in the Aldershot command, and was mentioned in dispatches.

Dr. Griffith was an active member of the B.M.A., and was one of the honorary local secretaries of the Annual Meeting held in London in 1910. In addition he was honorary secretary of the Section of Dermatology at the same meeting. For three years until 1913 he was honorary secretary of the Metropolitan Counties Branch, and was then elected a vice-president. He became honorary treasurer of the Branch in 1929 and served in that capacity until 1934, and was then elected president of the branch. For a short time, in 1927-8, he was a member of the Journal Committee of the Association. From 1927 to 1929 he was honorary secretary of the Marylebone Division, and from 1933 to 1934 he was its chairman.

During his long life Dr. Griffith saw great changes in the treatment of skin diseases, and himself took an important part in the development of treatment by Finsen light. At the old London School of Dermatology he was the Chesterfield lecturer in diseases of the skin. He was a Fellow and former President of the Dermatological Society of London, now merged in the Royal Society of Medicine, and published a number of papers in its *Transactions*.

Medico-Legal

LEGAL AID

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Recently in an action for negligence against three doctors the plaintiff at the trial unreservedly withdrew his allegations of negligence against them. The judge, when awarding costs against the plaintiff, observed that as the case had been brought under a legal aid certificate the order for costs would not be enforceable.

Although the English sanction that the unsuccessful litigant will be ordered to pay a substantial part of his

opponent's costs is an effective deterrent to the bringing of frivolous and ill-founded claims by people of substance, it has never effectively deterred those who have no property upon which an order for costs could be executed, and who have nothing to lose by being made bankrupt. In this respect the Legal Aid and Advice Act, 1949, has not affected the position, because, although it alters the liability of the assisted litigant for his opponent's costs, it does so by providing that he shall have to pay only what the trial judge thinks reasonable in all the circumstances, including the means of all the parties. The result in practice is that anyone who has anything to pay with will be ordered to pay, and the man who has nothing will not be ordered to pay, and the successful litigant will have no better and no worse prospect of getting his costs paid than he had before.

The real sanction operating on the impecunious plaintiff before the Legal Aid and Advice Act used to be that his own professional advisers would generally not act for him unless the prospect of success was such that it was likely that he would be left at the end of the day with something out of which to pay their bill. Since the 1949 Act their bill—it is true on an "austerity" scale—is met out of the Legal Aid Fund irrespective of the result of the litigation.

But although the 1949 Act has thus removed this sanction it has not left the matter purely to the conscience of the impecunious litigant's professional advisers. Anyone who applies under the Act for a State subsidy to bring his case, which is the form which legal aid under the Act assumes, has first to satisfy the Assistance Board that his means are within the limits laid down under the Act and be assessed according to his means for his contribution towards the costs of the litigation, which has to be paid into the Legal Aid Fund. But he has also to satisfy a Certifying Committee of practising solicitors and barristers appointed under the Act, and not in any way concerned in the impending litigation, that he has a good prima facie case on the information which he puts before them, and that the case is a reasonable "business risk." Not only would it be the Committee's duty to refuse a certificate for legal aid if the applicant did not appear to have a case on which he was likely to get judgment, it would equally be its duty to refuse it if any judgment the applicant got would obviously be barren because the prospective defendant could have no means of satisfying it.

This machinery cannot prevent the launching of the case in which there is no real prospect of success and in which allegations of negligence have to be withdrawn at the trial. The Certifying Committee can hear only one side of the story, and, even if everything told to it is true, truth may assume a wholly different aspect when the other side of the story is told. The Committee cannot and ought not to usurp the function of the court. However, it is difficult to see how, once the principle of State-subsidized litigation for the poor man is accepted in the interest of justice, a better filter could be arranged. It is probably a lesser evil for the community that someone who is not so impecunious as to be able to get legal aid to defend himself should have to pay for his own defence in an action which ought not to have been brought than that a man who has an action which ought to be brought should be prevented by poverty from bringing it.

Universities and Colleges

UNIVERSITY OF DUBLIN

SCHOOL OF PHYSIC, TRINITY COLLEGE

The following medical degrees were conferred on December 3, 1953:

M.D.—E. W. Lillie.
M.B., B.Ch., B.A.O.—S. Allen, I. C. Bailey, Anne Bewley, A. W. Browne, W. Brownlee, Barbara M. Cooke, W. Dobson, F. F. Doran, Dorothy A. Foster, J. B. Gill, H. Hardman, N. L. Harte, C. A. Isola, A. Kahnta, J. E. Latham, G. R. L. Lyons,

D. McCaughan, S. W. McVicker, J. R. Noble, J. O'Carroll, W. G. Speer, J. D. Tate, E. C. Tees, E. G. Weyhausen.
LICENCE IN MEDICINE, SURGERY, AND IN OBSTETRIC SCIENCE.
L. A. H. Oulton.

CONJOINT BOARD OF IRELAND

The following candidates were duly admitted Licentiates in Medicine and Midwifery on December 4, 1953, having passed the final examination in medicine, surgery, and midwifery of the Conjoint Board of Ireland: A. M. van Bergen, Constance M. Coogan, B. C. F. Dalton, J. T. Devlin, G. G. Dibue, Eileen M. Dodd, Kathleen M. N. Gibney, T. S. Gilpin, M. Jeffries, Wee Soon Lee, D. M. McCarthy, P. B. McKenna, Monica M. McLoughlin, Priscilla R. K. Nicol, A. N. Obonna, A. R. G. H. Peermohamed, N. B. Smyth, E. H. Wells, R. J. Whitty, W. J. Wilmot, M. Wright, Maria E. T. Wyganowska.

The following candidates have been approved at the examinations indicated:

D.C.H.—N. Adhya, Margaret Bell, Muriel Bannister, Rosaline Power.

D.A.—R. E. Bourke, Una B. Byrne, Mary M. Gordon, J. Levin, L. C. Luck, D. O'Leary, M. R. Porter, P. J. Boyle, J. G. Goodbody, R. C. Gray, J. Lomaz, R. W. Milner, E. F. O'Riordan.

Vital Statistics

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1944-52 are shown thus ———, the figures for 1953 thus ———. Except for the curves showing notifications in 1953, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Infectious Diseases

A rise occurred in the incidence of infectious diseases in England and Wales during the week ending January 2. The chief increases in the number of notifications were 860 for whooping-cough, from 1,424 to 2,284; 716 for measles, from 611 to 1,327; 377 for acute pneumonia, from 530 to 907; and 162 for scarlet fever, from 949 to 1,111.

The largest rises in the incidence of whooping-cough were 99 in Warwickshire, from 84 to 183; 79 in Lancashire, from 140 to 219; 73 in Essex, from 69 to 142; 63 in Glamorgan-shire, from 39 to 102; and 55 in Southampton county, from 54 to 109. A small rise occurred in the incidence of scarlet fever in most areas, but no large fluctuations were reported. A few well-defined centres were responsible for the rise in the incidence of measles; these included increases of 167 in Staffordshire, from 55 to 222; Lancashire 165, from 134 to 299; Cumberland 73, from 63 to 136; and Norfolk 53, from 86 to 139. Within these counties the largest centres of infection were Stoke-on-Trent C.B. 151, Norwich C.B. 109, and Whitehaven M.B. 89. 29 cases of diphtheria were notified, being 14 more than in the preceding week. The chief features of the returns were rises in Lancashire from 5 to 10 and in London from 0 to 3, 6 cases were notified in Liverpool C.B.

For the first time for 12 months no case of paratyphoid fever was notified. The only case of typhoid fever was in Shropshire, Shrewsbury M.B.

53 cases of acute poliomyelitis were notified; these were 21 more for paralytic and 3 more for non-paralytic cases

than in the preceding week. The largest returns were Gloucestershire 5 (Bristol C.B. 4), Lancashire 5, Yorkshire West Riding 4, Middlesex 3, Nottinghamshire 3 (Nottingham C.B. 3), and Derbyshire 3.

The number of notifications of dysentery increased from 309 to 340. The largest centres of infection were Lancashire 59 (Bolton C.B. 19, Preston R.D. 18), London 52 (Islington 16), Yorkshire West Riding 35 (Bradford C.B. 13), Middlesex 24, Norfolk 23 (Norwich C.B. 23), Warwickshire 21 (Birmingham C.B. 19), Leicestershire 18 (Leicester C.B. 14).

Infectious Diseases in England and Wales in 1953

The incidence of diphtheria continued to fall during the year, and the number of notifications was the smallest recorded in any year. During the 22nd week only 10 cases were notified, the lowest level yet attained. During the year Staffordshire, Warwickshire, and Lancashire were the chief sources of cases, and the important centres within these counties were Coseley U.D., Birmingham C.B., and Liverpool C.B. The incidence of scarlet fever, measles, and acute pneumonia was relatively high during the first quarter of the year, but declined to below the average of the preceding 10 years during the last quarter. Although fewer cases of measles were notified than in 1951, the outbreak in the first quarter of 1953 was very severe, and 39,127 more cases were notified than in the first quarter of 1951. In the 6th and 7th weeks the notifications of measles were 32,359 and 32,890, and were the largest numbers notified in any week since notification began. A comparison of the number of notifications with those of the three preceding years is as follows:

England and Wales	1950	1951	1952	1953
Scarlet fever	66,832	49,421	69,091	61,578
Whooping-cough	157,714	169,394	116,311	137,772
Diphtheria	2,858	1,969	1,473	1,022
Measles	366,116	615,332	400,838	534,020
Acute pneumonia	36,714	43,181	31,403	37,058
Meningococcal infections	1,745	1,956	1,687	1,783
Acute poliomyelitis	1,699	3,093	4,504	5,251
Dysentery	18,135	29,488	15,663	19,340
Typhoid and paratyphoid	654	1,438	1,190	569
Great towns: Influenza deaths	2,537	8,361	1,019	3,381

The seasonal rise of acute poliomyelitis began during the 21st week, the usual date, and the incidence rose steadily. During the 28th and 29th weeks the number of notifications reached the highest level yet recorded for these weeks, 223 and 266 cases. Further increases were small, and a maximum of 318 was reached in the 32nd week; from this date the incidence fell fairly steadily. Considerable variations were recorded in the proportion of paralytic to non-paralytic cases in the regions. The ratio varied from 0.9 in the southern region to 3.7 in the East and West Ridings. The distribution of paralytic and non-paralytic cases by regions is as follows:

Region	Paralytic	Non-paralytic
Northern	131	81
East and West Ridings	311	85
North-western	357	149
North-eastern	212	192
Midland	387	197
Southern	257	290
South-western	294	187
Eastern	253	160
London and S.E.	944	527
Wales	136	86

Week Ending January 9

The notifications of infectious diseases in England and Wales during the week included scarlet fever 792, whooping-cough 2,156, diphtheria 21, measles 1,134, dysentery 322, acute poliomyelitis 44, paratyphoid fever 1, and typhoid fever 2.

Smallpox in Holland

Up to January 14, 23 cases of variola minor have been identified as contacts of a case in The Hague.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending January 2 (No. 52) and week No. 52 of 1952.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES In Countries and London	1953-4					1952				
	Eng & Wales	Land	Scot	N. Ire	Eire	Eng & Wales	Land	Scot	N. Ire	Eire
Diphtheria	29	3	3	0		26	0	10	1	
Dysentery	340	52	105	3	13	184	23	75	2	1

* Measles not notifiable in Scotland, whence returns are approximate.
† Includes primary and influenzal pneumonia.
‡ Includes puerperal pyrexia.

Medical News

Royal Commission on Mental Certification and Detention.—Lord Percy of Newcastle has been appointed chairman of the Royal Commission which is to inquire into the certification and detention of persons suffering from mental illness and mental defect (see *Journal*, October 31, 1953, p. 998). Lord Percy is 65. He is best known in connexion with education. For many years he was Rector of the Newcastle Division of Durham University, and was President of the Board of Education from 1924 to 1929. Last year he was appointed chairman of the Burnham Committee on teachers' salaries. As Lord Eustace Percy he was M.P. for Hastings (1921-37).

Tobacco Industry's Reply.—The American Tobacco Industry, in an advertisement published in American newspapers on January 4, has announced the formation of a Tobacco Industry Research Committee to look into the question of cigarette smoking and cancer of the lung, thus acting on a suggestion made in the *British Medical Journal* of December 13, 1952. In charge of the research activities of this committee will be "a scientist of unimpeachable integrity and national repute." In addition there will be an advisory board of scientists disinterested in the cigarette industry. The advertisement states that a group of distinguished men from medicine, science, and education will be invited to serve on this board. So far none of these persons has been named, nor the chief scientific adviser. This move on the part of the American Tobacco Industry is in response to public anxiety in the United States following the report by Wynder, Graham, and Croninger on the production of skin carcinoma in mice painted with cigarette tar (see *Journal*, December 19, 1953, p. 1362). The Tobacco Industry's Committee, while reiterating the industry's belief that tobacco products are not injurious to health, states that it accepts "an interest in people's health as a basic responsibility, paramount to every other consideration in our business."

London School of Hygiene and Tropical Medicine.—One of the outstanding sections in the school's annual report for 1952-3 is Professor J. M. Mackintosh's account of the work of eight "study groups" which were formed by D.P.H. students. Each group was given a subject to investigate during the year and presented a report on it during the summer term. To illustrate the value of local history, one group studied the history of housing in the borough of Hammersmith. The modern tramp was the subject of another inquiry: here the group came down in favour of spending limited public funds on prevention rather than on attempts at rehabilitating the "end-product of this particular type of social misfit." Caravans and house-boats, the care of the elderly, the work of the occupational psychologist, and the role of the medical officer of health in slum clearance were tackled by other groups. A study on what factors had affected the results of the "eleven-plus" examination in children from a housing estate provided at least one surprising finding—among successful children there had been more changes of school. As might be expected, good health and good physique went with success, long absence from school with failure. An educated mother was more of an asset than an educated father. Television in the home was associated with poorer examination results. The last group investigated the part played by the popular press in health education. Contrary to their expectation, the group records that most of the newspaper articles were of high quality. The attitudes of three health editors interviewed were varied; one regarded promotion of circulation as his first duty and chose his articles for their news value; at the other end of the scale, another—an ex-nurse—felt the articles in her paper were filling a serious gap in the health services. In both cases the final result was much the same, the articles

having in the opinion of the group a high educational value. A popular article might draw as many as 16,000 letters from readers. The success of these study groups, which have now been in progress at the school for several years, must be judged by their capacity to educate the future medical officer of health. Professor Mackintosh has little doubt of this. "There is more in a D.P.H. course," he says, "than the diploma at the end of it." Study groups show how to reach agreement by discussion and teach the value of team-work.

Everest Doctors at the Royal College of Surgeons.—Two medical members of the successful Everest expedition gave a Hunterian Lecture, jointly, at the Royal College of Surgeons on January 13. Dr. Michael Ward described the climb up to 22,000 ft. and Mr. R. C. Evans continued with a description of the final stages of the attack on the summit. The speakers illustrated their remarks with photographic slides and with diagrams showing the results of some of the physiological investigations carried out by Dr. L. G. C. Pugh, who was in the audience. Later in the same evening the council of the College entertained Mr. Evans and Mrs. Ward and Pugh to dinner, and a large company of Fellows with their guests were present. Sir Reginald Watson-Jones presided, and introduced the three members of the expedition—whose health was drunk by the company in the favourite Everest drink, hot lemonade. After brief and modest speeches by the guests of honour, the company adjourned to another room to see part of the Everest film.

Treatment of Homosexuals.—The Howard League for Penal Reform has asked the Home Secretary, Sir David Maxwell Fyfe, for a committee to inquire into the treatment of homosexuals. In a letter to the Home Secretary, concerned particularly with male persons convicted of homosexual offences, the League states that it is not convinced that there are sufficient therapeutic facilities in prisons for all cases which might be amenable to treatment. "As for the psychopathic homosexual, he, in company with other psychopathic offenders, must await the opening of a special institution on the lines recommended by Sir Norwood East and Dr. Hubert." The League adds that any inquiry of this sort should also consider how far and in what circumstances male homosexuality should be considered a criminal offence.

University Grants Committee.—The reconstituted University Grants Committee includes three medical men: Dr. E. D. Adrian, P.R.S., Master of Trinity College, Cambridge; Professor W. Melville Arnott, professor of medicine at Birmingham and recently deputy president of the First World Conference on Medical Education; and Professor G. W. Pickering, professor of medicine of St. Mary's Hospital, London, a former Sims British Commonwealth Travelling Professor. The committee consists of 15 members and a full-time permanent chairman.

Paul Ehrlich Prize.—Dr. E. B. Chain, F.R.S., at present scientific director of the International Institute for Chemical Microbiology, Rome, has been awarded this year's Paul Ehrlich prize, a gold plaque. In 1945 Dr. Chain shared with Sir Alexander Fleming and Sir Howard Florey a Nobel Prize for his work on penicillin. This year is the centenary of Ehrlich's birth on March 14, 1854.

National Institute for the Deaf.—Mr. R. Scott Stevenson, F.R.C.S.Ed., has resigned from the chairmanship of the institute's council, a post he had held for nine years, as he is going to Gibraltar. His place is being taken by the present vice-chairman, Mr. Edward Evans, M.P., and another E.N.T. surgeon, Mr. I. G. Robin, F.R.C.S., has been elected as the new vice-chairman. At a farewell dinner on January 7 Mr. Scott Stevenson was presented with a radio-gramophone.

Dr. L. Cosin, clinical director, Geriatric Unit, United Oxford Hospitals, is visiting Israel for four weeks during

January and February to carry out a survey of chronic sick hospitals. He will be lecturing in Athens and Rome on behalf of the British Council.

Professor R. H. Parry, M.O.H., Bristol, has become the first president of the Bristol Branch of the Catering Managers Association of Great Britain.

25th Birthday.—*The Listener*, which is edited by Mr. Alan Thomas, celebrated its twenty-fifth birthday last week with a party at the Dorchester Hotel and a special number which included a selection of talks given over the wireless since 1929, beginning with H. G. Wells on "World Peace," and subtly ending with "The Uncertainty Principle," by Professor E. N. Da C. Andrade. *The Listener* is always packed with good things, and this birthday number is one to buy for keeps.

COMING EVENTS

Art Exhibition for Doctors.—Contributions from British doctors, pharmacists, dentists, and veterinary surgeons are invited for the twenty-sixth Salon des Médecins, Pharmaciens, Dentistes et Vétérinaires which will be held in Paris from March 7 to 21. There will be sections for paintings, sculpture, photographs, and applied decorative art. Those intending to exhibit should send their name, address, professional qualifications, and title of exhibit to Dr. Malet, 67, Avenue Pierre Larousse, Malakoff (Seine), France, and their exhibits (properly labelled) to Messrs. Davies Turner Ltd., 4, Lower Belgrave Street, London, S.W.1, not later than February 10.

Third International Congress on Diseases of the Chest.—The congress, held every second year by the American College of Chest Physicians, will take place from October 4 to 8 in Barcelona. The official languages will be Spanish, English, and French. Further information may be obtained from the general secretary of the congress, Córcega, 393, 40, 1^a, Barcelona, Spain.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, January 25

● **INSTITUTE OF CARDIOLOGY.**—9.30 a.m., Mr. P. R. Allison: Bronchoscopic Measurements of Left Auricular Pressure.

INSTITUTE OF PSYCHIATRY.—5.30 p.m., lecture-demonstration by Dr. E. Stengel.

MANCHESTER MEDICAL SOCIETY: SECTION OF ODONTOLOGY.—At Manchester Dental Hospital 5 p.m., Professor A. D. Hitchin: Post-operative Sequelae.

MANCHESTER MEDICAL SOCIETY: SECTION OF GENERAL PRACTICE.—At Large Anatomy Theatre, Manchester University, 9 p.m., Dr. C. S. D. Don: Treatment of Some Chronic Chest Conditions.

MEDICAL SOCIETY OF LONDON.—8.30 p.m., Meeting of Fellows; discussion to be introduced by Mr. J. Hamilton Doggart and Dr. S. Pinder Meadows: Ophthalmic Evidence of General Disease.

ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Refraction Work in the Young and the Old. Appalsia.

Tuesday, January 26

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor J. B. S. Haldane, F.R.S.: Genetics of Some Biochemical Abnormalities.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. F. Borrie: Vascular Disorders.

MANCHESTER MEDICAL SOCIETY.—At Physiology Theatre, Manchester University, 4.30 p.m., discussion by Dr. Lennox M. Johnston and Professor J. Crighton Bramwell: Tobacco Smoking and Health.

ROYAL STATISTICAL SOCIETY: STUDY CIRCLE ON MEDICAL STATISTICS.—At Westminster Medical School, 6 p.m., Dr. D. J. Finney: Bio-assay.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Professor J. C. McClure Browne: Dysmenorrhoea.

Wednesday, January 27

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Parapsoriasis, Psoriasis, and Mycosis Fungoides.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. R. Thomson: Laboratory Aids to Diagnosis.

● **LONDON UNIVERSITY: DEPARTMENT OF EXTRA-MURAL STUDIES AND ATOMIC SCIENTISTS' ASSOCIATION.**—At Beveridge Hall, Senate House, 7 p.m., Professor O. R. Frisch, F.R.S.: Atomic Weapons.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—7.30 p.m., Mr. A. G. Fishburn, F.P.S., F.R.I.C.: Formulary of the British Veterinary Codex; Dr. D. C. Garrait, Ph.D., F.R.I.C.: Standardization of the Drugs and Galenicals of the British Veterinary Codex.

ROYAL EYE HOSPITAL.—5.30 p.m., Mr. L. H. Savin: Ophthalmic Operations and Their Indications (5).

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—5 p.m., Dr. John Burna Lecture by Sir Ernest Finch: The Forerunner: Leonardo Da Vinci's Contribution to Anatomy and Physiology.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Professor T. F. Rodger: Lecture-demonstration in Psychiatry.

SOCIETY OF CHEMICAL INDUSTRY: FOOD GROUP—NUTRITION PANEL.—At Chemical Society, Burlington House, 6.30 p.m., Dr. L. J. Harris: Vitamins and Newer Concepts.

Thursday, January 28

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor E. Boyland: Chemotherapy of Cancer.

● **INSTITUTE OF CHILD HEALTH.**—5.30 p.m., Dr. P. H. Sandifer: Cerebral Deterioration in Childhood.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. O. Oliver: Disinfection and Sterilization.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., Mr. John C. McFarland: Bilateral Abductor Paralysis (with film); Dr. D. M. Zausmer: Some Cases of Tics in Childhood and Their Treatment.

NORFOLK ORTHOPAEDIC CENTRE.—At Wingfield-Morris Orthopaedic Hospital, Headington, Oxford, 8.30 p.m., Professor J. Trueta: Michael Servetus and the Development of Modern Science.

ROYAL ASSOCIATION, Ciba Foundation. 41, Portland Place, W. 4.30 p.m., Dr. R. V. Fildwood: Factors in the Excretion of Sodium.

ROYAL ARMY MEDICAL CORPS.—5 p.m., Dr. C. H. Andrews: Recent Research on the Common Cold and Influenza.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor R. H. C. Robins: Primary Reconstruction of the Injured Hand.

ROYAL EYE HOSPITAL. 5.30 p.m., Miss M. Savory: Demonstration of Instruments.

ROYAL SOCIETY.—2.30 p.m., discussion to be opened by Sir Bryan Matthews, F.R.S.: Physiology of Man at High Altitudes.

ST. ANDREW'S UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Professor N. M. Dott: Intracranial Aneurysms—Their Management.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., neurology demonstration by Dr. D. Williams.

● **SOCIETY FOR CULTURAL RELATIONS WITH THE U.S.S.R.: MEDICAL SECTION.**—8.15 p.m., Dr. Phyllis Dobbs: Care of Women and Children in the Soviet Union.

● **WEST LONDON MEDICO-CHIRURGICAL SOCIETY.**—At South Kensington Hotel, 41, Queen's Gate Terrace, S.W., 7.30 for 7.45 p.m., dinner meeting; 8.30 p.m., Sir Harold Gillies: Surgical Aspects of Plastic Surgery.

Friday, January 29

GLASGOW UNIVERSITY MEDICO-CHIRURGICAL SOCIETY.—At Edinburgh, 7.45 p.m., debate with Royal Medical Society.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. P. F. Borrie: Vascular Disorders.

INSTITUTE OF LARYNGOLOGY AND OTITIS.—3.30 p.m., clinical meeting for general practitioners. Mr. A. R. Dinale: Hoarseness Differential Diagnosis and Treatment.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION. At Royal Free Hospital School of Medicine, 8.30 p.m., Dr. Mary J. Wilmer: Children and Streptococci.

● **ROYAL INSTITUTION.**—9 p.m., Sir Lawrence Bragg, D.Sc., F.R.S.: X-ray Studies of Biological Molecules.

ROYAL MEDICAL SOCIETY, Edinburgh.—8 p.m., debate with Glasgow University Medico-Chirurgical Society. Motion: This House Deplores the Lack of Culture in the Present-day Doctor.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Crook.—On January 13, 1954, at the Military Hospital, Tidworth, Hants, to Ruth (formerly Bellamy), wife of Major J. C. Crook, M.D., D.T.M.&H., R.A.M.C., a son—Philip Laurence Cooper.

Evans.—On January 13, 1954, at Nuffield House, Guy's Hospital, London, S.E., to Winifred (formerly Groom), wife of Dr. M. L. Hudson Evans, Lewisham, London, S.E., a brother for Timothy, Sara, and Jonathan Simeon.

Habibis.—On January 12, 1954, at Queen Charlotte's Hospital, London, W., to Stella M. Murray, M.B., B.S., D.C.H., wife of Dr. Homer S. Habibis, 1a, Porchester Terrace, London, W., their fourth child a daughter.

Lyall.—On December 30, 1953, at the Rubislaw Nursing Home, Aberdeen, to Beulah, wife of Dr. Douglas J. Lyall, of 56, Station Road, Sedgfield, Co. Durham, a sister for Joan.

Nicholson.—On January 14, 1954, to Dorothy Christine (formerly Clarke), S.R.N., wife of Nigel Geoffrey Nicholson M.B., B.S., a brother for Susan Penelope—Alan Francis.

Stowers.—On December 17, 1953, at Maryfield Hospital, Dundee, to Mary (formerly Alabaster), M.B., B.S., wife of John M. Stowers, M.D., M.R.C.P., a second daughter.

Tucker.—On January 2, 1954, at the Rubislaw Nursing Home, Aberdeen, to Helen (formerly Rennie), wife of Dr. Hugh M. Tucker, Urquhart Villa, Lossiemouth, Moray, a sister for Malcolm and Gillian Amanda Dawn.

Waind.—On January 7, 1954, at Risedale Maternity Hospital, Barrow-in-Furness, Lancs, to Catherine (formerly Rycoft), M.B., Ch.B., wife of Philip Waind, D.S.C., M.D., M.R.C.P., a brother for John and Sarah—David Philip.

MARRIAGES

Neill-King.—On January 9, 1954, at St. Michael and All Angels, Wilmington, Kent, Alexander Edward Neill, M.B., B.Chir., to Sheila King, M.B., B.Chir., B.A.O.

DEATHS

Ashford.—On January 1, 1954, at Clynt Cottage, Topham, Devon, William Ashford O.B.E., M.R.C.S., L.R.C.P., J.P., aged 82.

Blackstone.—On December 29, 1953, at Woking, Surrey, Leonard Christopher Blackstone, O.B.E., M.B., B.S.

Burn.—On December 23, 1953, Ronald Edgar Russell Burn, M.R.C.S., L.R.C.P., of The White Cottage, North Petherton Somerset.

Hosford.—On December 20, 1953, at 61, Heathfield Road, Handsworth, Birmingham, Alfred Stroud Hosford, M.R.C.S., L.R.C.P.

Lyons.—On December 26, 1953, at Old Court Clinic, Ealing, London, W., Elmina, beloved wife of Dr. L. Carlyle Lyons of 42, Cornhill, Ealing, W.

Scott.—On December 16, 1953, at Sidmouth, Devon, William Thurburn Scott, M.B., B.Ch., late of Banchoy, Kincardineshire, aged 77.

Tellet.—On December 17, 1953, at West Winds, Grange-over-Sands, Lancs, William Edward Tellet, M.D., aged 77.

Walker.—On December 22, 1953, at Nailsea, near Bristol, James Alexander Walker, M.B., B.S., D.O.M.R.C.O.G., late of Cheddar, Somerset, and Parkstone, Dorset, aged 52.

Wilkie.—On December 20, 1953, at 109, Princess Road, Leicester, Charles Hamilton Wilkie, M.D.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Scaphocephaly

Q. I have had referred to me an 8-months-old baby with scaphocephaly. The child is healthy, above average weight, and appears of normal intelligence. The parents have been told that an operation may be necessary. What is the prognosis and treatment of this condition?

A.—In the presence of premature synostosis of cranial sutures operation is indicated to prevent mental retardation, visual failure, and severe cranial deformity. The weight of the brain is doubled during the first seven months of life, and 80% of its entire growth is completed in the first three years. Any factor which interferes with this rapid increase of brain volume in early life—and premature synostosis is of raised intracranial pressure and gross deformity of the head may result. While operation will not be indicated in all cases, there is evidence which strongly suggests that if operation is to be followed by a good result it must be performed in the early months of life before serious symptoms have appeared.

Various types of operation have produced satisfactory results. Linear craniectomy is perhaps now the most favoured. Strips of bone are excised along the line of the closed suture or sutures, and the bone margins covered with a thin film of "polythene." With adequate surgery in skilled hands the risks are extremely small and the results good.

Crickets

Q.—Are crickets capable of carrying infection or in any way dangerous apart from being a nuisance? Mrs. X lives in the country, and during the summer months her house is infested by these creatures from a refuse dump across the road; they emerge during the night from crevices and from the skirting. What is the best way of getting rid of them and keeping them away?

A.—It is difficult to envisage any possible way in which crickets could transmit infection, and the only danger seems to be a possible neurasthenia induced by their presence in large numbers. The chirruping of a solitary cricket may be an agreeable accompaniment to a boiling kettle (witness Dickens's *Cricket on the Hearth*); but few would appreciate invasion by one of the autumnal hordes that sometimes migrate from their perennial breeding sites in refuse tips. Malcolm Burr, in his little book on British grasshoppers, records the official report of a Cheshire coroner on a sanitary inspector who had been "driven by crickets to despatch and suicide." However, this cannot be a general reaction, for most travellers in the Tropics fall asleep to a continual din of assorted chirruping. One other aspect of cricket nuisances may be mentioned: they are prone to bite exploratory holes in various fabrics.

As regards control, a dust containing about 0.5% gamma-benzene hexachloride or 10% dicophane (D.D.T.) is probably the best weapon. This should be blown with a dust gun into crevices where the insects hide. The same dust scattered at the rate of 1 cwt. per acre (125 kg. per hectare) might be applied to the infested refuse tip should the nuisance be general. This may have to be repeated once or twice at fortnightly intervals if the infestation is severe.

Herpes and Facial Palsy

Q.—Is herpes zoster frontalis ever associated with facial palsy? A patient of mine developed facial palsy on the same side as the zoster four weeks after the onset of the latter. The paralysis cleared up completely in two weeks.

A.—A facial palsy can occur in herpes zoster. The type of the disease in which it occurs is the so-called geniculate zoster (Ramsay Hunt's syndrome): in this condition there is usually pain in the ear and sometimes in one side of the throat; vesicles may be scanty, but can usually be seen on the pinna, in the external auditory meatus, and on the pillars of the fauces; in the course of a few days a lower motor neurone facial palsy appears, and this may be accompanied by labyrinthine symptoms such as vertigo. The facial palsy has been ascribed to involvement of the geniculate ganglion by herpes zoster: pathological proof of this theory is, however, lacking, and it may be that the facial nerve itself rather than the ganglion is involved. It is probable that in the patient mentioned in the question Gasserian ganglion herpes zoster was complicated by geniculate herpes.

Treatment of Huntington's Chorea

Q.—What are the best measures of treatment in Huntington's chorea? What degree of improvement can be expected from treatment?

A.—Huntington's chorea is a relentlessly progressive disorder. No treatment is known which will stem its course. The most that one can expect from therapy is to abate the violence of the involuntary movements, and, secondly, to remove some of the more distressing emotional aspects of the progressive dementia. For the former symptoms, sedatives such as phenobarbitone or amylobarbitone, or drugs of the "artane" class, may at least be worth trying. Recently oral procaine amide had been advocated, in the dosage of 0.25 to 1 g., four times daily. The writer has no personal experience with this drug, however. For the latter set of symptoms, which may include depression, irritability, and violent unbridled behaviour, there may be a case for the serious consideration of the merits of electric convulsion therapy, or even leucotomy.

Operative Treatment of Bicornute Uterus

Q.—Is there any operative treatment for congenital abnormalities of the uterus, such as uterus bicornis, which result in repeated miscarriage? What is the prognosis with regard to achieving a live baby?

A.—If other causes for recurrent abortion can be excluded it is sometimes justifiable to recommend a plastic operation—on a bicornute uterus. Before this is done, however, there should have been at least three miscarriages and no pregnancies resulting in a viable child. Moreover, the patient should appreciate that the result of the operation cannot be guaranteed though the prognosis is quite good in certain cases. The prospects of success depend in large measure on the type and degree of abnormality present and on the development of the uterine horns. If the uterine cavities are narrow and widely separated the operation can be difficult and the result unsatisfactory. Factors such as these, some of which can be judged by hysterosalpingography, also determine the type of operation carried out. Sometimes a wedge of tissue between the two horns can be excised, sometimes it is better to open each horn longitudinally on its inner aspect and to suture the free edges of two horns together. If one horn is much better developed than the other, it may be advisable to excise the rudimentary horn.

In the event of pregnancy after uteruloplasty it is usually wise to deliver the baby by elective caesarean section before term. This is because this operation, unlike other operations on the normally developed non-pregnant uterus, often leaves a weak scar, and rupture of the uterus in late pregnancy or in labour is a real risk.

Unpleasant Sensations and Thundery Weather

Q.—I should be grateful for information regarding the cause of those unpleasant vasomotor effects from which some people suffer in thundery weather or whenever the atmospheric pressure varies widely within short periods of time. The ones particularly for which advice would be appreciated are headache, nausea, dizziness, and the peculiar sinking feelings in the lower abdomen.

A.—It is considered most unlikely that the unpleasant sensations described are directly due to barometric pressure changes. If the latter were sudden and marked it is possible that there would be some ear discomfort in the presence of a blocked eustachian tube, but there would be no more than slight deafness.

One cause of the symptoms described may be the great increase in relative humidity which occurs when the barometric pressure falls suddenly. This will greatly interfere with body heat loss, and the resultant vasomotor adjustments may be uncomfortable and disturbing, particularly in those with cardiac insufficiency, vasomotor instability, or excessive awareness of such changes. Finally, we are still very close to the primitive man who was no doubt frightened by the natural phenomena which often inaugurate violent storms. A conscious or subconscious fear of thunder and lightning, which is very common indeed, may also initiate these abnormal sensations, particularly the nausea and sinking feelings in the abdomen.

Laryngeal Vertigo

Q.—What is laryngeal vertigo? Is there any treatment for this condition?

A.—It was formerly thought that laryngeal vertigo was a disease in its own right, like Ménière's disease, but this is not so. It occurs as a rule in middle-aged men who are subject to a spasmodic type of cough. The episode may be provoked by eating or drinking, or by inhaling an irritant such as tobacco. Usually there is a fit of coughing, with spasm of the glottis, so that the combination of violent respiratory movements and complete closure of the glottis causes a violent variation in the cerebral circulation and momentary syncope. A detailed description of the physiological mechanisms in these cases has been given recently by Professor E. P. Sharpey-Schafer.¹

Any causal condition in the respiratory tract should be treated, and care exercised in the choice of food and drink, if these are precipitating factors. Smoking should be forbidden.

Iron Carbonyl

Q.—What are the toxic hazards of iron carbonyl? It is supplied as a liquid and added to the oil fuel used for certain diesel engines. Are any special precautions necessary in handling it?

A.—Little information is available on the practical question raised here. All carbonyls split into the metal and carbon monoxide when sufficiently heated, and when mixed as vapour with air may even explode. The penta iron carbonyl which is referred to is regarded as being somewhat less toxic than nickel carbonyl and no cases of industrial poisoning have been reported.

Upon inhalation of the vapour, these carbonyls are thought to decompose with the liberation of carbon monoxide and a fine deposit of the metal over the surfaces of the alveoli. The immediate symptoms are likely to be those of dizziness, headaches, and difficulty in breathing, while some 12 hours later pulmonary oedema may develop.

Steps should be taken to see that the concentration of the vapour in the air is kept in the neighbourhood of 1 p.p.m., and fire risk must not be overlooked.

Childbirth and Cataract

Q.—I have a patient, a young woman, who is shortly to be married. She is very worried because both her mother and her mother's sister developed severe cataracts after the birth of their first child. Both were about 30 years of age and apparently had completely normal pregnancies and confinements. There is no other relevant family history. Is post-natal cataract well known, and is there a special risk of my patient suffering from it if she has children?

A.—Childbirth does not directly cause cataract. It is difficult to make any realistic comment upon the cataract which is said to have afflicted the patient's mother and aunt after the birth of their first children without having precise information about its type. If the cataracts were of the familial type, then the patient in question might well be implicated, irrespective of any pregnancy.

NOTES AND COMMENTS

Facial Disfigurement after Dental Extractions. Mr. N. J. AINSWORTH (London, W.1) writes: I think that the question on facial disfigurement after dental extractions ("Any Questions?" December 19, 1953, p. 1388) was misunderstood by your expert. The vertical lines referred to were surely not the nasolabial groove but the fine furrows running vertically down to the vermilion edge of the lips. These are due to loss of skin elasticity and muscle tone; they are never seen in the young even with full or no dentures, and are only exaggerated in the elderly by inadequate restoration of contours by the dentist. "Plumping" is useless, and the only mitigation possible is the placing of the tips of the artificial upper incisors as far forward as natural appearance permits. Some sacrifice of function is permissible to obtain the lip eversion required, and stability is surprisingly little interfered with.

Prickly Heat.—SURGEON COMMANDER ALAN ROBINSON, R.N. (London, S.W.19), writes: In an answer to a question on the aetiology, diagnostic features, and treatment of prickly heat ("Any Questions?" January 2, p. 54) no reference was made to the use of a detergent in treatment. Between 1948 and 1950 we obtained, in Singapore, almost invariable cure of prickly heat by substituting cetrimide for soap. The effect was usually dramatic, and I have not known it to fail. Another treatment was to rub on gingelly oil (oil of sesame) before the bath, so that the oil could penetrate and soften the skin. This was quite successful, but not so efficient as the detergent.

OUR EXPERT writes: So many remedies have been enthusiastically claimed to be of value in prickly heat but have later been shown to be ineffective that caution is advisable regarding such claims. The treatments here mentioned have gained no wide degree of acceptance and time alone will show whether they are of real merit.

Correction.—In the leading article on cerebral arteriography (*Journal*, January 9, p. 85) the following sentence in the fifth paragraph should have appeared as printed here: "It is this effect on the blood brain barrier or vascular spasm which probably causes the transient hemipareses which may complicate arteriography."

THE VALUE OF PHYSIOLOGY IN MEDICINE*

BY

GEORGE GRAHAM, M.D., F.R.C.P.

Consulting Physician to St. Bartholomew's Hospital

First of all I wish to thank you for the honour you have done me in inviting me to deliver the two hundred and thirty-fourth Harveian Oration; secondly, to commemorate the memory of William Harvey, and all other benefactors of the College. Although I had learnt a little about Harvey in my physiology days, I did not really appreciate the magnitude of his achievement until the tercentenary of the publication of his great work, *De Motu Cordis*, which was celebrated in this College in 1928. I was especially impressed by the cinematograph film prepared by Sir Thomas Lewis and Sir Henry Dale, which demonstrated most clearly the arguments and experiments which he used to prove that the blood circulated through the heart. The film is now shown to all physiology students, but it is unfortunate that many of the men and women who qualified before 1928 have not had an opportunity of seeing it, and of appreciating to the full the value of Harvey's work. I should have liked to show the film this afternoon, but it would have taken too long. I hope, however, that all the members of the staffs of teaching hospitals, and not only the physicians, will take the opportunity of seeing it when it is demonstrated to their students, and so realize the difficulties which Harvey overcame. He has been called the first of the physiologists, and it is for this reason that I have chosen as a title "The Value of Physiology in Medicine."

Although the science of physiology progressed slowly throughout the centuries, there was often a tendency to decry its value. This is well shown by the experience of Sir Henry Dale, when a little more than 50 years ago he clerked for that very able clinician, Dr. Samuel Gee. He was told, "When you enter my wards your first duty is to forget all your physiology. Physiology is an experimental science—and a very good thing, no doubt, in its proper place. Medicine is not a science but an empirical art, and it is as such that you may learn something of it here" (Dale, 1950). I do not know how much Dale learnt of the "empirical art," but he has carried out himself, and has directed, much research work which has been of very great value in the whole field of medicine. He has therefore greatly helped to advance the day which Gee indeed foresaw, that "some day medicine, too, might become an experimental science." When I came down from Cambridge 49 years ago nothing so foolish was said to me, but no one seemed to pay any attention to physiology. Thus when I was a surgical dresser I was astonished to hear Sir

Anthony Bowlby, an able surgeon, call for very hot saline in the course of an operation, and I was told that this was done to stop haemorrhage. This seemed most extraordinary, as the heat would, I thought, cause dilatation of the blood vessels and capillaries, and increase the bleeding, but the house-surgeon assured me that it did stop haemorrhage. I was too frightened to ask Bowlby for the explanation, which I think he might have known.

Advances in Physiology

The advances in physiology have been made not only by those who work in the physiological laboratories but also by the whole army of clinicians, chemists, biochemists, biologists, physicists, anatomists, pharmacologists, and pathologists who have contributed their experiences. The final building up of the subject must, I think, be done by the physiologists and biochemists, who test out the evidence provided by their colleagues and finally assess the value of the work.

Some clinicians have, in the past, spoken contemptuously of the value of physiology in medicine and expressed a disbelief in results obtained from a "pithed" frog. The frog has been most useful to mankind; it is cheap to buy and the brain is easily destroyed, so that the student can do his experiments without causing any pain. Many important studies have been made on its heart, and it was of value in the study of nervous reflexes, but has now been displaced by Sherrington's decerebrate cats. But it is of importance to repeat the work on different animals, for they often differ considerably. Thus the great advance which has taken place in our knowledge of scurvy was made possible by the guinea-pig. This is the only animal besides man which is unable to synthesize ascorbic acid, and develops scurvy, which can be studied, under controlled conditions, at all stages of the disease. In man, scurvy is nowadays rarely seen and it is difficult to carry out controlled experiments. But the work of Crandon *et al.* (1940) is of importance because, while Crandon was doing his full work as a surgeon, he abstained from eating anything known to contain ascorbic acid. After 116 days he had slight symptoms of scurvy, and a surgical wound on the 182nd day did not heal. Again, the first investigations on anaphylactic shock were made on guinea-pigs, which develop bronchial constriction, whereas a dog develops congestion of the liver from spasm of the hepatic veins, and in the rabbit the arterioles are constricted.

The dog has been invaluable in the study of diabetes mellitus. It was used by von Mering and Minkowski

*The Harveian Oration delivered at the Royal College of Physicians of London on October 16, 1953.

(1890) when they removed the whole of the pancreas to study fat absorption and found that the puppy developed diabetes mellitus, and much useful information has been gained by experiments on the depancreatized dog. Young (1937) also used the dog in order to produce diabetes by injections of extracts of the anterior pituitary gland, and so destroy the islands of Langerhans. The rat, on the other hand, does not develop diabetes, no matter how much extract of the anterior pituitary is injected, and the islands of Langerhans seem larger than usual (Marks and Young, 1939).

Anaesthesia

Anaesthesia, so valuable in the treatment of patients, sometimes makes the clinical observations most misleading. Thus it is known, as a result of x-ray films and opaque meals, that the stomach of man in the erect posture has a J shape. But even after this had been fully established, more than 40 years ago, some surgeons refused to accept the proposition, saying that they had never seen it at operations, or in the post-mortem room. This was understandable in the operating theatre, because under the anaesthetic all the muscles are relaxed, and, if they are not, the anaesthetist is blamed. In the post-mortem room this is nearly always the case, but every now and then the stomach is found firmly contracted and of the J shape. After I knew about the shape of the stomach I was lucky enough to see it myself four times in the five years or so that I performed post-mortem examinations, the cases varying from that of a child to that of a woman who had died with her stomach full of blood from a leaking aneurysm. The stomach in this case was enormous and extended into the pelvis, and the muscles were still firmly contracted. Two specimens are now in the anatomical museum at St. Bartholomew's Hospital, but I regret to say that at first they were mounted with the long axis in the transverse instead of in the vertical position. Many others must have seen similar specimens throughout the ages, but the evidence was neglected until x-ray films proved the point.

In experiments on animals a doubt always exists about whether the anaesthetic has affected the results. Pituitrin was thought to be a diuretic since it caused a diuresis in the anaesthetized animal, but if an anaesthetic was not given the flow of urine decreased, and this action is of great value in the treatment of diabetes insipidus. Again, the English workers were unable to show that stimulation of the vagus caused a secretion of the juice because of the anaesthetic. Heidenhain and others in Germany also failed because they did not use any anaesthetic, and the pain prevented the secretion. Pavlov succeeded in 1895 because he isolated the vagus nerve in the neck and made an exterior pouch of the stomach under an anaesthetic. When the dog had completely recovered he stimulated the peripheral end of the nerve painlessly and observed the flow of gastric juice. Histamine, again, will kill a cat with "shock" if an ether anaesthetic is given, while the unanaesthetized cat is quite unaffected.

Animals as Test Subjects

The difference between animals, again, is of very great value and certain species will take certain diseases. Thus, the distemper of dogs also affects ferrets, and this enabled Laidlaw and his co-workers to prepare the vaccine which protects dogs from the disease. The ferret is the only

animal which develops influenza when injected intranasally, though the mouse can be infected through intrapulmonary injections. Among the diseases which cannot be communicated to any animal are the common cold and rheumatic fever and infective hepatitis, and it is to be hoped that some animal will soon be found which will take these diseases, so that they may be studied more easily. Another instance is the variety of animals used for determining whether a woman is pregnant. Thus an immature female mouse (Aschheim-Zondek test), an immature female rabbit (Friedman test), a female frog (*Xenopus*), and an adult male toad (*Bufo arenarum*) are used, and the results in these four different species are said to be equally reliable. The early tests on the potency of insulin were made on the rabbit, the veins on the ear being most useful for collecting blood, but the mouse and the guinea-pig are also used for this purpose. Harvey studied the hearts of mammals, birds, snakes, fishes, and even shrimps, and insects like wasps. It is not easy to time the contraction of the auricle and ventricle by the eye in small animals, but he found it easy to confirm his impressions by watching contractions of the long heart of the adder and of the dying heart of the tortoise. These illustrations suffice to show that results which appear of value in one species must be tested on other animals, and the final experiments must be made on man himself if possible. In the physiology laboratories a good many observations are now confirmed on the students themselves, though those which involve danger cannot, of course, be performed.

Clinicians often differ very much over which hypothesis is the right one, and physiology in its wide sense is often able eventually to settle which school of thought is right. An instance of this is the treatment of rickets. One school stated that cod-liver oil was of great benefit, whereas another school asserted with equal conviction that treatment with olive oil gave results which were just as good. Mellanby's work on puppies showed that vitamin D cured rickets, and that olive oil contained none whereas cod-liver oil did, and that, if given in sufficient amounts and not diluted with malt and iron to one-quarter of its value, would cure rickets, and thus settled this controversy. The physiology which I visualize is a living and growing subject, and the principles which govern it are, I believe, of great value in the theory and treatment of medicine.

Coagulation Time

I said earlier on that as a young student I had not understood why very hot saline was used to stop oozing haemorrhage. I did not learn the explanation until nearly 20 years later when I was estimating the coagulation time of a patient with haemophilia by Dale and Laidlaw's (1911) shot method. They chose to work at a temperature of 37° C. because the coagulation time was least affected by slight alterations of temperature, and Macfarlane (1948) confirmed this.

The great shortening of the coagulation time at temperatures between 40 and 45° C. (Fig. 1) explains why the bleeding stops, although there is an increased blood supply as a result of the heat. I have asked several surgeons, and they tell me that it works

FIG. 1.—Effect of temperature upon coagulation time of normal blood.

but that they did not know the explanation. This had been given by Lister (1863) in an interesting paper on the coagulation of the blood, when he said, "It has long been known that blood coagulates more rapidly at a high temperature than at a low temperature, and that a little

FIG. 2.—Effect of temperature upon coagulation time of haemophilic blood.

increase again. Haemophilic blood obeys the same law, and Macfarlane has observed the coagulation time at different temperatures (Fig. 2). I doubt, however, whether the shortening of the coagulation time to 12 minutes in this patient at a temperature of 55° C. would be enough to counteract the increased flow of blood.

Changes in Electrolytes after Operation

There are so many diseases in which physiology is of the greatest importance that it was difficult to choose what to talk about. I finally decided to discuss the changes which take place in the water and electrolytes of the body after severe operations. A proper understanding of these has greatly improved the treatment of patients. The co-operation of the surgeon and the physician with the physiologist, biochemist, pathologist, and others in the study of disease is necessary both to advance knowledge and to apply it to the treatment of the patient. Unless this co-operation exists, our practice lags far behind theory. The first advances in our knowledge were made by Sydney Ringer, Professor of Medicine to University College Hospital, 71 years ago, and were at first neglected by the clinicians. In the past ten years great advances have been made in our knowledge of electrolytes in medicine, which call for the closest co-operation of all concerned with the treatment of patients. These are well described by Gamble (1947), Darrow and Pratt (1950), and many others.

Ringer (1880-2) found that a frog's heart would beat for some hours in a solution of 0.65% NaCl—which is isotonic for the frog—as made up by his laboratory's assistant. But when the assistant fell ill, and Ringer made up his own solution with distilled water, the heart very soon ceased to beat. When the assistant recovered, and made up the solution, the heart once more continued to beat. Ringer then found that the assistant, being lazy, had not bothered to use distilled water but had used tap-water instead. This contains calcium and potassium, and Ringer (1883-4) proceeded to determine the ideal conditions for enabling the heart to beat. If calcium chloride was added to 0.65% saline, in the proportion of 1 in 19,500, a heart which had just stopped beating started again. The diastole, however, grew shorter and shorter and the heart eventually stopped in systole. If potassium chloride was added to 0.65% saline in a propor-

tion of 1 in 10,000 instead of calcium chloride, a heart which had just stopped beating in isotonic saline started again, but this time the diastole was lengthened and the heart eventually stopped in diastole. Ringer made numerous trials, and found that both potassium and calcium were necessary, and that the best results were obtained when they were present in the same concentration as in frog's plasma (Table I). If too much potassium was added so that the heart tended to stop in diastole, the addition of extra calcium prevented the poisonous action, so that poisonous doses of both

TABLE I

	Ringer's Solution for Frogs	Ringer-Locke Solution for Man
NaCl ..	0.65 g.	0.9 g.
KCl ..	0.014 "	0.042 "

NaHCO ₃ ..	0.02 "	0.05 "
NaH ₂ PO ₄ ..	0.001 "	0.1 "
Glucose ..	0.2 "	0.1 "
H ₂ O ..	to 100 ml.	to 100 ml.

potassium and calcium might be present without affecting the heart at all (Ringer, 1884-5). I do not think many intravenous injections were made in those days, as surgical operations were nothing like so numerous or severe as they have now become.

When I came to hospital in 1905, saline, if thought necessary, was usually given subcutaneously. Many students, fresh from their physiology, must have asked, as I did, why Ringer's solution was not used, only to be told by a house-surgeon that the potassium and calcium were not necessary. I think that this was correct then, as it was rare indeed for more than 1 pint (570 ml.) of isotonic saline to be given intravenously, and it was assumed, if it was thought about at all, that the reserves of calcium in the bones and potassium in the cells would supply the necessary amounts. During the past 48 years, however, operations have increased enormously in number and magnitude. Many operations on the stomach, oesophagus, and intestines prevent any feeding by mouth for several days, and also involve evacuating the stomach or intestines by suction to prevent dilatation of these organs. Under these circumstances the amount of fluid given intravenously has been as much as 3,000-3,500 ml. a day for many days. This was sometimes isotonic saline, so that 27 g. or more of sodium chloride might be given in the day; sometimes two-thirds or one-third isotonic, so that 18 or 9 g. of sodium chloride might be given together with glucose in 5 or 10% concentration, the patient receiving as much as 150-300 g. of glucose daily.

The syndrome which results from long-continued intravenous injections of sodium chloride was first described by Whipple (1923) under the name pancreatic asthenia. He had observed asthenia, amnesia, nausea, vomiting, tendency to bleed, ptalism, abnormal stools, epigastric pain and tenderness, rapid emaciation. These symptoms came on 2-10 days after operations on the pancreas and gall-bladder and disappeared when the patient could start eating. Hartmann (1934) stressed the importance of giving not only sodium chloride but also some potassium, calcium, magnesium, and phosphates, and used the Ringer-Locke solution. Many others, myself included (Graham, 1938), hoped that this solution would give better results, but it is now recognized that potassium is contraindicated for 24 hours or more after an operation, and that after this time the amount of potassium is too small to be of any value. Further, the proportion of sodium to potassium, 16:1, is so high that the action of the potassium is completely swamped by that of the sodium.

Excretion while Fasting

Since many patients are unable to take any food by mouth after serious operations, the observations which have been made on men who have fasted for 20-40 days are of importance, and I will first describe them and then discuss how the operation alters the normal reactions of the body. The

most comprehensive of these researches was carried out by Benedict in 1915, on a man aged 40 and weighing 60.1 kg., and lasted 31 days. I shall refer only to the excretion of water and nitrogen and the electrolytes in the first 14 days, though there are many other points of interest in the monograph which repay study (Table II). The amount of water given

TABLE II

Days	Intake		Output				
	Water (ml.)	Urine (ml.)	Nitrogen (g.)	Chlorine (g.)	Sodium (g.)	Potassium (g.)	Calcium (g.)
1	750	660	7.1	3.77	2.07	1.63	0.217
2-4	750	582	10.5	0.80	0.926	1.368	0.243
5-6	750	638	10.29	0.41	0.276	1.445	0.274
7-8	750	555	10.03	0.44	0.154	0.883	0.253
9-10	750	636	10.40	0.30	0.128	0.944	0.237
11-12	900	540	10.19	0.33	0.10	0.975	0.219
13-14	900	604	10.49	0.29	—	—	0.226
15-16	900	823	9.02	0.15	0.109	0.814	0.250
30-31	900	566	6.94	0.13	0.053	0.606	0.138

to drink was 750 ml. daily for the first ten days, and the volume of the urine was about 600 ml. daily. Although the man did not complain of thirst the intake was raised to 900 ml., and four days later the output rose to over 800 ml.; the average output in the last 10 days was 688 ml. The excretion of nitrogen before the fast was 11.54 g. and after an initial drop to 7.1 g. the average output for the second to fourth days was 10.5 g.; it then remained fairly steady above 10 g. up to the fourteenth day, when a sudden drop occurred to below 10.0 g. The small excretion on the first two days is ascribed to the sparing effect of the glycogen in the body. After the third day the nitrogen excretion must come solely from the breakdown of the muscle and other cells.

The excretion of chlorine, sodium, and potassium is higher on the first day than on the next three days, and this is thought to be due to the amount in the previous diet. The figures for the second to fourth days show that more potassium is excreted than sodium and that after the sixth day the sodium and chlorine decrease rapidly, while the potassium remains high. The muscles and other tissues of the body which are used up in a fast contain very little sodium, and this explains the great decrease in the output, though it is known that the kidney tubules are able to reabsorb some sodium and so reduce the amount lost from the body. The potassium excreted in the urine comes almost entirely from the breakdown of the muscle and other cells, and the N:K ratio is thought to be about 10:1. In Benedict's case the N:K ratio was 10:0.77 on the second to fourth days; altered to 10:1.1 on the seventh to ninth days, and then slowly changed to 10:1.21 on the 31st day. For a ratio of 10:1 on the second to fourth days the potassium excretion should be 1.05 g. instead of 1.368 g., so that rather more potassium was being excreted than the ratio allows; while on the 31st day 0.606 g. was excreted instead of 0.734 g. This decrease in the potassium excretion might be due to the broken-up muscle containing less potassium at the end of the fast or to the tubules of the kidney reabsorbing more of the potassium and so conserving it in the body; the latter hypothesis seems the more likely.

Metabolic Changes Following Shock

When an operation is performed the shock which may occur alters the metabolism of the patient very profoundly.

(1) Water Output

The fluid intake, 900 ml., with an output of urine of 700-800 ml., is much too small for patients after operation. Thus, Maddock and Collier (1937) have estimated that the water lost by the skin and lungs after operation varies from 1,000 to 1,500 ml. a day, and this amount will be increased by, say, 500 ml. if fever is present. The healthy kidney can excrete all the electrolytes in 500 ml., but the damaged kidney needs 1,500 ml. to achieve the proper excretion. Avery Jones and Naunton Morgan (1938) have also stressed

the importance of giving plenty of fluid, 3,000-3,500 ml. to patients after operation, and of increasing this amount to make up for the loss of fluid vomited or removed from the stomach after severe abdominal operations. They also stress the danger of giving too much salt in uncomplicated cases. Le Quesne and Lewis (1953) gave patients a fluid diet containing 4,000 ml. before operation, and the urine output decreased from 3,195 to 1,115 ml. (average of 15 cases) on the day of the operation. Hence the fluid intake after operation should be 1,500-2,000 ml. for the afebrile patient with healthy kidneys, and 3,000-3,500 ml. for the febrile patient with poor kidneys. If sulphonamides are required, an output of more than 1,000 ml. is necessary to prevent any ill effects in the urinary tract.

(2) Protein

If a patient after operation takes very little food there is bound to be much destruction of protein, such as occurred in Benedict's starving man. This may amount to 7-10 g. a day, and will coincide with the excretion of 1 g. or so of potassium a day. If, however, the patient is able to take the same diet on the operation and subsequent days as he did before operation, the extra nitrogen loss is so small that it does not seem that the operation causes any destruction of body protein (Werner *et al.*, 1949).

(3) The Electrolytes Sodium and Potassium

The effect of the operation on the sodium and potassium is to cause a considerable increase in the potassium excretion but a decrease in the sodium excretion. The increase in the potassium excretion is to be expected from the increased protein breakdown due to lack of food, but it is much greater than could be expected from this cause, and the paradoxical condition may arise in which the serum potassium may be very high at a time when the potassium in the muscle has been greatly depleted. This discrepancy is due to the kidney being unable to excrete the extra potassium. The giving of sodium as isotonic saline in amounts of from 9 to 27 g. of sodium chloride, which has been the current practice for so many years, has obscured the fact that, coincident with the increase in the potassium excretion, there is a decrease in the sodium excretion. This change has been studied by Tabor and Rosenthal (1945). They applied a tourniquet to one leg of a mouse for two hours, and estimated the change in the injured and uninjured muscles. One-third of the potassium left the muscles and was replaced by sodium. The excretion of potassium in the urine was greatly increased, but in spite of this the serum potassium was also increased. The excretion of sodium, on the other hand, was decreased and sodium chloride given intravenously might be retained. Fox and Baer (1947) repeated these observations on a rat and analysed the tissues four hours later (Table III).

TABLE III

	Sodium in Muscle		Potassium in Muscle		Sodium and Potassium in Serum	Na/K Ratio
	mEq/kg. Water	mg./100 g.	mEq/kg. Water	mg./100 g.		
Normal	81 ± 3	186 ± 5.75	126 ± 3	492 ± 7.8	207 ± 3	0.644:1
Shock leg	142 ± 2	327 ± 4.6	48 ± 3	187 ± 19.5	190 ± 4	2.96:1
Opposite leg	77 ± 4	177 ± 9.2	133 ± 3	520 ± 11.7	210 ± 4	0.578:1

This experiment shows a great reduction in the potassium and its replacement by sodium, and a change of the sodium/potassium ratio from 0.644:1 to 2.96:1. They also estimated the sodium space by means of the radio sodium and radio bromide method, and found that the sodium was much increased. Darrow (1945) showed that half the potassium might leave the muscles and that the intracellular sodium was equal to one-half the extracellular sodium. This was the case in animals, and he thought that similar, if less marked, changes occurred in man. Both the above pairs of workers observed that the mice were very ill after removal

of the tourniquet, and Tabor and Rosenthal produced symptoms of potassium poisoning by injecting small amounts of potassium. They were able to prevent death in shock by giving isotonic saline by mouth or through a stomach tube in 24 hours in a volume equal to 10 or 15% of the body weight. In severe cases it was necessary to give it intravenously. If only a volume equal to 5% of the body weight was given the percentage recovery was less (10% of the body weight in a man of 65 kg. would be 6,500 ml.). A 5% solution of glucose gave little better results than in the controls, but a 10% solution of glucose was not used. These amounts per kg. are much more than those used in man, and the shock produced must have been very great. The increase in the amount of sodium in the muscles and the decrease of potassium seemed very surprising, as it had been believed that the sodium could not enter the cells. But Darrow (1945, 1946) showed that sodium could cross the cell membrane and enter the cells and that potassium left them. This effect can be produced by giving sodium chloride intravenously, and as much as half the potassium may leave the cell.

It had previously been shown by Fenn and Cobb (1936) that when the muscle of the rat was stimulated for three hours, at a frequency of over 400 a minute, the potassium in the muscle decreased greatly, while the sodium increased. When the muscle was allowed to recover for two hours the potassium increased slowly while the sodium decreased rapidly. These observations on animals have been confirmed in patients after operation. Idris Evans (1950) showed that the amounts of sodium and potassium present in muscle were altered after operation (Table IV).

TABLE IV

Case		Muscle Removed at Operation		Serum Potassium	
		mEq/kg. Wet Muscle	mg./100 g. Wet Muscle	mEq/litre	mg./100 ml.
1	Sodium	39.2	90	3.63	14.2
	Potassium	72.4	282		
2	Sodium	46.5	107	1.7	6.65
	Potassium	41.3	161		

Both the sodium space and the bromide space after operation have been investigated by Eliel *et al.* (1950), by injections of radio sodium and radio bromide. They found a great increase in the sodium space—showing that sodium had entered the muscles—and a decrease in the bromide space. Another consequence of the migration of the sodium is that there may be insufficient sodium to combine with bicarbonate, and a persistent hypochloreaemia may result. The sodium/potassium relation in muscle is also upset by injections of deoxycortone. Darrow and Miller (1942) injected 2-4 mg. a day into rats for 30 days, and showed that the potassium in muscle decreased from 48.9 to 38.4 mEq per litre (191 to 150 mg. per 100 ml.) per 100 g. of fat-free solids, and that areas of necrosis occurred in the cardiac muscle, which resembled those produced by low-potassium diets.

When a dog is injected with 25 mg. of deoxycortone daily for four weeks it develops a polyuria at once, and, after some time, weakness and finally a paralysis of the muscles (Ferrebee *et al.*, 1941). The potassium in the serum decreased from 4 to 2.9 mEq per litre (15.6 to 11.4 mg. per 100 ml.) after four weeks; the sodium and chlorine increased slightly. The potassium in the muscle decreased from 82.5 to 54 mEq per litre (325 to 211 mg. per 100 ml.) per 100 g. of fat-free muscle in one experiment, while the sodium increased from 33.9 to 55.6 mEq per litre (78 to 128 mg. per 100 ml.) and the chlorine from 24.7 to 26.6 mEq per litre (87.6 to 94.5 mg. per 100 ml.). Eliel *et al.* (1950) have suggested that the surgical trauma increases the production of A.C.T.H. from the pituitary fluid, and this stimulates the adrenal cortex and is thus responsible for the excretion of the potassium and retention of the sodium. MacPhee (1953) also thinks that these "electrolytic charges

are the result of increased adrenocortical activity" and "are the natural response of the body to trauma." These observations suggest that the use of deoxycortone after operation is contraindicated, since the changes in the potassium and sodium of muscles are similar to those which occur two to four days after operation.

Effects of Potassium-deficient Diets

The changes which occur in the potassium after operation, and the symptoms which may arise, are so remarkable that the effect of diets containing little potassium has been studied on rats, dogs, and man. Follis *et al.* (1942) observed the effects in rats. After the 15th day opaque white areas could be seen macroscopically beneath the epicardium. Microscopically, definite changes could be seen as early as the eighth day. These were a loss of structure of individual muscle fibres and a failure of the hyaline fibres to stain with eosin. By the 15th day the opaque areas were shown to be necrotic and the heart muscle contained 35% less potassium than the controls. The skeletal muscle did not show any change, but the first convoluted tubules of the kidneys were dilated and the cells were vacuolated. Dogs kept on low-potassium diets developed periodic paralysis and respiratory failure, which was made worse if excess of sodium was given. On microscopic examination the myocardium was unaffected, but a waxy degeneration of the skeletal muscle was present.

The effect of a diet containing little potassium has been studied by two pairs of workers in England. A diet was given from which the potassium had been absorbed by means of an exchange resin "zeo-karb 225 sodium" (Black and Milne, 1952a, 1952b), or the resin was eaten with a fixed diet (Fourman and Ainley-Walker, 1952). Black and Milne's experiments lasted six to seven days, and a loss of 268 and 289 mEq (10.48 and 11.3 g.) of potassium was observed. A metabolic alkalosis was produced and the serum potassium decreased from 4 to 3.1 mEq per litre (15.6 to 12.3 mg. per 100 ml.) and 3.2 mEq per litre (12.5 mg. per 100 ml.), but the potassium in the red cells was unaltered. The symptoms observed were a little general apathy. The only change in the E.C.G. was the appearance of a U wave. Fourman and Ainley-Walker's three experiments lasted longer, 12 and 11 days, and the negative balance for potassium varied from 338 to 839 mEq per litre (13.2 to 32.8 g. per 100 ml.) and in their cases a slight acidosis instead of a metabolic alkalosis occurred. The subjects felt and looked ill, became absent-minded and then confused, and one developed oedema of the face and legs. The change in the E.C.G. was the appearance of a prominent U wave. Black and Milne pointed out that the amount of potassium lost was about equal to that lost after an operation, and doubted whether the symptoms occurring after operation were due to the lack of potassium. If these experiments are repeated it would be of great interest to determine the sodium and bromide space and also the amount of potassium and sodium in the muscle tissue. The injection of 18 g. of sodium chloride a day intravenously might also intensify the symptoms, since some of the sodium might enter the cells and increase the loss of potassium. The giving of glucose and insulin might produce great weakness or even paresis of the limbs like a periodic paralysis. This sometimes occurs after serious operations.

The changes which occur as a result of intravenous injection of sodium chloride before and after operation have been studied by Marks (1950). He carried out a complete water, nitrogen, chlorine, sodium, and potassium balance for three days on a patient with pyloric obstruction before operation. The actual amounts of fluid and electrolytes given intravenously varied from day to day, and the figures are given for the three-day period in Table V. The amounts excreted in the urine or removed from the stomach by suction were measured, and enable a proper balance to be struck.

Table V shows that there was an apparent positive balance of 1,020 ml. of fluid in the three days. But no allowance is made for the loss of fluid from the skin and lungs, and it is probable that a negative balance of more than 2,000 ml.

TABLE V

Fluid	Intake for 3 Days	Output for 3 Days			
		Urine	Gastric Contents Obtained by Suction	Balance	
				mEq	g.
Sodium	10,850 ml.	4,390 ml.	5,440 ml.	+1,020 ml.	
Calculated as sodium chloride	907	20.86	134	3.08	191
Potassium	7.4	0.29	156	6.1	37
Calculated as potassium chloride	0.55	11.6	2.76	11.2	34.0
Nitrogen	7.2	36.5	4.4	11.2	34.0
				-185.6	-7.25
				-13.8	-33.7

occurred in the three days in spite of the large intake of fluid. This was due to the large amounts of fluid removed from the stomach, which amounted to 5,440 ml. in the three days. It is now recognized that the fluid vomited or removed from the stomach or intestine by suction should be measured and an equivalent volume added to the intravenous injection so as to ensure that the body does not suffer from lack of water. Since some potassium as well as sodium is lost from the stomach, the intestines, and biliary tract, the appropriate solutions for each tract should be used (Darrow, 1945). The chlorine and sodium figures show that a retention of 13.39 g. of sodium or 34 g. of sodium chloride occurred in three days, while there was a loss of 7.25 g. of potassium or 13.8 g. of potassium chloride. The nitrogen intake was very small and a loss of 33.7 g. occurred in the three days, which would account for a loss of 3.37 g. of potassium, leaving 3.88 g. of potassium unaccounted for.

The changes in the blood, which occurred in the three days (Table VI), show that the treatment with saline was satisfactory in that there was a decrease from 42 to 24.1 mg. in the blood urea nitrogen, although it is still a little too high. The alkali reserve, which had been very high, was now within normal limits. The chloride, which had been on the low side, was within normal limits; the sodium content, which had been slightly on the low side, was within normal limits. The potassium, which had been normal at 4.3 mEq per litre (16.8 mg. per 100 ml.), was now very low at 2.75 mEq per litre (10.75 mg. per 100 ml.). The patient developed gastric retention after the gastrectomy and was quite ill for three weeks. Small doses of potassium chloride were given by mouth, but two and a half weeks elapsed before the serum potassium and the electrocardiograph returned to normal. Table VI shows the changes in the blood serum during the course of the treatment.

TABLE VI

Days	Blood Urea Nitrogen mg./100 ml.	HCO ₃ mEq/L	Vol. CO ₂ per 100 ml.	Chloride		Sodium		Potassium	
				mEq/L	mg./100 ml.	mEq/L	mg./100 ml.	mEq/L	mg./100 ml.
1	42.2	50.2	112	85	303	137.0	315	4.3	16.8
2	36.8	45.2	102	89	316	139.0	320	3.4	13.6
		38.3	85.7			141.5	325	3.1	12.2
3	32.2	37.4	83.7	96	340	137.0	315	3.2	12.5
		32.0	71.6			139.0		2.8	10.95
4	24.1	27.0	60.5	102	362	140	322	2.75	10.75

Another patient was studied four days after operation. Sodium was omitted and the potassium was increased to 2.34 g. in four days. The potassium excreted in the urine and that removed from the stomach in four days was 4,395 g. The negative balance of potassium was 2,005 g., which is much less than in the other patient, to whom 20.82 g. of sodium was given in four days.

Randall *et al.* (1949) have also made careful observations which show that the loss of potassium that occurs after operations considerably exceeds the amount of potassium that could possibly come from the breakdown of

protein, and which emphasize the decrease in the serum potassium which occurs after three to four days. This can be prevented by giving potassium by mouth or intravenously, starting 24 hours after the operation.

Symptoms Ascribed to Hypopotassaemia

These have been analysed by Eliel *et al.* (1950) in 32 patients, and are similar to, though more severe than, those described by Whipple (1923). They consisted of lethargy, apathy, and depression, 17; nervousness, irritability, and apprehension, 7; confusion, disorientation, and delusions, 4; irregular pulse, 3; muscular twitching and tetany, 3; muscular weakness, 13; abdominal distension and cramps, 19; anorexia, nausea, and vomiting, 15; paralytic ileus, 7; shallow respiration, 7; oedema, 9 cases. When the serum potassium is less than 4.2 mEq per litre (16.4 mg. per 100 ml.) the E.C.G. shows definite changes. The T wave becomes smaller and smaller the lower the serum potassium, and may be almost absent. When potassium chloride is given intravenously the T wave reappears. Fig. 3 shows the changes in the electrocardiogram due to hypopotassaemia, and the restoration to normal after potassium has been given.

FIG. 3.—Electrocardiogram showing the changes which occur when the serum potassium is low, and after treatment with potassium.

Effect of too Much Potassium in the Serum after Operation

Ever since Ringer (1883-4) showed that the heart stopped in diastole if too much potassium was present, there has been great fear of causing potassium poisoning if any potassium was given intravenously, even the small amount in Ringer-Locke solution. This fear has been intensified by the work of Winkler *et al.* (1939). They showed that when an isotonic solution of potassium chloride was injected into a 21-kg. dog at a rate of 112 mg. a minute the dog died in 50 minutes after 5.96 g. of potassium chloride had been injected. In this time the potassium in the serum increased from 4.1 to 14.7 mEq per litre (16 to 57.5 mg. per 100 ml.). Death occurred with the heart in diastolic arrest, and the E.C.G. showed characteristic changes—an increase in the amplitude and a shortening of duration of the T wave. This occurred in a concentration of 5 to 7.8 mEq per litre (19.5 to 30.6 mg. per 100 ml.) and the T increased in size until it equalled that of the QRS complex. Later the ST segment dropped below the isoelectric line, and the QRS complex became wider and finally completely disorganized. The critical concentration seemed to be 14-16 mEq per litre (55-62.5 mg. per 100 ml.), or nearly four times the normal figure. Fig. 4 shows the changes in the electrocardiogram due to hyperpotassaemia.

Three points in that paper seem to have escaped general notice: (1) If this amount was given slowly to healthy dogs no ill effects occurred. (2) The effect of adding glucose to the solution was not tried. The glucose would have enabled the muscles and liver to lay down more potassium with the glycogen and thus reduce the amount of potassium in the serum more rapidly. (3) The equivalent amount of potas-

FIG. 4.—Electrocardiogram taken when the serum potassium was 10.3 mEq per litre (40 mg. per 100 ml.).

sium chloride for a man of 65 kg. is 19.3 g., which is rather more than has been suggested even for patients suffering severely from hypopotassaemia.

It is very remarkable that these experiments on healthy dogs should have deterred many workers from using potassium in the past and should still frighten some. Since the giving of potassium is regarded by many as a dangerous procedure it is important to consider how much potassium is present in the blood and extracellular and intracellular fluids. If 1 g. of potassium (1.9 g. of potassium chloride) is quickly given intravenously to a man weighing 65 kg. whose serum potassium was 4.5 mEq per litre (17.6 mg. per 100 ml.) the maximum increase would be 12.3 mEq per litre (48.4 mg. per 100 ml.), which would be nearly a poisonous dose. But if the solution was given slowly, say in eight hours, the potassium would enter the extracellular fluid and then the intracellular fluid, and some would be excreted in the urine. The maximum rise would be 2 mEq per litre (7.8 mg. per 100 ml.) if the extracellular fluid alone was entered, and 0.56 mEq per litre (2.2 mg. per 100 ml.) if it was spread equally over the intracellular fluid. It follows that if the potassium is taken up equally by the extracellular and intracellular fluids of a 65-kg. man, a deficit of 1 mg. per 100 ml. in the serum potassium will mean a deficit of 0.0079 g. of potassium per kg. (0.0133 g. of KCl)—that is, 0.455 g. = 0.87 g. KCl per 65 kg.

It is generally agreed by those who have found potassium valuable in post-operative treatment that it should not be given until more than 24 hours have elapsed since the operation, when the kidneys have recovered their power of excreting water and the chance of a retention of potassium in the blood has passed.

Symptoms due to Hyperpotassaemia

These have been described in patients with renal failure (Finch *et al.*, 1946). The patient rapidly develops a true paralysis of two or four limbs, with shallow, laboured breathing. The reflexes are absent, but sensation of pain is present though numbness of hands may occur. The condition is said to resemble a Landry's ascending paralysis. The heart sounds are characteristically "dulled, prolonged, as if the heart were beating in slow motion"; bradycardia is present, with frequent irregular pauses. Bull *et al.* (1953) have also reported the rather sudden onset of paralysis in three patients with uraemia. At first sight the symptoms of hyperpotassaemia resemble those due to hypopotassaemia. But in the latter they develop slowly several days or more after the patient has been operated on. Again, the condition of the limbs is described as a weakness rather than a paralysis such as occurs in hyperpotassaemia. These differences should be enough to make a differential diagnosis easy after an operation. Thus, hyperpotassaemia may occur after a severe operation if the kidney fails to excrete the potassium liberated from the muscles.

Eliel *et al.* (1950) found one patient with a serum potassium of 12.2 mEq per litre (48.5 mg. per 100 ml.) on the day after operation, and Tabor and Rosenthal (1945) noted that mice were very sensitive to injections of small amounts of potassium some hours after the tourniquet had been removed from the leg. Any risk of this occurring should be

past by 24-36 hours after operation, provided sufficient water, sodium chloride, and glucose are given. In the next two to six days hypopotassaemia may develop, and any weakness of the limbs occurring at this time must be due to the lack of potassium, which can be confirmed by the flat T wave in the E.C.G., and a serum potassium which may be very low. This condition must be treated with potassium, and the weakness of the limbs will soon disappear. If, now, paralysis of the muscles develops suddenly in a patient who is receiving or has just finished a potassium injection, the condition can safely be diagnosed as due to hyperpotassaemia. The fact that paralysis or weakness of the limbs occurs both with excess and with lack of potassium seems extraordinary, but there is a parallel in diabetes mellitus, in which coma develops, owing to ketosis, when insulin is lacking, but also when insulin is in excess, owing to the lack of sugar in the blood. In this case, also, the history of the onset is of value, since when insulin is lacking the coma develops slowly, whereas when insulin is in excess the coma develops very rapidly. Thus in both hyperpotassaemia and hyperinsulinism the treatment consists in giving glucose as soon as the diagnosis is made.

Treatment for a Dangerous Hyperpotassaemia

An immediate injection of 20-30 units of insulin should be given, followed by 50 g. of glucose by mouth, or, in an emergency, by injection of 1,000 ml. of 10% glucose (Bywaters, 1944; Bull, 1951-2). This will cause an immediate deposit of glycogen and potassium in the liver and muscle (Fenn, 1939) and will cause a reduction in the serum potassium. Bull (1951-2) has reported a case of anuria in which the potassium was 10 mEq per litre (39.1 mg. per 100 ml.), and two hours after the giving of 50 g. of glucose intravenously and 50 units of insulin, the potassium had decreased to just over 7 mEq per litre (27.4 mg. per 100 ml.) and the character of the T wave of the E.C.G. was much less abnormal. But the action of the glucose can only be temporary, for as soon as the glycogen is needed for energy requirements the potassium will be liberated and will again enter the serum. It is probable that by this time, 6-12 hours, some of the potassium will already have been excreted in the urine, unless renal failure is present. If necessary the glucose and perhaps the insulin can be repeated in eight hours, but the possibility of hypoglycaemia occurring must be remembered, and the blood sugar estimated before more insulin is given. Darrow and Pratt (1950) found that a calcium injection was as useful but had a temporary effect only. To be of real value the dose of calcium necessary to neutralize the poisonous action of potassium would also have to be a poisonous one (Ringer, 1884-5), and after the potassium excess had passed the calcium might cause equally serious symptoms. If it is known that the serum calcium is definitely lowered, 1-2 g. of calcium gluconate should be given intravenously, and 1-2 g. of calcium carbonate given by mouth every four hours if vomiting is not present, together with 10,000 units of calciferol or 3.75 mg. of tachysterol by mouth to ensure the absorption of the calcium from the gut.

Pre-operative Treatment

It is important to consider how the patient should be prepared for operation so as to steer between the Scylla and Charybdis of too much and too little potassium. The diet taken by patients with a good appetite contains about 3 g. of potassium, but patients who are being strictly dieted for a gastric ulcer with, say, 20 oz. (570 ml.) of milk, 25.6 mEq (1 g.) K; 3 eggs, 5.27 mEq (210 mg.) K; 2 oz. (57 g.) of biscuits, 2.56 mEq (100 mg.) K; 3 oz. (85 ml.) of orange juice, 3.84 mEq (150 mg.) K, will take 37.4 mEq (1.46 g.) K daily. If an oesophageal or pyloric obstruction is present the amount of potassium imbibed may be very much less, and a diarrhoea or a biliary fistula (Darrow, 1948) will cause great loss of potassium. In this type of case 1 g. of potassium should be given three times a day in order to ensure that the body has a proper store of potassium. The serum potassium should be estimated and an E.C.G. taken. The following amounts of potassium salts each contain

approximately 1 g. of potassium and can be taken in 30 ml. (1 oz.) of orange juice and water.

Potassium chloride, 1.91 g. = 1 g. K. = 25.6 mEq K
Dipotassium hydrogen phosphate, 1.36 g. } = 1 g. K. = 25.6 mEq K
Potassium dihydrogen phosphate, 1.36 g.
Potassium citrate, 1 g.
Potassium acetate, 1 g. } = 1.15 g. K. = 29.4 mEq K
Potassium bicarbonate, 1 g.

If a patient is vomiting, or is unable to swallow, the potassium should be given intravenously. Before this is done the serum potassium and the size of the T wave should be determined. If these show a definite lack of potassium, 1 g. of K (1.9 g. KCl) in 1,000 ml. of 5% glucose in distilled water should be given intravenously in eight hours twice a day until the serum potassium and the T wave are within normal limits. An operation should not be performed, except in an emergency, until the serum potassium and the other electrolytes are within or nearly within normal limits. This procedure might reduce the necessity for gastric and duodenal suction after the operation.

Post-operative Treatment

From what has been said already it is plain that the problem is very complex, and the correct treatment varies according to the degree to which the sodium and potassium balance has been upset (1) by the "shock" of the operation; (2) by the treatment necessary to combat the effects of the "shock"; and (3) by the rapidity with which the serum potassium returns to normal, making it possible to give adequate amounts of potassium and so enable it to re-enter the muscle cells and displace the sodium. In most patients the "shock" of the operation is not serious. Soon after recovery from the anaesthetic the patient may be able to take fluid by mouth, and an effort should be made to give some 3,000 to 3,500 ml. a day. The next day some food may be given, and, since this will contain potassium, the chances of a serious lack of potassium developing is negligible. If fluid cannot be taken by mouth (or this is not considered desirable) it should be given per rectum—2,000–3,000 ml. If fluid only is needed, tap-water is probably the best, as it does not seem to irritate the rectal and sigmoid mucous membrane and is well absorbed. Avery Jones and Naunton Morgan (1938) have found that one-fifth isotonic saline is well tolerated, and 3,000 ml. will contain 5.4 g. of sodium chloride, which is adequate for patients in whom the "shock" is slight and in whom food containing both sodium and potassium will soon be eaten. The shock of the operation and the 5.4 g. of sodium chloride will have probably displaced little potassium from the intracellular space, and as soon as food containing potassium is taken by mouth the convalescence should be smooth. When the "shock" is more severe it may be necessary to give the fluid intravenously, since more sodium chloride will be needed than can be absorbed from the sigmoid and colon. The volume of intravenous fluid should be 3,000–3,500 ml., but the amount of sodium chloride given must depend on the assessment of the degree of "shock" which has occurred. If 9 g. of sodium chloride is needed, the 3,000 ml. can all be given as one-third isotonic saline, with 5 or 10% glucose; if 18 g. is needed, 2 litres of isotonic saline and glucose and 1 litre of 10% glucose; while if 27 g. is needed, it can all be given as isotonic saline with 5 or 10% glucose. Any fluid recovered from the stomach and intestines must be added to the volume given as I have already pointed out. The composition of this additional fluid depends on whether the fluid lost comes from the stomach or intestines, since the amount of potassium lost directly in this way varies (Darrow, 1945). Cooke and Crowley (1952) have suggested the use of two solutions for this purpose.

For loss of gastric fluid:

	mEq		
Ammonium	70		
Sodium	63		
Potassium	17		
Chlorine	150		
		or	
		Ammonium chloride	3.74
		Sodium chloride	3.68
		Potassium chloride	1.27
		Water to 1,000 ml.	
		Sodium to potassium, 3.7:1	

For loss of intestinal fluid:

	mEq		
Sodium	138		
Potassium	12		
Lactate	50		
Chlorine	100		
		or	
		Sodium chloride	5.15
		Sodium lactate	5.6
		Potassium chloride	0.895
		Water to 1,000 ml.	
		Sodium to potassium, 11.5:1	

Some 24 hours after the operation, when the "shock" is over and the urine output good, an assessment of the case is necessary to determine how much sodium chloride is necessary and when the potassium can be started to replace that which has been lost from the intracellular space. In these severe conditions it is usually impossible to give the potassium by mouth, and there is no evidence at present that it is absorbed per rectum. It is necessary to give it as an isotonic solution with 5% glucose either subcutaneously or intravenously. If the hypopotaemia is not very marked a mixture of sodium and potassium chloride can be given, and that used by Randall *et al.* (1949) seems suitable. After 24–36 hours, if the patient is not seriously ill they give:

110 mEq sodium, 2.53 g.		Sodium chloride, 6.44 g.
30 mEq potassium, 1.172 g.	or	Potassium chloride, 2.44 g.
140 mEq chloride, 4.87 g.		Glucose, 50 g.
		Water to 1,000 ml.

This gives a proportion of sodium to potassium of 2.16:1, compared with 16:1 in Ringer-Locke solution. Either 2,000 or 3,000 ml. is given in the day. If the patient is more seriously ill and the serum potassium is already low and the E.C.G. suggests a hypopotaemia Randall *et al.* give:

30 mEq potassium, 1.173 g.		or potassium chloride, 2.24 g.
30 mEq chloride, 1.066 g.		
		In 1,000 ml. of 5% glucose.

Two or three litres is given, depending on serum potassium and the E.C.G.

Conclusion

I spoke earlier of steering between Scylla and Charybdis, and I would like to elaborate the point. During the period after the operation, when the serum potassium may be high, it is necessary to steer away from the Scylla of hyperpotassaemia and towards Charybdis, using plenty of water, salt, and glucose, but as soon as the danger of being wrecked on Scylla is passed, and Charybdis with its low serum potassium and ileal stasis is being neared, the helm must be put over for Scylla, using water, potassium, and glucose, and either greatly reducing or omitting the sodium altogether. In this way the ship will slip easily between these two hazards and reach port safely—that is, the patient will make a rapid recovery. To ensure the proper co-ordination of treatment of these difficult cases it is necessary to have a team consisting of a surgeon and a physician, who should both have a real appreciation of the physiological principles involved. They should be able to call on the electrocardiograph department and on the biochemist for the essential determinations which govern the treatment. The registrar, house-surgeon, and nursing staff should appreciate the difficulties which may arise and report them promptly. The giving of potassium injections should not be left to the night nurse, and if it is necessary to do so at night a senior person should be responsible.

I have here been concerned with the changes which take place in the sodium and potassium in the body. The work on Addison's disease has shown that the sodium in the body is controlled by the hormones of the adrenal cortex. If they are deficient, the sodium in the blood decreases. At present there is no direct evidence on how the potassium is controlled, though it is clear that the sodium and potassium are closely linked. The giving of deoxycortone causes an excretion of potassium in the urine (Ferree *et al.*, 1941; Darrow and Miller, 1942) and the giving of potassium to a patient with Addison's disease causes an excretion of sodium. The conditions under which hypopotaemia occurs are "surgical shock," diarrhoea due to any cause, loss of bile (Darrow, 1945), and periodic paralysis, and all these can be

successfully treated with potassium salts. A syndrome associated with cardiac symptoms, muscular weakness, and hypotension has been described by Kjerulf-Jensen *et al.* (1951). The hypopotaemia in these conditions suggests that a hormone directly concerned must be present, though where it is formed is unknown. If this indeed exists, it would seem that it is upset in surgical shock and that if and when it is known it would be of great use in preventing this condition. I realize that I am putting forward a wholly unproved hypothesis, but the analogies to the control of other electrolytes like iodine by the thyroid, calcium by the parathyroid, and sodium by the adrenal cortex are very close. I believe that each electrolyte in the body is controlled by a hormone and not by pure physical laws, and that it is only a question of time before the hormone is discovered.

I wish to thank my friends with whom I have discussed my problems: Dr. R. G. Macfarlane for the slides, Professor V. H. Mottram, Professor A. Wormall, Dr. E. F. Scowen, and especially Dr. F. Avery Jones for much assistance.

Since the Oration was delivered my attention has been drawn by Professor E. C. Dodds to the papers by Simpson *et al.* (1952) and Grundy *et al.* (1952). These show that a hormone has been isolated from the adrenal which has a specific effect on the potassium as distinct from the sodium.

A COMPARISON OF CORTISONE AND CODEINE MEDICATION AS AN ADJUVANT TO MANIPULATION IN RHEUMATOID ARTHRITIS

A REPORT TO THE JOINT COMMITTEE ON CORTISONE AND A.C.T.H. IN CHRONIC RHEUMATIC DISEASES OF THE MEDICAL RESEARCH COUNCIL AND THE NUFFIELD FOUNDATION

A common problem in dealing with rheumatoid arthritis patients is that of flexion deformities of the knee-joints. These commonly arise during periods of rest in bed when the position of the knees has not been controlled by rest splints. In a proportion of cases these contractures cannot be corrected by conservative methods, and manipulation under a general anaesthetic is required. It was thought that the period of increased pain and disability due to the trauma of this operation might be curtailed, or even avoided altogether, by performing the operation under cover of cortisone. At the same time it would be possible to observe the effect of such treatment on the general as well as on the local reaction following manipulation, to note any general exacerbation of the disease that may sometimes, it is said, follow this procedure, and to assess the long-term usefulness of such therapy as it affects the manipulated limb and its function. Accordingly a small-scale controlled trial was set up by a Subcommittee of the Medical Research Council/Nuffield Foundation Joint Committee on Cortisone and A.C.T.H. in Chronic Rheumatic Diseases* in which four centres participated: Bath (Dr. G. D. Kersley and Mr. J. Bastow), Sheffield (Dr. H. F. West and Mr. G. Gordon), Stanmore (Dr. Harwood Stevenson and Mr. H. J. Seddon), and Taplow (Dr. E. G. L. Bywaters and Mr. G. P. Arden). The analysis of the results of the trial was made by Dr. J. T. Boyd, of the Statistical Research Unit of the Medical Research Council, London School of Hygiene and Tropical Medicine.

Type of Patient

The patients selected were between the ages of 5 and 64 years; they had been diagnosed as having arthritis beyond any clinical doubt, and had four joints or more involved. Each had a knee contracture which had been present for at least six months and was in need of manipulative correction. Patients with severe disease activity or with completely ankylosed knees were excluded.

Allocation to Treatment

After admission to the trial patients were allotted to treatment with cortisone acetate or tab. codein. co. according to instructions given in serially numbered and sealed envelopes prepared in advance in random order. Approximately half the patients were allotted to each type of therapy.

Dosage

Following five days of preliminary observation and assessment, a total of 2.15 g. of cortisone was given to 18 patients over a period of 16 days at the level of 200 mg. for the first day; 300 mg. on the second and third days; 200 mg. on the fourth and fifth days; 150 mg. on the sixth, seventh, and eighth days; 100 mg. on the ninth and tenth days; and 50 mg. on the eleventh to the sixteenth day. The drug was given by mouth in three divided doses daily.

*The members of the subcommittee were: Dr. E. G. L. Bywaters (chairman), Mr. W. D. Coltart, Dr. J. J. R. Duthie, Professor A. Bradford Hill, Dr. G. D. Kersley, Dr. F. H. Stevenson, and Dr. H. F. West.

Tab. codein. co. were given orally to 15 patients over the same period of 16 days at the rate of two tablets three times daily throughout. If any further analgesics were needed, pethidine only was used.

Technique of Manipulation and Assessment

All the manipulations at each centre were performed by the same person, who was unaware whether the patient belonged to the codeine-treated or to the hormone-treated series. The manipulation took place on the second day of therapy in the afternoon after the second 100-mg. dose on that day—that is, after a total of 400 mg. of cortisone or 10 tablets of tab. codein. co. After the manipulation the knee was placed in plaster which was bivalved for assessment at the twenty-fourth hour, the posterior shell thereafter being replaced. Assisted active movements were carried out by the physiotherapist daily after assessment and every endeavour was made to get the patient walking as early as possible. Daily assessments were made for five days prior to treatment, for five days following its commencement, and thereafter at five-day intervals for a total period of 26 days from the patient's admission to the trial. During this time the patient remained in hospital. These assessments were made by the same group of observers at the same time each day. They had, inevitably, to know the treatment. A follow-up examination was made at approximately two months from the time of manipulation on all but 6 of the 33 patients.

The assessments included (a) observations on the manipulated knee; (b) observations on another of the affected joints, usually the contralateral knee; and (c) assessments of general reaction.

(a) The observations on the manipulated knee included pain on pressure (grades 0-3), pain on active and passive movement (grades 0-3), range of movement measured between maximum flexion and maximum extension, circumference of the knee at the top of the patella, and skin temperature (the last-named was recorded in only 17 of the 33 patients).

The time taken to do five complete flexion-extensions with the heel supported on a skate in the horizontal position was used as a test of function. Observations were also included on the strength of thrust and on the time at which the patient began to walk, but these records proved not to be comparable from one centre to another and have not been used.

(b) Observations on an affected but unmanipulated joint included similar tests to the above, particular attention being given to pain, range of movement, and the functional test.

(c) The general assessments included maximal daily oral temperature (taken four-hourly for the first 10 days of the trial and thereafter twice daily), total and differential white blood cell counts, sedimentation rate (Westergren method), and haematocrit reading. These last estimations were performed twice before manipulation and subsequently at five-day intervals up to day 26. A note was made of any complications.

Results

In total, 33 cases were admitted to the trial, 18 being manipulated under cover of cortisone and 15 under cover of tab. codein. co. Initially the two treatment groups were closely similar in age and sex and also in the length of time that the manipulated knee had been contracted (Tables I and II).

3-10	3	2
10+	1	0
Not stated	1	0
All durations	18	15

The main results of treatment are given in Table III and the Chart, which show the mean assessments of the treated joints at intervals from the start of the trial. After some slight decrease in pain after institution of treatment there is, as would be expected, a sharp increase on the day following manipulation. The mean values are, however, very similar in the two treatment groups (2.33 cortisone and 2.40 codeine for pain on pressure and 2.44 cortisone and 2.20 codeine for pain on motion). This increased pain declines somewhat in both groups during the subsequent two days, but it remains above the average pre-manipulation level and is similar under both treatments. By about day 15-16 it has returned to the pre-manipulation values in each group.

The average range of movement, which improved slightly with the start of treatment, is decreased in both groups for one day following manipulation; it thereafter immediately rises to a mean value above its original level and improves somewhat with the passage of time. If anything, the codeine group fared slightly better in this respect than the cortisone group.

The joint circumferences showed no great change throughout. The functional timing test showed, as expected, considerable lengthening in both groups following manipulation and returned to pre-manipulation levels by day 15-16. The

Joint assessment at intervals from start of trial. Mean values for each treatment group.

skin temperature over the manipulated knee rose in both groups during the two days following manipulation (Table IV), but it had subsided in both by the twenty-first day.

Analgesics (pethidine) were needed, most commonly on the day of manipulation, in approximately two-thirds of the patients in each group—namely, in 12 of the 18 patients on cortisone and 9 of the 15 patients on codeine. There was

TABLE IV.—Mean Skin Temperature (°C.) Over Manipulated Knee* and Mean Skin Temperature Ratio†

Day	Temperature		Skin Temperature Ratio	
	Cortisone	Codeine	Cortisone	Codeine
1-5	32.0	32.4	1.002	1.001
6	31.4	32.5	0.999	1.001

15-16	32.5	32.3	1.030	1.012
20-21	32.3	32.7	0.996	1.001
25-26	32.0	32.1	0.997	1.021

* Based on the 9 patients on cortisone and the 8 patients on codeine for whom the necessary data were available.

† Skin temperature ratio = Skin temperature (°C.) over manipulated knee / Skin temperature (°C.) over contralateral knee. Based on data from 8 patients in each treatment group.

little evidence of any general reaction as judged by the packed cell volume, the white blood cell count, the polymorph percentage, and the sedimentation rate, although the latter fell temporarily in the cortisone-treated group. Isolated peaks of body temperature to above 99° F. (37.2° C.) occurred during the period following manipulation in five patients on cortisone and in five on codeine. Only one patient in the entire series showed a reaction in other joints (on days 23 to 26 inclusive and at follow-up on day 67). He had been treated with cortisone.

There was no marked difference between the two groups in the subsequent progress as judged from the data available on patients who were assessed at days 25-26 and also at day 67 ± 7 (see Table III).

As would be expected, the observations on the contralateral knees which were not manipulated showed them, as a group, to be less severely affected than the knees chosen for manipulation. Under treatment with cortisone or codeine they showed some improvement as measured by pain on pressure, range of movement, and functional timing test recordings (Table V). On the other hand, there was

TABLE V.—Assessment of Contralateral Knee-joints (Non-Manipulated) At Intervals from Start of Trial (Mean Values for Each Treatment Group)

Day†	Joint Assessment					
	Pain on Pressure (Arbitrary Units)		Range of Movement (Degrees)		Timing Test (Sec.)

20-21	0.29	0.29	97.8	98.2	5.3	5.2
25-26	0.53	0.36	97.4	98.4	5.1	5.0

Based on data from 17 patients in cortisone group and 14 patients in codeine group.

clearly no material difference between the cortisone-treated and the codeine-treated groups. In short, both in the manipulated knee and in the contralateral knee these treatment groups were more remarkable for the similarity of their reactions than for a dissimilarity.

Conclusion

In this investigation cortisone revealed no advantage over tab. codein. co. as a cover for manipulation of the knee. There was little, if any, systemic disturbance attributable to the manipulation in either treatment group except an occasional temperature spike which appeared equally in both groups. A general exacerbation in other joints was seen only once and could be attributable in this case to cortisone rebound rather than to the effects of manipulation. There is no evidence, therefore, that cortisone was of any greater value than tab. codein. co. given in this dosage and for this period of time as a cover for manipulative correction of contracted joints in rheumatoid arthritis.

Summary

A controlled trial has been made of the value of cortisone as a cover to manipulation of the knee-joint in patients with rheumatoid arthritis. Each patient had a knee contracture of at least six months' standing. Eighteen were treated with cortisone and 15 with tab. codein. co., this treatment being allocated in a random order. In the dosage given there was no evidence that cortisone was in any way superior to tab. codein. co. for the purpose at issue.

The Ministry of Pensions and National Insurance has compiled a large *Digest of Statistics Analysing Certificates of Incapacity, 1950*, copies of which may be obtained from the Ministry at 10, John Adam Street, London, W.C.2. The figures will not be published in the ordinary way, because they are not considered to be of sufficient general interest. They are based on medical certificates given in support of claims to State insurance benefits. Like many other statistics of this kind, they are of necessity incomplete in several respects: for instance, they do not include figures for illnesses of two or three days' duration. Moreover, the certifying medical practitioners do not always indicate the diagnosis with precision. Now that certificates are being used for statistical purposes, the Ministry hopes that doctors will show on them the cause of incapacity as accurately as possible. If the present volume is found to be useful, similar digests will be issued for 1951 and some later years.

ACTIVITY OF ERYTHROMYCIN AGAINST STAPHYLOCOCCUS AUREUS

BY

DEREK HOBSON, M.B., Ch.B.

Lecturer in Bacteriology, Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, W.2

Erythromycin is a new antibiotic derived from *Streptomyces erythreus*. Its chemical and physical characteristics were described by McGuire *et al.* (1952), and its biological properties were investigated by the same workers and by other groups (Haight and Finland, 1952a, 1952b; Heilman *et al.*, 1952). Erythromycin was found to be active *in vitro* in very low concentrations against a wide range of Gram-positive organisms, but was inactive against Gram-negative organisms with the exception of *Neisseria*, *Haemophilus influenzae*, *Haemophilus pertussis*, and strains of *Brucella*.

Erythromycin, which can be given orally, has low toxicity for man and laboratory animals; it gives satisfactory concentrations in the blood and urine but not in the cerebrospinal fluid of normal persons (Heilman *et al.*, 1952). The ability of erythromycin to protect mice against experimental infections was found to parallel the sensitivity *in vitro* of the infecting organism and to be related to the blood concentration of the drug (McGuire *et al.*, 1952). Clinical trials of erythromycin have been reported by Heilman *et al.* (1952) and by Haight and Finland (1952c). Favourable results have been obtained in various streptococcal, pneumococcal, and staphylococcal infections. Erythromycin has been shown to be particularly effective against staphylococci, whether the strains were penicillin-sensitive or penicillin-resistant (McGuire *et al.*, 1952).

There is an increasing emergence of strains of *Staphylococcus aureus* which are resistant to penicillin, streptomycin, and to one or more of the "broad-spectrum" antibiotics. The high incidence, especially in hospitals, of infections caused by such strains makes it highly desirable to have a new antibiotic at our disposal which is effective against staphylococci. Since it seems likely that this will be the chief potential role of erythromycin, the present report is devoted to laboratory experience of the drug's activity against pathogenic staphylococci.

Materials and Methods

A supply of pure crystalline erythromycin (potency 915 µg./mg.) was provided through the courtesy of Abbott Laboratories. A stock solution of the white powder was made in distilled water in a concentration of 2 mg./ml. To aid solution a little ethyl alcohol was used. This stock solution could be stored in the frozen state at -20°C for as long as eight weeks.

Many of the strains of *Staph. aureus* used were recently isolated from patients with staphylococcal infections or from normal nasal or oral flora. Stock laboratory strains were also included.

Sensitivity tests were performed with serial dilutions of erythromycin either by a tube method with digest broth as the medium or by a plate method (modified from May and Morley, 1952) with Levinthal agar. Five-hour broth cultures of organisms to be tested were obtained by picking individual colonies from

the growth on blood-agar plates. In the tube test the final concentration of antibiotic ranged from 20 to 0.01 µg./ml. The inoculum was estimated to yield a final concentration of 5×10^3 organisms per ml. The sensitivity of the organism was taken to be the minimum final concentration of antibiotic that completely inhibited growth as judged by visible turbidity after 18-24 hours' incubation.

The inoculum in the plate test was one 2-mm loopful of the broth culture (approximately 10^5 organisms). The sensitivity of the strain was expressed as the concentration of antibiotic which completely inhibited growth of the organism. The sensitivity of staphylococci to other antibiotics was estimated by a plate method (May and Morley, 1952).

In the production of resistant variants of originally sensitive strains of staphylococci two methods were employed. The first was that of Haight and Finland (1952c) in which the organism was subcultured serially at 48-hourly intervals on a series of 10% blood-agar plates containing increasing concentrations of erythromycin. The inoculum was one loopful of a broth suspension of the growth from the plate with the highest concentration of antibiotic allowing good growth. The second method was a modification of that of Barber (1953). The organism was subcultured serially on erythromycin ditch plates. These were of 10% blood agar with a ditch cut at one side of the plate and filled with the same medium containing at first 20 and later 100 µg. of erythromycin per ml. Subcultures were made from the edge of growth nearest to the ditch.

In both methods each parent strain was subcultured on antibiotic-free medium at the same intervals as the derivative strain.

Result of Experiments

Factors Influencing *in vitro* Sensitivity

The sensitivity of *Staph. aureus* G 1 was not affected by variations in the size of the bacterial inoculum, ranging from 5×10^3 to 50 organisms, in either the tube or the plate method. The effect of continued incubation was slight. In the tube test, incubated for 24 hours, *Staph. aureus* G 1 was inhibited by 0.25 µg. of erythromycin per ml. After 48-72 hours' incubation slight growth was visible in this tube. No new growth was visible in tubes containing higher concentrations of antibiotic.

It has been shown by Knox *et al.* (1952) that in sensitivity tests of mycobacteria with isoniazid the end-point is more unstable at some temperatures than at others, and that results obtained after arbitrary periods of incubation may vary widely. In tube sensitivity tests of *Staph. aureus* with erythromycin, variation of the temperature of incubation over a range 26-40°C. did not affect the results previously obtained.

The sensitivity of four strains of *Staph. aureus* was not affected by performing the tube test with broth to which 25% serum had been added. Plate tests with blood agar or nutrient agar in place of Levinthal agar gave identical results.

In comparative tests of 50 strains of *Staph. aureus* by the tube and plate method the results were identical with 40 strains. The sole discrepancy in the remaining 10 cases was that a scanty growth was observed on the plate corresponding in erythromycin concentration with the minimum inhibitory concentration in the tube test. On continued incubation this growth became complete, but no growth developed in plates containing higher concentrations of antibiotic.

The plate method has been adopted for routine sensitivity testing of large numbers of strains of *Staph. aureus*. Prepared

plates maintain unimpaired erythromycin potency for over two weeks after preparation if the plates are kept in the refrigerator until required.

Growth of Staphylococci in Varying Concentrations of Erythromycin

A five-hour broth culture of *Staph. aureus* G 1 was added in a final concentration estimated at 5×10^3 organisms per ml. to serial broth dilutions of erythromycin and to a tube of broth containing no antibiotic. After varying periods of incubation at 37°C., 0.1-ml. samples were taken from each tube and bacterial counts were made by the method of Miles, Misra, and Irwin (1938). At daily intervals the whole of 1-ml. samples was plated out from the tubes containing 4, 1, and 0.5 µg. of erythromycin per ml. The results are shown graphically in Fig. 1. With increasing concentrations of erythromycin the number of viable organisms re-

FIG. 1.—Effect of various concentrations of erythromycin (µg./ml.) on the growth of *Staph. aureus* G 1.

mained stationary for decreasing periods of time and then declined progressively. There was no growth in 4 or 1 µg./ml. after 24 hours. With 0.5 µg./ml. complete sterilization was not achieved even after 72 hours. At lower concentrations of erythromycin the number of organisms re-concentrations of erythromycin for long periods or fell slightly maintained almost stationary for long periods or fell slightly and then began to rise. In the case of 0.1 µg./ml. the bacterial count was almost the same as in the control culture after 24 hours.

Sensitivity of a Large Number of Strains of *Staph. aureus*

A total of 213 strains were tested. All strains were coagulase-positive and fermented mannite. The distribution of sensitivity of staphylococci to erythromycin is shown in Table 1. Thirty-three strains of *Staph. aureus* of known phage type were selected. These fell into each of the three main phage groups. There was no difference in erythromycin sensitivity between any of these strains. All were sensitive to 0.25-0.5 µg./ml. The sensitivity of 47 strains of

FIG. 2.—Comparative sensitivity of 47 strains of *Staph. aureus* to five antibiotics, tested by a plate method (May and Morley, 1952).

TABLE 1.—Sensitivity of 213 Strains of *Staph. aureus* to Erythromycin (Plate Method)

	Minimum Inhibitory Concentration of Erythromycin (µg./ml.)					
	>1	0.5	0.25	0.1	0.05	0.01
No. of strains sensitive to each concentration of antibiotic	0	157	49	6	1	0
Percentage of strains sensitive to each concentration	—	100	26.5	3.5	0.5	—

Staph. aureus to penicillin, streptomycin, chloramphenicol, and oxytetracycline ("terramycin") was tested. The strains selected included penicillin-resistant and penicillin-sensitive organisms and strains with varying combinations of resistance to other antibiotics. All were sensitive to 0.25-0.5 µg. of erythromycin per ml. whatever their behaviour to any of the other antibiotics. The results are shown in Fig. 2.

Resistance to Erythromycin

It is believed that resistance to antibiotics may develop by mutation of organisms in a "sensitive" strain to resistant forms. On contact with the antibiotic these resistant forms will be selected out. By serial subculture in the presence of antibiotic it is thus possible to develop strains whose antibiotic resistance is much greater than that of the parent. Two patterns of resistance have been described: (a) the penicillin pattern, in which resistance is gradual and "step-wise," depending on a series of small mutations; and (b) the streptomycin pattern, in which "one step" resistance of a high order can occur owing to selection of highly resistant variants in the original culture.

From an overnight culture of *Staph. aureus* G 1 a sample was taken for bacterial count and 1-ml. aliquots were spread evenly over the surface of 10% blood-agar plates containing erythromycin. Various concentrations of antibiotic were tested in separate experiments, 15 plates being used each time. The average inoculum was estimated at 2×10^4 organisms. No growth was discovered on plates containing 100, 50, 20, 10, or 5 µg. of antibiotic per ml. There was confluent growth on control plates with no antibiotic. In an experiment with 1 µg./ml., six plates gave no growth, and on eight plates a small number of colonies (2-10) appeared. On plates containing 0.5 µg. of erythromycin per ml. a variable number of colonies appeared on all plates.

These colonies could represent either mutants present in the culture or organisms which had undergone adaptation in some way during their contact with erythromycin. To decide this point the fluctuation test designed by Luria and Delbrück (1943) and adapted for work with antibiotics by Demerec (1948) was performed. From a single culture of staphylococcus G 1, small inocula (approximately 300 bacteria) were subcultured into 16 bottles of broth. After overnight incubation 1 ml. of each of 15 broth cultures was plated on to blood-agar plates containing 0.5 µg. of erythromycin per ml. From the 16th broth culture 15 samples were similarly plated (approximately 2×10^3 organisms per plate). After incubation the number of colonies on each plate was counted. The variation between plates was 15 times greater in the series of independent cultures than in the series of replicate platings of a single culture. These findings suggest that erythromycin-resistant bacteria in a culture of a sensitive organism arise spontaneously by mutation. If these bacteria originated by a process of adaptation when the culture and the antibiotic came into contact, a similar number of colonies would occur on all plates whatever the origin of the sample plated.

Development of Erythromycin-resistant Strains

Fourteen strains of staphylococci sensitive to 0.25–0.5 μg . of erythromycin per ml. were serially subcultured by the method of Haight and Finland (1952e), as described above. All the strains increased in erythromycin resistance rapidly. Two strains grew on plates containing 80 μg ./ml. after only

FIG. 3.—Changes in antibiotic resistance occurring during repeated subcultures of four strains of staphylococci on blood agar containing erythromycin.

five subcultures. The behaviour of four strains during 12 transfers is shown in Fig. 3. The parent strains subcultured on antibiotic-free agar retained their original sensitivity.

The resistant variants of all 14 strains of staphylococci have shown no significant change in resistance to erythromycin after 10 subcultures on antibiotic-free medium.

Metabolic Effects of Acquired Erythromycin Resistance

The 14 parent strains of staphylococci and their resistant variants were observed for colonial appearance, mannite fermentation, and coagulase production. The phage-pattern of six strains and their resistant variants was examined. None of these characteristics was changed following development of erythromycin resistance. The only

FIG. 4.—Growth curves of *Staph. aureus* G 82 and its derivative strain G 82v resistant to 80 μg . of erythromycin per ml.

difference noted was that growth of resistant variants was less active than growth of the parent strain. The growth in broth of *Staph. aureus* G 82 and its variant resistant to 80 μg ./ml. was estimated turbidimetrically. The growth rate of the resistant variant was slower than that of the parent strain (Fig. 4). Each resistant variant was examined to exclude the possibility that acquired resistance might be associated with the production of an erythromycinase. The test employed for this purpose was a modification of Got's plate test for penicillinase (Haight and Finland, 1952d). There was no evidence of erythromycinase production.

The 14 staphylococci and their resistant variants were tested for their sensitivity to penicillin, streptomycin, chloramphenicol, and oxytetracycline. In no case was the development of resistance to erythromycin associated with the development of cross-resistance to any of the other antibiotics. During the course of this investigation a sample of a new antibiotic, carbomycin ("magnamycin"), was obtained through the courtesy of Messrs. Charles Pfizer, Ltd. The antibacterial activity of this agent has been described by Tanner *et al.* (1952) and by English *et al.* (1952). The range of activity of carbomycin closely resembles that of erythromycin. Cross-resistance between the two antibiotics has been reported by Finland *et al.* (1952). Four of the staphylococci used in the present investigation, and erythromycin-resistant variants selected at various levels of erythromycin-sensitivity, were tested against the two antibiotics by the plate method already described. It will be seen from Table II that increase in resistance to erythromycin was accompanied by an increase in resistance to carbomycin. Each strain tested required two to four times as much carbomycin, weight for weight, as erythromycin to produce complete inhibition.

TABLE II.—Cross-resistance Between Erythromycin and Carbomycin

Strain of Staphylococcus	Sensitivity of Strain (μg ./ml.)	
	Erythromycin	Carbomycin
G 3	0.25	1.0
G 3v	10.0	40.0
G 6	0.5	5.0
G 6v	40.0	160.0
G 5	0.25	1.0
G 5v	80.0	160.0
G 7	0.5	0.5
G 7v	10.0	20.0

Three strains of staphylococci were subcultured serially on blood-agar plates containing erythromycin in a lateral ditch. There was a similar progressive increase in resistance, but no colonial variants were seen of the type described by Barber (1953) in her study of penicillin- and streptomycin-resistant staphylococci, nor were any erythromycin-dependent variants isolated.

Discussion

Laboratory tests with erythromycin have shown that it may be readily adapted to standard procedures used routinely for other antibiotics. The tube dilution and the agar-plate dilution methods of testing gave comparable results. Growth curves of *Staph. aureus* in varying concentrations of erythromycin show that concentrations of antibiotic higher than the minimum inhibitory concentration cause a reduction in the number of viable organisms, and may sterilize the culture, whereas with lower concentrations the organisms escape from the inhibitory effect of erythromycin after a period of bacteriostasis.

In the present study the sensitivity of 47 strains of *Staph. aureus* to erythromycin was shown to be independent of the pattern of sensitivity to four other antibiotics. Even strains which were resistant to penicillin, streptomycin, chloramphenicol, and oxytetracycline were completely inhibited by 0.5 μg . of erythromycin per ml. Sensitivity to erythromycin was also shown to be independent of phage type of the strain.

Resistance of staphylococci to erythromycin developed readily *in vitro* but appeared to follow the "stepwise" pattern of acquired resistance to penicillin rather than that of streptomycin. From the experiments described above it would appear that a culture of a sensitive strain of staphylococcus may contain spontaneous mutants which are more resistant to erythromycin. Mutants resistant to high levels of erythromycin were not found in these experiments. However, by serial subculture on media containing erythromycin progressive increase of resistance occurred in 14 strains of staphylococci tested. These strains differed from each other in the speed of development of resistance, but in no case was the first "step" to a resistance more than four times that of the original strain. Apart from some reduction in rate of growth, the biological characteristics and phage pattern of the resistant variants were unchanged. Haight and Finland (1952e) observed that development of resistance was associated with loss of coagulase activity. This finding has not been confirmed in the present study or by later experience of the same group of workers (Purcell *et al.*, 1953). Resistant variants were not found to have developed cross-resistance to any other antibiotic except carbomycin. Similar experiences have been reported by Haight and Finland (1952e) and Finland *et al.* (1952). The fact that originally sensitive strains of staphylococci rapidly develop resistance *in vitro* and also *in vivo* (McGuire *et al.*, 1952) is a potential drawback to the use of erythromycin. However, recent work (Purcell *et al.*, 1953) shows that *in vitro* combinations of erythromycin with penicillin or with streptomycin will delay or depress the emergence of resistance to both erythromycin and penicillin or streptomycin.

Summary

Methods for sensitivity testing of staphylococci with erythromycin are described. Factors affecting these tests are discussed.

The sensitivity to erythromycin of a large series of strains of *Staph. aureus* is shown to be of the order of 0.5 μg ./ml., and to be independent of their phage type or their behaviour to four other antibiotics.

The effect of erythromycin on the growth rate of staphylococci has been shown to vary according to the concentration of antibiotic. Concentrations above the minimum inhibitory concentration produce a fall in the number of viable organisms.

The development in staphylococci of resistance to erythromycin appears to follow a stepwise pattern resembling that seen with penicillin.

Resistant staphylococci were found to differ from the erythromycin-sensitive parent organism only by slight differences in growth rate and by the acquisition of cross-resistance to carbomycin.

My thanks are due to Dr. R. E. O. Williams, Staphylococcal Reference Laboratory, Central Public Health Laboratory, Colindale, for performing phage-typing on the strains of *Staph. aureus* used in the resistance experiments.

SOME LESSONS FROM 4,000 UTERO-TUBAL INSUFFLATIONS*

BY

ALBERT SHARMAN, M.D., D.Sc., Ph.D.

F.R.C.O.G.

Senior Assistant Surgeon, Royal Samaritan Hospital for Women, Glasgow

Personal experience of just over 4,000 utero-tubal insufflations has taught several practical lessons. The foremost lesson, in my opinion, concerns the gas employed and its safety.

Rubin's Test

Utero-tubal insufflation was first described by Rubin in 1920, so that more than 30 years have elapsed to permit the evaluation of a large number of these tests by investigators all over the world and the accumulation of recorded complications and untoward sequelae. It must not be overlooked, of course, that details of mishaps and even fatalities might pass unpublished. An illustration of this is to be found in the report of the meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland on November 7, 1947, in which a speaker made the bald statement that he knew of eight deaths in Ireland following the Rubin test. Nevertheless, a study of the replies to Rubin's (1947) detailed questionnaire, returned by 356 gynaecologists and involving 80,376 insufflations, must supply the data to answer the more important questions, including the safety of the procedure. Among all these insufflations, embolism occurred in 15 patients, of whom 3 died. These deaths are additional to the 10 known post-insufflation deaths from embolism reported in the literature; Frommolt (1925), 1 case; Moench (1927), 2 cases; Mansfeld and Dudits (1934), 1 case; Weitzman and Cohen (1937), 1 case; Dible *et al.* (1938), 1 case; Feiner (1942), 1 case; Finn (1945), 1 case; and Faulkner (1946), 2 cases. In all these fatal cases air or oxygen was used; in no instance is there a record of death from embolism following insufflation with carbon dioxide. Non-fatal but alarming clinical effects, in varying degrees, have been observed by many investigators, but these are rarely seen with the use of carbon dioxide.

At the Royal Samaritan Hospital for Women, Glasgow, insufflation has been employed for nearly 25 years, and at no time has any gas other than carbon dioxide been used. The test has been carried out by various members of the staff on an aggregate of over 6,500 occasions. My personal share of these experiences amounts to just over 4,000 insufflations. None of us has seen any evidence of embolism and there certainly has been no fatality. It is reasonable, therefore, to conclude from accumulated clinical experience that carbon dioxide is the gas of choice. Moreover, it must be pointed out that Rubin, in more than 10,000 insufflations personally carried out, with the exception of approximately the first 100 cases in which he used oxygen (a procedure which was quickly abandoned by him because of the disadvantage that it takes 24–100 hours to be absorbed from the peri-

*The basis of a lecture given to Greenock and District Faculty of Medicine on March 3, 1953, at Greenock Royal Infirmary.

to operate. No great difference, either in the level at which patency is established or in the appearance of tubal-contraction waves, is usually seen when insufflation is repeated even after several months. Rubin (1939) maintains that the tracings can be correlated with phases of endometrial or ovarian activity. I have not been able to confirm this. More active or more frequent peristalsis may be seen at various stages of the menstrual cycle and spasm may also be exhibited for no apparent reason. Moreover, if two or three insufflations are performed on the one day—that is, within a few hours of one another—the tracings obtained need not be closely similar.

Summary

Some of the more important lessons gained from just over 4,000 utero-tubal insufflations during the past 25 years are:

- (1) Practice bears out the theoretical advantages of carbon dioxide. There were only five cases of infection and no deaths.
- (2) Two or more tests, with the pressure advanced to 250 mm. Hg, one at least without anaesthesia, provide a reliable diagnosis of non-patency.
- (3) Primary sterility patients numbering 902 were traced for 12 months; 30% became pregnant. In a group of 253 patients in whom a uterine sound was passed, only 17.7% became pregnant within twelve months.
- (4) The kymograph is a useful adjunct.

"Arterial Grafting" was the subject of a meeting of the Section of Surgery of the Manchester Medical Society at which Professor C. G. Rob spoke on December 12, 1953. He began by outlining the history of the subject. In 1912 Carrel had been awarded the Nobel Prize for his researches on blood vessel grafting and the transplantation of tissues and organs; in 1913 Lexer reported that he had resected three aneurysms of peripheral arteries and restored continuity with an autogenous vein graft. The first successful arterial graft in man was inserted by Gross in 1947; he established an artery bank based on the principles elaborated by Carrel. The indications for blood vessel grafting included congenital abnormalities, such as certain coarctations of the aorta, some aneurysms and arterio-venous fistulae, wounds, primary thromboses, after some emboli, occasionally in malignant disease, and in arteriosclerosis after very careful selection. Most of these indications were obvious, but the question of arterial grafting in patients with arteriosclerotic occlusion of major vessels was debatable. These patients had a general disease; the arteriogram often showed a lesion anatomically suitable for grafting, but one was treating a patient and not an arteriogram. In all Professor Rob had grafted 35 arteries, but had treated in this way less than 3% of patients with arteriosclerosis who presented with the complaint of intermittent claudication.

DIAGNOSIS AND TREATMENT OF GALACTOSAEMIA

BY

F. PIERCE HUDSON, M.R.C.P.Ed., D.C.H.

Paediatrician

(From the Alder Hey Children's Hospital, Whiston County Hospital, and the Department of Child Health, University of Liverpool)

Galactose, formed during the metabolism of lactose, is normally converted into glycogen in the liver. In the condition known as galactosaemia this process is defective, resulting in a high concentration of galactose in the blood and its excretion in the urine. It is probable that galactose in such concentrations is toxic to some tissues and is itself responsible for the main pathological changes, but the exact pathogenesis is still uncertain. This disease is of more than academic interest because prompt treatment may bring excellent results. The original clinical description was by von Reuss (1908). Göppert (1917) was the first to report a familial incidence. Articles on the subject have appeared with increasing frequency in the past seven years, mainly in American paediatric journals. Gorter (1951) gave an account of the disease at a meeting of the British Paediatric Association, but no cases were reported in this country until Bray, Isaac, and Watkins (1952) published three and gave a full review of the literature. We know of other cases that have been diagnosed in this country, but we feel sure that knowledge of the disease is not yet widespread enough. An increased awareness will lead to earlier and more frequent detection of the disease.

The earliest signs appear in the neonatal period. The infant is reluctant to feed, may vomit occasionally, and is slow to gain weight. Jaundice is common but varies in intensity. In the most severe cases deep jaundice and ascites develop in 4 to 5 weeks and the infant dies from hepatic failure. In milder cases the infants pass gradually into a state of marasmus, and at 6 months may be only a few ounces over their birth weight. Enlargement of the liver is a constant physical finding, the edge being firm and extending nearly to the umbilicus. The spleen may be palpable. Lamellar cataracts are often found, but are not easy to detect in the early stages. Mental retardation is usually obvious by the end of the first year. Early routine investigations should reveal albumin and a reducing substance in the urine. The latter must be identified as galactose to establish the diagnosis.

Basically the treatment consists in removing lactose from the diet. When this is done rapid improvement may follow. The appetite returns, the weight increases, and the liver edge gradually recedes. Galactose disappears from the urine in one to two days and albumin a few days later. Cataracts may disappear in cases in which treatment is started early, in others needling may be necessary. Mental impairment has persisted in many

published cases, but further observation is needed to show whether early treatment will prevent this. The galactose-tolerance test is likely to remain permanently abnormal. Two patients at the ages of 18 years (Townsend, Mason, and Strong, 1951) and 7 years (Bray, Isaac, and Watkins, 1952) have been able to take some lactose in the diet without excreting galactose in the urine. Experience of the disease is still too limited for an accurate assessment of the prognosis following treatment. Reports of four recent cases are given below.

Case 1

A full-term male infant weighing 7 lb. (3,175 g.) was born on February 2, 1952. Two siblings were said to have died from pneumonia, one at 3 months and the other at 11 months. It was not possible to obtain information from the mother on the question of consanguinity.

FIG. 1.—Case 1 on admission, aged 3 months.

Early feeding difficulties and poor home conditions necessitated several admissions to hospital and then to a residential nursery. When 3 months old he was transferred to Whiston County Hospital under the care of one of us (R. H. W.-J.). Because of the disproportionate size of his head to his wasted body he was sent in with a provisional diagnosis of hydrocephalus. His weight was 8 lb. (3,630 g.) and his head circumference 15 in. (38 cm.). He was emaciated and miserable (Fig. 1). His heart and lungs were normal; his liver was enlarged, the edge being firm and palpable four fingerbreadths below the costal margin. Because of a wide and rather tense fontanelle a lumbar puncture was performed. The sugar content of the C.S.F. was 222 mg. per 100 ml. (as glucose), the other constituents being normal. This was the first clue to the correct diagnosis. The urine contained albumin but no casts. A reducing substance was present. The latter was thought to be galactose because mucic acid crystals were formed and Tollen's test was negative for pentose and glycuronic acid but positive for galactose. The fasting blood sugar was 190 mg. per 100 ml. (as glucose), and the glucose-tolerance

FIG. 2.—Case 1. Weight curve.

curve was abnormal, rising to 285 mg. after one hour. A paper chromatogram of the urine before starting treatment showed a normal amino-acid pattern.

The mother's Wassermann reaction was negative. The patient's Wassermann reaction was negative; blood urea, 47 mg. per 100 ml.; haemoglobin, 8.9 g. per 100 ml.; thymol turbidity, 3 units; alkaline phosphatase, 6.6 units per 100 ml. serum (King-Armstrong). X-ray films of the skull and long bones showed slight generalized osteoporosis. Mr. J. M. Broderick (ophthalmic surgeon) reported fine but distinct lineal opacities towards the periphery of each lens which were thought to be early lamellar cataracts.

From the time of admission the baby was reluctant to take feeds of dried milk and sometimes vomited. In the first week he lost 1 lb. (454 g.) in weight. A formula containing lactose-free protein, "dextri-maltose," and fat was given, but this was persistently refused and it was necessary to return to unmodified dried milk. When "nutramigen" was obtained the effect was dramatic. From the first feed the baby took well, and the weight, which had remained at about 7 lb., began to rise steeply and continued to do so (Fig. 2). The liver gradually returned to normal size, the cataracts disappeared, and the urine remained free from reducing substances. A galactose-tolerance test (Fig. 3) was performed when the baby weighed 15 lb. (6,800 g.). This helped to confirm the diagnosis, but for two weeks afterwards he was apathetic and listless, and lost weight. When 11 months old his condition had greatly improved (Fig. 4); he could raise his head from the pillow, smile, recognize people, and play with a rattle. He continued to take nutramigen well, and later had a lactose-free mixed diet.

Case 2

This infant, the first baby of healthy and unrelated parents, was born in 1949. She weighed 6 lb. 8 oz. (2,948 g.) at birth, and was delivered spontaneously after an uneventful pregnancy which went to term. Slight jaundice was present on the sixth day. It was deeper on the ninth day, and as she was feeding badly she was admitted to Alder Hey Children's Hospital. She was afebrile, the um-

FIG. 3.—Case 1. Galactose-tolerance curves (1.75 g. galactose per kg. body weight).

FIG. 4.—Case 1 aged 8 months.

Case Report

A male infant aged 4 months was admitted to hospital on August 30, 1951, because of failure to thrive. He was born at term, weighing 7 lb. 10 oz. (3.5 kg.). The labour was normal. His mother thought that he was a little jaundiced for a few days after birth. Breast feeding was not attempted and the baby was fed on a proprietary food until admission to hospital. Although he took his feeds eagerly and neither vomited nor had diarrhoea, he did not thrive prior to admission to hospital. His mother, father, and brother aged 4 years were stated to be in good health. The brother was examined clinically and no abnormality was detected.

On admission the infant did not look ill but was obviously underweight. His weight was 8 lb. 9 oz. (3.9 kg.), temperature 98° F. (36.7° C.), pulse 146, and respirations 30. On clinical examination the only abnormality was a firm enlargement of the liver to three fingerbreadths below the costal margin. The haemoglobin was 80% Sahli, the white blood cells numbered 21,000 per c.mm., and his blood was group O Rh-positive. The mother's blood was group O Rh-positive. On chemical examination of the urine no albumin or sugar was detected and microscopically no white blood cells or red blood cells were seen. Urine culture gave a light growth of *Streptococcus faecalis* and *Bact. coli*. The stools appeared to be normal, and on culture no pathogens were obtained. The Mantoux reaction (1:1,000) was negative. The Wassermann reaction was negative.

The infant fed well on full-cream National dried milk, but did not gain weight. Throughout the course of his illness bouts of pyrexia, as described above, occurred. The urine was repeatedly found to be normal, both chemically and microscopically, until the 35th day after admission, when a trace of albumin was detected. This albuminuria persisted, and on the 46th day Benedict's test became positive. Further laboratory investigation (see below) showed this reducing substance to be galactose. On the 97th day the infant was put on a lactose-free soya-flour mixture, which he took well. This resulted in the urine becoming sugar-free within 48 hours. He started to gain weight and his general condition improved, although there was no change in the size of his liver. A return to milk feeding for 24 hours resulted in the reappearance of a positive Benedict's test and the development of slight pitting oedema. However, these both disappeared when a lactose-free diet was recommenced. On the 147th day he developed an upper respiratory infection with pyrexia, vomiting, and diarrhoea. Chloramphenicol therapy was instituted. His condition appeared to be improving, when on the 156th day he collapsed suddenly after a feed and died within a few seconds.

Biochemical Investigations

Urine.—Chemical and microscopical examinations for cystine were negative on four occasions (October 17 and 25, and November 2 and 19). Amino-acid nitrogen on October 17, 23, and 31, and November 2 and 19 was 60, 116, 35, 40, and 30 mg. per 100 ml. respectively.

Blood.—September 6: serum proteins, 5.5 g. per 100 ml.; serum albumin, 4.2 g. per 100 ml.; serum globulin, 1.3 g. per 100 ml.; serum bilirubin, 0.5 mg. per 100 ml.; serum alkaline phosphatase, 42.1 units per 100 ml.; thymol turbidity, 3 units. October 16: blood urea, 31 mg. per 100 ml.; blood cholesterol, 140 mg. per 100 ml. October 17: serum alkaline phosphatase, 23.5 units per 100 ml. October 26: serum proteins, 6.25 g. per 100 ml.; serum albumin, 4 g. per 100 ml.; serum globulin, 2.25 g. per 100 ml.; serum bilirubin, 1.4 mg. per 100 ml.; serum alkaline phosphatase, 15 units per 100 ml.; thymol turbidity, 3 units. November 9: blood-sugar curve after 20 g. glucose orally was: fasting specimen, 110 mg.; ½ hour after 20 g. of glucose orally, 194 mg.; 1 hour after, 206 mg.; 1½ hours after, 183 mg.; 2 hours after, 181 mg. per 100 ml. (Further investigations were planned—for example, galactose-tolerance test—but owing to the clinical condition of the patient these were not carried out.)

Identification of the Reducing Substance in the Urine.—The reducing substance present was provisionally identified as galactose on the following grounds: it was not fermented by yeast; Bial's test for pentose was negative; Tollens's phenylglucosyl test was positive on prolonged boiling, as with pure galactose. The osazone was identical in crystalline form and in melting-point with that prepared from galactose. No depression of melting-point was produced on mixing the osazone isolated from the urine with known galactosazone. Mr. A. P. Kenny kindly confirmed the identification of the reducing substance in the urine by means of paper partition chromatography. He reported that the conclusion to be drawn from the chromatograms was that the principal reducing sugar in the urine was galactose, with a possible trace of free amino-sugar in certain specimens.

Aminoaciduria.—In no specimen of urine was the gross aminoaciduria recorded by Holzel *et al.* observed. Dr. H. Ellis C. Wilson kindly carried out two-way paper chromatograms of the urinary amino-acids. No gross aminoaciduria was observed. The following amino-acids were identified: glutamic acid, glycine, threonine, glutamine, alanine, phenylalanine, valine, histidine, oxyproline and nephrotoxic peptide.

Post-mortem Examination

The liver was regularly enlarged and of normal contour. On section there was marked pallor of the parenchyma with blurring of the lobular markings in places, giving a homogeneous appearance to the liver tissue. The lungs showed superficial areas of collapse in both lower lobes and there was congestion of all lobes, most marked basally. There was also marked pallor of the renal parenchyma and of the bowel mucosa.

Histology

The liver showed a diffuse monolobular cirrhosis with early fibrosis, formation of new bile ducts, and round-cell infiltration in the portal tracts. A few foci of round cells were seen among the liver cells. There was no glycogen present in the sections of liver examined. The ileum showed congestion of Peyer's patches with some lymphoid hyperplasia and slight round-cell infiltration in the villi. The mesenteric glands showed sinus hyperplasia. The spleen showed congestion of the pulp with reticulo-endothelial hyperplasia.

Discussion

Portal cirrhosis is a recognized complication of galactose diabetes, and although several theories have been advanced to explain its occurrence none has gained general acceptance. One theory is that the portal cirrhosis is due to galactose being directly toxic to the liver; another that it results from the absolute or relative hypoglycaemia which accompanies galactosaemia; while a third suggests that an inadequate diet leads to a deficiency of lipotropic substances.

The discovery by Holzel *et al.* of aminoaciduria in two patients suffering from galactose diabetes suggested a further possible explanation—namely, that a deficiency of lipotropic substances results from an excessive urinary loss of these. Such a mechanism has previously been suggested by Himsworth (1950) to explain the cirrhosis of the liver present in hepato-lenticular degeneration and Fanconi's syndrome, in both of which aminoaciduria occurs.

In the present case cirrhosis of the liver developed, although there was no gross aminoaciduria. However, the work of Bickel and Hickmans (1952) suggests that some of the amino-acids found do not occur in normal urine.

Summary

A case of galactose diabetes complicated by cirrhosis of the liver is described. The biochemical investigations are detailed with special reference to the identification of galactose in the urine and to the detection of the amino-acids in the urine. The pathogenesis of the cirrhosis of the liver is discussed.

We are indebted to Dr. J. B. McMillan, of Stobhill Hospital, Glasgow, for the pathological report; and to Dr. H. Ellis C.

Wilson, Royal Hospital for Sick Children, Glasgow, and Mr. A. P. Kenny, Victoria Infirmary, Glasgow, for undertaking the chromatography.

ACRODYNIA ASSOCIATED WITH
EXCESSIVE INTAKE OF
MERCURY

BY

J. G. DATHAN, M.R.C.P.E., D.C.H.

Consultant Paediatrician to the Stoke-on-Trent Group of Hospitals

Acrodynia is a disease of comparatively recent recognition, being first described in detail by Swift (1914) in Australia, and not reported in England before 1922. Since these earlier descriptions the disease has been recognized with increasing frequency in Europe and America as well as Australia, and in England it appears to be particularly prevalent in the neighbourhood of large industrial towns and cities of the North and Midlands—a distribution which may be of some significance, as is shown later. Another feature of some possible significance is the rather unusual fact that this disease is exceptional in that it affects breast-fed just as readily as artificially fed infants.

It being accepted that the cause and pathogenesis of acrodynia are unknown, it is not surprising that there have arisen a number of theories as to its origin, none of which is proved or even generally accepted. Warkany and Hubbard (1948) recorded several cases in which they suggested that the cause might be chronic metallic poisoning, incriminating mercury, and, in particular, the mercury administered so often to infants in the form of teething powders.

Bivings (1949) summarized all the recorded cases of acrodynia and found that mercury had been present in the urine of 28 out of 31 patients examined. He recorded also that of 15 patients treated with dimercaprol at least 11 showed prompt improvement or recovery; that is to say, these patients responded to the accepted treatment for mercurial poisoning.

There have been other brief references to the association of acrodynia with high levels of mercury in the urine, notably by Gaisford (1949), who states that in Manchester, where the condition is common, there is in almost every case a history of the ingestion of mercury, usually as calomel in teething powders. He states later (1950) that the general consensus of opinion appears to be that acrodynia is a general reaction to some poison in an infant hypersensitive to the offending substance, in most cases mercury. This opinion has been made widely known to chemists, being quoted in full in the *Extra Pharmacopoeia*, 1952.

Wilson, Thomson, and Holzel (1952), in describing five cases of nephrosis due to mercurial ingestion, urged that mercurial compounds should be eliminated from all teething powders, and that other mercurial compounds, such as grey pills, be used with care, and prolonged administration be avoided in young children. Less than a month later Holzel and James (1952) described 176 cases of acrodynia, over 50% of which gave a history of ingestion of teething powders, whereas of 1,561

healthy infants in the same area only 109, or 6.9%, were habitually given these powders.

Despite these numerous warnings of the potential danger of the administration of calomel to young infants, Miss Hornsby-Smith, replying on behalf of the Minister of Health to a question in the House of Commons in April, 1952, stated: "Inquiries are already in progress at various children's hospitals. Although indiscriminate use of teething powders is clearly undesirable, there is not yet definite evidence to justify general publicity."

Twenty months after that statement it does not appear that the results of the inquiries to which she referred have been made public, nor does it appear that physicians in general as yet regard the theory of Warkany and Hubbard as having been fully substantiated; for no concerted effort seems to have been directed towards the elimination of mercury from teething powders, or even towards the education of the public in the possible harmful results that may follow their administration.

The experience gained from a study of this disease in one of the industrial areas of the North Midlands, where acrodynia is particularly common, emphasizes the need for such action.

Case 1

A male child aged 9 months was seen at his home on August 6, 1952, because he was showing increasing irritability and loss of appetite. He had photophobia, was restless and miserable, sweating, had lost weight, and his hands and feet were puffy and peeling. He had marked tachycardia, and a slight sweat-rash was seen about the trunk—in fact, he presented the typical picture of acrodynia. He had been given teething powders on alternate days for the preceding three months.

On admission to hospital his urine was found to contain 1,450 µg. of mercury per litre. X-ray examination showed that his chest was free from disease and his Mantoux reaction was negative.

Treatment with dimercaprol was begun: 34 mg. for the first dose, followed by 17 mg. four hours later, and 17 mg. twice daily for a further two days. Ephedrine sulphate, 25 mg., was given orally before each injection.

By the fourth day after the starting of treatment the child seemed much happier, and the photophobia was less. After this course of treatment the urinary mercury dropped to 860 µg. per litre. A further course was given, using the same dosage of dimercaprol, following which his urinary mercury dropped to 300 µg. per litre.

At this stage the child became feverish, although his general condition was vastly improved, and an x-ray film showed an opacity in the right upper lobe. This took several weeks to resolve, not responding to antibiotics at all. At the same time radiographs of his long bones showed no abnormality; his serum calcium was 10 mg. and phosphorus 4.3 mg. per 100 ml.

A month later x-ray examination showed extensive decalcification of the long bones. As a result of this he was given "sterogyl," 300,000 units monthly, with calcium and phosphates by mouth daily, and it was decided not to give a further course of treatment with dimercaprol. A series of x-ray examinations showed that the decalcification had been arrested. Some six months from his admission to hospital his urinary mercury was down to 90 µg. per litre, his skeleton presented normal radiological appearances, and his general condition was satisfactory.

Case 2

A male child aged 10 months was admitted to hospital presenting the typical picture of acrodynia, except for the absence of any photophobia, and with a history of having been given teething powders on alternate days for a period

samples of mature milk from the 21st day of lactation or later were collected from a variety of sources; two subjects were still lying-in patients of the Aberdeen Maternity Hospital on account of post-partum complications; nine were resident in the mother and baby unit of the Royal Aberdeen Hospital for Sick Children with babies requiring some medical or surgical treatment; and another nine had been admitted with some feeding difficulty. Ten subjects were unmarried and living in the Aberdeen Mother and Baby Home. From eight of these latter subjects and from three others samples were obtained on the seventh post-partum day and also later in lactation. (c) From five women whose infants were premature and unfit to be put to the breast samples were obtained on a number of days during the lying-in period, and, from two of these, further samples were obtained by manual expression.

Method.—The whole contents of both breasts were removed by the "humalactor" at the usual feeding-times of 6 a.m., 10 a.m., 2 p.m., 6 p.m., and 10 p.m. After the last feeding prior to the sampling period the

maintain a stable fat content in the more rapidly increasing total milk yield. The trend beyond the end of the first week is illustrated by Table VI, in which 11 subjects, from whom samples were collected on the seventh day and again later in lactation, are detailed. The day of lactation on which the second specimen was taken is shown in the last column.

Four cases from whom serial milk samples were taken during the first nine days of lactation, showing the steep drop in total nitrogen content which occurs in the first three days, after which there is a gradual fall and a convergence to a narrow range of values.

It is clear, even from these few samples, that there is a rise in the fat content of milk beyond the seventh day, but, more important, Table VI shows that, unlike nitrogen and lactose, there is no tendency for the range to narrow towards what

TABLE VI.—Fat Content of Milk on the Seventh Day and in Mature Milk in Eleven Subjects

Case No.	7th Day Fat (g./100 ml.)	Mature Milk	
		Fat (g./100 ml.)	Day of Collection
74	2.20	2.55	30
75	3.20	4.00	135
110	2.70	2.95	53
116	2.70	3.60	48
119	3.00	3.90	41
121	4.10	4.65	62
139	3.60	3.90	50
163	3.65	4.15	48
183	3.20	3.75	28
205	3.10	4.90	58
235	4.20	4.70	42

might be a physiological norm. The difference which occurs between subjects at the seventh day is maintained, and there is a high correlation between the fat contents of the seventh-day milks and the fat contents of more mature milks ($r = +0.88$). There does not appear to be a continuous rise, because mature samples taken two or three months after the seventh day show no greater increment than those taken after an interval of only a month. It is likely, therefore, that the mature fat content of the milk is reached by the beginning of the second month of lactation.

Discussion

Volume.—The few results presented here conform broadly to the accepted picture. The enormous range of milk outputs is well recognized clinically, and has been studied in far greater numbers by the indirect method of test-weighing the baby.

Nitrogen.—The decline in the content of total nitrogen which occurs during the progress of lactation has never been explained. It has been suggested that the initially very high protein content, showing as it does a preponderance of globulin, is due to equilibration with the blood of milk secreted during pregnancy and lying in the acini. But this mechanism cannot explain the further decline which occurs after the milk is being secreted in large volumes. On the seventh day the protein content varies considerably, and in some subjects it is still as high as that found typically on the fourth or fifth day. By the end of the first month these variations have practically all disappeared.

Lactose.—The rate at which the lactose content reaches its mature value also varies, and the values are inversely correlated with total nitrogen content. (The partial correlation coefficient of lactose with total nitrogen, volume and other constituents remaining constant, was -0.49 , significant at 0.1% .) Thus, if milk on the seventh day has a low lactose content, then it will almost always have a high protein content, and the milk secretion as a whole will resemble that of earlier lactation. This difference in maturation will be more fully discussed in Part V of this paper, dealing with the seventh-day milk alone. The lactose content of mature milk has a coefficient of variation of less than 4% , and it seems reasonable to consider the value of 6.9 g. per 100 ml. as the physiological norm for the species.

Fat.—There can be little doubt from the figures presented that the fat content of milk increases from the beginning of lactation up to the second month. The fluctuations which occur during the initial stages of lactation appear to be due to an asynchronism between the increasing fat production and the more rapidly increasing total yield of milk, suggesting that there is a separate mechanism for the control of fat secretion. The differences in fat content on the seventh day seem to be the expression of individual characteristics and are not due, like differences in nitrogen and lactose contents, to differences in the speed of maturation of the milk. The fact that these individual differences in fat production are maintained throughout lactation means that the seventh-day sample can be used as a reliable index of the general level of fat production. For example, if the fat content of the milk on the seventh day is low, it will be low at any subsequent point in lactation.

In view of the above findings, it seems worth while to examine the meaning of the word colostrum in relation to human lactation. The colostrum period has been defined in the past by a number of authors as varying from three to twenty days, and some have refined the division still further by adding, between the colostrum and the mature milk, a period for "transitional milk." It is impossible to fix a time for the colostrum period, such as the first seven days, since a number of subjects will be producing milk within this period which is chemically similar to mature milk. It would appear, therefore, that if a term is required which will indicate an immature secretion, then it should be based on the chemical characteristics and not on some arbitrary date-line. Since the term seems to have little practical value in clinical medicine it is not intended to suggest any criterion by which it could be redefined.

Summary

Fat, lactose, total nitrogen, and non-protein nitrogen have been estimated in 240 24-hour samples of milk collected at different stages of lactation from 194 subjects.

During the first week of lactation there is a wide range of values for total milk yield, and for all the constituents examined.

The yield rises rapidly during the first week and more slowly thereafter; the lactose content rises from an initially low level to a stable level of about 6.9 g. per 100 ml. within the first month of lactation; total nitrogen and protein content fall steeply from an initially high level during the first three days and then much more slowly until at least the second month.

The fat content is usually low during the first few days of lactation, but increases slowly to a level which is characteristic of the individual by the second month. The value, however, is stable enough by the seventh day to indicate fairly accurately the fat content of the mature milk in the individual case.

The use of the term "colostrum" is discussed.

V. INDIVIDUAL DIFFERENCES IN COMPOSITION OF MILK

When all the variations in milk composition which may be due to sampling methods have been eliminated so far as is possible by the taking of 24-hour samples under specified standard conditions (see Part III), the composition of the milk yielded by different individuals varies widely. The study of this variation has been confused in the past by the use of unreliable sampling methods or by the selection of such unrepresentative subjects as professional wet-nurses. There is still a widely held belief that the composition of human milk varies very little, and this point of view has been summed up by Bourne and Williams (1953) as follows: "Researches on the quality of milk, that is the percentages of the main constituents, show that there is not much variation, even under harsh nutritional or other conditions or when the quantity is seriously falling." In the lay mind, on the other hand, the quality of milk is often blamed for unsatisfactory breast-feeding; a plentiful milk supply with a baby losing weight seems to be a not uncommon clinical syndrome.

It has been shown in Part IV of this paper that by the seventh day the composition of milk is stable enough in the individual case to indicate the composition of the mature milk. Detailed studies of individual variations in the seventh-day milk are here discussed.

Methods

All the subjects were in the lying-in wards of the Aberdeen Maternity Hospital. It is necessary to limit studies of individual variation to milks obtained at one period of lactation in order to minimize differences of maturity. The seventh day of lactation was chosen for the reason indicated above and because there was a day or two in which to re-establish the infant at the breast after the 24-hour break, before the mother was discharged from hospital. In addition to these considerations, it is desirable to obtain milk as early as possible in lactation, because breast milk of low calorie value is likely to be replaced before long by artificial feeds, and then will not be available for analysis.

Analyses were carried out on seventh-day milk from 121 primiparae and 29 multiparae. For six of the latter, volume and fat content of the seventh-day milk were known for a previous lactation.

The methods of milk collection and chemical analysis have been detailed in Parts I and II of this paper. The calorie value was calculated by using the factors 9.0 , 3.75 , and 4.0 for fat, lactose, and protein respectively. (The absolute calorie equivalents for human milk are not known, but the above factors are likely to be accurate enough for present purposes.)

Results

The results of the analysis of 150 samples collected on the seventh day have already been given (Part IV, Table II). There was no statistically significant difference in average volume and composition between the 121 primiparae and 29 multiparae.

The fat content and volume of seventh-day samples of milk obtained from six subjects during their first lactation in 1949 and during a subsequent lactation in 1952 are shown in the accompanying Table. No consistent trend can be

Fat Content and Volume of Milk During Two Lactations

Subject No.	Fat (g./100 ml.)		Volume (ml.)	
	1949	1952	1949	1952
52	2.40	1.70*	765	695*
65	3.60	4.50	880	990
66	2.80	2.75	158	220
70	3.30	2.00	910	710
122	2.75	3.40	1,100	930
227	2.50	2.75*	100	235*

* Third lactation; the remainder from 1952 are second lactations.

seen in the Table, but it is curious that in each subject the fat content is different in the two lactations. There is also some clinical evidence of gross differences between lactations of the same woman. Subject 161, for example, had fed her first baby for eight months with great ease (the milk was not analysed), but in the second lactation, although the milk yield was adequate, the baby lost weight and the fat content at seven weeks was found to be only 2.05 g. per 100 ml.

It is clear that more data will be needed to understand changes with parity; meanwhile analyses of individual differences will be restricted to the results from the 121 primiparae.

The mean values, together with their coefficients of variation (to illustrate the relative variability), are as follows:

		Coefficient of Variation
Volume	414 ± 172 ml.	41.5%
Fat	3.17 ± 0.78 g./100 ml.	24.6%
Lactose	6.29 ± 0.45 g./100 ml.	7.2%
Total nitrogen	296 ± 38 mg./100 ml.	12.8%
Protein	1.44 ± 0.22 g./100 ml.	15.3%

The mean calorie value, which is very closely associated with the fat content ($r = +0.97$), was 578 ± 73 calories per litre.

The frequency distributions of values for volume and for fat, lactose, and total nitrogen contents are shown in Figs. 1, 2, 3, and 4. The curves for volume and fat are not significantly different from normal. The distribution of values for lactose is skewed to the left (there is an excess of low values) and significantly so ($P < 0.05$), and the distribution of values for total nitrogen is obviously skewed to the right (an excess of high values), although the deviation from normal is not statistically significant. These deviations from a truly normal distribution suggest that there is a physiological upper limit to lactose content and a lower limit to protein content.

FIG. 1.—The frequency distribution of milk volume secreted on the seventh day. The normal curve is superimposed.

FIG. 2.—The frequency distribution of the fat content of milk secreted on the seventh day. The normal curve is superimposed.

Tests were applied to discover to what extent values for the several constituents were related to each other.* Briefly, it was found that the fat content of a given milk sample is virtually unpredictable without direct analysis. On the other hand, milk produced in large volume is likely to have a high lactose content and a low protein content, and vice versa.

Discussion

It has been pointed out in Part IV of this paper that, when samples from different individuals are considered, the values for the fat contents cover a wide range at all stages of lactation, but that the lactose and protein contents, although they may show a wide range in early milk, converge to within narrow limits as the milk matures. This is confirmed by the present study of the seventh-day milk: the fat content is clearly independent of volume and of lactose and protein, which are equally clearly closely concerned with each other. Simplified, the results indicate that if the volume of a sample is low then the lactose content is likely to be low and the protein content to be high; or that if one of these values is "immature," then the milk as a whole will be "immature." It therefore seems that the differences which are found in lactose and protein content on the seventh day of lactation are due to variation in the maturity of the milk. The skewness of the frequency distributions for the values of lactose and total nitrogen also lends support to this view, the longer tail of

*The regression equations are:
(1) Fat = $1.90(\text{protein}) + 0.0010(\text{volume})$
 $\pm 0.33 \quad \pm 0.0004$

(The effect of lactose was negligible). The standard deviation about the regression line was 0.70, compared with 0.78 for the standard deviation for fat content about its mean.

(2) Lactose = $-0.0062(\text{total N}) + 0.00086(\text{volume}) + 0.0014(\text{N.P.N.}) + 6.80$
 $\pm 0.0011 \quad \pm 0.00020 \quad \pm 0.0003$

The standard deviation about the regression line was 0.34, compared with 0.45 for the standard deviation for lactose content about its mean.

the graph comprising those milks which are maturing more slowly (and are therefore relatively immature at the seventh day), and the more abrupt drop at the other end indicating that a physiological norm is being approached.

Since the fat content of milk retains its wide range of values throughout lactation, it is reasonable to suppose that in mature milk there will be a distribution of fat similar to that shown in Fig. 2, shifted by perhaps 0.5 g. per 100 ml. to the right to accommodate the increase in concentration which occurs as the milk matures. On this basis there will be about 20% of women whose mature milk will have a fat content of 3 g. or less per 100 ml., and a calorie value of 570 calories or less per litre. Assuming that these women are capable of producing a litre of milk daily, which is a high yield (Morrison, 1952), and assuming that the calorie requirements of an infant are 115 calories per kg. body weight (Smith, 1951), then one-fifth of the lactating population will be incapable of adequately nourishing an infant beyond a weight of 11 lb. (5 kg.). The mother who explains her lactation failure by saying "my milk was too thin" may, in fact, be telling the truth.

The reason for these individual differences in fat content is at present obscure. That it should be a peculiarly human characteristic is understandable, since alternative methods of rearing an infant have probably always been available, either by wet-nursing or by artificial feeding, so that selective breeding for the ability to breast-feed, which has occurred in other mammals, has been avoided. However, although the level of fat production is an individual characteristic, it does not appear to be entirely genetically determined, since it is not always maintained in subsequent lactations.

In a later publication the relation of the fat content to a number of physical attributes of the mother, and also to some environmental factors, will be examined.

FIG. 3.—The frequency distribution of lactose content of seventh-day milk. The normal curve is superimposed.

FIG. 4.—The frequency distribution of total nitrogen content in seventh-day milk. The normal curve is superimposed.

Summary

The differences occurring in the composition of milk on the seventh day of lactation have been studied in 150 women, 121 of whom were primiparae.

There is no statistically significant difference between the milk of primiparae and multiparae in this series, but evidence is presented to show that the same individual, in two lactations, may produce milk differing greatly in fat content.

There is a wide range of values for all the major constituents as well as for the total yield at this stage of lactation. The variability of the lactose and protein seems to be due to differences in speed of maturation of the milk.

There is a wide range of fat content, and consequently of calorie value. The fat content is not apparently related to the content of other constituents, and seems to be an individual characteristic. In some milks the fat content is so low that, even with a high milk volume, the child may be undernourished.

IODODERMA OF THE FACE AND MARKED EOSINOPHILIA

BY

R. D. T. CAPE, M.B., Ch.B., B.Sc., M.R.C.P.Ed.
Senior Registrar in Medicine, Selly Oak Hospital; Fellow
in Clinical Investigation, Vancouver General Hospital
(1951-2)

Iodine has a long-established place in the history of medicine. There are few drugs which have been used more freely in the treatment of coughs, syphilis, and thyrotoxicosis, apart from its popularity as a skin disinfectant. Relatively few cases of iodism have been reported despite the commonness of its use and importance in radiological contrast substances.

The present case draws attention once again to the dangers of iodine intoxication and demonstrates two features of some interest—an unusual skin lesion and a pronounced eosinophilia.

Case Report

A 60-year-old white man of French extraction, resident in British Columbia for over 30 years, was admitted to the Vancouver General Hospital on February 27, 1952. Asthma had troubled him at infrequent intervals for many years without producing any severe disability. During 1951 he had two major surgical procedures—a suture of a perforated gastric ulcer in April and a transurethral prostatectomy in November—and during this period his general health deteriorated and his asthma became increasingly severe.

In October, prior to his prostatectomy, he was submitted to intravenous pyelography, and developed a severe but temporary reaction to the iodine-containing contrast substance. In November, for a four-week period following his operation, he was given 5 gr. (0.32 g.) of potassium iodide three times a day in an attempt to avoid any fibrous con-

traction of the prostatic bed. During January, 1952, his asthma became more troublesome. Towards the end of the month he treated himself with proprietary asthma tablets, each containing about 1½ gr. (0.1 g.) of potassium iodide. He took an average of six tablets daily. A few days after beginning this treatment he noticed red vesicular raised spots appearing on his arms and trunk. He described them as being like "pimples from which no pus came." By the middle of February he had developed several spots on each malar region, and these gradually spread and coalesced to form fungating tumour-like masses. These lesions and his severe asthma caused his admission to hospital.

Physical examination on admission showed a firm raised reddish mass with an irregular surface over each malar region of the face; severe asthma with an emphysematous chest; hypertension (B.P. 190/108); and a few vesicular spots on the upper trunk and arms.

Laboratory studies on February 28 showed: Hb, 97%; W.B.C., 32,950 (P. 22%, staffs 1%, lymphs 6%, monos 4%, eosins 66%, basophils 1%); N.P.N., 38 mg. per 100 ml. Urinalysis: Sp. gr. 1.022; protein +++; W.B.C. +++; R.B.C. ++; and an occasional hyaline cast seen.

During the week February 28 to March 6 the patient's condition steadily deteriorated and oxygen was given continuously. Treatment included adrenaline, aminophylline, penicillin, and potassium iodide—5 gr. (0.32 g.) three times a day. Bacteriological examination of the facial lesions on three occasions revealed the presence of only coagulase-negative *Staphylococcus albus*.

A sternal puncture and haemogram were performed on March 4, the findings being: (1) Peripheral blood: Hb, 98% (14.2 g.); R.B.C., 5,300,000; platelets, 350,000; reticulocytes, 1%; haematocrit, 44%; W.B.C., 31,800 (neut. polys 16%, neut. staffs 2%, eos. polys 55%, eos. staffs 15%, lymphs 8%, monos 4%). (2) Bone marrow: On a 300-cell differential count 37.3% were lobed eosinophils, 11.3% staff eosinophils, 4.3% metamyelocyte eosinophils, 5% myelocyte eosinophils, and 0.6% promyelocyte eosinophils. The marrow was not as hypercellular as one would expect in a leukaemic condition, and in view of this, the absence of splenomegaly, and the excessive rarity of eosinophilic leukaemia it was felt that the latter was probably not the diagnosis.

On March 6 the patient was seen with a view to the possible administration of A.C.T.H. as a life-saving measure. His condition was critical. The striking lesions on the face had extended and the surface was now a blackish-red colour (Fig. 1). He was in an oxygen tent, his breathing was asthmatic and very laboured and noisy, and he was roused only with difficulty, his answers to questions being irrational. In addition to hypertension he had a marked tachycardia (pulse rate 160) with numerous extrasystoles. Examination of the upper trunk and arms revealed the presence of numerous rounded raised red papular spots of varying size, while similar spots were evident on the chin and ears.

The patient was put at once on intravenous A.C.T.H., digoxin, pethidine hydrochloride, and diphenhydramine hydrochloride, the pre-

FIG. 1.—Photograph of patient showing facial lesions.

vious drug treatment being stopped. After 48 hours under this regime he showed marked improvement, oxygen was discontinued, and a steady uneventful recovery was made.

The day following the change in treatment the full story of iodine intake was obtained and the diagnosis made of iododerma, the facial lesions being typical of some previously described in this condition.

A biopsy from one of the facial lesions was taken. The pathologist reported: "The surface of the lesions is covered by hyperkeratosis and parakeratosis. Extending deeply into the underlying cutis there is marked epitheliomatous hyperplasia with both large and small epithelial pearls. In the centre of many of the smaller projections are minute micro-abscesses. Despite this irregular and marked acanthosis, however, the constituent cells are well differentiated and prickle-cell bridges can be demonstrated. Nowhere does the lesion suggest cytologically a squamous-cell carcinoma, though the picture superficially is somewhat similar. The dermis in both the superficial and deeper parts of the lesion suggests a fibrosis and is heavily infiltrated with subacute and chronic inflammatory cells. The picture is consistent with a diagnosis of iodism."

In all only 85 mg. of A.C.T.H. was given intravenously over a period of eight days, the infusion being kept going almost continuously. The effect of the A.C.T.H. on the eosinophils and 17-ketosteroids is illustrated in Fig. 2.

FIG. 2.—Showing effect of A.C.T.H. on 17-ketosteroid excretion and eosinophils.

During the recovery period the facial lesions slowly regressed. The asthma improved greatly without being completely relieved, while the pulse rate fell to between 80 and 90. The albuminuria remained +++ for about a week, and then gradually subsided, only a trace of albumin being noted on March 20, the day before discharge.

The patient was readmitted three weeks later for further study. At that time his total eosinophil count was about 1,000 per c.mm., his asthma was still troublesome, but the facial lesions had completely disappeared apart from some slight residual pigmentation of the skin. There was no albuminuria.

Comment

This case presents several unusual features which stimulate speculation on the mechanisms involved. Reactions to drugs can be broadly divided into two types; (1) toxic

signs and symptoms due to acute or chronic overdosage, and (2) signs and symptoms due to a personal idiosyncrasy producing hypersensitivity to the drug. In this particular case there are features of both types of reaction. The vesiculo-papular rash and tumour-like masses are recognized features of iodism due to chronic intoxication with the substance, while the sharp reaction to the pyelography and the very high eosinophilia of the later acute illness both suggest a hypersensitivity type of reaction. It is interesting to note that two months after the reaction to the pyelography a four-weeks course of potassium iodide produced no obvious symptoms, but after the beginning of the second course, six weeks later, the rash appeared almost immediately. The first course appeared to be a "sensitizer" which resulted in a hypersensitive response to the second. Seymour (1937) reported a similar effect with iodine applied to the skin. A 7.5% tincture was used for the skin preparation for the induction of an artificial pneumothorax. After the sixth treatment a rash developed which settled in a few hours. Eleven days later the procedure was repeated, and within a week the patient was dead from an exfoliative dermatitis.

The marked eosinophilia in the present case supports the idea of a sensitivity reaction. The patient was susceptible to allergic manifestations, being a chronic sufferer from asthma. As such he may have had a moderate eosinophilia for years, but the level of the eosinophils in the blood in this acute illness was much higher than normally found in asthma *per se*. Iodine in the blood stream is largely bound to protein. "Foreign protein" is regarded as exerting a "chemotactic stimulus" to the production of eosinophilia (Whitby and Britton, 1947). One may postulate, therefore, that in this hypersensitive individual the iodine-protein complex has acted as a "foreign protein."

During the past 20 years two clinical entities have been described in which asthma and extreme eosinophilia are the main features. These are Löfner's (1936) syndrome and tropical eosinophilia. Apley and Grant (1945) thought there was a good case for classifying them under the one heading "eosinophilia with pulmonary disease" or the "E.P. syndrome." Two cases of this syndrome have been reported due to chronic brucellosis (Elsom and Ingelfinger, 1942). Herbert *et al.* (1950) have observed a difference between the two conditions in their response to A.C.T.H. therapy. The present case also shows the main features of the syndrome, and a clear aetiology. It supports the suggestion that the "E.P. syndrome" is probably a non-specific response to a variety of different hypersensitive conditions.

It is difficult to assess the role of A.C.T.H. in this patient's recovery. It seems possible, however, that the hormone did accelerate it. It is of interest to observe the satisfactory response to relatively small amounts of A.C.T.H. administered by slow and almost continuous intravenous infusion. In a previous paper (Cape *et al.*, 1952) it was shown that the minimum intravenous dose of A.C.T.H. given in this way which produced a maximum effect on the eosinophils was about 0.2 mg. per hour. Approximately double this dose was given in the above case with entirely satisfactory results. The fact that this dose will not produce a maximum stimulation of adrenal steroid production suggests that adequate therapeutic responses may be obtained without such full stimulation. The effect on the peripheral eosinophils was dramatic, as in less than 48 hours the count had fallen to 19 per c.mm. from almost 9,000. (See Fig. 2.)

After stopping A.C.T.H. the eosinophils rose to a level varying between 600 and 1,000. This level appeared to be fairly stable, as on the second admission three weeks later it was 1,000. This is consistent with the eosinophilia seen in chronic asthmatics and suggests that this patient did normally have an increased level of the cells in his blood.

The significance of the urinary findings in the acute stage of the condition was not entirely clear in view of the previous history of prostatic trouble. However, older records showed that, while some white cells and a trace of

protein were present in the urine following the prostatectomy, no red cells were found. This and the manner in which the urinary abnormalities cleared up during the recovery period indicate that the iodism was accompanied by a moderately severe degree of an acute renal disturbance, part of a generalized allergic reaction.

Summary

A case of iododerma, with striking facial lesions, is described. The patient was a severe asthmatic treated, *inter alia*, with potassium iodide. Hypersensitivity to the iodine resulted in skin lesions, a marked eosinophilia, tachycardia, and proteinuria.

Recovery followed the withdrawal of iodine and the administration of A.C.T.H.

The mechanism of the intoxication is discussed with particular reference to the significance of the eosinophilia. A comment is made on the so-called "E.P. syndrome" and on the effect of A.C.T.H. in the recovery of the patient.

I would like to thank Dr. A. S. Turner for permission to publish this case, and Dr. R. A. Palmer, director of the metabolic unit, Vancouver General Hospital, for his stimulating advice and criticism.

PRE-ERYTHROCYTIC STAGES OF HUMAN MALARIA: PLASMODIUM OVALE

A PRELIMINARY NOTE

BY

P. C. C. GARNHAM, M.D., D.Sc., D.P.H.

R. S. BRAY, B.Sc.

W. COOPER

R. LAINSON, B.Sc.

F. I. AWAD, B.V.Sc., M.R.C.V.S.

AND

J. WILLIAMSON, M.Sc., Ph.D.

From the London School of Hygiene and Tropical Medicine

Four species of malaria parasites are found in man—*Plasmodium vivax*, *P. falciparum*, *P. malariae*, and *P. ovale*. Pre-erythrocytic stages of *P. vivax* were demonstrated by Shortt *et al.* (1948) and of *P. falciparum* by Shortt *et al.* (1949) and Jeffery *et al.* (1952). Elucidation of this cycle in the remaining types presents two special difficulties: (1) the comparative rarity of the parasite, and (2) the poor infections usually obtainable in mosquitoes (an essential factor for success of an experiment of this kind is a large supply of heavily infected mosquitoes). Fortunately, *P. malariae*—the agent responsible for quartan malaria—has a replica in monkeys, *P. inui*, which in length of blood cycle (72 hours), length of infection in mosquitoes, and morphology closely resembles the human form; and the demonstration by Garnham (1951) of the tissue cycle of *P. inui* probably indicates the nature of the pre-erythrocytic stage of *P. malariae*. No such simian counterpart exists

in the case of *P. ovale*, and a human experiment was necessary if the problem were to be solved. A further practical difficulty to-day is the scarcity of cases of general paralysis in need of malaria therapy; practically none were available for this experiment, and, except for a short break when the infection was kept at Horton Mental Hospital, the strain had to be maintained amongst ourselves. The strain was obtained from Dr. A. R. D. Adams, who had originally isolated it from a patient from Liberia and had passed it through two patients by blood transfer before sending it to us.

The Experiment

Repeated attempts to infect mosquitoes (*Anopheles maculipennis atroparvus*) were made, but results were poor until the last trial (on J.W.), when 84% of a batch of approximately 750 became infective, with concentrations of sporozoites in the salivary glands varying from heavy to very light. These mosquitoes were allowed to feed on one of us (W.C.) on December 18, 19, and 22, 1953; many were made to bite more than once on each day by the process of interrupted feeding. Nine days after the first feed Mr. H. R. I. Wolfe excised a wedge-shaped piece of liver (about 1½ inches at the base) from the patient's left lobe.

Sections were prepared, and revealed the presence of pre-erythrocytic schizonts of *P. ovale*. A few hours after the operation the blood of the patient became flooded with ring forms of the parasite. The tissue forms were in two stages, nearly mature and completely mature schizonts. Their morphology more resembles that of the quartan parasite than of *P. vivax*, but further study of material is necessary before a definite conclusion about the affinities of this parasite can be reached.

Acknowledgments.—We are indebted to Dr. A. R. D. Adams for providing the strain and to Sir Gordon Covell and Mr. P. G. Shute for help in maintaining it. We are very particularly appreciative of the generous help of workers in Dr. Martin D. Young's laboratory in Georgia, U.S.A.—and particularly Dr. G. M. Jeffery—for taking the strain and passing it through numerous patients and mosquitoes, for the purpose of supplying us with an infective batch of mosquitoes if our own experiments had failed. We gladly acknowledge also the invaluable assistance rendered by the surgeon, Mr. H. R. I. Wolfe, Mr. R. Molloy, anaesthetist, and Professor A. W. Woodruff, Dr. S. Bell, and other members of the staff of the Hospital for Tropical Diseases, where we were looked after with kindness and efficiency.

The Invalid Children's Aid Association's John Horniman Home at Worthing, Sussex, will admit from next April children (girls 7-16, boys 7-14) who need holidays, or care in family crises, but are so severely handicapped that they cannot be received in ordinary convalescent homes. It is hoped to provide for such cases as those with spina bifida, poliomyelitis, congenital deformities, haemophilia, muscular dystrophy, cerebral palsy (I.Q. not below 65), fragilitas ossium, and heart disease (congenital or rheumatic if quiescent). Children suffering from mental defect, epilepsy, blindness, or pulmonary tuberculosis cannot be received. The daily programme will be designed to provide the children with as many interests as possible, and will include handicrafts, painting, modelling, and probably a Guide company and Scout troop. Physiotherapy will be available. Holidays may be arranged ordinarily up to eight weeks. Accommodation will also be available for one or two nights for mothers whose presence may help a child to settle happily. Inquiries should be directed to the general secretary of the association, Miss Rattenbury, 4, Palace Gate, London, W.8.

Medical Memoranda

Thiopentone Injection into an Aberrant Artery

The following case is reported because of its unusual character and as a warning to anaesthetists to be ever alert against the possibility of inadvertent intra-arterial injection.

CASE REPORT

The patient, a woman aged 35, was admitted for dilatation and curettage. A venipuncture was made into what appeared to be a vein in the middle of the proximal part of the ventral aspect of the right forearm (at the point marked X in Fig. 1). About 2 ml. of 5% sodium thio-

FIG. 1.—Photograph of the patient's forearm. The black line shows the course of the aberrant vessel.

pentone had been injected when the patient complained of burning pain passing down the arm to the hand. Injection was stopped and the "vein" palpated; it was found that, proximal and distal to the point of injection, along the line of the "vein," pulsation could be felt. The needle was kept *in situ* and 5 ml. of 2% procaine slowly injected through it. On removal of the needle after injecting the procaine, blood issued from the puncture in little intermittent spurts. The pulse in the punctured artery was observed for some minutes; it remained unaltered. Anaesthesia was restarted and the operation carried out uneventfully. The patient was kept under careful observation for a few days before discharge; the colour, temperature, and pulses in the right arm remained unaltered.

An angiogram was taken two days later (Fig. 2). It showed the aberrant vessel arising at the bifurcation of

FIG. 2.—Angiogram of right forearm

the brachial artery and pursuing its course through the forearm to the ulnar border of the wrist. It will also be seen that the brachial artery bifurcates above the level of the elbow joint.

COMMENT

The vessel injected in this case was almost certainly an aberrant ulnar artery. Gray (1935a) states that when the ulnar artery arises above the elbow "it is usually superficial to the flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and the skin." In the present case the vessel was certainly subcutaneous. Macintosh and Heyworth (1943) report two cases of intra-arterial injection of thiopentone, in one of which the injection was made into an aberrant ulnar artery.

They also quote a further case in which thiopentone was injected into an aberrant ulnar artery (Van der Post, 1942).

Other arteries in the arm may occasionally be mistaken for veins. Thus, according to Gray (1935b), the radial artery occasionally takes a superficial course through the forearm. Again, Hoyer (1944) states that sometimes "the brachial artery takes an abnormally superficial course through the antecubital fossa."

It is recommended that, in order to avoid puncturing a superficially placed artery in mistake for a vein, the vessel to be injected should always be palpated *before* the tourniquet is applied to the limb.

I am grateful to the staff of Hope Hospital, Salford, for their co-operation.

Presternal Oedema in Mumps

The occurrence of swelling over the manubrium sterni in cases of mumps does not appear to be well known in this country, and references to it in the literature are scanty. Radin (1918) writes: "There are a few cases in which mumps expresses itself by a general swelling of neck and chest, like Hodgkin's disease, a doughy gelatinous mass. . . . There is no tenderness. The tissues are soft and elastic and are easily agitated. . . . Rarer symptoms . . . were . . . dysphonia." He presents evidence of thymus enlargement in one case with presteral oedema. Barker (1943) reported three such cases from an outbreak involving 438 persons. Two of these three had dysphagia, and in one the epiglottitis and the right wall of the hypopharynx were seen to be swollen. Rappaport (1943) described two cases, both boys and both with mumps of normal severity. In an outbreak of mumps involving 502 patients at Fort Benning, Georgia (Gellis and Peters, 1944), 30 cases developed presteral oedema, two of them with dysphagia also. Twenty-five had one or both submaxillary glands swollen at the time the presteral swelling became evident, whereas the other five had parotid mumps only.

Among 263 cases of mumps encountered in a semi-rural area of Gloucestershire presteral oedema was seen five times, twice in males aged 4 and 8, and three times in females aged 4, 7, and 41. The circumstances of the study make it likely that the true incidence is far higher than these figures suggest, and that presteral oedema is as common a feature as swelling of the gonads. In our cases the oedematous area varied in size, sometimes attaining 3 in. (7.5 cm.) in diameter. The skin covering it was of a normal colour, and in at least one case pitting definitely occurred. Gellis and Peters reported that the skin became a dull red over the swelling in 3 of the 30 cases. The degree of presteral swelling was unrelated to the severity of the glandular involvement.

In describing his first case Barker mentioned that the oedema seemed to be more gelatinous than ordinary oedema and did not pit well on pressure. Gellis and Peters state that in all their cases the oedematous tissues pitted easily, and they demonstrated the fact by lateral soft-tissue x-ray films. Probably the swelling is due to obstruction of the lymphatic drainage, but it is a little difficult to see how this is brought about mechanically in those cases in which the parotids only are involved.

Reviews

THE KINSEY REPORT

Sexual Behavior in the Human Female. By Alfred C. Kinsey, Wardell B. Pomeroy, Clyde E. Martin, and Paul H. Gebhard. (Pp. 842; 115 figures. 50s.) Philadelphia and London: W. B. Saunders Company. 1953.

The advertisement columns of the *Journal* have described this as "the most discussed and controversial book of the year." It has already received important notice by the more responsible press in this country, as well as lurid comment by those papers which enjoy a reputation for the unwholesome exploitation of sex and crime. It has not escaped the attentions of music-hall comedians—even those employed by the B.B.C. Indeed, the name of Kinsey is as well known to adolescent boys (and possibly girls as well) as was that of Freud in the days when their parents and grandparents were young.

This kind of introduction prejudices the reader's approach to the book; and a detached appraisal is made even more difficult because sex is so strong and basic an instinct that it cannot be viewed without an emotional bias governed by the personal experience and upbringing, and, in the case of the doctor, by the disclosures of his patients. This is well illustrated by the report itself. It sets out to be an impartial scientific statement of facts, but the authors cannot resist commenting on moral implications. They suggest, for example, that if premarital coitus were not taboo then homosexual practices might be prevented in large measure. The fact that 2,094 of their unmarried women who admitted coitus had produced 476 pregnancies is dismissed by pointing out that this means only one pregnancy in 1,000 sexual acts, and that methods of contraception are improving and becoming more widely known. Forty-four cases of venereal disease amongst these women is counted of little consequence because the treatment of these conditions is becoming more efficient. Again, figures in the report show that those men and women who have sinned according to the moral or legal codes of the community are less likely to condemn similar transgressions by others and are more likely to transgress again. Those who are sexually promiscuous before marriage are more likely to be unfaithful after marriage. fore marriage should be emphasized that the approach

Nevertheless it should be emphasized that the approach is basically scientific and the authors have set out to supply facts to replace impressions. The report is a companion to one on *Sexual Behaviour in the Human Male*, which was also written by Dr. Kinsey and his associates of the Institute of Sex Research at Indiana University and published in 1948, and the authors have wisely included summaries of their previous findings for purposes of comparison. The book is divided into three main sections. The first provides a general historical background and describes the methods of sampling and statistical analysis used in the inquiry. The last is concerned with the anatomy, physiology, and psychology of sex and sexual responses in both male and female. Nervous and hormonal controls are discussed, and there are interesting observations on the effect of castration on sex drive. The detail given and the variety of the approaches can be judged by the fact that there are even reproductions of electroencephalographs taken during orgasm in the human being.

The middle section and the main body of the report consist of an analysis of confidential information given by 5,940 white women interviewed during 15 years up to January 1, 1950. During the same period 934 coloured women and 915 white women serving prison sentences were also questioned, but the findings among these selected groups were used only for the general information of the authors. If the 8,603 males questioned at the same time are included, the authors' views and findings can be taken generally to be based on a study of 16,392 human beings. To this may be added several other sources of information, including a large literature on both animals and man (the list of refer-

ences occupies 50 pages), not to mention complete records of all the wall inscriptions found in 353 men's and women's public lavatories.

The work involved must have been considerable, for each individual was asked about 300 questions, and the duration of interview averaged 1½ to 2 hours. The writers evidently took great trouble to establish the validity of their data, but they nevertheless recognize that it is not always easy to get the truth, even from volunteers who are guaranteed secrecy by a special code system of recording. It was found in fact that there were not too many discrepancies when men's and women's statements were compared, and, interestingly enough, that women are not more likely than men to distort the truth.

The aspects of sex which are covered are both numerous and diverse. They include homosexual as well as heterosexual experiences of all types and degrees in infancy and adolescence, before and after marriage, and after the menopause. Masturbation, "petting," sex dreams, premarital coitus, extramarital coitus, marital coitus, and animal contacts, all find a place. Incidence, frequency, and techniques are considered as a whole and in relation to age, parental occupation, decade of birth, environment, and religion. No one could complain of lack of detail, and the revelations may surprise many who did not know of or did not wish to admit the existence of certain sexual practices or their extent. Much of it is disturbing as judged by accepted standards unless the reader realizes that terminology can turn an innocent kiss or a harmless flirtation into something rather sinister. Moreover, the figures do not distinguish between lust and love, and the latter is in danger of being completely overlooked.

The ultimate assessment of the reliability of the facts presented and the extent to which they can be applied can be made only by statisticians qualified to judge the methods of sampling and analysis. The authors do not claim that their findings necessarily apply to any except certain communities in their own country. To obtain their material they haphazardly approached a variety of groups of people—the staff and employees of a factory, the members of a church, college and school classes and their staffs, the members of women's organizations, patients attending a certain clinic, etc. These were distributed throughout the States and covered all levels of society in both rural and urban districts. An attempt was made to persuade all in a chosen community to give evidence, but on an average only 75% of women agreed to participate in this soul-searching and passion-probing investigation. It is natural to wonder what motives prompted some to refuse and others to comply. They might be such as to cause considerable distortion of the record in either direction. Again, the distribution of the women investigated by age and by religion is clearly different from that which obtains among the population as a whole. These and other points raise serious doubts about the selection of material.

If the statistics are accepted as reliable for the communities investigated, what is their value? People whose work brings them in close contact with human nature are already aware that the sex impulse is strong, that not all men and women are virginal at the time of marriage or faithful afterwards, and that masturbation occurs almost universally among both sexes at some stage of development. Is it any advantage to have figures which show that 62% of all women masturbate at some time in life, and which indicate the technique and incidence according to age, occupation, religion, and marital status? What value is it to learn, without full knowledge of all the attendant circumstances, that nearly 50% of married women have had premarital coitus (half of them only with their fiancé), and that 90% of women have had petting or flirting experience of one sort or another? The authors argue that "There is an honesty in science which refuses to accept the idea that there are aspects of the material universe that are better not investigated, or better not known, or the knowledge of which should not be made available to the common man." They point out, moreover, that to criticize their presentation on

the ground that it may be misinterpreted or misused is as idle as to condemn atomic scientists for the reason that their discoveries have been turned into atomic bombs. Splitting the atom, however, is a precise impersonal exercise, the validity of which cannot be put in doubt. Is this true of the mathematical dissection of sex? Cold figures take little account of the all-important context and they can distort perspective.

Knowledge for the sake of knowledge is all very well, but the dissemination of a little knowledge and the advertisement of evil can create or aggravate a problem. Would there be any "teenage" problem in the U.S.A. if parents and social workers ceased to talk of it? Would there be so many cosh boys and adolescent delinquents in Britain if crime were not reported in newspapers and gangsterism flaunted in the cinema? Might not many girls whose moral fibre is only as strong as public opinion be influenced in their behaviour by accepting Dr. Kinsey's statements on how many of their sex defy accepted codes either before or after marriage? Morality, after all, is not absolute but relative to the behaviour, opinion, and, indeed, faith of any particular community at any given epoch. And the standards of one community may not suit those of another.

Whatever view is taken of this latest import from the U.S.A.—and, as pointed out above, views will inevitably differ widely and strongly—it would be a mistake to underestimate its importance. It is not only monumental; it carries the backing of a university and has been financially sponsored by a research committee whose members include men of the highest integrity and scientific renown. This report will inevitably serve as a reference book for all concerned with human relations, and will be quoted throughout the world for many years to come. Those who use it and quote from it have a duty to do so wisely.

T. N. A. JEFFCOATE.

PHONOCARDIOGRAPHY

Fonocardiografia Clinica. By A. Caniggia. (Pp. 290; 232 figures. 3,000 lire.) Turin: Edizioni Minerva, 1953.

This book is described as a practical manual for doctors and students. In Britain clinical phonocardiography has no very general use, and in Italy this is the first monograph to be published on the subject. One may at the outset compliment the author on the clarity and elegance of the illustrative tracings; they are indeed excellent. It will be noted that the large majority of the tracings reproduced in this volume are recorded by the logarithmic method. This procedure eliminates any vibrations of too weak periodicity and increases others in a measure which is directly proportional to the sensibility of the human ear. The linear or stethoscopic technique has been used when it was thought important to stress the value of this method or to bring forward evidence of some vibrations of low periodicity. The actual tracings seem to have been done mostly by an oscillographic system which registers the differences of potential by an optical method on a photographic film; perhaps in some cases pens have been used, but it is not clear which they are. The timing is done by means of the electrocardiogram; this is chosen because of the convenience with which such a record can be obtained. Owing to technical difficulties, the jugular and carotid pressure tracings are thought to be less reliable. The author gives various examples of artifacts. He fully discusses the different sounds of the heart, and their modifications are beautifully illustrated. The effect of arrhythmias on the sounds is made very clear. There is an interesting account of gallop rhythm. As usual, in this thorny matter nomenclature introduces certain difficulties. The rest of the book is devoted to the murmurs, and very well illustrated they are. The value of this book does not rest solely on the illustrations; the text is also good. In fact we might say it is really a treatise on auscultation illustrated by phonocardiograms. The book can certainly be recommended, and the illustrations are suitable for teaching students.

TERENCE EAST.

RENAL DISEASE

Mechanisms of Urologic Disease. By Professor David M. Davis, M.D. (Pp. 156. £1 2s. 6d.) Philadelphia and London: W. B. Saunders Company, 1953.

The title of this book suggested an authoritative work on a section of the physiology of the urinary tract which has received less attention than it deserves—the mechanics and hydrostatics of the organs of the urinary system. But the author has preferred to use it to denote the way in which the whole urinary tract is affected when one of the common pathological changes involves one or more of the organs of this system. Thus the first chapter is on obstruction as it affects various organs. This is followed by chapters in a similar manner on infection, stone formation, neoplasms, congenital abnormalities, trauma, and neurogenic changes. In treating his subject on these lines the author briefly describes nearly all the commoner urological diseases and discusses the most recent treatments. But the brief way in which even the most important diseases are dismissed makes it difficult to understand for whom the book was written. The author claims that it was written for beginners and physicians who are not urological specialists, but it is unlikely to help the student pass his examinations, while the physician is unlikely to learn much he does not already know. Nevertheless its brevity allows it to be read rapidly, and the treatments described are the latest and most widely accepted. The chapter on history taking and physical examination is excellent, as is that on the technique of catheterization. This book may appeal to readers who want to refresh rapidly their knowledge of urology from a somewhat novel approach.

J. E. SEMPLER.

CHILD PSYCHOTHERAPY

Practical Child Psychotherapy: A Guide for the General Practitioner. By Curt Boenheim, M.D. Second edition (Pp. 184. 15s.) London and New York: Staples Press, 1953.

Psychotherapy is given an unusually wide connotation in this book, which is written as a guide to the general practitioner. Children provide the most plastic material the doctor encounters, and so all re-educative methods, such as dieting, exercises, environmental changes, and parental instruction, must find a place in child psychotherapy. An exclusively psychological approach, without needed somatic treatment, is bound to fail. Dr. Boenheim holds that the general practitioner should, and indeed must, himself treat the majority of the children who require psychotherapy. Hence the aim of the book is to show the significant part played by emotion in common complaints such as loss of appetite, vomiting, enuresis, stammering, and cardiac neurosis—to mention a few of the topics discussed. Treatment by a specialist or reference to a child guidance clinic will be desirable from time to time. It is not clear where the "minor psychotherapy" conducted by the family doctor ends and that of the specialist begins.

The classification adopted is based on symptoms, and this admittedly is unsystematic. But, it is argued, when symptoms are related to the personality of the child and to environmental influences the method is practical and can give considerable enlightenment on the problem of the sick, peevish, and difficult child. Whereas relief of the symptom can often be considered successful treatment, Boenheim insists that child psychotherapy—presumably by the specialist—should be based on a clear differential diagnosis and distinct indications. There is, on the whole, too much discussion of conflicting opinions on the psychotherapy of infants and children. The family doctor will be puzzled by these, and he cannot be expected to assess their relative merits. The sections on alimentary disorders, enuresis, and stammering deserve special attention.

E. A. BENNET.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 30 1954

ERYTHROMYCIN

Erythromycin ("ilotycin," Lilly; "erythrocin," Abbott), which has hitherto been available in this country only in very limited quantities to hospitals in the National Health Service, will next week be freely obtainable on prescription. A statement issued by the Ministry of Health is published elsewhere in this issue (p. 270). It is more than usually important for the profession to decide what use it should make of this antibiotic. What the consequences of this decision will be depends on one entirely unknown factor, the extent of the natural resources which have yet to be tapped for further antibiotic drugs. If erythromycin is but one of a series of discoveries which is to continue—not indefinitely, for that is inconceivable, but at least for a comfortable period of years—then one can afford to use it freely, confident that when it begins to fail another will take its place. If, on the other hand, it proved that this series had come to an end, we should be well advised to husband our existing resources and to see that erythromycin retained its present inestimable value as long as possible by selective and careful use. It has already been shown¹ that its extensive use rapidly breeds a bacterial population resistant to its action.

Erythromycin has a similar "spectrum" to that of penicillin, Gram-positive organisms predominating among those sensitive to it, although these also include gonococci and other neisserias, *Haemophilus* spp. and rickettsias. There is no doubt of its efficacy in acute infections due to haemolytic streptococci or to pneumococci; thus the average acute sore throat or pneumonia will respond well to it. On the other hand, these species are also invariably sensitive to penicillin and to the broad spectrum antibiotics. It is particularly active, much

more so than penicillin, against *C. diphtheriae*, and should certainly be given an extended trial in diphtheria and even in the less promising task of eliminating the diphtheria carrier state. Without question its greatest usefulness is in the treatment of staphylococcal infections resistant to other antibiotics. That these are now often resistant to penicillin is well known, and we are beginning to be familiar in this country with their resistance also to aureomycin and terramycin, although this condition is so far much less frequent than in the United States, where 36% of strains were recently found to be resistant to these antibiotics at the Mayo Clinic² and 61% in Seattle.³ Such findings refer to hospitals where cross-infection is largely responsible for increasing resistance, but it is in hospital that serious staphylococcal infections often arise, and a drug capable of dealing with them may be necessary in order to save life.

Advantages of erythromycin are ease of administration, which is usually oral, although the intravenous route can be used if necessary, and freedom from toxic effects, other than gastric disturbance from large doses. Although some of the bowel flora, including clostridia, are suppressed, coliform bacilli are insensitive and hence unaffected, and the enteritis sometimes caused by aureomycin and terramycin has not been seen. One minor disadvantage is that according to most authors^{4,5} only low concentrations are attained in the cerebrospinal fluid, and a failure in the treatment of pneumococcal meningitis with subsequent rescue by penicillin has recently been recorded.⁶

The outstanding weakness of erythromycin is the ease with which bacterial resistance to it can be acquired, a property which is illustrated in Dr. D. Hobson's study of the drug published at page 236 of this issue. This change occurs more rapidly than with any other antibiotic except streptomycin, and has been shown to be the cause of failure in the treatment of infections which do not respond readily to treatment, particularly bacterial endocarditis. In the experience of Haight and Finland⁷ staphylococci isolated from the blood of two unsuccessfully treated cases of acute endocarditis had increased in resistance 32- and 250-fold. The results of treating subacute bacterial endocarditis have also been in general unfavourable, although there is some suggestion that erythromycin may be indicated in combination with streptomycin or bacitracin for infections resistant to penicillin.

How should a drug with these properties be regarded in the present situation of antibiotic therapy? Its novelty and efficacy in a wide range of conditions will in the ordinary course of events

VARIATION IN HUMAN MILK

Infant feeding is often a source of worry to the family doctor, and, although feeding troubles are more common in artificially fed infants, everyone with experience of general practice knows that breast-feeding is by no means always free of them. Yet it is considered to be such a natural process, and the product so constant and uniformly adequate and satisfying, that the difficulties and inconstancies associated with it have perhaps received insufficient attention. Why do some mothers with apparently well-developed breasts and an abundant milk supply fail to satisfy their infants? Why do others feed one baby successfully and fail with the next or a subsequent one? What is the particular value of colostrum?

Colostrum has long been recognized as of different composition from mature milk, and great interest has been aroused by the possibility that the infant may absorb immune bodies in it, but its composition and day-to-day variation have not been much investigated. In general, mature milk has been accepted as a fairly constant product containing about 2% of protein, 6-7% of lactose, and 3-4% of fat. That it varies in volume is appreciated, as are the facts that the first feed in the morning is the biggest of the day and that worry or exercise may diminish the flow, but variations in the constituents of the milk at individual feeds and from day to day have not been considered important. Test weighing has generally been the method used in practice to determine the efficiency of breast-feeding, and it is often said that if the infant receives 2½ oz. per pound body weight per day (165 ml. per kg.) he is getting sufficient—without thought of the composition of the milk. The generalization is often made, too, that if an infant is not thriving on breast milk he is unlikely to do better on an artificial feed. There has rightly been much propaganda for breast-feeding, for breast-fed infants are better specimens, withstanding infections better, and, when they do get infections, recovering more quickly. It is difficult to reproduce the intestinal flora found in breast-milk stools with any modification of cow's milk, and this flora is of importance in vitamin synthesis and perhaps also in the production of a growth factor. The end products of protein and fat digestion of cow's milk are different from those of human milk, and the digestive processes are understandably not as complete. Furthermore, any organisms found in normal breast milk are harmless, but great care has to be exercised in the sterilization of cow's milk to ensure constant freedom from harmful bacteria. But it is well to

pause from time to time and examine our basic reasoning for this propaganda for natural feeding. Difficulties in breast-feeding do occur, and not all breast-fed infants are satisfactory in their progress. The reasons for this should be considered.

In a timely series of papers published in this and last week's issues of the *Journal* Dr. F. E. Hytten has drawn attention to the many variations in human breasts and their secretions. His carefully controlled experiments show that in any investigation it is necessary to collect the complete 24-hours milk output, and the mechanism of removing the milk is of great importance if errors are to be avoided. It is not always possible to empty the breasts completely by manual expression, but the use of an electric breast pump gives the maximum yield without disturbing the normal processes of secretion and production. With regard to variations in fat, lactose, and protein during any individual feed, Dr. Hytten confirmed that the fat increased as the feed proceeded and that the sugar decreased. By an ingenious mechanical device he showed that the most likely explanation for the progressive rise in fat was simply the mechanical adsorption of the fat globules on to the secretory and duct surfaces; the change in sugar and protein was probably secondary to the change in fat concentration, though the variation in the protein depended also on the maturity of the milk. In addition to these individual feed variations there is also a diurnal variation, both in quantity and particularly in fat content. Hytten's findings suggest that the volume changes are due not only to the interval between feeds but also to the storage capacity of the breast. He did not find any evidence that there was a constant secretion rate of milk, or that individual variations were due to any genetic influence. Another interesting finding was that milk produced in large volume (and therefore the most likely to find its way to a milk bank) generally had a high carbohydrate and low protein content. Hytten estimated that some 20% of women will have less than 3 g. of fat per 100 ml. in their milk and that it will have a caloric value of less than 570 per litre. It will therefore be incapable of adequately nourishing an infant after he has attained a weight of 11 lb. (5 kg.). Whether such poor milk can be enriched by changes in the mother's diet remains to be seen.

What practical conclusions can be drawn from Hytten's work? Human milk is not a static or constant product; it varies from day to day and from feed to feed perhaps—both in volume and composition, and if an infant is not gaining satisfactorily the explanation should be sought promptly.

First, the possibility of infection or of constitutional disturbance should be considered. Either of these is, in general, more likely to be responsible than faulty or insufficient maternal milk. But if no such evidence is found additions to the diet in the form of complementary feeds should be given. In view of the marked variations in human milk, which are without any ill effect on the infant's digestive tract, it seems illogical to insist on the need for a completely standard composition for artificial feeds; they might well vary as much as human milk without any detriment. So long as the milk offered is of adequate caloric value, clean, and digestible, and contains a sufficient amount of protein and carbohydrate and is supported by vitamin supplements, strict insistence on the exact composition of the formula is not of first importance. Few general practitioners will have the facilities available for examination of the mother's milk and may well be in doubt both about the total volume secreted and about the infant's caloric intake over 24 hours. Common sense must prevail in infant feeding, as in every other branch of medicine, and the decision to wean an infant, or to give complementary feeds, must be made at the doctor's discretion, with the infant's general condition and progress in mind above all else.

TEETHING POWDERS

Purging the newborn has been a traditional custom for many centuries, inspired perhaps by a desire to rid the infant of inborn evil spirits. So long ago as 1748 Cadogan objected to this practice, complaining that nurses "often do much harm where they intend to do good, by fancying Nature has left a great deal to their Skill and Contrivance." But in the nineteenth century and up to the present day various purgative mixtures have found a ready sale to the public as "teething powders," and countless millions have been forced down the throats of helpless infants. Indeed, mothers often give the powders to children of all ages as a laxative regardless of the claim that they assist teething. Others have confined themselves to giving one when the child is fretful "to soothe it" or "to cool the blood," but many give a regular dose as a kind of charm to ward off unknown hazards ahead. It has even been known for a mother to dip her finger in the powder and rub her baby's gums with it. Grandmothers impress upon their daughters the value of such remedies just as their mothers had done before them, and the popularity of these products has been maintained, against all medical progress, for over a century.

In recent years opinion has been growing among paediatricians not only that such powders are ineffective but that they have been dangerous also. The taint but that they have been incriminated as an important

tant aetiological factor in pink disease and also in some cases of nephrosis.¹ Dr. J. G. Dathan shows in a paper at page 247 of this issue of the *Journal* how dangerous they may be. It is not certain whether other factors are involved in the causation of pink disease (many have been postulated), but there will be a good opportunity for investigating the residual cases which occur after the present supplies of powders containing calomel have disappeared from the chemists' shops—provided all concerned follow the lead already given by one manufacturer in marketing these powders without calomel in future. If they fail in what is now their obvious duty, Parliament will no doubt intervene immediately, and it is to be hoped that there will be no need for the legal prohibition sought by Mr. S. T. Swinger, M.P., on January 21.² It would be as well also for doctors to refrain from prescribing grey powders for such conditions as jaundice, skin rashes, or gastro-enteritis, for which calomel has been a time-honoured remedy.

In paediatrics the aim should be to interfere as little as possible with the course of nature where normal processes are concerned. Non-interference is now recommended for many aspects of the care and management of the newborn; thus, the premature baby is left undisturbed for several days after delivery, the ritual of frequent bathing and vigorous cleaning of the mouth and eyes has been curtailed, restrictions on the time and quantity of feeds have been relaxed, unnecessary operations for tongue-tie and "phimosis" are in disrepute, and complicated orthopaedic measures for straightening the natural curves of the lower limbs are happily being abandoned so that spontaneous recovery (if indeed that is the right word) may take place unaided. A worthwhile task for family doctors is to do all they can to discourage mothers from the routine administration of unnecessary medicaments to their offspring. At present about 75% give gripe water and teething powders from the second month of life, incidentally thus initiating from the outset the bottle-of-medicine habit which is no credit to the N.H.S. Gallons of gripe water are given to young babies for the wind, but often unsatisfied hunger is the cause of the crying and more milk the appropriate remedy. Gripe water usually contains sodium bicarbonate, which gives off carbon dioxide when it reacts with the acid gastric contents; burping results, and its efficacy is plain for all to see. Teething powders seem likely to contain phenolphthalein in the future, so that their purgative action will be maintained, and mothers will presumably still be calmed by the fact that something is being done. Nevertheless teeth will continue to erupt at their own rate with or without causing symptoms and completely unaffected by any form of therapy.

UTERO-TUBAL INSUFFLATION

The procedure of utero-tubal insufflation will always be associated with the name of Rubin, who introduced it into gynaecological practice over 30 years ago and recently devoted a book to his long experience with it.¹ In this issue of the *Journal* (p. 239) Dr. Albert Sharman

¹ *British Medical Journal*, 1953, 2, 1317.
² See Medical Notes in Parliament, p. 281.

retails some of the lessons he has learnt from performing over 4,000 tests. He follows Rubin in advising the use of carbon dioxide as the test gas because no fatal case of air embolism or of pelvic infection has been reported from its use, whereas fatalities from these complications have occurred after the use of air and oxygen. Carbon dioxide is unquestionably the safest gas, but some gynaecologists remain satisfied with the careful use of air, for it requires only the simplest apparatus, an advantage of some importance if the test is to be performed in consulting-room or out-patient department. If the Bonney insufflator with a bulb without a valve is used, and if the capacity of the bulb, about 45 ml., is not exceeded, the risk of fatal embolism is almost obviated. Whatever gas is used, insufflation very rarely introduces infection into the genital tract; any reaction is almost invariably a recrudescence of an old infection, and, if severe, should raise the suspicion that genital tuberculosis is present. Tubal patency tests should be avoided if there is any acute or chronic vaginal discharge, if menstruation is imminent, in progress, or overdue, or if a previous test has caused a reaction; but, if a history of old pelvic infection is regarded as a contraindication, the test will be omitted when the information it may give is most needed.

It is generally realized that tubal patency tests can give false or misleading results, and White¹ has detailed some of the reasons, but the extent of their fallibility is often not appreciated. Dr. Sharman found that, of 102 consecutive women with negative tests, a further testing a few days later showed normal patency in 70. In a paper read at the 1953 Annual Conference of the Society for the Study of Fertility, Jeffcoate reported that 37% of negative insufflation tests were subsequently proved false by salpingography, laparotomy, or pregnancy. The proved false positive rate was much lower, about 3%. Dr. Sharman recommends that salpingography should be performed in all cases diagnosed as non-patent by insufflation. This complementary procedure more than halves the rate of proved error but does not obviate it; and indeed Jeffcoate found that even when both tests were negative the margin of error was 15%.

It might be argued therefore that, if only in the interests of accuracy, salpingography should replace insufflation as a diagnostic measure, but it is unlikely to do so for three reasons. First, insufflation is simpler, cheaper, safer, and more easily combined with other procedures such as endometrial biopsy. Secondly, many gynaecologists have implicit faith in kymography as an adjunct to insufflation. Dr. Sharman, like Rubin,² believes that the kymograph enables the observer to distinguish not only between patency and non-patency but also between tubes which are normally patent and those which are the site of spasm, stenosis, or peritubal adhesions. This belief presupposes that the oscillations of the recording needle are produced by tubal contractions and that these accurately reflect tubal health. These two assumptions may not be accepted unreservedly, especially by those who have performed insufflation with

kymography when the tubes are under direct vision at laparotomy. The third reason for retaining insufflation is that, whether the test proves positive or negative, if the patient does not become pregnant within six or twelve months thereafter, a different test, salpingography, can then be performed. If one tubal patency test can have a therapeutic value, how much more valuable are two, suitably spaced, for in the treatment of infertility time is a powerful ally for success on the side of the gynaecologist.⁴

GROUP PRACTICE ENCOURAGED

One of the recommendations of the Working Party on the Distribution of Remuneration among General Practitioners⁵ was that a provisional sum of £100,000 should be set aside annually to be used to encourage the formation of group partnership practices. Now, after consultation with the General Medical Services Committee of the Association, the Minister has decided that this money should be used to provide interest-free loans to those "general practitioners taking part in general medical service who propose to form a group practice or who, having formed a group, propose to provide new practice premises or substantially to improve the existing premises" (see *Supplement*, p. 27).

The last reports of the Medical Practices Committees of England and Wales⁶ and of Scotland⁷ show that the Working Party's recommendations about the loading of capitation fees and the fact that partnerships can gain the maximum advantage from this loading by arranging to be paid on notional lists have already done much towards increasing the number of partnerships. The Minister's decision to assist capital expenditure on premises for group practice purposes should help further to increase this trend by removing what has been, in some cases at all events, an obstacle to expansion.

Inquiries made by the B.M.A.'s General Practice Review Committee⁸ showed that enthusiasm for health centres was lukewarm and that fewer G.P.s were in favour of them than were against them. The Committee thought it preferable that any changes in the form of general practice should develop spontaneously from within practice itself rather than from the imposition from outside of some organization such as health centres. Certainly general practitioners have been showing an increasing interest of recent years in the advantages attached to group practice, and the Minister's proposals will give practical encouragement in a way which should be acceptable.

The annual sum of £100,000 for loans will be swollen in due course by repayments until eventually much more capital will be available. The favourable terms are likely to stimulate inquiry from many doctors into the possibilities of group practice, and at first the Group Practices Loans Committee—to be composed equally of G.P.s and Ministry officials—may well find their resources unequal to the demand on them.

CLINICAL PATHOLOGY IN GENERAL PRACTICE THE LABORATORY DIAGNOSIS OF PULMONARY TUBERCULOSIS

BY

J. W. CLEGG, M.R.C.S., L.R.C.P., D.C.P.

Pathologist, Brompton Hospital

In any case of pulmonary tuberculosis the laboratory has two important roles to fulfil. First, it plays an essential part in the diagnosis; for until *Mycobacterium tuberculosis* has been demonstrated in exudate or tissues of a patient the diagnosis remains incomplete. Secondly, the laboratory has an important function to fulfil in the control of treatment. This paper is concerned only with the diagnosis of pulmonary tuberculosis. Nevertheless, at the stage of diagnosis there are certain steps which should be taken if the laboratory is to exercise its function in the control of treatment. These steps are mentioned in the course of the paper. The essential step in diagnosis is the demonstration of tubercle bacilli, and consideration is given first to the various tests that may be employed for this purpose. Later, their application to specific excretions or tissues is discussed.

Microscopical Detection of Acid-fast Bacilli

This is the most widely employed laboratory investigation in tuberculosis and has the great merit of speed. A report on the presence or absence of acid-fast bacilli in a given specimen is available in a few hours.

Unfortunately, there is no method of differentiating between *Myco. tuberculosis* and non-pathogenic acid-fast saprophytes under the microscope. *Mycobacteria* are, by definition, a group of bacteria which, when stained, resist decolorization with acid and alcohol. Since 1894, the Ziehl-Neelsen technique has been the accepted standard procedure all over the world. In this method the bacilli on the film are stained with carbol-fuchsin, decolorized with acid and alcohol, and counter-stained with methylene blue. The acid-fast bacilli thus appear under the microscope as red rods against a blue background, as viewed by reflected light. Recently a new technique has been developed whereby the acid-fast bacilli are stained by fluorescent dyes, decolorized in the normal way by acid and alcohol, and counter-stained. The stained bacilli, when irradiated by ultra-violet light, have the property of emitting visual light. This makes them appear larger and more easily seen under the microscope. While this new technique is a big advance from the laboratory point of view, it is essential to remember that it does not constitute a new development and that the property of acid-fastness is still the property which is recognized by both procedures.

Cultural Methods

Myco. tuberculosis is a slow-growing organism. Even when seeded on a culture medium favourable to its growth an inoculum containing viable tubercle bacilli may take from two to eight or more weeks to produce a recognizable colony. The length of time taken depends upon the number of viable bacilli in the inoculum, the smaller the number the longer the time. Obviously, if other bacteria are present in the material to be examined, these will overgrow the whole surface of the culture medium and will swamp the *Myco. tuberculosis*. It is therefore necessary to kill off the other bacteria in the specimen before inoculating it on to a culture medium. It is also desirable to concentrate as many as possible of the viable tubercle bacilli from the whole specimen into a small volume, for the larger the number of bacilli used the quicker the growth will become evident.

Fortunately, mycobacteria are far more resistant to the action of acids and alkalis than other bacteria, and the most satisfactory methods of concentration are based on this difference. It must be remembered that in a grossly contaminated specimen with much pus and secondary infection the amount of exposure to acid or alkali which is necessary to kill the secondary organisms in the specimen may also kill the majority of tubercle bacilli in that specimen. Therefore such specimens are apt to give false-negative results.

Animal Inoculation

Until the development of modern egg media, animal inoculation was a much more sensitive method of detecting *Myco. tuberculosis* than culture. From the large number of investigations which have been performed to compare the relative merits of the two methods, it is clear that cultures are now as sensitive as animal inoculation, and the high cost of the latter would prohibit a high proportion of the investigations now usefully performed by culture. In material in which contamination by acid-fast saprophytes is likely, as in specimens of urine, and in which typing of the strain is required, animal inoculation is still the method of choice. Indeed, the usefulness of animal inoculation is now very limited, and cultural methods on the more normally submitted material are every bit as accurate.

Pathological Material

These standard methods of investigation must now be considered in relation to the pathological material which is available for diagnosis in cases of pulmonary tuberculosis.

Sputum

The material most often examined in cases of suspected or proved pulmonary tuberculosis is undoubtedly sputum. The specimen should contain little saliva and be free from food particles. The early morning, before breakfast, is the best time to collect such a specimen and the patient should be provided with a clean, dry, wide-mouthed sterile container. If the disease has not previously been diagnosed the specimen should be examined by a direct film for microscopy, and whatever the result the specimen should be concentrated and cultured for *Myco. tuberculosis*. Unless the first specimen shows many acid-fast bacilli in the direct film, it should be followed by two further specimens, which will also be put up for culture if the diagnosis of pulmonary tuberculosis is regarded as likely on clinical grounds. If these three specimens prove negative on microscopy it will be necessary to repeat the test at frequent intervals until either a positive result is obtained or some diagnosis other than tuberculosis is established. In any event, the wisest course at this stage is to persist in cultures until a positive result is obtained, especially if there is any likelihood that chemotherapy will be instituted or any possibility that the patient has contracted the disease from a patient who has been treated with streptomycin.

Gastric Lavage

The stomach washings are useful material from which to cultivate *Myco. tuberculosis* in patients with pulmonary tuberculosis who fail to expectorate.

The specimen should be taken before breakfast and there should be no delay in submitting it to the laboratory. It must be remembered that the gastric juice is strongly acid and if the specimen is left unneutralized for more

¹ Rubin, I. C., *Utero-tubal Insufflation*. Mosby, St. Louis, 1947.
² White, M. M. J., *Obster. Gynaec. Brit. Emp.*, 1951, 58, 573.
³ Rubin, I. C., *Fertil. and Steril.*, 1952, 3, 179.
⁴ Bender, S., *British Medical Journal*, 1952, 2, 409.

⁵ *British Medical Journal Supplement*, 1952, 1, 283.
⁶ *Ibid.*, 1953, 1, 74.
⁷ *Ibid.*, 1954, 1, 9.
⁸ *Ibid.*, 1953, 2, 13.

than one hour it is probable that the tubercle bacilli will be killed. To the gastric washings 5 ml. of 10% trisodium-phosphate should be added to neutralize the acid. The presence of acid-fast bacilli in a smear made from the gastric contents is not conclusive evidence of the presence of *Myco. tuberculosis*. Many foodstuffs, notably butter, are often contaminated with saprophytic acid-fast bacilli. It is therefore essential to culture all specimens of gastric contents.

Laryngeal Swab

Gastric lavage is often difficult and usually impossible in general practice, and to meet this situation with patients who do not expectorate the technique of a laryngeal swab has been developed. A sterile swab, moistened with sterile water, is passed with the aid of a laryngeal mirror into the larynx. The patient then coughs, and any sputum in the upper part of the bronchial tree will adhere to the swab. This swab is treated with 10% sulphuric acid for five minutes, and then placed in 2% sodium hydroxide for a further five minutes. It is then inoculated on to Löwenstein-Jensen medium and incubated in the ordinary way. Nassau* obtained a positive swab from 44% of 273 sanatorium patients who did not expectorate, and Forbes and his colleagues† showed that the results of laryngeal swabs were as reliable as gastric lavage in out-patients.

Faeces

In children the faeces may be investigated for the presence of *Myco. tuberculosis* in cases of pulmonary tuberculosis in preference or in addition to the gastric lavage. This method is also sometimes used in adults, but here the presence of large numbers of tubercle bacilli are more likely to indicate tuberculosis of the intestinal tract than pulmonary tuberculosis.

Pleural Fluids

Simple non-turbid pleural effusions, although most commonly of tuberculous aetiology, often contain only few tubercle bacilli. The probability of demonstrating *Myco. tuberculosis* is increasingly likely the larger the volume of fluid used. As these fluids often contain fibrinogen, an anticoagulant should be added—for example, 1 ml. of 20% sodium citrate. If possible about 100 ml. of fluid should be examined microscopically. If no organisms or only acid-fast bacilli are seen, six slopes of Löwenstein-Jensen medium may be inoculated. If other organisms are seen the material is used first for culture of secondary organisms and then treated by Petroff's or the trisodium-phosphate techniques before cultivation for *Myco. tuberculosis*. A small volume of the fluid should be examined for cells, and in simple tuberculous effusion the lymphocytes will predominate.

Turbid and purulent fluids should be treated in the same way, and in these cases there will be greater probability of successful cultivation.

One of these procedures will result in a positive culture from a case of pulmonary tuberculosis. With the widespread use of chemotherapeutic agents in treating tuberculosis, it is inevitable that some cases of pulmonary tuberculosis will be found in which the organisms are resistant to one or other of the chemotherapeutic agents. It is therefore necessary that the first culture from a new case of pulmonary tuberculosis should be preserved and preferably have its sensitivity tested against streptomycin, P.A.S., and isoniazid, as, even if not immediately, chemotherapy is very likely to be used sooner or later in the course of the patient's treatment.

The definitive diagnosis of pulmonary tuberculosis depends upon the demonstration of *Myco. tuberculosis* in the tissues or excretions. Nevertheless, there are other ancillary tests which, while not actually diagnostic of pulmonary tuberculosis, are of great assistance in estimating its severity and the course of treatment. These tests may be divided into the serological tests and the haematological tests.

Ancillary Investigations

Middlebrook and Dubos‡ showed that sheep's erythrocytes suitably activated with an extract of the strain *Myco. tuberculosis* H37Rv were agglutinated by the blood serum of some cases of pulmonary tuberculosis. Various other workers have made investigations along these lines, each of them making minor modifications in the technique. Sohler, for instance, used purified tuberculin to sensitize the red cells and obtained good results with tuberculous sera but had a high percentage of false-positive results in normal controls. While this relatively recent development may eventually prove satisfactory, there is at present no serological diagnostic test of proved value available.

Haematology

The most constant alteration in the blood picture in all forms of pulmonary tuberculosis is a progressive hypochromic anaemia. This usually reacts well to adequate treatment.

There have been many investigations into the changes in the total and differential leucocyte counts which may be associated with pulmonary tuberculosis. The only fact which emerges with certainty is that there is no specific change in the leucocyte count of diagnostic value. On the other hand, the disease may be associated with either a leucopenia or a moderate leucocytosis. There have also been reports of a leukaemoid reaction in a few cases of tuberculosis. The monocyte count is often raised (over 10%), especially when fresh tuberculous tissue is being formed, while a raised lymphocyte count is often associated with healing tuberculous lesions.

Erythrocyte Sedimentation Rate

Although the erythrocyte sedimentation rate is not in any way specific for tuberculosis, it is nevertheless of great value. In all toxic conditions associated with tissue destruction the sedimentation rate is raised, and thus the test is no more specific than pyrexia or leucocytosis. The sedimentation rate is always raised in active tuberculosis and falls as healing takes place. Serial examinations are thus of great value in the control of patients suffering from pulmonary tuberculosis, and a spread of the disease may manifest itself by a rise in the sedimentation rate before there is any radiological or clinical evidence of it. The test is also often valuable in cases in which radiographs reveal a lesion which is of doubtful activity, and in these cases a raised sedimentation rate is strong evidence of activity.

Westergren's method is commonly employed in tuberculosis. In this method 0.4 ml. of 3.8% citrate solution is drawn into a syringe which is then introduced into a vein. Blood is withdrawn until there is 2 ml. of mixed blood and citrate in the syringe. The sedimentation tube, which has an internal diameter of 2.5 mm. and is calibrated in millimetres from 0 to 200, is then filled in the manner of an ordinary 1-ml. pipette. The column of blood is drawn up to the zero mark on the scale and the tube is placed to stand vertically in a rack. At the end of one hour the number of millimetres through which the erythrocytes have sedimented is recorded. The disadvantage of the method lies in the fact that it is impossible to correct for anaemia, but the ease of the technique more than compensates for this somewhat technical disadvantage. It has been found in practice that serial readings of the sedimentation rate by the Westergren method are of very great assistance in controlling individual cases, and it is therefore always desirable to take a reading as early as possible in every case of pulmonary tuberculosis.

Next article on Clinical Pathology.—"The Normal Blood Count," by Dr. George Discombe.

THE MONTREAL GENERAL HOSPITAL

BY

WILLIAM STORRAR, M.B.E., M.B., Ch.B.

Medical Director, Montreal General Hospital

Great developments have taken place in Canada in the last decade, and with the large increase in population more hospital beds have become necessary. In the City of Montreal alone 3,000 hospital beds are being built at present to meet the demands of this rapidly expanding cosmopolitan city. The largest single hospital building project in Montreal, in fact in Canada, now being undertaken is the construction of the new buildings of the Montreal General Hospital.

The Montreal General Hospital, a teaching hospital of McGill University, was founded in 1821, and ranks as the oldest teaching hospital in Canada and one of the oldest on the North American continent. Founded by four Edinburgh graduates, it was built in the style of the Royal Infirmary of Edinburgh and throughout the years has maintained close ties with that city. In 1949 a survey of the hospital revealed that modernization of the present buildings would be impossible, and consequently it was decided to erect an entirely new hospital expanding from 640 beds to 750 beds. The hospital authorities were fortunate in securing an area of land of 360,000 sq. ft. (33,450 sq. metres) almost in the centre of the city and within easy reach of suburbs. On this site the new Mon-

FIG. 1.—Architect's drawing of the new buildings of the Montreal General Hospital.

trical General Hospital is being erected and one-half of it has now been completed. The cost of the hospital amounts to \$20m. (£7m. at the present rate of exchange). Two-thirds of this money has been obtained by public subscription, the remainder being provided by the Federal Government of Canada, the Government of the Province of Quebec, and the City of Montreal.

Internal Design

When completed the hospital will have 750 beds and 50 bassinets and a nurses' home to accommodate 250 nurses. The design of the hospital is unusual, as can be seen from the drawing, with an out-patient wing housing full out-patient services, a dental teaching school, and a floor devoted to a psychiatric department with some 20 in-patient beds and 15 beds which will be used for psychiatric patients who receive treatment during the day and go home at night. These same beds will also be used for psychiatric patients who are working during the day and have their treatment at night. The connecting wing will house all the ancillary and diagnostic services, kitchens and staff dining-rooms, and operating suites. The remaining wing is devoted entirely to in-patients, each floor providing accom-

modation for 64 patients each with two nursing units of 32. In order to make the maximum use of beds and have as flexible a plan as possible no ward will contain more than four beds; private patients will be accommodated in single rooms and numerous single and two-bed rooms have been provided on the public patient-floors. The nurses' home and interns' home are both connected with the main hospital by tunnel, every nurse having her own room and toilet facilities.

All the ten operating-room suites are air-conditioned, and provision has been

made for the installation of a cobalt bomb or million volt x-ray therapy machine. Oxygen will be piped to every bed. Automatic-pneumatic tubes will carry records, specimens, and drugs to thirty different outlets throughout the hospital, thus saving many man-working hours. It is hoped to install also a new "walkie-talkie" call system for interns, thus eliminating audible and visual call systems. Eight high-speed elevators are to be fitted, with provision for additional elevators should the need arise.

An amphitheatre to seat 230 people has been provided for. This is in addition to the numerous small lecture theatres available throughout the hospital for the teaching of undergraduates and postgraduate medical men. Every patient-floor has a waiting-room, lecture room, and sun lounges; all patient rooms are equipped with a nurses' call system allowing the patient to talk to the nurse direct from the bed to the nurses' station.

On the domestic side, there is an automatic ice-making machine on every patient-floor. A laundry is to be installed to meet the needs of the whole hospital, with linen chutes on every floor to carry the dirty laundry. All windows will be of the double-hung reversible type to allow easy cleaning. Heating will be by means of oil furnaces, and an independent generator will be installed in case of main electrical breakdowns. The basement will provide food storage space for a minimum of six months' supply of non-perishable foods at any time. All preparation of meat and vegetables will be carried out in the basement, thus allowing more freedom of movement in the central kitchen on the fourth floor, which also houses three large staff dining-rooms.

* Proc. roy. Soc. Med., 1941, 34, 397.
† Lancet, 1948, 2, 141.

It is thought the new Montreal General Hospital will be in operation by 1955. It will be the most modern teaching hospital on the North American Continent and its opening will be a great milestone in the history of medical and nursing teaching in Canada. It is hoped that many members of the British Medical Association when they visit Canada for the joint meeting with the Canadian Medical Association in 1955 will find time to visit this new hospital, which has such a strong tie with the Scottish and English medical schools.

ERYTHROMYCIN

Erythromycin in limited amounts has lately been made available by the Ministry of Health to hospitals in the National Health Service, and very shortly it will be freely available on prescription. The Ministry is therefore sending to all hospitals the following note by the Medical Research Council on its use.

Indications and Dangers

Erythromycin has a range of activity similar to that of penicillin and has been shown to be effective in acute infections due to haemolytic streptococci, pneumococci, and staphylococci. Organisms resistant to all other antibiotics are nevertheless sensitive to it; hence its greatest value is in treating staphylococcal infections not responsive to other drugs, the frequency of which, particularly in hospitals, is showing a disturbing increase. A peculiar form of this infection in which its action may be life-saving is the severe staphylococcal enteritis complicating therapy with the broad-spectrum antibiotics or with penicillin and streptomycin. Some other species, including members of the genera *Neisseria* and *Haemophilus* and *Rickettsia*, are also sensitive to it.

Erythromycin is itself a drug to which bacterial resistance can be acquired rather rapidly, and this may be a cause of treatment failure in infections difficult to eradicate, such as endocarditis. It has also to be remembered that bacteria rendered resistant in one patient may later cause infections in others which are insusceptible to the drug from the outset. It might be disastrous if a staphylococcal population were built up which was resistant to erythromycin as well as to earlier antibiotics. It is therefore most necessary that this drug should be prescribed with due regard to the risks of indiscriminate use. Penicillin should be preferred, on this ground—and, it may be added, that of economy—when it will serve equally well. Erythromycin should not be prescribed for most chronic conditions which respond poorly to it as compared with acute conditions—for trivial indications, or for those in which the bacterial cause is unknown.

ORDER OF ST. JOHN OF JERUSALEM

The London Gazette has announced the following promotions in, and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem:

As Commanders (Brothers): Colonel F. A. Bearn, C.B.E., D.S.O., M.C., M.D., Major C. D. Donald, M.B., F.R.C.S., Mr. H. S. Taylor-Young, F.R.C.S., and Drs. D. J. Johnson, M.B.E., J. A. L. Roberts, J. B. McKay, W. Bain, N. J. L. Rollason, F. W. Hebblethwaite, T. F. Briggs, O.B.E., T.D., J. F. C. du Toit, and the Hon. W. Nicol. **As Officers (Brothers):** Surgeon Captain E. J. Mockler, M.B., Major G. Brown, M.B., Messrs. H. I. Mariner, F.R.C.S., E. A. Malkin, F.R.C.S., and St. J. M. C. Birt, F.R.C.S., and Drs. G. G. W. Hay, C. L. Worthington, A. E. Pinzger, A. T. G. Thomas, W. R. A. Line, J. W. Silversides, A. M. Boyne, W. M. Dinwoodie, M. C. Cooper, M.C., C. Homi, J. A. R. Lavoipierre, J. S. Binning, E. F. Baines, W. G. McAfee, H. A. Johnson, R. C. Webster, J. M. de Ville-es-Offrans, M.B.E., and R. E. Anderson. **As Officer (Sister):** Dr. Marian Maxwell-Roberts. **As Serving Brothers:** Mr. H. B. Walker, M.C., F.R.C.S., and Drs. A. B. Wallace, J. C. K. Chilcott, F. H. Cleveland, W. B. Boone, A. Burns, O.B.E., M.C., R. Cubitt, D. S.

Chowdhary, T. H. McLeod, J. F. D. Boyd, D. W. Hendry, V. F. Lyndall, J. A. H. Goldacre, A. Stewart, C. T. Newtham, J. E. Hilton, A. Hamerton, J. G. Wilson, A. S. Boyd, W. B. Wishart, L. N. Gollan, and J. V. Vaughan. **As Associate Serving Brothers:** Drs. J. B. Solomon and S. Adler. **As Serving Sisters:** Drs. Betty M. White and Ruth Hull. **As Associate Serving Sister:** Dr. Ray Schauder.

Reports of Societies

THE MANAGEMENT OF THE ALCOHOLIC IN GENERAL PRACTICE

A meeting of the Section of General Practice of the Royal Society of Medicine on January 20 was devoted to a discussion on the management of the alcoholic in general practice. Dr. A. TALBOT ROGERS was in the chair.

Dr. J. YERBURY DENT, Editor of the *Journal of Addiction*, gave an account of alcoholic patients whom he had successfully treated with apomorphine. He used apomorphine by mouth in the treatment of 75% of the addicts who came to him, and he knew of nothing so satisfactory in removing the compulsion. An overdose could not easily be given by mouth. For the first 24 hours the patient might still have a craving for alcohol; if so, he should remain in bed; on the following day the craving was likely to be much less or even gone, but the treatment should be continued for three or four days. A more drastic treatment, with intramuscular injections of apomorphine, usually lasted for a week or ten days, and after it the patients returned to work immediately. Some might relapse, but these could and often did treat themselves successfully by mouth.

Dr. Dent then gave an account of one man who, although a publican, had been treated and had remained a total abstainer for eleven years. The publican then proposed to marry and his intended bride asked him to drink to their future happiness. He told her of his earlier craving and his fear of relapse, but she said, "Then I am not going to marry a coward." He drank one glass of sherry with her, and the next day he drank nearly a bottle of whisky, whereupon she threw him over, saying: "I am not going to marry a drunkard." The man had a second course of treatment and was now once more a total abstainer and a bachelor.

Although there was an enormous literature on the subject of alcoholic addiction the general practitioner did little for his alcoholic patients. Practically nothing was to be found in the textbooks and little was done for the thousands of addicts and their families. The old idea that all troublesome drunkards should be dealt with by the police still obtained. It was not yet realized that addiction was a disease, however much the act of drunkenness might be considered a moral lapse. The general practitioner could do a great deal to help his patients, and the patient and his friends should bully the doctor, if necessary, into treating the condition seriously. Dr. Dent protested against alcoholic patients being handed over to the psychoanalyst, though he admitted that psychotherapy and psychology had their place in treatment.

The Role of Psychotherapy

Dr. J. A. HOBSON agreed that apomorphine was the most useful drug available for the treatment of alcoholism, but he did not agree with what he considered to be Dr. Dent's disparagement of psychotherapy. Probably Dr. Dent himself practised far more psychotherapy with his patients than he was aware of; he was interested in his patients as human beings and not as "cases." He was sure that "Dent without apomorphine would cure more alcoholics than would apomorphine without Dent."

Psychotherapy was something which general practitioners could practise. Many alcoholics coming to doctors were coerced by their relatives and consequently very suspicious and guarded in their demeanour. Unless the general practitioner could win their confidence he was likely to fail.

Accuracy in diagnosis was, of course, important and of great academic interest, but diagnostic history-taking should be postponed if there was any risk that it would antagonize the patient. Most alcoholic patients showed some psychological abnormality, but it was difficult to decide whether the alcoholism was secondary to a neurosis or the neurosis secondary to alcoholism; he thought the latter was more likely to be the case. Very frequently symptoms of anxiety and tension disappeared under treatment. Often, of course, the alcoholic, after he became teetotal, was left with some psychiatric symptoms, and in such cases then proper psychiatric treatment was given. The alcoholic presenting himself for treatment exhibited a sense of shame and failure, and was always on guard against moral accusations. A doctor who was himself an alcoholic had described his own state as an intense dislike of himself, his habits, his behaviour, his reactions to his friends, and imagined himself guilty of unspeakable infamies. An attempt must be made to combat the alcoholic's feeling of complete loneliness and extreme self-reproach. To this end it was preferable to treat alcoholics in groups of two or three at a time rather than in isolation. Fostering a group spirit was one of the ways in which Alcoholics Anonymous was of most help in reinforcing medical treatment.

Team-work

Dr. LINCOLN WILLIAMS pleaded for team-work in the treatment of alcoholism. To understand the alcoholic was to understand his needs. These could be summarized under several headings.

First came his physical needs. It was essential to eliminate organic disease and to repair the ravages of alcoholism by fortified vitamin therapy. Over the last 50 years medicine had concentrated almost entirely on physical treatment—gold cures, courses of atropine and strychnine, and the like—which enjoyed a fleeting reputation, afterwards to be discredited. Modern therapy was carried out by means of aversion conditioned-reflex treatment, using apomorphine and "antabuse" (tetraethylthiuram disulphide).

Then there was the need for a personality diagnosis. It was very important to understand what the patient was like before the onset of his excessive drinking. Was he fundamentally a normal person, or one suffering from neurosis, mentally a normal person, or was he a "bad hat" alcoholic or had he a mental disorder, or was he a "bad hat" alcoholic with an underlying psychopathic personality? One often came across patients who suffered from a chronic tension state which demanded more and more alcohol to allay it. This type of person responded extremely well to subconvulsive electrostimulation which removed the tension.

Furthermore, the environmental needs of the alcoholic must be considered. His wife must be helped to understand that compulsive drinking is an illness and not a moral failure. Where desirable, contacts might also have to be made with his employer, for many alcoholics held responsible positions in industry and had many years of productive work ahead of them. The social needs of the alcoholic could be met by membership of a group, and here the speaker gave wholehearted support to the work of Alcoholics Anonymous.

Finally the spiritual needs of the alcoholic also called for attention. The effect of religious conversion was well known. The Church to-day showed complete readiness to work with doctors and Alcoholics Anonymous and all others towards the successful rehabilitation of the alcoholic sufferer.

Dr. E. P. SCOTT said that he was disappointed that they had been told so little about the cause of alcoholism, whether physical or psychological, and also about its sequelae.

Three members of Alcoholics Anonymous also contributed to the discussion. One of them said that he had for 22 years been a hard drinker, and he had since spent two years in association with Alcoholics Anonymous and had won through to sobriety. It was very important that members of that organization should work under medical superintendence. Alcoholics Anonymous consisted of men and women

of every social grade who had learnt to live without alcohol and by their fellowship and sharing of experiences to help one another. Another member of the organization said that he was sure that the drinking of alcohol was due to a state of mind and not so much a physical urge.

Complications of Alcoholism

Dr. HOBSON, in replying on the discussion, said that to argue whether the cause of alcoholism was physical or psychological was a trick of language rather than a true dichotomy. As for the sequelae of alcoholism, he had been struck by the very low incidence of cirrhosis in alcoholic patients. He had not seen a case of cirrhosis of the liver in an alcoholic for four or five years. Nor had he seen cases of gout. A disease which was rather similar to gout was diabetes, and there was a high incidence of diabetes not only among alcoholics but among their friends. The complications he saw most frequently were peripheral neuritis and mental changes. With regard to the compulsive craving for alcohol, he mentioned one woman patient who had retrobulbar neuritis and was told that if she persisted in drinking alcohol she would go blind. Her reply was, "Even if I go blind I cannot give it up." In marked contrast with this were patients with tobacco amblyopia. One of these, who was addicted to excessive cigar smoking, gave up the habit at once on being given a similar warning.

Dr. DENT, also in reply, said that he had his doubts about the value of psychoanalysis in these cases, but he had no prejudice against psychotherapy. He had never suggested, however, in dealing with patients that he had an interest in their past. The past had to be forgotten so far as possible. He had seen several alcoholic patients with diabetes, but not a single case in nearly 20 years with cirrhosis of the liver.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Press Publicity

SIR,—As chairman of the Association of British Science Writers, I have been asked by our members to thank you for your tolerant and constructive leading article on "The Press and The Profession" (*Journal*, January 16, p. 141), and to tell Professor Ian Aird that we fully appreciate the circumstances which provoked his letter (p. 153).

No responsible journalist will defend or excuse the behaviour of certain newspaper men on that occasion. Such conduct (of the few) brings discredit on the press—except that when there is a matter of wide public interest, a "human story," like the case of the Siamese twins, there is no such entity as "the press," only a large number of competitive newspapers and competing representatives, each trying to secure an individual account or an exclusive picture. It would be an exaggeration to say that the jobs of those representatives depended upon getting the story, but it would be true to say that they would be unpopular with their news editors or picture editors if others got what they did not. Any newspaper (even the most dignified) likes a scoop, but every newspaper is aggrieved by a "miss." It is the proper function, therefore, of every journalist to get the information which his newspaper wants by fair means. But not by foul.

The question which Professor Aird raised and your leading article discussed was: What is "fair means" in terms of the medical profession, with its concern for the special relationship between patient and doctor and of the ethic of anonymity of both patient and doctor? The further question was raised of the proper understanding, and competent handling, of medical facts.

the first group the average dose was 88 mg. and in the second group it was 96 mg. Very few of my patients have had more than 50 mg.; most have had 30 to 40 mg. This may account for the higher incidence of muscle pains encountered by Dr. Churchill-Davidson.—I am, etc.,

Glasgow, S.2.

A. KILPATRICK.

Malaria Prophylaxis

SIR.—In "Any Questions" under the heading of "Malaria Prophylaxis" (*Journal*, January 9, p. 107) it is advised that daily proguanil ("paludrine") prophylaxis should begin a fortnight before entering a malarious area. Why a fortnight? There appears to be no pharmacological basis for this procedure, and one of the advantages of proguanil as a prophylactic drug is that a loading dose is unnecessary. Provided 100 mg. is being taken every day, I know of no advantage in administering it before the individual enters a malarial area, other than establishing the habit of the daily dose. The question is one of considerable practical importance. In air travel in malarious countries, for example, it is not feasible to give proguanil to travellers and air crews for a fortnight before each journey.

Evidence that proguanil prophylaxis need not be commenced before exposure to infective biting was first obtained by Fairley *et al.*¹ Seventeen out of 17 non-immune volunteers receiving one single dose of either 50 mg. or 100 mg. of proguanil between 39 and 120 hours after exposure to mosquitoes harbouring a New Guinea strain of *P. falciparum* failed to develop malaria, though the controls did. Nine out of 10 volunteers receiving a single dose of 25 mg. of proguanil between 48 and 131 hours after exposure were likewise protected, and 6 out of 8 volunteers receiving a single dose of only 10 mg. of proguanil between 48 and 120 hours after exposure to infective biting were completely protected. On the other hand, a single dose of 100 mg. of proguanil failed to protect 24 hours and 144 hours or later after exposure to infective biting. Two out of 3 volunteers receiving a single dose of 300 mg. of proguanil at 168 and 192 hours respectively after exposure to infective biting developed overt malaria; the third who received 0.3 g. at 144 hours was protected.

Subinoculation experiments² in non-immune volunteers experimentally infected with *P. falciparum* while taking a daily dose of an antimalarial drug for the prevention or suppression of malaria revealed that with quinine, mepacrine, and chloroquine asexual parasites appeared in the blood of the recipient in sub-microscopic density on the 7th day (>144 hours) just as they did in the controls, whereas with proguanil asexual intracorporeal parasites were never demonstrable in the recipients who invariably failed to develop malaria.

The Cairns experiments indicated that in falciparum malaria (New Guinea strain) (1) proguanil in one single dose of 50 to 100 mg. prevented malaria if given between the 39th and 131st hours following exposure to infective biting, (2) pre-erythrocytic parasites were much more susceptible to proguanil than were the corresponding asexual blood parasites, (3) when daily proguanil was being given to prevent malaria asexual trophozoites never reached the circulating blood.

As far as is known, these results hold for typical strains of *P. falciparum* everywhere. Even with the atypical West African strain studied by Covell *et al.*³ where proguanil failed to clear the blood of falciparum parasites during overt malaria, no difference was demonstrated in its action as a causal prophylactic. Thus 10 out of 10 individuals receiving proguanil in a dosage of 50 or 100 mg. daily were completely protected against multiple infective biting.

In vivax malaria evidence obtained by subinoculation experiments² showed that (1) vivax parasites appear in the blood on the 9th day (>192 hours) after infective biting in volunteers taking quinine, mepacrine, or chloroquine just as they do in controls taking no drug, but with proguanil

they never do so, and (2) proguanil inhibits schizogony of the pre-erythrocytic cycle, delays the appearance of asexual parasites in the blood, and prolongs indefinitely the incubation period while the drug is being taken. The fact that vivax relapses occur after proguanil administration is not due to failure of the drug to eradicate parasitaemia in typical strains of *P. vivax* but to the persistence of late exoerythrocytic parasites in the liver which from time to time erupt asexual trophozoites into the blood stream.

In the B.O.A.C. it has been the practice for the past 8 years to give 100 mg. of proguanil from the day of departure until the 10th day after leaving a malarious area. Sir Harold Whittingham, Director of Medical Services, B.O.A.C., informs me that during this period there have been only one or two malaria infections a year among a B.O.A.C. air crew strength of 1,360, about 1,000 of whom were constantly at risk. During this period the malaria rate has not exceeded 0.2% per annum, and careful inquiry has shown that every member of the air crew developing malaria had failed to take proguanil regularly.

No antimalarial drug has been studied more completely in man than proguanil. It would be unfortunate if a dosage regimen for malaria prevention and suppression so clearly indicated by extensive experimental studies under controlled conditions were not followed.—I am, etc.,

London, W.1.

SIR.—Dr. Mary G. Phillips's experience with the ineffectiveness of pyrimethamine ("daraprim") as a prophylactic against *P. falciparum* is interesting (*Journal*, January 16, p. 155).

There can by now be little doubt that proguanil ("paludrine") taken daily, and the dose never missed, is by far the most effective drug in the prophylaxis against malignant tertian malaria; proguanil is, of course, a true causal prophylactic against the *P. falciparum* parasite. One wonders whether the dose of pyrimethamine, or alternatively the frequency of its administration, might be increased before it is condemned as being useless as a prophylactic against malignant tertian malaria.—I am, etc.,

Isleworth, Middlesex.

JOHN C. L. ADAMS

"Status Lymphaticus"

SIR.—Dr. H. B. Dodwell must be congratulated for tracing so satisfactorily to its ultimate source the "myth of status lymphaticus" (*Journal*, January 16, p. 149). The concept is fed to every student of medicine; it is mentioned in most textbooks of surgery and pathology, and most anaesthetic textbooks devote a section to the matter. It will be a difficult task to abolish the notion that status lymphaticus does exist, especially as it offers a plausible excuse for some "anaesthetic" deaths.

Some such deaths occurring in the first few minutes of anaesthesia could without doubt be traced to some lapse on the part of the anaesthetist, but may be ascribed to the "myth" on official records. This does not necessarily reflect upon the integrity of the anaesthetist, who may sincerely believe at the time that nothing untoward had occurred during the administration up to the moment of death; however, later investigation by an independent observer would, I am sure, bring to light little incidents which could in retrospect be interpreted as danger signals: the little cough, breathholding, tinge of cyanosis, pulse irregularities, etc.—and which could have been corrected by appropriate action in time to obviate the crisis.

Most cases of death allegedly due to status lymphaticus fall naturally into the age group 0-20 years, where the thymus is probably still in evidence and has not atrophied to the extent of making the diagnosis untenable or even ridiculous. The majority of cases of which I have heard occur in babies or young children undergoing a surgical operation of a comparatively trivial nature—for example, circumcision, herniotomy, excision of small skin tumours, tonsillectomy, incision of abscesses, etc.: occasionally

it occurs in the young adult and may be associated with circumcision or dilatation of the cervix. In such cases, where death unfortunately occurs, the child is reckoned to be a pretty normal specimen of humanity—it is only in retrospect that the possibility of status lymphaticus is considered and details are accumulated to prove it. The thymus gland exposed at necropsy is magnified to a suitable size in the imagination and the diagnosis is clinched. Everyone is satisfied that death was, perhaps, inevitable.

The commonly quoted fatal combination is that of a struggling, screaming child saturated with circulating adrenaline and a pad soaked in chloroform pressed firmly to his face, the child in the meanwhile being held down by a body of nurses and porters; the child suddenly goes limp, and this is assumed by all to be due to the action of chloroform—it is (with apologies to the addicts), the action of chloroform added to the growing list of victims. Thus one more unfortunate is added to the growing list of victims of status lymphaticus. This state of affairs does not of course obtain in a well-run children's hospital, the children being asleep, in a "couldn't care less" frame of mind, or fully awake and prepared to co-operate, this latter state being achieved mainly by the manner and carefully chosen words of intelligent ward staff and to a lesser extent by the manner of the sympathetic, proficient, expert anaesthetist.

Similar deaths occur also with other anaesthetic agents in common use. Ethyl chloride is a well-known potent killer in expert hands. Soluble thiopentone certainly used to be a great lethal agent—due to actual or relative overdosage—and probably still is. Many deaths associated with its use in anaesthesia can be attributed to the rapid vasodilatation, greatly reduced venous return, lowered arterial pressure, coronary insufficiency, and ultimately death, which can and often does occur very quickly especially in toxic, dehydrated patients. Such cases can be labelled by thoughtless anaesthetists as idiosyncrasy, vagal inhibition, or status lymphaticus. Again, other deaths occur following "safe" agents—for example, gas-oxygen-ether sequence—where the rapid manipulation of patients for surgery occurs in association with the too rapid onset of surgery.

One could multiply and elaborate these instances, but enough has been said to illustrate the idea that bad anaesthetic technique can be a potent source of these mysterious cases of status lymphaticus.—I am, etc.,

Aberdeen.

DAVID A. FORBES.

SIR.—As Dr. H. B. Dodwell's article on "Status Lymphaticus," the Growth of a Myth" (*Journal*, January 16, p. 149) is largely a criticism of the views expressed by me in the seventh edition of *Recent Advances in Anaesthesia* I may perhaps be permitted to reply. I cannot possibly cover the many points raised in the article by a letter and will confine myself to two only. Dr. Dodwell states in two places that W. N. Kemp, while believing in the existence of the condition, does not cite any actual cases. In Dr. Kemp's book *Elementary Anaesthesia* chapter 23 is devoted to an excellent account of status lymphaticus and includes detailed reports of seven patients with anaesthesia.

Dr. Dodwell also states that he cannot find any account of the late Sir Bernard Spilsbury's views on the subject. Sir Bernard kindly discussed the condition with me fully at a time when I was about to consign it in my own mind to the category of discarded fables. Although he disliked the term status lymphaticus, Sir Bernard was convinced of the existence of a condition in children and young people who were more likely to die from sudden cardiac failure than normal individuals and in whom certain definite pathological changes could be demonstrated post-mortem. The chief findings were an enlarged thymus, general lymphatic hyperplasia, a narrowed aorta, and fatty infiltration of the heart muscle. I was later fortunate enough to see Sir Bernard demonstrating two classical examples of the condition in children who had died suddenly for no obvious reason and with no other post-mortem abnormalities than those mentioned above. Sir Bernard Spilsbury told me after his retirement he proposed to go through his post-mortem notes on cases of status lymphaticus (between 100 and 200) and to write a paper based upon them. Unfortunately, his tragic death prevented this project from being accomplished, but I would think that, if anyone had the time and ability to peruse and classify the immense number of meticulously accurate case reports which he left, not only would status

lymphaticus be clarified but also other obscure pathological conditions. Nobody who saw Sir Bernard's superb technique in the post-mortem room or who had listened to his logical reasoning in the lecture theatre or in the law courts could possibly imagine him capable of slipshod work or muddled thinking, and it is incredible that he should have pursued a chimera for so many years.

For this and other reasons I personally changed my view, and, while freely admitting that status lymphaticus has often been used quite unjustifiably as an escape mechanism by anaesthetists and others, I now believe that the condition does exist.—I am, etc.,

London, E.C.1.

Radiology and Lumbar Disks

SIR.—In his letter (*Journal*, January 23, p. 213) Mr. J. R. Armstrong has left out an important step in the treatment of disk lesions. The immediate treatment of most cases is not mere rest and immobilization, it is *reduction* followed by resting the joint in a good position by various forms of immobilization. Were this principle, so often applicable to fracture with displacement, applied equally to displacement of part of a disk, much of the prolonged disablement that Sir Max Page rightly deprecates would be avoided. Moreover, the reproach to our profession represented by osteopaths' successes would cease as well.

When a displacement is present, reduction followed by its maintenance compares favourably, in theory and in practice, with immobilization alone.—I am, etc.,

London, W.1.

JAMES CYRIAX.

SIR.—Your leading article (*Journal*, December 19, 1953, p. 1363), entitled "Radiology and Lumbar Disks," interested me greatly, as it was inclined to bear out my own personal opinion, that radiology is useless in the diagnosis of disk protrusions, but should be used to rule out any differential diagnosis.

The great number of disk lesions presenting themselves to the doctors nowadays surely rules out myelography as a diagnostic procedure. Thorough clinical examination should give the proper diagnosis without any radiological aid, except in a few cases.

I ought to agree with all that Sir Max Page says in his letter on this subject (*Journal*, January 9, p. 97), as I had the great fortune to be one of his dressers as a student, but I cannot agree with him that any diagnosis can be premature if correct. The sooner a disk protrusion is diagnosed the easier the treatment and the earlier the recovery. I do, on the other hand, agree with his complaint of the time wasted when the patient has to wait to see a specialist and have an x-ray. As I explained in my article "Manipulation and Accurate Manual Methods in General Practice" (*Journal*, July 4, 1953, p. 18), general practitioners should be trained in this work, both to save time and to prevent complications.

I also agree with him that prolonged partial immobilization is a too frequent routine, as manipulation or spinal traction will quickly relieve the majority of cases.—I am, etc.,

Hoddesdon, Herts.

R. BARBOR.

A Cosmetic Amputation

SIR.—Contrary to reactions of almost unqualified disapproval which Mr. Ian Lawson Dick's letter (*Journal*, January 2, p. 45) aroused in Professor Bryan McFarland (*Journal*, January 16, p. 159), Mr. Dick's strongly expressed and important observations concerning the cosmetic amputation brought me great satisfaction.

May I record that 28 years ago, when I was a surgical registrar, following accidental infection in the operating

theatre eventuating in chronic periosteomyelitis, it became necessary for me to have my left index finger amputated. Desiring an oblique section of the distal third of the shaft of the metacarpal bone, and anxious to have weighty approbation for this then seldom-performed operation, I consulted the late Professor Schoemaker, of The Hague, Professor Ernest Groves, of Bristol, Sir Robert Jones, of Liverpool, Professor de Quervain, of Geneva, as well as Sir Hugh Rigby, Mr. James Sherren, and Sir Robert (then Mr.) Milne, of the London Hospital. Independently, with the single exception of Professor de Quervain, this illustrious assembly were adamant : " Retain the head of your metacarpal bone—a surgeon requires manual strength as well as skill " was the refrain. Notwithstanding, I persuaded Sir Hugh Rigby to carry out the operation of my choice. Had the then orthodox operation been performed, for several reasons it is unlikely that I would have been able to follow my calling *in toto*.

Since then I have performed this cosmetic amputation several hundreds of times, always to the patient's eventual satisfaction. The cosmetic operation is suited eminently to women (without exception), those who follow the learned professions, business men, clerks, and the majority of highly skilled workmen. In my considered opinion it is the greater amount of compensation awarded to the plaintiff at law for the sacrifice of the head of a metacarpal that has unavoidably biased current practice.—I am, etc.,

London, W.1.

HAMILTON BAILEY.

Sickle-cell Anaemia

SIR.—With reference to Dr. H. Lehmann's letter on sickle-cell anaemia (*Journal*, November 28, 1953, p. 1217) and to the possible explanation as to the survival of the sickle-cell trait—including the evidence produced by Brain¹ that the sickler may have an advantage over the non-sickler in respect of some protection against red-cell parasitization by the malaria parasite—we are able to support this latter hypothesis, our evidence having been published in the *Tanganyika Annual Report of the Medical Laboratory* for 1952, in which it is stated:

"One of the unexplained facts about the congenital sickling abnormality is its apparent survival value in spite of the fact that the rapid homozygous sickler is liable to die in the early years of life of sickle-cell anaemia. It appeared that this survival value may lie in there being some advantage to the heterozygous sickle-cell trait individual in respect of decreased susceptibility of a proportion of his red cells to parasitization by *P. falciparum*. To test this theory watch was made for a heavy *P. falciparum* parasitization in a sickle-cell trait individual. This was eventually found. This patient's blood was then sickled by the simple wet sealed preparation technique, after which the cover slip was removed, the cells fixed by rapid drying and stained by Leishmann. The stained film showed large numbers of parasitized cells, but it was very obvious that these were well formed and not sickled. On the other hand, very few of the sickled cells were parasitized, although the majority of the cells were in fact sickled. The explanation of this phenomenon needs careful investigation; there is the possibility, however, that the sickle-cell haemoglobin may be an unsuitable intracellular environment for the growth and metabolism of the trophozoite. Alternatively, parasitization of a cell containing a certain proportion of a sickle-cell haemoglobin may lead to its *in vivo* sickling and phagocytosis, thus terminating the reproduction cycle in the case of cells so invaded."

It should be noted that, although the sickle-cell trait incidence in Dar es Salaam is 20%, only one of 16 heavy malaria infections was in fact sickle-cell trait positive. It is also relevant to record that in a sickle-cell survey carried out by Mackey³ in Dar es Salaam 16% of 330 infants, average age 6 months, were sickle-cell trait positive as opposed to 23% of 283 adults, average age 26 years. Dar es Salaam is in a hyperendemic malarious area, and it would seem that in this area the sickler has a better chance of survival to adult life than the non-sickler.—We are, etc.,

J. P. MACKEY.
F. VIVARELLI.

Ophthalmic Surgery in India

SIR.—Dr. J. N. Tennent's article (*Journal*, January 2, p. 39) does far from justice to Rai Bahadur Dr. Mathra Das, the founder of blind relief camps. As the Rai Bahadur put it to me, he had early realized that the Rolls-Royce methods employed in hospitals were not capable of touching the fringe of the problem of cataract in India. Something of the nature of modern mass production was required, and he found it in the blind relief camps. When I last saw him he had the intention of retiring when he reached his 200,000th extraction, but the many calls on his skill prevented it. His records showed a "casualty" rate of less than 1%.

In company with a member of our staff, who had completed six months as junior and six months as senior ophthalmic surgeon, I visited one of Dr. Mathra Das's camps, and watched his methods. The average patient, after walking from his village to the camp, presented himself in the early part of the day and, after he had his preliminary examination by the surgeon, was given a card the colour of which decided whether he was deemed fit to stay for operation or to be sent back home again. Selected patients were given a wash-out, the anaesthetic, and might be on the table within the half-hour. With the help of a well-trained assistant, Dr. Mathra Das removed four cataracts per minute. Bandaging, etc., was done by trained assistants, and by the time the surgeon had finished at table four a fresh patient was ready at table one. He did nearly 400 operations that day, and a week later I returned to the camp to ascertain the results. Three of them had gone "wrong," and one of the three was a woman who disliked the surgical dressing enough to replace it by the softer stuffing of her mattress. Even if she be included among the casualties, the rate was still less than 1%, a truly remarkable achievement. The rate for that particular camp correctly sampled Dr. Mathra Das's overall rate for 200,000.

In my travels round India I heard much criticism of Dr. Mathra Das's technique, so, from his lecture, did Dr. Tennent. If such criticisms were comprehensively based there should have been something like 300 casualties at the camp which I visited and inspected instead of 3. The missing factor, so I suggest, is the high degree of acquired immunity which the Indian ryot's cornea must acquire against septic organisms through its owner living amid so much dust. Dr. Mathra Das had his own private camp hospital just outside Lahore where he did an easy hundred operations weekly, and trained his assistants in after-care before he took them to any outside camp. A month in that camp would give even a compounder more experience of this after-care than many of our own young specialists have had. Some of the assistants left behind for after-care were of compounder status, but they were far from inexperienced at the after-care of cataract. The head assistant was of the sub-assistant surgeon grade with a four-year qualification period.

My own opinion of Dr. Mathra Das, given in my book, *Climate and Labour*, is that no other Indian has done so much good to other Indians as he has. After all, 200,000 cataracts make an easy record which none of our eye specialists can even approach, and, doubtfully, any of our hospitals.—I am, etc.,

Malta, G.C.

W. BURRIDGE.

Eosinophils in the Sputum

SIR,—In connexion with the paper by Dr. John Vaughn (*Journal*, January 2, p. 27) I should like to mention the following case in which I was concerned, from the laboratory point of view, a couple of years ago, and which he may think supports his thesis that the presence of eosinophils in the sputum is a manifestation of a blood eosinophilia.

The patient was a man of 18 who presented with fever and migrating opacities in the lungs on radiography. These individual lesions were present for a few days and would then disappear, to be followed after a short interval by a

similar shadow in another part of the lung field, together with a brisk rise of temperature. I no longer have the records of the case, but as far as I remember the blood leucocytes numbered about 20,000 per c.mm., with up to 92% eosinophils. Between attacks the total count was about 5,000 per c.mm., with 40 to 50% eosinophils. There was also anaemia. At all times during the illness, and particularly during the acute pulmonary incidents, the sputum contained very large numbers of eosinophils. The most interesting point about the case is that the patient died a few weeks later in another hospital, where at necropsy the morbid anatomical findings were those of a classical myeloid leukaemia. I did not have an opportunity of seeing the sections myself. Such cases of eosinophilic leukaemia, though rare, are described in the literature. The important point, however, is that in this case a high blood eosinophilia, caused by a primary marrow dysplasia, was associated with what might be considered a Loeffler's syndrome and a marked excretion of eosinophils in the sputum.

Liverpool, 7.

C. H. JONES.

Ulcerative Colitis

SIR.—I read with interest Sir Robert Hutchison's letter on ulcerative colitis (*Journal*, January 9, p. 98), and, whilst not wishing to venture into the aetiology of the condition, I should like to mention one point of interest.

When Case 4 in Mr. Stanley O. Aylett's series (*Journal*, December 19, 1953, p. 1348) was admitted to hospital there was for some time doubt about the diagnosis in view of her extreme youth (in actual fact she was aged 9 years when first admitted). In view of this, exhaustive tests were carried out and much questioning of the parents took place. Eventually it was discovered that the bowel symptoms were of acute onset dating from a most peculiar incident. She had met her parents returning from a Jewish funeral and had rushed in hysterics to a friend living in a flat in the same block, where she remained at her own request for several days. During that stay her bowel gave trouble for the first time. I am aware that this can be dismissed as coincidence, but at least it is peculiar coincidence.

In all fairness I would say, and I think Mr. Aylett would agree, that none of the other patients in the series could be classified as "emotionally immature."—I am, etc.,

Fowey.

MARTIN LUTHER.

SIR.—With reference to Sir Robert Hutchison's plea for the return of appendicostomy and colonic lavage as "far the best treatment" for ulcerative colitis (*Journal*, January 9, p. 98), I hasten to suggest danger. The results of our research in the x-ray department at St. Mark's Hospital for Diseases of Rectum and Colon reveal that quite a large number of cases labelled "ulcerative" colitis by the clinician have been shown at x-ray examination, and later confirmed by colectomy, to have no ulcers at all. Some of the so-called "fibrous strictures" have been found to relax after the employment of antispasmodics, as recorded at subsequent x-ray examination. Those that have had colectomy performed show only hypertrophy of the muscle wall and no fibrous changes. Perhaps most alarming of all has been the finding by Dr. Dukes at St. Mark's of seven microscopic cancers lined up in a section of the colon in a case of ulcerative colitis. Then there is the devastating, rapidly advancing destructive "polypoid" type of colon, studded with numerous groups of polyps, essentially inflammatory in nature, which do not turn malignant, whereas the familial variety do of course. The picture in these cases can alter so rapidly, showing in the beginning an almost normal bowel, and then within the short space of six months present a shrunken colon literally studded with polypi, with practically complete destruction of the mucous membrane. The patient goes downhill rapidly. Such cases are easily demonstrated by opaque enema examinations and especially if reduction density technique is carried out. Then there is

tuberculous colitis, the syphilitic colon, the dysenteric colon, and our old friend diverticulosis with diverticulitis which essentially starts as a localized colitis (sometimes preceded by a period of obstinate constipation) and so ending eventually as a state of diverticulosis, with possibly from time to time recurrent diverticulitis. Modern medicine to-day does not approve of such crude methods of treatment as appendicectomy to dissipate seven microscopic cancers, or some of these tragic cases of polypoid colitis.

I have great respect and admiration for Sir Robert's brilliant talents and his numerous contributions to medicine, and therefore, as a countryman of my own, same university, etc., I make the following suggestion with great respect. Might it just possibly be that some of these cases Sir Robert treated with appendicostomy and lavage with such success were cases the clinicians labelled in those days as ulcerative colitis, but in the light of modern advances they were probably only cases of chronic colitis, admittedly of long duration, but not ulcerative? Indeed, until recently some of the so-called "ulcerative" colitis cases were only labelled "ulcerative" for no better reason than that the course of the illness had been long and uninterrupted over a period of years. I have cases on record at St. Mark's of 5, 10, 20, and 27 years' standing labelled as "ulcerative" colitis, which at x-ray examination present a colon with circular and longitudinal muscle tone not far from normal and no signs of fatigue at all, and certainly no ulcers. In other words the clinical classification of "acute," "subacute," and the "chronic" is quite out of date, and in the *Lancet* (January 16, 1954, p. 159) I have briefly described our new x-ray classification of colitis which has now been in operation at St. Mark's for some time back.

No, as I see it, ileostomy is only performed essentially as a preliminary, prior to colectomy, and only resorted to in these true cases of ulcerative colitis where medical treatment has failed and appendicostomy or any other form of treatment has proved useless in what really amounts to a disease which is a potential precancerous disease of the colon.—I am, etc.,

London, W.1.

NORMAN P. HENDERSON.

Antibiotics in Bacteraemia

SIR,—In the discussion on antibiotics in bacteraemia (*Journal*, December 19, 1953, p. 1376) Dr. M. Anthony Peyman states that "it is perfectly possible for a patient to be cured of a bacterial infection by an antibiotic while *in vitro* tests demonstrate the organism to be insensitive to that antibiotic." This rash statement is partly upheld by Dr. A. Lawrence (*Journal*, January 9, p. 100). I know of no satisfactory evidence whatever to support it.

The difference of opinion may be due to lack of definition of "in vitro resistance." Unfortunately there is no standard method for sensitivity tests and therefore reports vary from different laboratories. The popular and rapid paper disk method is a good indicator of sensitivity when inhibition zones are large, but it is not always appreciated that small zones, or even absence of inhibition, may not indicate an untreatable degree of resistance. If a weak solution of antibiotic is used to prepare the disks (for fear of overestimating sensitivity) and if the potency of each disk is not controlled on each plate culture, resistance is likely to be falsely reported from time to time. I would not consider a microbe isolated from the blood to be resistant *in vitro* until titration in a serum medium, in parallel with a control strain of known sensitivity, had shown its growth to be unaffected by a concentration of antibiotic higher than that obtainable in the patient's serum.

Cure of a patient suffering from bacteraemia by a drug which has been reported inactive in the laboratory must not lightly be taken as evidence that conditions in the blood stream favour antibiotic action. It is an indication for further tests on "resistant" microbes, not for submitting patients to large doses of toxic drugs regardless of the laboratory report.—I am, etc.,

London, W.C.1.

E. JOAN STOKES

Studies of a General Practice

SIR.—The survey of work in general practice in an urban area undertaken and reported upon by Dr. E. M. Backett and others (*Journal*, January 16, p. 109) is of the greatest interest, and it may be opportune to report, and compare where possible, a survey taken over a period of one year (November, 1952, to October, 1953) in an N.H.S. practice classified as rural. This survey was concerned only with diseases and the amount of work involved.

The practice consists of a partnership of two, each partner, as far as possible, seeing his own patients. The survey was taken of one of the partners' work, the N.H.S. list varying over the year between 2,100 and 2,200 persons. The practice area is in a radius of 10 miles from the surgery with a handful of patients up to 12 miles. The hospital and maternity home are 11 miles away.

The N.H.S. medical work was 9,675 items, consisting of 5,017 visits (51.8%) and 4,658 consultations at the surgery (48.2%). Work such as the signing of pension forms, certificates for coal and housing, life assurance reports and examinations, telephone conversations to hospitals, etc., was not included in the 9,675 items listed, nor were long conversations with patients (if they did not directly concern that person's disease—if any). For the purpose of the survey, diseases were classified under 17 headings as shown on the chart. The small number of patients referred for specialist opinion is mainly due to the fact that the hospital laboratory and x-ray department are willing to carry out any investigation on our direct request. This facility is very much appreciated.

	No. of Consultations Plus Visits	Consultations Plus Visits % (Approx.)	No. of Cases Seen (New)	New Cases % (Approx.)	Referred to Specialist
1 Respiratory ..	1,932	20	578	20	33
2 C.V.S. ..	1,315	14.5	144	5	8
3 Digestive system ..	640	6.75	229	8	12
4 Blood diseases ..	433	4.5	62	2	2
5 Orthopaedic ..	790	8	285	10	27
6 Endocrine distur- bances ..	155	1.5	41	1.5	1
7 Midwifery ..	483	5	34	2	4
8 E.N.T. ..	751	7.75	443	15.5	24
9 Neurosis ..	424	4.5	94	3.25	9
10 Skin diseases ..	555	5.75	266	9.25	12
11 Infectious diseases ..	350	3.5	105	3.5	1
12 Minor surgery ..	327	3.25	117	4	2
13 Accidents ..	325	3.25	167	6	8
14 Renal system ..	287	2.75	60	2	6
15 Gynaecology ..	225	2.25	50	2	14
16 Eyes ..	174	1.75	118	4	8
17 Surgical ..	489	5	62	2	25
Total ..	9,675	100	2,875	100	196

Comparing Dr. Backett's figures in the urban practice with the above rural practice, it can be seen that there is no great variation—that is, (1) psychiatric disorders, or neurosis, involved 5% of all cases in the urban area and 3.25% in the rural, while work involved was 1 to 7% urban and 4.5% rural; (2) cardiovascular system: 3% of all cases urban and 5% rural, work involved 2 to 10% urban and 14.5% rural; (3) skin: 11% of all cases urban, 9.25% rural, work involved 6 to 12% urban, 9.25% rural. The one outstanding variation between the two practices is in the percentages of work involving visits to the patient's home—36% urban, 51.8% rural. There are a few patients who think that it is easier for the doctor to travel to his house than for him or her to get to the surgery. There is also the "snob" element in a few patients which is difficult, and not always wise, to break. It may be that the rural patient has to be iller than his urban brother before he seeks advice (although up till now this had never occurred to me). Or perhaps it just goes to show that no two practices are alike. If the latter is the case, is it really worth wallowing in a mass of figures?—I am, etc.,

Brightlingsea, Essex.

JOHN MIDDLETON.

Training General Practitioners in Psychotherapy

SIR.—Dr. Michael Balint's warm-hearted and sympathetic article on "Training General Practitioners in Psychotherapy" (*Journal*, January 16, p. 115) must have been read with gratitude by many analytical psychotherapists. The practitioner's relationship to the psychiatric consultant of the analytical persuasion is one of the most complex and paradoxical issues in present-day medicine. The author describes certain aspects of this relationship which exist on both sides. From the long waiting-lists in all psychiatric institutions and the longer ones in the few existing analytical clinics, it becomes quite obvious how much in need the practitioner feels of the help of medical psychotherapists. Yet when he sends his patient to the analyst, he is often—certainly more often than not—ignorant of the analytical methods and its many implications. He so often feels that analysis is glorified pep-talking, only more expensive, and that if he had the time he could do most of it himself. He usually has heard little of positive and negative transference and less of the meaning of symbols in dreams and free associations. He may marvel at the long time an analysis with one of his patients may take and at the continuation of symptoms even after many months of treatment. He may even wonder whether the relationship between patient and analyst, which is based on the transference, is the right thing for his patient.

All this may make the practitioner into a far from whole-hearted ally of the very specialist whom he has called in. As soon as the practitioner's co-operation with the psychotherapist becomes less than whole-hearted, the analysis may be adversely affected, and the patient may then, with the intuitiveness of the neurotic, begin to see a way of "escape from cure" by playing off the two authorities one against the other. I am quite sure that the practitioner has sometimes most unsympathetic colleagues among the analytical specialists and finds that the latter may have little idea of his own work and its complexity. Ideally, therefore, not only should the practitioner learn much more about analytical psychotherapy in practice, but equally the analyst should miss no opportunity to acquaint himself with the work confronting the practitioner in his daily tasks. Dr. Balint's article may inspire many of his readers to seek a closer understanding and more intimate knowledge. Perhaps it will become possible, not only in London, to have training and discussion groups established, which would be such a blessing to both practitioner and specialist and bring more effective help to so many neurotic patients. I am, etc.,

Edinburgh, 9.

W. P. KRAEMER.

SIR.—In his good and stimulating paper, "Training General Practitioners in Psychotherapy" (*Journal*, January 16, p. 115), Dr. Michael Balint says that "the only training which systematically caters for these difficulties [difficulties in personality of the prospective psychotherapist] is the psycho-analytic training."

May I be allowed the hospitality of your columns to correct and supplement this statement? The Society of Analytical Psychology also provides a training with identical aims.—I am, etc.,

London, W.1.

MICHAEL FORDHAM.

Treatment of Angina

SIR.—Dr. David Weitzman's paper (*Journal*, December 26, 1953, p. 1409) on penta-erythritol tetranitrate (P.E.T.N.) raises a number of interesting points, and his somewhat inconclusive results correspond to those which other observers have found with this preparation and with its precursor, erythrol tetranitrate (E.T.). Twenty years ago Evans and Hoyle¹ reached the conclusion that E.T., in common with a large number of other potential vasodilators, had practically no value in the management of angina pectoris, but their conclusion is not borne out by practical experience spread over a large number of cases.

Obituary

Lord GEDDES, P.C., G.C.M.G., K.C.B., M.D.

Dr. J. B. WRATHALL ROWE writes: Your obituary notice (January 16, p. 160) of Lord Geddes makes no mention of the fact that, in addition to his other talents, he was an accomplished musician. During the first few years of the century he composed a number of airs for marching songs and wrote choruses for smoking concerts. One of the best known of these songs is "Route Marchin", with words by Rudyard Kipling, published in the *British Students' Song Book*. It is probable that other compositions of his would have become well known had it not been for the fact that his musical MSS. were stolen from his tent when he was in camp at the Curragh before the 1914-18 war.

Dr. D. SAGE SUTHERLAND, formerly medical superintendent of Monsall Isolation Hospital, Manchester, died suddenly at Edinburgh, where he was living in retirement, on January 9 at the age of 78. Donald Sage Sutherland was born at Lochaber, Inverness-shire, on March 19, 1875, the son of the late Rev. Donald Sutherland, and was educated at Garnethill School and Glasgow University, where he graduated M.B., Ch.B. in 1898. He received a commendation for his M.D. thesis in 1903. After a brief period in general practice at Keighley, Yorkshire, he held the post of senior resident house-physician and surgeon at the Cumberland Infirmary, Carlisle, his work there being interrupted by a period of service as a medical officer in the South African Field Force in 1900-1. From Carlisle he moved to London to begin his long association with the fever hospital service. After holding the appointment of assistant medical officer at Brook Fever Hospital, Woolwich, under the old Metropolitan Asylums Board, he became medical officer at the South-Western Fever Hospital, Stockwell, in 1906 and remained there until 1914. An enthusiastic Territorial—he joined the force in 1909, when he was attached to a London brigade of artillery—he was transferred to the 2/1 City of London Field Ambulance as second in command when war broke out in 1914. He served throughout the war, and in 1917 became commanding officer of an isolation hospital at Calais.

On his return to civilian life Dr. Sage Sutherland became senior medical officer at the Eastern Fever Hospital, Homerton, in 1918 and held the post until 1923, when he was appointed medical superintendent of Monsall Isolation Hospital, Newton Heath, Manchester. He also became clinical lecturer in infectious diseases in Manchester University. In Lancashire he continued his connexion with the Territorial Army, first with the Manchester Artillery as medical officer and then, in 1930, when he was promoted to the rank of lieutenant-colonel, as officer commanding the 2nd Western General Hospital. He was awarded the Territorial Decoration in 1925 and he retired from the Territorial Army in 1934. When war broke out again in 1939 he was engaged for a short time as officer in command of administration at the Territorial depot of the R.A.M.C. in Manchester. On his retirement from the post at Monsall Hospital in 1941, Dr. Sage Sutherland went to live first at Ambleside and later at Edinburgh. He leaves a widow and two young sons.

Dr. J. W. DEW, who was in practice at Horsham in Sussex for many years, died at his home on December 15, 1953, at the age of 66. John Westcott Dew was born at Hoddesdon, Hertfordshire, on January 10, 1887, and was educated at Tonbridge School, where he was head boy and for two years captain of football and cricket. His career at Cambridge, where he was at Clare College, was equally distinguished,

The unpredictable effect of P.E.T.N. and E.T. is common to both preparations, but the former has fewer side-effects and has been better tolerated in my own series.

The error into which we seem to have fallen is that of regarding all cases of angina pectoris as having identical aetiology, although everyone is familiar with the mild sclerosis which can be found at necropsy in a patient who has had severe angina and, at the other end of the scale, the gross calcification of the main coronary arteries in the patients who have never suffered from ischaemic pain. It is hardly surprising that some patients do not respond to these long-acting vasodilators whose potency is relatively low, even though they respond so well to glyceryl trinitrate. In view of the findings in my own series, which are comparable with those reported by Dr. Weitzman, I am now concentrating on treating those patients who derive benefit from P.E.T.N., and I am trying to assess its value by the use of genuine and identical dummy tablets.

This seems to be an example of a condition where a direct statistical approach may give a fallacious answer, and to work on an unselected series may bring into disfavour a drug which seems to me to have a definite place in the management at least of some patients with angina pectoris.—I am, etc.,

A. L. WINGFIELD.

London, W.1.

POINTS FROM LETTERS

Disease and the Pig Bin

Dr. KATHLEEN VAUGHAN (London) writes: I have not seen any report on the remarkable disappearance of the ordinary house-fly with a soft proboscis and its replacement by a fly looking much the same but furnished with a spike with which he draws your blood. Squash one of these and there is always red blood inside. Where do they breed? In those awful tins labelled "Pig's Food," where bits of meat, stale vegetables, tea leaves, carpet, and paper bags are deposited and left without early removal or disinfection. No self-respecting pig would eat the contents. May not the stinking pig's food bin prove to be the breeding ground of diseases whose origin is still obscure?

Masked Appendicitis

Dr. R. G. WIGGERS (London, S.E.6) writes: A male patient, aged 50, walked into my surgery complaining of upper abdominal pain, which he said had been present for about 24 hours. He had no nausea or vomiting and felt well except for this pain. His temperature and pulse were normal, tongue clean, lungs normal, and the only abnormal physical sign found was, to my mind, slight rigidity and guarding in the right iliac fossa. There was no tenderness in the right iliac fossa, but there was rebound tenderness present. He was sent immediately to hospital—query tenderness present. He was found only some voluntary guarding in the right iliac fossa, but no rigidity. A laparotomy was performed and an acutely inflamed appendix was removed. The patient made a satisfactory recovery following operation. This case serves as a reminder that an acute appendix can be present with only minimal symptoms and signs.

Sale of Antibiotic Lozenges

Dr. G. FIELDING (Nottingham) writes: It appears that "tyrozoets" and similar antibiotic throat lozenges can be freely bought in any chemist's shop over the counter. I saw a patient to-day with a typically inflamed denuded "antibiotic" tongue who had treated herself with a tube of these lozenges. As these tablets are potentially dangerous and also contain 5 mg. of benzocaine, their sale should be restricted in the same way as penicillin lozenges already are.

Disposal of Anaesthetics

Dr. L. RUNDLE-BAKER (Cardiff) writes: In his letter Dr. M. Essex-Lopresti (*Journal*, December 26, 1953, p. 1433) complains that its blue colour prevents the use of waste trichlorethylene ("trilene") for cleaning purposes. He will find that a small bag containing activated charcoal (as used in laboratories for gas absorption) will remove the waxolene-blue dye from the trichlorethylene, leaving a clear fluid which is quite suitable for cleaning and degreasing purposes. The waste trichlorethylene and ether can then both be of use.

and he took a first in Part I of the Natural Sciences Tripos and went on to the London Hospital with an exhibition. He graduated M.B., B.Chir. in 1912, and held the appointments of house-surgeon and ophthalmic house-surgeon at the London Hospital. He served throughout the war of 1914-18 with No. 10 Casualty Clearing Station, becoming a surgical specialist with the rank of major. He was twice mentioned in dispatches and in 1918 was awarded the Military Cross for attending wounded under heavy fire. After the war he settled at Horsham in 1919 and soon acquired a busy private practice. He also joined the staff of Horsham Hospital and became responsible for a large share of the operative work there. Dr. Dew was in fact that rare combination, a first-class general practitioner and a very good surgeon: not only was he a skilled operator but he possessed that invaluable asset, sound surgical sense. His opinion on a difficult abdomen was eagerly sought and willingly given, and he rarely made a mistake. But he will be remembered chiefly as a most lovable individual. By nature he was modest and unassuming and his innate honesty and sincerity made him beloved by his patients, to whom he was counsellor and friend. Many of his poorer patients could tell stories of his kindness quite outside the accepted obligations of a doctor. His tact and common sense were a great asset to the various hospital committees on which he served for many years. He was honorary secretary of the Horsham Division of the British Medical Association from 1922 to 1925, and he had a wide range of interests outside his profession. He was a first-class shot and a keen sportsman, and excelled at all games. Not only did he play them very well but he had a gift of inspiring others with his enthusiasm and obvious enjoyment. He was a keen philatelist and a talented musician, being a faithful member of the church choir. But probably his greatest love was bird-watching and bird-photography. Some of his happiest memories were of holidays spent, together with his wife, following this hobby, in some distant corner of Scotland or on some small island off the coast. His photography was of a very high order, evidence of many hours of patient watching and waiting. He worked hard and played hard, and never spared himself. He worked to the end, knowing well that the cardiovascular disease from which he was suffering might at any time prove fatal. Our sincere sympathy goes out to his widow, and to his two sons, the elder, Dr. J. A. Dew, having recently joined him in practice at Horsham.—G. S. M.

Dr. W. H. ROWELL, who was in general practice for 14 years before he joined the public health service, died suddenly in hospital on January 4 at the age of 79. Born on May 8, 1874, William Henry Rowell studied medicine at Newcastle-upon-Tyne and graduated M.B., B.S. from the University of Durham in 1895. He proceeded to the M.D. three years later, and obtained the degree of B.Hy., with honours, in 1899. Serving as a volunteer in the South African war, he took part in actions at Kimberley and in the relief of Mafeking in 1900. On his return home he was elected an honorary freeman of the city of Newcastle-upon-Tyne. After taking the D.P.H. in 1901, he settled at Grimsby, where he spent the first part of his professional career in general practice until the outbreak of war in 1914. Already a Territorial attached to the Lincolnshire Yeomanry, he served throughout the first world war, attaining the rank of major and being twice mentioned in dispatches. In 1919 he was appointed O.B.E. He then returned to civilian life and in 1920 he took the degree of D.Hyg. before joining the staff of the public health department at Stockport, where he was one of the pioneers in the school health service. He worked as assistant school medical officer in that town until 1943, when he retired to Grange-over-Sands to be near the lakes he loved so well. The pleasant and soft surroundings of Grange, where he enjoyed his 10 years of leisure, were in keeping with his own nature, for he was a modest man, full of love and sympathy for his fellow men. His end came quickly, with a sudden heart attack, as he would have wished. He is survived by his wife.—J. Y.

Medical Notes in Parliament

Treatment of Blindness

Mrs. EIRENE WHITE asked the Minister of Health on January 21 if he had considered the report of Professor A. Sorsby on the causes of blindness, and what action he proposed.¹

Mr. IAIN MACLEOD said he had asked hospital authorities to review urgently, and where necessary improve, their arrangements for the treatment of persons suffering from eye diseases, in particular cataract and glaucoma. He had also asked medical officers of health to include in their annual reports for 1953 information about the steps taken to follow up cases shown on registration as requiring remedial treatment. He was considering whether the examination at registration could be used to obtain better information on the possibilities of the blindness being relieved.

Mr. SOMERVILLE HASTINGS suggested that the Minister should consider sending to general practitioners a request that all cases of incipient blindness not due to errors of refraction might be sent at once to an eye specialist. Mr. MACLEOD said he would consider it.

Mr. BARNET JANNER asked the Minister of Health what response he had received from his circular to hospital boards asking them to review urgently their arrangements for the treatment of ophthalmological patients. Mr. MACLEOD replied that there had not yet been time for boards to decide what action should be taken, and in any case he had not thought it necessary to require boards to submit formal proposals on this.

Cancer Research

Mr. NORMAN DODDS, questioning Mr. Iain Macleod on January 21 about cancer research and treatment, said there was a feeling among the public, rightly or wrongly, that not all that might be done was being done. Mr. MACLEOD replied that it was important to keep the matter in perspective. Apart from cancer of the lung, of which there had been a considerable increase, the causes of which were still in medical and scientific dispute, and a small number of other sites, the death rate for cancer had not increased when allowance was made for the increase in the age structure of the population. The increase was not confined to this country, and they were doing everything they could to combat it.

Health Service Specialists

Mr. A. BLENKINSOP asked the Minister of Health on January 21 for information about the number of full-time and part-time specialists employed in the Health Service, and asked him also to keep this matter very much in mind, in view of the strong feeling that part-time specialists were being too much favoured, to the detriment of full-time specialists, and that this might have a dangerous effect on the Service. Mr. MACLEOD said that he would bear it in mind.

Mr. H. MARQUAND asked the Minister if he would care to deny the feeling in some parts of the medical profession that he might have been encouraging or directing a change from full-time to part-time service. Mr. MACLEOD stated that it was not a matter in which he had taken any initiative at all.

Health Service Frauds

Mrs. EIRENE WHITE asked the Minister of Health on January 21 if he was satisfied that safeguards against frauds in the Health Service were adequate, in view of the statement by the President of the G.M.C. on undisclosed fraudulent practices.² Mr. IAIN MACLEOD replied that the matter was under constant review, but he had no reason to think there was any serious inadequacy.

¹See *Journal*, November 7, 1953, p. 1038.
²See *British Medical Journal Supplement*, December 5, 1953, p. 217.

Mrs. WHITE said that a statement by such a prominent medical authority naturally caused uneasiness. Had the Minister taken any action since it was made? Mr. MACLEOD said that he had not, but it was fair to say that perhaps the right interpretation had not been put on what was said. As he understood it, this was a warning that the G.M.C., quite rightly, took a grave view of any laxity in these matters, and was not an allegation that fraudulent practices or conduct were at all widespread.

Pay-beds in Hospitals

Dr. BARNET STROSS asked the Minister of Health on January 21 whether he was satisfied that pay-beds in hospitals were being fully used, and why, at some hospitals, their use was much less than in the service as a whole. Mr. IAIN MACLEOD said that statistics for last year were not yet available, but he had impressed on hospital authorities the importance of ensuring that the total occupancy of these beds, whether by paying or by non-paying patients, was no lower than that of other beds. Reasons for any unusually low occupancy would depend on the circumstances of the particular case.

Dr. STROSS suggested that the high cost was a factor, and that the whole matter should be reviewed. Would the Minister consider abolishing pay-beds as such, and turning them into normal beds and amenity beds, which would be very much better? Mr. MACLEOD said he certainly would not abolish pay-beds, which he believed had a valuable part, just as had private practice, in the development of the Service.

Welsh Health Statistics

The Minister of Health is arranging for a separate section of the state of the public health in Wales to be included in the next annual report of the Ministry of Health, together with separate statistics of special interest to Wales, according to a Parliamentary answer he gave on January 21.

Calomel in Teething Powders

Mr. S. T. SWINGLER asked on January 21 if the Home Secretary would now prohibit the use of calomel in the manufacture of teething powders. Sir DAVID MAXWELL FYFE replied that he had no power to prohibit the use of calomel in the manufacture of teething powders, but he understood that the only firm known to have been manufacturing such powders wholesale in recent times had decided to omit this ingredient. Retail pharmacists who manufactured their own brands of teething or soothing powders had been advised in the *Pharmaceutical Journal* to use safe aperients in lieu of calomel.³

Food and Drugs Bill

When the Food and Drugs Amendment Bill was considered in committee by the House of Lords on January 20 Viscount BLEDISLOE moved a new clause requiring that all milk sold for public consumption must contain at least 3% of butter fat. He said the present policy in regard to the quality of milk sold to the public was fair neither to the dairy farmers who tried to produce high-quality milk, nor to the public who were getting a lower quality of milk. What was called the legal presumptive minimum of butter fat content, 3%—which was low compared with requirements in other civilized countries—could be reduced by what was called "an appeal to the cow." He mentioned the practice in several countries where a higher standard was demanded, and said that in Canada and the United States, where 3.5 and even 4% tested milk was not infrequently found, recently the craze for slimming had produced a so-called "skim milk," which was reduced to a 2% content of butter fat; and that a small but significant quantity of skimmed milk was now being sold to those anxious to maintain willowy figures. The "appeal to the cow" was definitely putting a continuing premium on the production of low-quality milk.

³See annotation at p. 265.

LORD SILKIN expressed some doubt that the amendment would result in a shortage of milk. It would mean that there would be a considerable quantity which could not be sold as milk. To improve the quality involved breeding and housing problems that could not be solved immediately. The cost would also be increased.

LORD BALFOUR OF BURLEIGH said that in Kensington sample figures taken over many years showed that the quality of milk sold there was steadily deteriorating. The Government should study the possibility of payment by quality, giving some premium for additional fat content.

LORD WEBB-JOHNSON supported the desire of Viscount Bledisloe to improve the quality of milk, but thought the amendment would lead to a decrease in milk available for consumption, and that would be unfortunate. He agreed with suggestions that the price as well as the milk might be graded. Anything below 3% fat content should be labelled sub-standard milk, but it should be cheaper. For culinary and domestic purposes many people might prefer to buy cheaper milk, leaving available a larger amount of high-grade milk for the infants and children who needed it.

LORD CARRINGTON, Parliamentary Secretary, Ministry of Agriculture, defended the presumptive minimum of 3% and the "appeal to the cow." They were all agreed on the necessity to protect the consumer against deliberate fraud by adulteration of milk, but it would be an entirely new principle to make it a criminal offence to sell a natural product merely because the quality of the product was poor. Farmers had done a magnificent job, and were producing better-quality milk than ever. The proper way to deal with low-quality milk was to see that a lower price was paid for it.

The amendment was withdrawn, after Viscount BLEDISLOE had asked for an assurance that the Government would accept the objective of establishing at no distant date a minimum fat content of 3%, and Viscount WOOLTON had promised to represent this to the appropriate Minister.

Blackburn Maternity Home

Mr. H. HYND asked on January 21 whether the closing of Springfield Maternity Home, Blackburn, was carried out with the Minister of Health's approval, and what consultations took place with the doctors before their patients were ordered to leave the maternity home.⁴ Mr. IAIN MACLEOD replied that his approval was not needed, but he was aware of the proposal and saw no reason to dissent. Seven patients were sent home and five transferred elsewhere. Steps were taken to consult all the doctors concerned before action was taken. The doctors of the seven patients accepted the proposal. The doctor of one of the five transferred patients objected. The other four unfortunately could not be reached before transferring, but a message was left for them. He regretted more time was not available for consultation, but understood that no ill effects had followed the transfer.

Mr. HYND indicated that the Minister had been misinformed about whether the doctors were consulted, and asked him to look into the matter again, because of the local indignation about the high-handed way in which the closing took place. Mr. MACLEOD said he would do so. In reply to Mr. R. FORT he said that Springfield, formerly a 20-bed general-practitioner maternity home, was to become a home for 30 chronic sick.

Mrs. BARBARA CASTLE asked whether the Minister was aware that many women were being compelled to have their babies at home owing to the shortage of maternity beds, and that the closing of Springfield would make the situation worse. Mr. MACLEOD replied that even after the Springfield closure the number of general-practitioner beds available was 50%, which was much higher than in most parts of the country.

Mr. HYND gave notice that he would raise the matter on the Adjournment.

⁴See *British Medical Journal*, January 23, p. 205.

object of the Fellowships, as defined in the Trust Deed, is to give special opportunities for study or research to suitably qualified British subjects of either sex "intending to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis in all or any of its forms." The Fellowships will, as a rule, be awarded to candidates who wish to make their studies or inquiries elsewhere than in the United Kingdom. The Fellowships provide for the payment of a maintenance allowance at the rate of £650 per annum for a single Fellow and £900 per annum for a married Fellow, subject to appropriate adjustment in the case of Fellowships tenable at centres outside the sterling area; in addition, an allowance will be made for travelling and other approved expenses.

Further particulars and forms of application may be obtained from the Secretary, Medical Research Council, 38, Old Queen Street, Westminster, S.W.1, with whom applications must be lodged not later than March 15, 1954.

Medical Auxiliaries.—It is nearly a year since the Minister of Health, answering a Parliamentary question about the Cope report, stated that he would make regulations laying down the qualifications required of medical auxiliaries employed in the National Health Service. The National Health Service (Medical Auxiliaries) Regulations, 1954, have now been issued, and after April 1, 1954, hospitals and local health authorities may employ only those qualified under them. The regulations refer to two groups of auxiliaries—those who on March 31, 1954, come within the definition of being qualified on that date, and those who will qualify on or after April 1. The first group comprises (1) those who are already employed in the N.H.S.; (2) those who hold qualifications recommended by the Cope Committee as appropriate; and (3) certain holders of qualifications given by the Joint Council of Chiropodists and the Physiotherapists Association. Those qualifying after April 1 must obtain a certificate from one of the appropriate bodies named in the regulations. Employing authorities can accept the certificates when the Minister has approved the course of training and examinations to which the certificate refers. The Cope Committee recommended that there should be statutory registration for medical auxiliaries. The Minister said in Parliament that there was insufficient agreement on fundamental matters to proceed with this—an opinion with which we disagreed (June 6, 1953, p. 1267). The Minister has now announced that he is setting up a Working Party to draw up a scheme of registration which will be acceptable to him and to the professional bodies concerned.

Rockefeller Grants.—Among the Rockefeller grants announced this quarter perhaps the two of most interest to medical men are those to Professor Vincent du Vigneaud, of Cornell University, for the continuation of his work on what appears to be synthetic oxytocin (see *Journal*, December 5, 1953, p. 1260), and to the School of Public Health, Harvard, the Christian Medical College of Ludhiana, Punjab, and the Government of India for a pilot study in the Punjab preparatory to a long-term investigation of "population dynamics" in India. Individual British workers who are awarded grants include: Professor J. M. Yoffey at Bristol for research in experimental histology and physiology (£6,200); Dr. Max Perutz, director of the M.R.C. Unit for Research on the Molecular Structure of Biological Systems at Cambridge, for equipment (£4,000); Dr. H. Lehmann, to visit centres of sickle-cell research in the United States (£2,505); Dr. Robert Murray, a medical inspector of factories in Lancashire, for a visit to occupational health and hygiene centres in the United States and Canada (£2,350); Professor A. V. Hill for visits to the scientific conferences and centres of biophysical research in the United States (£2,100); and to Oxford University for equipment to be used in the Subdepartment of Microbiology under Dr. D. D. Woods.

President's Tour.—Sir Cecil Wakeley, P.R.C.S., has just returned from a two months' visit to Ceylon and the Middle East. He went to open the ninth annual session of the Ceylon Society for the Advancement of Science, where he

spoke on "Surgery through the Ages." While in Ceylon, he gave a broadcast on "Positive Health" and a B.M.A. lecture on the surgery of the temporo-mandibular joint, as well as lectures to the Medical Society of Kandy and the Dental Society. On his return journey, at the invitation of General Sir Charles Keightley, Sir Cecil spent a day inspecting the Army medical services in the Canal Zone. He saw a demonstration of the Fleming mass inoculation technique, which is rapidly becoming the standard method there, and a hospital surgical service where the regimental medical officer brings his patients for minor surgery instead of doing it in the unit medical inspection room. In the afternoon there was a joint clinical meeting of the medical services of the Royal Navy, Army, and R.A.F. at the British Military Hospital, Fayid, under the chairmanship of Major-General W. A. D. Drummond.

The Common Cold.—Aptly situated on one of the bleakest hilltops in England, the Common Cold Research Unit at Harvard Hospital, just outside Salisbury, opened its doors to the Press on January 21. This hospitality is rarely possible, because the claims of complete isolation must normally come first. Dr. C. H. Andrewes, F.R.S., director of the studies there, outlined the work that had been carried on for the last six years. Some advance has been made towards the control of this exceedingly obdurate virus in that, as reported last year, it is being serially propagated in fragments of human embryonic lung, but human volunteers are still needed to detect its presence. It has been found that the most active nasal washings produce colds in only 55% of women and 43% of men aged 18–40, and a possibly fruitful line for further research is thought to be a study of why individuals differ in their susceptibility.

North of England Obstetrical and Gynaecological Society.—At the annual general meeting of the North of England Obstetrical and Gynaecological Society, held in Manchester on January 15, honorary fellowship was conferred on Sir William Fletcher Shaw (Manchester), Dr. Henry Brown (Brighton), and Dr. W. A. MacKay (Southport), all of whom have been members of the society for over 45 years. The following officers were elected for 1954: *President*, Dr. K. V. Bailey; *Hon. Treasurer*, Dr. C. H. Walsh; *Hon. General Secretary*, Mr. D. C. Racker; *Hon. Reporting Secretary*, Mr. S. Bender.

COMING EVENTS

Society for Endocrinology.—The next meeting will be held jointly with the Endocrinological Section of the Royal Society of Medicine at 1, Wimpole Street, London, W.1, on February 24 at 10 a.m. It will take the form of a symposium on "The Technique and Significance of Oestrogen Determinations." Those wishing to attend who are not members of either society should write to Professor N. F. MacLagan, Westminster Medical School, 17, Horseferry Road, London, S.W.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, February 1

INSTITUTE OF DERMATOLOGY.—Fifth of series of semi-permanent exhibitions by Mr. R. J. Lunn: Medical Photography. (February 1 to 20.)

Tuesday, February 2

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor L. P. Garrod: Causes of Failure in Antibiotic Therapy.

LIVERPOOL MEDICAL INSTITUTION.—At Newsham General Hospital, Liverpool, 3 p.m., clinical meeting.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Mr. J. R. Armstrong and Mr. Aleck W. Bourne: Backache in Women.

Wednesday, February 3

EDINBURGH CLINICAL CLUB.—At the City Infectious Diseases Hospital, Edinburgh, 4 p.m., clinical meeting. Dr. G. Sangster: Gastro-enteritis in Infants.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. W. Riddell: Practical

Diagnosis of Superficial Mycoses.

INSTITUTE OF LARYNGOLOGY AND OTITIS.—5.30 p.m., Professor P. Van der Calkwyck (Bruged): Bronchial Diseases and Pathology of the Upper Respiratory Tract. Clinical Aspects and Therapeutic Conclusions.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Dr. J. J. Stevenson: X-rays.

● **LONDON UNIVERSITY. DEPARTMENT OF EXTRAMURAL STUDIES AND ATOMIC SCIENTISTS' ASSOCIATION.**—At Beveridge Hall, Senate House, 7 p.m., Professor F. E. Simon, F.R.S.: Power from Atomic Energy.

MANCHESTER MEDICAL SOCIETY. SECTION OF MEDICINE.—At Large Anatomy Theatre, Manchester University, 4.30 p.m., Dr. W. H. Trethowan: Psychopathological Reactions to A.C.T.H. and Cortisone.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Dr. T. L. Hardy: Functional Disorders of the Colon.

Thursday, February 4

BRITISH POSTGRADUATE MEDICAL FEDERATION.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., Professor A. A. Miles: Reactions to and Bacterial Invasion.

FACULTY OF HOMOEOPATHY.—5 p.m., Drs. W. Lees Templeton, L. R. Twentyman, E. K. Ledermann, C. O. Kennedy, and N. J. Pratt: Reports on Research.

● **INSTITUTE OF CHILD HEALTH.**—5.30 p.m., Mrs. J. M. Williams: Prevention of Backwardness at School.

LONDON UNIVERSITY.—(1) At School of Pharmacy, 5.30 p.m., Special University Lecture in Pharmacy by Professor J. H. Gaddum, F.R.S.; (2) At Senate House, 5.30 p.m., Special Discoveries in Pharmacology.

MANCHESTER MEDICAL SOCIETY. SECTION OF ANAESTHETICS.—At Medical School, Manchester University, 8 p.m., Dr. E. A. Pask: James Brown.

SCHOOL OF MEDICINE.—At Southfield School, Glenville Road, Cowley Road, Oxford, 8 p.m., Dr. A. G. M. Weddell: Science and Medicine.

ROYAL COLLEGE OF SURGEONS OF ENGLAND AND INSTITUTE OF LARYNGOLOGY AND OTITIS.—At Royal College of Surgeons of England, 5.30 p.m., Professor G. Hadfield: Co-carcinogenesis.

ST. ANDREW'S UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Dr. J. N. Morris: Epidemiological Approaches to Coronary Disease.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., psychiatry demonstration by Sir Paul Mallinson.

UNIVERSITY COLLEGE LONDON.—Public Lecture by Professor F. Bergel, Physiology Theatre, 5.30 p.m., Public Lecture by Professor F. Bergel: Ph.D., D.Sc.: Some Chemical Aspects of Abnormal Growth.

Friday, February 5

INSTITUTE OF CARDIOLOGY.—9.30 a.m., Dr. S. J. Sarnoff (Harvard): Haemodynamic Effects of a New Sympathomimetic Amine, Aramine, and the dynamic Effects of its Use in the Hypotension and Low Cardiac Output of Rationale for its Use.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. H. W. Gordon: Benign New Growths.

INSTITUTE OF NEUROLOGY.—5 p.m., Professor H. Gastaut (Marseilles): So-called "Psychomotor" and "Temporal" Epilepsy.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Mr. J. E. Richardson: Unusual Presentation of Common Gastric Disorders.

ROYAL MEDICAL SOCIETY. Edinburgh—8 p.m., Dissertation by Mr. D. Q. Sutherland: Mind over Matter.

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Dr. Hugh Ramsay: Tuberculosis Services, Yesterday and To-day.

Saturday, February 6

KENT PAEDIATRIC SOCIETY.—At Royal Star Hotel, Maidstone, 2.15 p.m., discussion by Mr. R. H. Percival and Dr. P. N. Swift: Circumcision.

MIDLAND TUBERCULOSIS SOCIETY.—At Birmingham Chest Clinic, Mr. P. R. Allison: Some Diseases at the Lower End of the Oesophagus.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—G. L. Davies, M.R.C.S., L.R.C.P., D.P.M., Assistant Psychiatrist, Ipswich Child Psychiatry Clinic; W. Boyd, M.B., Ch.B., Senior Registrar in Mental Deficiency and Child Psychiatry, Little Plumstead Hospital; W. P. D. Green, M.B., B.S., Senior Medical Registrar, East Suffolk and Ipswich Hospital; K. W. Baruch, M.B., Ch.B., Anaesthetic Registrar, West Suffolk General Hospital; J. A. Reynolds, M.R.C.S., L.R.C.P., and T. K. Thorlakson, M.D., F.R.C.S., Surgical Registrars, East Suffolk and Ipswich Hospital; E. A. Burdett, M.R.C.S., L.R.C.P., D.P.M., Assistant Psychiatrist, Hellesdon Hospital, Norwich.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Arndt.—On January 15, 1954, at Queen Charlotte's Hospital, London, W. to Frances (formerly Ondatie), M.B., B.S., D.Obst.R.C.O.G., wife of Reverend George Arndt, a daughter—Theonie Frances.

Gibb.—On January 3, 1954, at St. Bartholomew's Hospital, London, E.C., to Mary (formerly Feetham), wife of William Eric Gibb, D.M., F.R.C.P., a son.

Griffiths.—On December 18, 1953, at King's College Hospital, London, S.E., to Barbara (formerly Grand), wife of Dr. Glyn I. T. Griffiths, a second daughter—Caroline Barbara.

Levis.—On December 31, 1953, at the Central Middlesex Hospital, London, N.W., to Renée (formerly Anderson), wife of R. D. Levis, M.B., D.A., a daughter—Julia Allison.

Rutherford.—On January 19, 1954, at 192, Staines Road, Bedford, Middlesex, to Tess (formerly Tomlinson), wife of Dr. G. T. Rutherford, a son.

Williams.—On December 21, 1953, in Nairobi, Kenya, to Philippa Gaffikin, M.B., Ch.B., wife of John G. Williams, a daughter.

DEATHS

Clarke.—On January 9, 1954, at 74, Earham Green Lane, Norwich, Norfolk, Andrew Campbell Clarke, M.B.E., M.D., aged 79.

Corcoran.—On January 1, 1954, at 48, Queen's Gate, London, S.W., Gerald Corcoran, L.R.C.P.S.I.&L.M., D.P.H., formerly of Southsea, Hants.

Cramer.—On January 7, 1954, at The Whin, Snape, Suffolk, John William Cramer, M.B., F.R.C.S.Ed., of Maryport, Cumberland, aged 86.

Davies.—On January 2, 1954, at 113, Fox Lane, Palmer's Green, London, N., Sidney Richard Davies, M.R.C.S., L.R.C.P., D.P.H., aged 87.

Lloyd.—On December 22, 1953, at 4, Overdale, Ashted, Surrey, Richard Harry Lloyd M.R.C.S., L.R.C.P., late R.A.M.C., retired, aged 87.

West.—On December 27, 1953, at St. Lawrence's Hospital, Bodmin, Cornwall, Sigmund Henry West, M.R.C.S., L.R.C.P., aged 87.

Roberts.—On January 1, 1954, at his home, Garth, Fairfield Avenue, Rhyll, Flint, Anceuria Evan Roberts, M.B., B.S., D.P.H.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Mouth-breathing

Q.—Is there any effective treatment for re-establishing nose-breathing in children who have had tonsils and adenoids removed and in whom there is no nasal obstruction? Is diastolization still used for this?

A.—Defective nose-breathing in a child may be due to a cause within the nasal cavity itself, to excessive lymphoid tissue in the post-nasal space (adenoids), or to habit.

It is customary to attribute any nasal symptoms in a child to adenoids, just as it is usual to attribute such symptoms in an adult to "catarrh." In both cases a proper examination of the nose after a careful history has been taken should be the rule. In not a few instances it will be found that the nasal obstruction is variable, possibly being worse in the morning on rising, and then an allergic cause should be considered. If the possibility of allergy has been excluded, and enlarged tonsils and adenoids have been removed, and the nasal airway seems clear, then the possibility of habit must be considered. Children who have of necessity been habitual mouth-breathers acquire a pattern of mouth-breathing which is continued even when the nasal airway has been restored. For these, breathing exercises are needed.

In some there may be a dental malformation which requires correction, and in very persistent mouth-breathers who have a good nasal airway it may be necessary to prescribe an obturator for wearing at night.

Diastolization is not generally practised now, though at one time it was popular in some children's clinics.

Anticoagulant Therapy at Sea

Q.—I sometimes have to treat cases of coronary occlusion while at sea, where no elaborate laboratory facilities are available. Should anticoagulants be used in these circumstances? If so, which are advised, how should they be given, and what is the minimum essential laboratory control?

A.—None of the anticoagulants which act by depressing the liver function should be used without laboratory facilities for measuring the prothrombin time from day to day: this applies to dicoumarol, ethyl biscoumacetate ("tromexan"), and "dindevan." Heparin, however, may be used safely without laboratory tests, and may be given in doses of 12,500 units twice daily, intramuscularly or intravenously. Intramuscular heparin is usually painful, and is best combined with 1 ml. of 2% procaine. Heparin is supplied in ampoules of 25,000 units per ml., or in a weak strength of 5,000 units per ml. The injections should be given with the least trauma possible; severe bruising at the site of the injection occurs sometimes despite precautions, but it is very rarely serious. At sea, the clotting time could easily enough be measured if there was any doubt about dosage, but the test would vary considerably according to the time it was done after the injection. One should aim at keeping the clotting time between two and three times normal. Protamine sulphate should be available so that the heparin could at once be neutralized if spontaneous haemorrhage occurred. It should be given intravenously in a dose of about 100 mg., repeated if necessary. One milligram of protamine neutralizes approximately 1 mg. of heparin. Anticoagulant treatment, if used at all, should be continued for three weeks at a minimum.

Travellers' Diarrhoea

Q.—Does the intestinal flora change when a person moves from one locality to another, and is this the cause of the attacks of enteritis which quite often accompany a change of habitat? What can be done to prevent them?

A.—Little is known about the normal composition of the intestinal flora, and no studies have been made of changes, if any, which follow movement of an individual from one locality to another. It has been conjectured that such changes might form the basis of the attacks of diarrhoea which commonly affect new arrivals in various districts, but of this there is no proof. The recent discovery that in children certain coliform organisms may cause enteritis opens up the possibility that diarrhoea in adults may be caused by similar organisms.

To make special efforts to maintain a high standard of hygiene while moving from one locality to another is the best method of preventing these attacks of enteritis. When travelling in the Tropics or setting up house in a new station, food and drink are often obtained, or may only be obtainable, from dubious sources. In these circumstances bacterial infections are readily acquired, as it may be difficult to boil drinking water or to ensure that salads and other uncooked foods are adequately prepared. To avoid such articles of diet and unboiled drinking water is probably the most important single hygienic measure in the prevention of the attacks of enteritis.

Burial of the Dead

Q.—What is the law on the burial of the dead? In particular, what regulations must be complied with before burial? Must the fact of burial be notified? May burial be elsewhere than in a churchyard? May it be an entirely secular affair? May burial be performed after dark?

A.—The law on burial of the dead cannot satisfactorily be compressed into a brief statement. It is embodied in a number of statutes, enacted between 1853 and 1906. Repeal or amendment of several of their provisions has created a situation which calls for the reconsideration of the whole field and consolidation of the law in a new statute. Reference should be made, in particular, to *The Law of Burial* (Fellows, A., 2nd edition, Madden, Best & Co., London, 1952) and to *The Disposal of the Dead* (Polson, C. J., Brittain, R. P., and Marshall, T. K., English Universities Press, London, 1953).

The regulations which apply to burial will depend upon the circumstances. When the death is due to natural causes, and is not a matter for report to the coroner, the first step is the issue of a medical certificate of cause of death and a notice to the informant by the registered medical practitioner who was in attendance upon the deceased during his or her last illness. These documents are required by the registrar of births and deaths before he may register the death, which step, in normal circumstances, must also be taken before burial is lawful. In addition, the person effecting disposal of the remains must notify the registrar within 96 hours of so doing. Burial after an inquest, or after a post-mortem examination ordered by the coroner but without the holding of an inquest, calls for modified procedure. It is also possible to effect burial prior to registration of the death provided written notice, supported by a medical certificate of cause of death, is received by the registrar. In these circumstances the informant is required to attend at the office of the registrar in order to complete the process of registration of the death.

Burial may take place not only in a churchyard but also in a burial ground, cemetery, or, for that matter, in any place conforming with regulations that relate to public health and town and country planning. Burial at sea is also lawful.

Burial may be an entirely secular affair. The Burial Laws Amendment Act, 1880, provides that burials may take place in the churchyard or burial ground of any burial board, without the service of the Anglican Church (section 1); and

the burial can take place without any kind of religious service if the person in charge of the burial so desires (section 6).

Burial may take place after dark, but it is advisable to consult the authorities in charge of the proposed place of burial, since their by-laws will probably include special provisions which concern unusual times of burial.

Streptomycin in Pregnancy

Q.—I would be grateful for an answer to the following query on the antibiotic treatment of pulmonary tuberculosis during pregnancy. It has been suggested that streptomycin reaches a high concentration in the amniotic fluid and causes damage to the vestibular apparatus of the foetus. Is this correct?

A.—Streptomycin has now been given to many pregnant women. There is no evidence that it has ever caused damage to the vestibular apparatus of the foetus. Streptomycin should not therefore be withheld from pregnant women who need it.

Ascorbic Acid and Phenylbutazone

Q.—I have gained the clinical impression that the administration of 50 mg. ascorbic acid with phenylbutazone increases the effectiveness of the latter drug. Is this effect recognized, and, if so, what is its mechanism?

A.—There is no scientific basis for believing that ascorbic acid increases the effectiveness of any analgesic drug, although "clinical impressions" to this effect have been recorded not infrequently. There is no contraindication to such a combination being given if this belief is held.

NOTES AND COMMENTS

Ergot Preparations and Migraine.—Dr. J. N. G. Druy (Blaby) writes: In your expert's reply to a query about ergot preparations and migraine ("Any Questions?" November 28, 1953, p. 1230) he says that dihydroergotamine may be used prophylactically, but the results are capricious, and its major value is when given at the first warning of an attack. I started to use this preparation two years ago and have had a small series of cases—ten or so—under observation for most of the time. No males have been treated. The frequency of onset of headache has been from two headaches a week to one a fortnight. All patients stated they had been nearly "laid out" by the headaches, and occasionally had to go to bed. I beg humbly to differ with your expert in that I believe the use of dihydroergotamine prophylactically is of more value (almost) than when given for an attack. All my patients have been taking five drops or so daily with 30 drops at the onset of an attack. I can say that in all cases the interval has been lengthened considerably—possibly one per month—and the "knock-out" attack now occurs infrequently. I have not observed any untoward side-effects. The patients complain only if for any reason they have not kept up taking the drops and the headache returns.

Our Expert writes: This is an interesting series and further observations would be useful. Certainly dihydroergotamine is not always a successful prophylactic.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

THE BASIS OF SENSATION*

SOME RECENT STUDIES OF OLFACTION

BY

E. D. ADRIAN, O.M., M.D., D.Sc., F.R.C.P., P.R.S.

Master of Trinity College, Cambridge

It is probably inevitable that there should be a period when successive Banting lecturers will find themselves with little to say about their proper theme. We commemorate a man whose work was directly responsible for the prolongation of many million lives, whose biography should be far more interesting than that of most successful scientists. But those best qualified to give a picture of his unusual talents have already spoken, and he did not live so long ago that the lecturer can deal with the historical setting of his career. Successive Harveian Lectures add to our knowledge of Harvey's discoveries by describing the theories and politics of the Jacobean age: it is so far away and the thought of that period is so different from ours that the more we hear about it the better we shall understand Harvey. But the period of the first world war is too close to many of us to be treated objectively. A century hence historians may have plausible theories to show why we thought and acted as we did, and may try to explain why the sustained emotional pressure of the first war seemed different in quality from that of the second; but these lectures will be much more convincing when there is no one left alive to say that we did not feel like that.

Impressions from a Wartime Meeting

I am, in fact, too much a contemporary of Banting to pass historical judgment, and I had too little contact with him for personal reminiscence. Indeed, I met him only once—at the beginning of the second world war, when he was on a mission in England. Naturally it was difficult not to colour one's impression of him to match the almost legendary background of the insulin period, but even if one had known nothing about it I think one would have set him down as a man capable of great achievement. He was gentle and friendly, but one could feel his energy and determination. I had the impression that he would grasp at the essentials and be impatient of the details, and that he would face the simple issues which never occur to subtle but more conventional minds; and, of course, like all of us, he wanted very badly to be doing something. I think my strongest impression is of this impelling desire for action: since he had once scored so notably by taking the bull by the horns, he might have been even more impatient than he was. But he certainly gave me the impression of someone who had

*Banting Memorial Lecture delivered in Toronto on September 16, 1953.

it in him to take the bull by the horns again and would put through what he wanted to do by convincing everyone not so much that it was the best and the only thing to do, but that he would not rest till he had done it.

Soon after that he was killed, but, whatever he might have done, it is difficult to believe that the outcome could have satisfied his vision of what science might accomplish. His laurels came early, and he was not the kind of man to think he had done all that he ought to do. That was how he seemed at a brief meeting in the last war, and I have mentioned that impression because it is still curiously vivid. But wartime memories are notoriously coloured by the mood we were in; at that time the prevailing mood of biologists and medical scientists led them to believe that their science could have great practical uses in war if people in high office could only be persuaded to grant facilities and if the scientist could make up his mind what he wanted them for. The medical history of the war shows that they were not far wrong. But these were prodromal symptoms; after the temperature rose in the summer of 1940 we should probably have shown a different complexion. In this place where Banting lived and worked you know far better what sort of man he was, and it is enough for me to set down my feeling of the unusual kind of ability and courage which made him still a leader, not at all weighed down by the thought that no one could score again as he had done twenty years before.

Banting and Best's work has saved innumerable lives, but it has another reason to make it memorable—the fact that it was conceived by a young medical practitioner, able and ambitious, but with little training in research. It stands, therefore, as a constant beacon to young people who enter on the study of physiology or medicine and are not content to think as they are told. It should encourage them to believe that the first sight of the wood may give the clue that cannot be seen by all the experienced professors who are lost among the trees. Most of us are more or less lost and would be grateful for fresh light, though the older we get the more grudgingly we might accept it. At all events, most of us could point to chapters in the textbooks which seem to need the fresh outlook of a mind not weighed down by too much knowledge of details. Advertising our difficulties may not be the best way of getting out of the wood, for if our hearers paid much attention to what we told them we should

4857

drag them into the forest to share our obscurity. But it is better to speak of the mess we are in ourselves than to enlarge on that of our colleagues; and so the best tribute I can pay to Banting's memory must be to tell you how much we want new light in the field I know best, that of the physiology of sensation.

A Fundamental Difficulty

There is, first of all, a fundamental difficulty which does not seem to me to be soluble at all by experimental science—the difficulty of connecting physical and mental events, of bringing sensations and thoughts into the framework that we use so effectively for describing our external world. I cannot myself see how further knowledge of brain physiology will help us to reconcile mind and matter, but I am prepared to believe that a hundred years hence it will be difficult to understand why we ever puzzled about it. Even now there are many scientists and many philosophers who themselves find no difficulties and think they arise from faulty premises and outworn habits of thought. They may well be right. I should have more courage in thinking them wrong if I could forget the curious chapter in the history of biology when the scientific world was divided between the Ovists, who held that the embryo was a development of the ovum alone, and the Animalculists, who held that it was essentially a development of the spermatozoon. The notion that it might come from both together seemed too absurd to be considered—until something happened to break the spell and the joint origin became a reasonable idea.

No doubt the Renaissance produced many examples of the same sort, difficulties which vanished when ideas which had seemed inherent and unchangeable were found to be out of date. And so I am ready to believe that future generations will not find it as difficult as I do to include my mind in the scientific picture of the world. I am content to think that it is a puzzle for me, but that it may be no puzzle at all to someone without my particular preoccupations.

Cellular Mechanism of the Nervous System

If we discuss sensation we can scarcely leave the mind out of it, but I want to do so in what follows, for it will be mainly concerned with the cellular mechanism of the nervous system. I want to discuss the general organization of the nervous system which makes us react differently to different external events. We have a large number of receptor cells sensitive to different material changes, and we have a large number of motor neurones coupled to the muscles which produce our reactions. The environment and our reactions to it are changing all the time, and much of what we do cannot well be related to any one sensory stimulus, but it is a convenient simplification to think of a particular pattern of receptor stimulation as the cause of a particular pattern of response, and I make no apology for doing so. Admit, then, that the stimulation of certain receptors will produce a particular sequence of movement and the stimulation of others will produce a different sequence. What sort of organization is there to account for all the differential reactions which our nervous system will produce?

Obviously a great deal depends on the course of the pathways from the receptors to the motor nerve cells. We turn right or left when the stimulus is one-sided, because the signals enter the central nervous system from that side and are not evenly distributed; and we react differently to a sound or a light because the signals come by the auditory and the optic nerves and follow a different route. In less elaborately organized animals—sea anemones, for

instance—each group of receptors may serve a particular group of muscle fibres; the connexions are fixed and there is no central integration. But in the vertebrates there is a great deal of integration, and that means that the connexions and the route travelled by the signals can be varied considerably. The responses are different movements, and each involves a particular spatial and temporal distribution of activity in the motor nerve cells—a particular changing pattern of excitations and inhibitions. In the same way the signals from the receptors have particular spatial and temporal distribution for each event. The afferent and the efferent pattern are partly related by anatomical connexions, but there is an intermediate region where the connexions are sometimes open and sometimes closed and where a great variety of transmission is possible.

Sensory Excitation

The gross distribution of the sensory excitation is obviously of the first importance. We can recognize and react appropriately to a spoken word because it produces a particular sequence of excitation patterns in the cochlea, and we can recognize a face because the retinal excitation has the right shape. But the receptors of the eye show us colours as well as shapes, and the receptors of the skin give sensations of hot and cold and of various sorts of pain as well as of contact. We are aware of (or, if the mind is to be kept out of it, we react to) particular qualities of the stimulus as well as to its location and its intensity. Differences in the colour of adjacent patches in the visual field may perhaps be signalled by differences in the temporal evolution of the signals from them. This would avoid the need to credit the retina with special nerve fibres for colour from each point, but we know that the skin does use a different set of fibres to signal contacts, temperature, and pain, fibres of different diameter which lead to different pathways in the spinal cord. So we must be prepared to find that a sensory surface uses a variety of fibres to signal differences in the quality of the stimulus and that the result depends both on the general distribution of the excitation and on the particular varieties of nerve fibre which convey it.

How do these different sorts of fibre produce different effects in the central nervous system, different kinds of sensation, and a different reaction of the body? Though the fibres may be intimately mixed in the nerve trunks, there is often an anatomical sorting out when they enter the central nervous system; for instance, the fibres from the skin which signal touch extend up to the brain stem, whereas the non-medullated C fibres end in the cord. Even where there is no detectable sorting out it remains an obvious possibility that fibres from different kinds of receptor may have different kinds of dendritic connexion. But we are still faced with the need for a process which balances one excitation against another, and I believe we may be mistaken in thinking of the central nervous system as though it were made up of neurones which differ only in their structural features. I think we ought to consider the possibility of some variation in their chemistry as well.

So I am going to discuss the suggestion that the neurones from different varieties of receptor may liberate somewhat different material when an impulse reaches their dendritic endings and that the precise composition of the molecular output decides which of the succeeding neurones will be stimulated. It is true that this merely substitutes differences in humoral excitants for differences in dendritic structure, and there is more evidence for the latter, but I make the suggestion because I have been forced to realize how nervous elements which look much the same may differ greatly in their chemical sensitivity.

Olfactory Receptors

I am thinking, of course, of the olfactory receptors. The nose can distinguish an immense variety of molecules brought to it in the air drawn in at each inspiration. When we smell something we are aware of the intensity of the

smell, and we can usually tell where it comes from, but our chief awareness is of pure quality without any spatial or temporal attributes. Now the olfactory receptors are nerve cells furnished with hairs, which project into the mucous layer on the olfactory surface, and at the opposite pole with a non-medullated axon, which runs through the cribriform plate to end in the olfactory bulb. The number of these cells runs into millions even in a relatively small olfactory organ like that of man, and they are so closely packed that the position of the bulge formed by the nucleus varies from cell to cell. In some the nucleus is nearer the hairs and in others nearer the axon, but this is the only histological difference visible in a stained preparation. Two kinds of olfactory hair have been described in fresh preparations from the frog, and it is possible that they are parations from the frog, and it is possible that they are present in the mammal too, but there is no indication of any sharp division into two or more kinds of cell. In fact, the organ seems to be composed of a large surface packed with receptors which differ from one another only in the position of the nucleus in the cell and the position of the cell in the olfactory surface.

It is not possible to record the signals which pass to the olfactory bulb in the non-medullated axons, but we can record axon spikes in the neurones to which they lead. These are the mitral cells: large nerve cells with medullated axons which can be reached by a wire electrode thrust into the olfactory bulb. Since there are only 70,000 of them in the rabbit's bulb for many million receptors, the axon discharge must be a condensed version of the receptor signals, and a great deal of interaction may have taken place in the synaptic regions. But the receptors in touch with one mitral cell seem to be confined more or less to one part of the olfactory epithelium, though the extent of the receptive field is unknown.

Not only are the mitral-cell signals at one remove from the receptor signals, but they can be recorded profitably only in highly abnormal conditions, under anaesthesia deep enough to suppress all the spontaneous activity in the bulb. But if in such conditions we find that different smells give distinctive discharges they would scarcely fail to do so in the normal animal.

In the early stages, before I had learnt how to record from single units, I could get little satisfactory evidence of differential sensitivity in the receptors leading to any one point in the bulb. Smells strong enough to produce a mitral discharge would usually cause one in many units; sometimes the axon spikes seemed larger or smaller according to the nature of the stimulus, but that was all. On the other hand, there was no doubt that the different regions of the olfactory organ were not equally sensitive or equally accessible to all the molecules which could stimulate some part of it. Amyl acetate, ethyl acetate, and ether would always evoke a discharge in the anterior part of the bulb—corresponding to the anterior part of the olfactory surface—and the less volatile oils would rarely stimulate there, though they would give a large discharge at the back of the bulb. I still think that this large-scale difference in the distribution of the excitation is probably an important factor in the discrimination of smells, for in many animals the olfactory surface is so large and is folded into such complex channels that molecules of different properties carried in by the air stream would be unlikely to be deposited in an identical pattern. Another distinguishing feature may be the undoubted difference in the temporal evolution of the excitation with different substances. Volatility and solubility in water both favour a rapid rise and decline of the discharge, with little persistence between one inspiration and another. Thus the spatial and temporal pattern of the excitation will vary with the molecules which enter the nose, in much the same way as the pattern varies for the eye with the object in view and for the ear with the sound.

But these differences in timing and distribution cannot be shown to give more than a rough sorting out into a few categories, possibly dependent on the behaviour of the

material in water and in lipoids. Some further discriminating mechanism is needed to account for the great variety of smell which can be recognized even by the human nose, and it is supplied by the selective sensitivity of the individual receptors.

Selective Sensitivity

This was not evident until a method was devised for exposing the rabbit's nose to a concentration of the stimulating molecules which could be increased gradually from zero, the relative strength being signalled at each moment on the record of the impulse discharges. The method is simply to send two streams of air into the facepiece which covers the snout. Both are purified by filtration through charcoal (a necessary precaution to make them inodorous), and one is passed through a small bottle containing the substance to be tested, usually in liquid form. The rate of flow of this stream can be gradually increased by opening a screw valve, and the extent of the opening is signalled on the recording film.

With this arrangement and with a suitable position of the electrode and a good cranial circulation it is nearly always possible to show that different substances in threshold concentration will employ different mitral cells for signalling the stimulus. Usually a particular substance can be found that will evoke a discharge which is confined to a single unit near enough to the electrode to give large axon spikes. Another substance may give a threshold discharge confined to another single unit, though there will often be several units in action, and none of them close enough to the electrode to give distinctive axon spikes.

A discharge confined to one mitral unit is presumably due to an excitation confined to the particular group of receptors which lead to it, and since adjacent mitral units react to different substances it follows that adjacent groups of receptors have some degree of selective sensitivity. The degree of specificity varies greatly from one unit to another. The electrode may be close to a mitral cell which is in such unstable equilibrium that a very slight lightening of the anaesthesia will make it discharge spontaneously. Such a cell will usually start a discharge when the nose is tested with a wide variety of smells, and it may be impossible to pick out one which seems to have any specific relation to that cell alone. And the specific relation is a matter of degree; when one substance gives a threshold discharge confined to a single unit, related substances will usually stimulate that unit in low concentration, though they will stimulate other units as well. For instance, if benzene vapour gives a single series of large axon spikes, toluene and xylene will evoke similar spikes, though even at the threshold they will be mixed with smaller spikes from other units.

Many substances have been used in searching for these specific effects, but no attempt has been made to cover the whole range of odours. Yet enough experiments have been made to show that the substances tested fall into distinct groups, each tending to pick out particular mitral units, and that within each group one substance usually shows the greatest specificity—that is, one substance is most often found to give a discharge limited to a single one of the units within range of the electrode. Such substances are acetone in a group which includes esters like amyl acetate and ethyl acetate, benzene in the group of aromatic hydrocarbons, octane in the group of paraffin hydrocarbons, heavy oils, etc. Dipentene, cedar-wood oil, and eucalyptus belong to the large group of terpenes and related compounds, and all three have often given single unit discharges. Probably there are many other groups—for example, mercaptans. At least ten different substances have been found to pick out a single unit, but sometimes the same unit is picked out by several substances from different groups—for example, dipentene and acetone, benzaldehyde and amyl acetate, etc. In fact, the evidence suggests that particular types of molecular configuration have an affinity for particular varieties of receptor, but that the physical properties of the substance are also important.

In view of the regional differences in sensitivity found in the earlier experiments one would expect that the units responding, for example, to acetone would be found more often in the front part of the bulb and those responding to heavy oil at the back. There is undoubtedly a segregation of this kind, although, in the middle region, unit discharges have been obtained with substances from all the groups. It is true that most of these units can be made to discharge to a wide range of stimuli if the concentration is raised, but there will always be outlying parts of the olfactory organ where it has the threshold value needed to bring out the differential effects.

Assessment of the Different Factors

A great deal remains to be done before we can assess the different factors concerned in olfactory discrimination, but the important point is that neighbouring groups of olfactory receptors have marked differences in their sensitivity to different smells. I have no doubt, therefore, that olfactory discrimination is not due solely to the complex structure of the organ—that is, to the deposition of the material in different patterns on its surface owing to differences in the rate of air flow, size of molecules, etc.

In fact the olfactory epithelium proves to be a large collection of nerve cells which look alike, apart from the position of the nucleus, but differ so much in their properties that some will be excited by a trace of acetone vapour and others by a trace of benzene. This, of course, is no more than would be expected by anyone who contemplates the remarkable discriminative power of the nose. But it is an important point to have established, and I do not regret the time I have spent in trying to develop a different hypothesis.

It may be that the point is important only in connexion with the working of the olfactory organ; the receptors there may be the only cells which have developed such a high degree of chemical discrimination. But nerve cells in other places may show traces of the same discriminative power. Let us suppose, then, that there are sheets of such cells in the central nervous system with dendrites ending freely amongst the dendrites of afferent neurones, so that material liberated from these might come into contact with the dendrites from more than one cell. It cannot be expected that the terminations of the afferent neurones would liberate molecules as different as acetone and benzene, but if some neurones liberate acetylcholine and some noradrenaline it is not impossible that the molecules liberated by the fibre from a temperature receptor might differ considerably from those liberated by a pain fibre. The ultimate destination of the different signals reaching the dendritic network would then be determined by the different chemical sensitivities of the neurones whose dendrites are stimulated.

It is perhaps worth pointing out that the excitation of an olfactory receptor is a rapid process which ceases usually at the end of inspiration when the delivery of vapour is suspended, that the number of molecules needed to excite must be very small, and that they must be removed or neutralized rapidly. The same could be said of the excitation of a nerve cell by a humoral transmitter. I am bound to admit the difficulty of believing that all the different groups of molecules which stimulate the olfactory receptors are dealt with by different specific enzymes, as cholinesterase deals with acetylcholine, but they are certainly inactivated rapidly and completely.

Speculations which cannot be put to experimental test are seldom worth elaborating, and I cannot pretend that we should be in a much better position if this speculation turned out to be correct. A selective transmission determined by the nature of the material set free in the dendritic network might allow more variation than one determined by the detailed connexion of dendrites, but that is all that can be claimed for it.

Yet I think the olfactory organ may have something to teach us about the organization of the nervous system.

Since its nerve cells are found to have such selective properties we must be ready to look for similar properties in nerve cells elsewhere.

Conclusion

That, I am afraid, is a poor conclusion to a lecture which commemorates a man whose researches were of such immediate practical benefit to so many people. I wish I had something better to offer than these incomplete results on a sense organ which has never roused much interest. I can still recall the intense interest which the work of Banting and Best aroused in all of us, in physiologists as well as in every doctor. But such triumphant victories come very rarely, and they are separated by the slow, plodding attack on a wide front. I have described a minor incident in that attack with a speculation attached to it; but I have done so because most of our research is like that, and because it is with such inconclusive results that you must contrast the spectacular advance which came with the finding of insulin.

PROTECTION AFFORDED BY SICKLE-CELL TRAIT AGAINST SUBTERTIAN MALARIAL INFECTION

BY

A. C. ALLISON, D.Phil., B.M.*

(From the Clinical Pathology Laboratory, the Radcliffe Infirmary, Oxford)

The aetiology of sickle-cell anaemia presents an outstanding problem common to both genetics and medicine. It is now universally accepted that the sickle-cell anomaly is caused by a single mutant gene which is responsible for the production of a type of haemoglobin differing in several important respects from normal adult haemoglobin (Pauling *et al.*, 1949; Perutz and Mitchison, 1950). Carriers of the sickle-cell trait who are heterozygous for the sickle-cell gene have a mixture of this relatively insoluble haemoglobin and normal haemoglobin; hence their erythrocytes do not sickle *in vivo*, whereas some at least of the homozygotes, who have a much greater proportion of sickle-cell haemoglobin, have sickle cells in the circulating blood, with inevitable haemolysis and a severe, often fatal, haemolytic anaemia. There is also a much smaller group of sickle-cell anaemia patients who are heterozygous for the sickle-cell gene as well as for some other hereditary abnormality of haemoglobin synthesis (Neel, 1952).

It is thus possible to approach the problem from the clinical or the genetical side. From the clinical point of view it is important to distinguish between carriers of the sickle-cell trait who show no other haematological abnormalities and patients with sickle-cell anaemia, who have a haemolytic disease which can reasonably be attributed to sickling of the erythrocytes. From the genetical point of view the main distinction is to be drawn between those who are homozygous and those who are heterozygous for the sickle-cell gene. In the great majority of instances two classifications coincide—that is, most individuals with the sickle-cell trait are heterozygous and most cases of sickle-cell anaemia, in Africa at least, are homozygous for the sickle-cell gene.

*Staines Medical Research Fellow of Exeter College, in receipt of a grant from the Medical Research Council.

The sickle-cell trait is remarkably common in some parts of the world. Among many African negro tribes 20% or more of the total population have the trait, and frequencies of 40% have been found in several African tribes (Lehmann and Raper, 1949; Allison, 1954). In parts of Greece frequencies of 17% have been described (Choremis *et al.*, 1953), and as many as 30% of the population in Indian aboriginal groups are affected (Lehmann and Cutbush, 1952).

Wherever the sickle-cell trait is known to occur sickle-cell anaemia will also be found. For a time it was thought by some workers that sickle-cell anaemia was rare among African negroes, but so many cases have been described during the past few years that this view is no longer tenable (Lambotte-Legrand and Lambotte-Legrand, 1951; Foy *et al.*, 1951; Edington, 1953; Vandepitte and Louis, 1953).

The main problem can be stated briefly: how can the sickle-cell gene be maintained at such a high frequency among so many peoples in spite of the constant elimination of these genes through deaths from the anaemia? Since most sickle-cell anaemia subjects are homozygotes, the failure of each one to reproduce usually means the loss of two sickle-cell genes in every generation. It can be estimated that for the lost genes to be replaced by recurrent mutation so as to leave a balanced state, assuming that the sickle-cell trait—that is, the heterozygous condition—is neutral from the point of view of natural selection, it would be necessary to have a mutation rate of the order of 10^{-1} . This is about 3,000 times greater than naturally occurring mutation rates calculated for man and, with rare exceptions, in many other animals— 3.2×10^{-5} in the case of haemophilia (Haldane, 1947). A mutation rate of this order of magnitude can reasonably be excluded as an explanation of the remarkably high frequencies of the sickle-cell trait observed in Africa and elsewhere.

Possibility of Selective Advantage

Of the other explanations which can be advanced to meet the situation, one has received little attention: the possibility that individuals with the sickle-cell trait might under certain conditions have a selective advantage over those without the trait. It was stated for many years that those without the trait was in itself a cause of morbidity, but the sickle-cell trait was in itself a cause of morbidity, but this belief seems to have been based upon unsatisfactory criteria for distinguishing the trait from sickle-cell anaemia. The current view is that the sickle-cell trait is devoid of selective value. Henderson and Thornell (1946) found that in American negro air cadets who had passed a searching physical examination the incidence of the sickle-cell trait was the same as in the general negro population of the United States. Lehmann and Milne (1949) were unable to discover any correlation between haemoglobin levels and the presence or absence of the sickle-cell trait in Uganda Africans. And Humphreys (1952) could find no evidence that the sickle-cell trait was responsible for any morbidity in Nigerian soldiers.

However, during the course of field work undertaken in Africa in 1949 I was led to question the view that the sickle-cell trait is neutral from the point of view of natural selection and to reconsider the possibility that it is associated with a selective advantage. I noted then that the incidence of the sickle-cell trait was higher in regions where malaria was prevalent than elsewhere. The figures preliminary to Lehmann and Raper (1949) for the frequency of the sickle-cell trait in different parts of Uganda lent some support to this view, as did the published reports from elsewhere. Thus the trait is fairly common in parts of Italy

and Greece, but rare in other European countries; in Greece the trait attains its highest frequencies in areas which are conspicuously malarious (Choremis *et al.*, 1951).

Relation between Malaria and Sickle-cell Trait

Other reports appeared suggesting more directly that there might be a relationship between malaria and the sickle-cell trait. Beet (1946) had observed that in a group of 102 sicklers from the Balovale district of Northern Rhodesia only 10 (9.8%) had blood slides showing malaria parasites, whereas in a comparable group of 491 non-sicklers 75 (15.3%) had malaria parasites. The difference in incidence of malaria in the two groups is statistically highly significant ($\chi^2=19.349$ for 1 d.f.)*; hence Beet's figures imply strongly that malaria is less frequent among individuals with the sickle-cell trait than among those without the trait. The difference in malarial susceptibility between sicklers and others seemed to be most pronounced at the time of the year when malaria transmission was lowest.

Later, in the Fort Jameson district of Northern Rhodesia, Beet (1947) found that the same difference was present, although it was much less pronounced. Of 1,019 non-sicklers, 312 (30.6%) had blood slides with malaria parasites, whereas of 149 sicklers 42 (28.2%) showed malaria parasites. This difference is not statistically significant. However, among the sicklers from Fort Jameson enlarged spleens were less common than among non-sicklers. In a series of 569 individuals there were 87 with the sickle-cell trait; 24 (27.9%) of these had palpable spleens, as compared with 188 (39.0%) with splenomegaly out of 482 non-sicklers. This difference is again statistically significant ($\chi^2=4.11$ for 1 d.f.). Beet concluded that Africans with the sickle-cell trait were probably liable to recurrent attacks of thrombosis, with resultant shrinkage of the spleen.

Brain (1952a), also working in Rhodesia, confirmed Beet's observation that the spleen is palpable in a much lower proportion of sicklers than of non-sicklers; he went on to suggest that the finding might be explained by diminished susceptibility to malaria on the part of the sicklers. Moreover, Brain (1952b) compared the proportion of hospitalized cases in groups of African mine-workers with and without the sickle-cell trait. He found that the sicklers actually spent less time in hospital, on an average, than did the control group of non-sicklers. The incidence of malaria and pyrexias of unknown origin was much lower in the group with sickle cells.

It became imperative, then, to ascertain by more direct methods of investigation whether sickle cells can afford some degree of protection against malarial infection, thereby conferring a selective advantage on possessors of the sickle-cell trait in regions where malaria is hyperendemic. An opportunity to do this came during the course of a visit to East Africa in 1953.

Incidence of Malarial Parasitaemia in African Children with and without the Sickle-cell Trait

The observations of Beet and of Brain on differences in parasite rates and spleen rates are open to criticism because the populations were heterogeneous and were drawn from relatively wide areas. It was decided, therefore, to carry out similar tests on a relatively small circumscribed community, where all those under observation belong to a single tribe. Children were chosen rather than adults as subjects for the observations so as to minimize the effect of acquired immunity to malaria. The recorded incidence of parasitaemia in a group of 290 Ganda children, aged 5 months to 5 years, from the area surrounding Kampala (excluding the non-malarious township) is presented in Table I. The presence of sickling was demonstrated by chemical reduction of blood with isotonic sodium metabisulphite (Daland and Castle, 1948). Fresh reducing solutions were made up daily.

*These and other statistics in this paper are my own, using available figures.

TABLE I

	With Parasitaemia	Without Parasitaemia	Total
Sicklers	12 (27.9%)	31 (72.1%)	43
Non-sicklers	113 (45.7%)	134 (53.3%)	247

It is apparent that the incidence of parasitaemia is lower in the sickle-cell group than in the group without sickle cells. The difference is statistically significant ($\chi^2=5.1$ for 1 d.f.). In order to test as many families as possible only one child was taken from each family. There is no reason to suppose that these groups are not comparable, apart from the presence or absence of the sickle-cell trait.

The parasite density in the two groups also differed: of 12 sicklers with malaria, 8 (66.7%) had only slight parasitaemia (group 1 on an arbitrary rating), while 4 (33.3%) had a moderate parasitaemia (group 2). Of the 113 non-sicklers with malaria, 34% had slight parasitaemia (group 1), the parasite density in the remainder being moderate or severe (group 2 or 3).

It may be noted, incidentally, that of the four cases in the sickle-cell group with moderate parasitaemia three had *P. malariae*, even though this species is much less common than *P. falciparum* around Kampala. It seems possible from these and other observations that the protection afforded by the sickle-cell trait is more effective against *P. falciparum* than against other species of plasmodia, but much further work is necessary to decide the point.

These results suggest that African children with the sickle-cell trait have malaria less frequently or for shorter periods, and perhaps also less severely, than children without the trait. Further evidence regarding the protective action of the sickle-cell trait could be obtained only by direct observation on the course of artificially induced malarial infection in volunteers.

Progress of Malarial Infection in Adult Africans with and without the Sickle-cell Trait

Fifteen Luo with the trait and 15 Luo without the trait were accepted for this investigation. All the volunteers were adult males who had been away from a malarious environment for at least 18 months. The two groups were

of a similar age and appeared to be strictly comparable apart from the presence or absence of the sickle-cell trait. Two strains of *P. falciparum* were used: one originally isolated in Malaya and one from near Mombasa, Kenya; in Table II these are marked with the subscripts 1 and 2 respectively. The infection was introduced by subinoculation with 15 ml. of blood containing a large number of trophozoites (B in the table) or by biting with heavily infected *Anopheles gambiae* (M in the table). At least 3 out of the 10 mosquitoes applied had bitten each individual, and the presence of sporozoites was confirmed by dissection of the mosquitoes.

The cases were followed for 40 days. Parasite counts for each case were made by comparison with the number of leucocytes in 200 oil-immersion fields of thick films, the absolute leucocyte counts being checked at intervals. The abbreviated results of these counts are shown in Table II. In the few cases in which parasitaemia was pronounced and the symptoms were relatively severe the progress of the disease was arrested. At the end of the period of observation in every case a prolonged course of antimalarial chemotherapy was given.

Discussion

It is apparent that the infection has become established in 14 cases without the sickle-cell trait. The parasitaemia is relatively light, however, when compared with that observed in non-immune populations—for example, the Africans described by Thomas *et al.* (1953). This is to be expected: the Luo come from a part of the country where malaria is hyperendemic, and they have acquired a considerable immunity to malarial infection in childhood. This factor makes the interpretation of the observations rather more difficult; however, it could not be avoided, since all the East African tribes who have high sickling rates come from malarious areas, and the acquired immunity should operate with equal force in the groups with and without sickle-cells. The acquired immunity was actually an advantage, since the symptoms were mild and the chances of complication very slight.

In the group with sickle cells, on the other hand, the malaria parasites have obviously had great difficulty in establishing themselves, in spite of repeated artificial infec-

Figures represent parasite counts in hundreds per mm.³ of blood. ST—Stopped by chemotherapy.

tion. Only two of the cases show parasites, and the parasite counts in these cases are comparatively low. The striking difference in the progress of malarial infection in the two groups is taken as evidence that the abnormal erythrocytes in individuals with the sickle-cell trait are less easily parasitized than are normal erythrocytes.

It can therefore be concluded that individuals with the sickle-cell trait will, in all probability, suffer from malaria less often and less severely than those without the trait. Hence in areas where malaria is hyperendemic children having the trait will tend to survive, while some children without the trait are eliminated before they acquire a solid immunity to malarial infection. The protection against malaria might also increase the fertility of possessors of the trait. The proportion of individuals with sickle cells in any population, then, will be the result of a balance between two factors; the severity of the gene, and the rate of elimination of the sickle-cell genes in individuals dying of sickle-cell anaemia. Or, genetically speaking, this is a balanced polymorphism where the heterozygote has an advantage over either homozygote.

The incidence of the trait in East Africa has recently been investigated in detail (Allison, 1954), and found to vary in accordance with the above hypothesis. High frequencies are observed among the tribes living in regions where malaria is hyperendemic (for example, around Lake Victoria and in the Eastern Coastal Belt), whereas low frequencies occur consistently in the malaria-free or epidemic zones (for example, the Kigezi district of Uganda; the Kenya Highlands; and the Kilimanjaro, Mount Meru, and Usumbara regions of Tanganyika). This difference is often independent of ethnic and linguistic grouping; thus, the incidence of the sickle-cell trait among Bantu-speaking tribes ranges from 0 (among the Kamba, Chagga, etc.) to 40% (among the Amba, Simba, etc.). The world distribution of the sickle-cell trait is bit, etc.). The world distribution of the sickle-cell trait is also in accordance with the view presented here that malarial endemicity is a very important factor in determining the frequency of the sickle-cell trait. The genetical and anthropological implications of this view are evident.

The fact that sickle cells should be less easily parasitized by plasmodia than are normal erythrocytes is presumably attributable to their haemoglobin component, although there may be other differences, not yet observed, between the two cell-types. Sickle-cell haemoglobin is unlike normal adult haemoglobin in important physico-chemical properties, notably in the relative insolubility of the sickle-cell haemoglobin when reduced (Perutz and Mitchison, 1950). The malaria parasite is able to metabolize haemoglobin very completely in the intact red cell, the haematin pigment remaining as a by-product of haemoglobin breakdown (Fairley and Bromfield, 1934; Moulder and Evans, 1946). That plasmodia are greatly affected by relatively small differences in their environment is suggested by their remarkable species specificity. Thus the difficulty of establishing an infection in monkeys with human malaria parasites, and vice versa, is generally recognized.

How far species differences in the haemoglobins themselves, known from immunological and other studies, are responsible for the species specificity of plasmodia it is impossible to say. However, the physico-chemical differences between human adult haemoglobin and monkey haemoglobin appear to be less pronounced than the differences between either type and sickle-cell haemoglobin. It is clear that the natural resistance to malaria among individuals with the sickle-cell trait is relative, not absolute. This is perhaps attributable to differences in the expressivity of the sickle-cell gene, which may be responsible for the production of from nearly 50% to only a very small amount of sickle-cell haemoglobin (Wells and Itano, 1951; Singer and Fisher, 1953). Moreover, the sickle-cell haemoglobin may not be evenly distributed in the cell population; most observers recognize that there are cases in which only some of the red cells are sickled even after prolonged reduction. However, even a relative resistance to malaria may be

enough to help those with the sickle-cell trait through the dangerous years of early childhood, during which an active immunity to the disease is developed.

The above observations focus attention upon the importance of haemoglobin to plasmodia in the erythrocytic phase. Hence it is worth considering whether erythrocytes containing other specialized or abnormal types of haemoglobin might be resistant to malaria also. Thus, human foetal haemoglobin differs from human adult haemoglobin in many properties. Red cells containing foetal haemoglobin continue to circulate in the newborn for the first three months of life, after which they are quite rapidly replaced by cells containing normal adult haemoglobin. It has long been known that the newborn has a considerable degree of resistance to malarial infection; Garnham (1949), for instance, found that in the Kavirondo district of Kenya at the end of the second month of life only 10% of babies were infected; after this age the percentage affected rises rapidly, until by the ninth month practically all children have the disease. The correspondence between the appearance of cells containing normal adult-type haemoglobin and malarial susceptibility is illustrated in the Chart. The correspondence may of course be fortuitous, but it is striking enough to merit further investigation, even though other factors, such as a milk diet deficient in *p*-aminobenzoic acid (Maegraith *et al.*, 1952; Hawking, 1953) and immunity acquired from the mother (Hackett, 1941) may play a part in the natural resistance of the newborn to malaria.

Finally, it is possible that the explanation offered above for the maintenance of the sickle-cell trait may also apply to thalassaemia. The problems presented by the two diseases are very similar; many homozygotes, and possibly some heterozygotes, are known to die of thalassaemia, and yet the condition remains remarkably common in Italy and Greece, where as many as 10% of the individuals in certain areas are affected (Bianco *et al.*, 1952). Greek and Italian authors have commented that cases of thalassaemia usually come from districts severely afflicted with malaria (Choremis *et al.*, 1951). Perhaps those who are heterozygous for the thalassaemia gene suffer less from malaria than their compatriots: the fertility of the heterozygotes appears to be greater (Bianco *et al.*, 1952). Selective advantage of the heterozygote with the sickle-cell gene, and possibly the heterozygote with the thalassaemia gene also, would explain why such high gene frequencies can be attained in the case of these conditions while other genetically transmitted abnormalities of the blood cells remain uncommon, not very much above the estimated mutation rate—for example, hereditary spherocytosis (Race, 1942).

Summary

A study has been made of the relationship between the sickle-cell trait and subtertian malarial infection. It has been found that in indigenous East Africans the sickle-cell trait affords a considerable degree of protection against subtertian malaria. The incidence of parasitaemia in 43 Ganda children with the sickle-cell trait was significantly lower than in a comparable group of 247 children without the trait. An infection with *P. falciparum* was established in 14 out of 15

The apparent relationship between the appearance of adult-type haemoglobin (dots) and malarial infection (circles) in the newborn. Each dot represents a test on a single individual, using an alkali denaturation technique (Allison, unpublished observations); the circles represent the percentage of Luo children showing malaria parasites (Garnham, 1949).

Africans without the sickle-cell trait, whereas in a comparable group of 15 Africans with the trait only 2 developed parasites.

It is concluded that the abnormal erythrocytes of individuals with the sickle-cell trait are less easily parasitized by *P. falciparum* than are normal erythrocytes. Hence those who are heterozygous for the sickle-cell gene will have a selective advantage in regions where malaria is hyperendemic. This fact may explain why the sickle-cell gene remains common in these areas in spite of the elimination of genes in patients dying of sickle-cell anaemia. The implications of these observations in other branches of haematology are discussed.

This investigation was made possible by a grant received from the Colonial Office at the recommendation of the Colonial Medical Research Committee. Acknowledgment is made to the Directors of Medical Services, Kenya and Uganda, to Dr. E. J. Foley, Nairobi, to the staff of the Mulago Hospital, Kampala, and to the volunteers for their kind co-operation. To Dr. G. I. Robertson, Nairobi, a special debt of gratitude is due for constant help and advice. Drs. A. E. Mourant, R. G. Macfarlane, and A. H. T. Robb-Smith read the manuscript and made valuable comments and suggestions.

In 1950 a mass-miniature-radiography survey was undertaken in Los Angeles County, California. The population concerned numbered over three million, and more than half—1,736,703—responded and were x-rayed satisfactorily. This was the largest survey undertaken up to that date in the United States. Abnormalities were found in 67,966 individuals, of whom ultimately 2,404 were classified as tuberculosis suspects. 1,857 previously unknown cases of active tuberculosis were discovered—a rate of 1.08 per 1,000. Among 10,899 cardiovascular suspects the diagnosis of heart disease was confirmed in 3,388, but of these only 697 were previously unknown: the discovery rate for cardiac cases was 0.4 per 1,000. Exactly 3,500 lung cancer suspects were registered. Ultimately neoplasms were confirmed in 329 cases, of which 246 or 0.14 per 1,000 were malignant. (Los Angeles County-wide Chest X-ray Survey of 1950, by G. J. Drolet. Published by the Tuberculosis Control Foundation, Los Angeles, 1953.)

THE VARIABILITY OF SICKLE-CELL RATES IN THE TRIBES OF KENYA AND THE SOUTHERN SUDAN

BY

HENRY FOY, M.A., Ph.D., D.Sc.

AND

FARDIL BUSHRA, M.D.

Principal Medical Inspector, Sudan Government

We have recently completed a survey of the distribution of sickle cells in the blood of 44 tribes and subtribes in Kenya, and 26 in the southern provinces of the Sudan. The results are given in Tables I and II. In a certain number of tribes the ABO blood groups were also done the results being given in Table III.

In the present communication we wish to stress that, while the sickling phenomenon is very widespread throughout Africa, south of the Sahara the most striking

variations are found in its frequency and in that of the ABO blood groups; we also suggest reasons for this variability. Although the rates are based on relatively small samples, the differences noted are statistically highly significant.

any admixture of Caucasian blood as suggested by Lehmann and Raper (1949). We think, however, that the simple homozygous-heterozygous hypothesis may not take into consideration all the known facts, since it is not uncommon to find cases of sickle-cell anaemia, only one of whose parents have the trait, or only one the anaemia. It should, however, be remembered in this connexion that daily variations sometimes occur in the sickling of the same individual, especially in the trait condition, for reasons which at present are not clear. Further, we have noticed in our surveys that some individuals may have large numbers of sickle cells, whilst in others only one or two characteristic sickle cells can be found in the whole film. In view of this, it is possible that internal or external environment has some effect on the manifestation of the condition. However, since wide variations are found between tribes and subtribes occupying apparently similar external environments, this possibility appears to us to be rather unlikely, and, so far as we are aware, external environment has not been shown to effect the frequencies of ABO groups, yet similar variations occur, as with sickling.

2. Inter-marriage of neighbouring tribes with different rates in certain areas might produce groups with rates intermediate between them. If this were an important factor, then one would expect it to operate in the subgroups of the same tribe living under similar conditions and related geographically and culturally. Thus, the Mandari of Tali Post, who might originally have had a high sickling rate, could have intermarried with the low rate Dinkas, yet similar Mandari of Terakeka, also surrounded by similar Dinkas, have a high rate. The Nyika subtribes living in the same location and in the closest proximity have very different sickling rates. For example, the contiguous Durumas and Digos have rates of 10% and 22% respectively, and, similarly, the rates for the Ribe and Jibanas are 26% and 13%.

It is also difficult to imagine how inter-marriage could have caused differences as large as those found. For example, among the Makonda, where the rates in the two subgroups are 4% and 40%, the original racial strain with a high sickling rate must, on this hypothesis, have been diluted, in the low-rate group, to one-tenth by inter-marriage, and have very little "Makonda" left in it.

In addition, if racial or tribal mixtures were the complete explanation of the variability, we would expect differences in the blood-group frequencies to be associated with the sickling rate, but this does not occur, as will be seen from Table III. For example, a low frequency of the B blood group is associated with a high sickling rate among the Chonyis and Ribe, but with a low rate of sickling among the Sanya of Witu.

3. If sickle-cell anaemia often causes death among Africans before the reproductive period, how is it that the trait condition is so common? Our own experience in Kenya is that mortality in the anaemic condition is high, especially in the age group of 0-10 years. This being so, there must be some counteracting factor which prevents reduction in the gene frequency. This maintenance of a high gene frequency may indicate: (1) spontaneous mutations; this would seem unlikely in view of the probable rarity of mutation compared with the rate of mutation necessary to replace the genes lost by death. (2) Heterosis, in relation to reproduction, the heterozygote being more fertile than the homozygote (Boyd, 1950). Although no direct evidence of this is available for the sickle-cell trait, it is perhaps worth while to note that the effect of deaths in young children—or in utero—on the gene frequency might not be as large as would be expected, since the African woman would then be able to bear another child at a shorter interval than normally, this being linked with the custom, almost universal in East and Central Africa, of long periods of lactation, during which coitus is prohibited. If hybrid vigour is a factor in the situation, it might be affected by environment, and this would introduce a further source of variation in the incidence of the trait rate. It seems improbable, however, that these considerations could apply to blood-group variations; and if we are searching for a common cause for the variability in the two characteristics (blood groups and sickling), then this suggestion must be ruled out.

4. Genetic drift may be a factor where small groups of people are virtually isolated genetically—that is, they marry almost entirely within their own small group. In such small groups purely chance factors operating over a long period may cause the gene frequency to change greatly. If the population of such a small group then increases, the changed gene frequency will remain fairly stable unless inter-marriage or other factors are introduced to upset it. The discussion under inter-marriage, above, indicates that inbreeding may have been the rule among the groups examined. Our knowledge of African conditions of living and the effects of famine, epidemics, etc., leads us to

suppose that the present tribes and subtribes may have been very small in number at some period in the past. It seems reasonable, therefore, to suppose that conditions suitable for the action of genetic drift may have existed among these tribal groups, and that the variation thus introduced has not yet been equalized by widespread intermixture of tribes. Such genetic drift would affect the genes both for sickling and for blood groups, but each one independently, so that, while variability would follow in each case, there would be no association between the drift for sickling and that for blood groups. The situation that would develop would be precisely that found to exist in our surveys.

In short, it is evident that there are variations in the rate of sickling (a) among what are generally regarded as the major African races, such as the Eastern Hamites, with rates below 1%, and the Nilotics and Bantu, sometimes with high rates; (b) among individual tribes within the major African races—for example, among the Bantu group of East Africa, such as the Taveta, Kikuyu, Pokomo, etc., which have high rates, and the Teita, Chagga, Pare, Boni, etc., who have almost no sickling; and (c) between subgroups of the same tribe as described above for the Nyika.

Ethnological Significance

In view of our findings, what can be said regarding the ethnological significance of sickle-cell trait in Africa—or, in fact, about the significance of the ABO blood groups?

It would appear from our results that rates taken from only one group of any particular tribe cannot be regarded as characteristic for the tribe as a whole, nor can the overall rates for a tribe represent the situation in a major African race.

If the hypothesis of genetic drift is applicable, then it follows that the present sickling rate in a tribe or sub-tribe may not bear much relationship to the frequency of the trait as originally introduced. Rates for individual tribes would therefore have little significance ethnologically. On the other hand, random drift is as likely to increase as to decrease the rates, and averages over a number of different tribes which originally had much the same sickling frequency would tend to approximate to that frequency. It is possible that widespread and detailed information on the sickle-cell distribution might give important ethnological information. Such detailed information is not at present available.

Nevertheless, we feel that some of the results presented here may be of ethnological significance. For example, the widely distributed Nilotes in Central Africa are divided according to sickling rates into two main groups—namely, the Dinka, Shilluk, and Nuer of the Sudan, with very low rates, and the Jaluo, Lango, Alur, and Acholi of Kenya and Uganda, with medium to high rates. We do not think that these differences can be ignored ethnologically, although the languages of the two groups have close affinities. It may be worth noting that the frequency of sickling in the Dinka, Nuer, and Shilluk resembles closely that of the Eastern Hamitic races, such as the Masai, Galla, Turkhanas, etc., as do their pastoral and dietetic habits. On the other hand, the Luo, Lango, and Alur have high sickling rates, and are a predominantly agricultural people, with dietetic habits that are unlike those of the Eastern Hamites.

Unless it has a selective value, the frequency of a gene, appearing by mutation in an isolated population, has a negligible probability of increasing. The sickle-cell gene may have been introduced into Africa from outside, perhaps from the East, either overland or by sea. The sea route seems to be the more likely, considering the high rate among the riverine Pokomos and the Makua and Makonda, and the very low rate among the Eastern Hamites, through whose forebears, if it came overland, the gene would have to pass; and it would have persisted among their present-day descendants. The high frequencies found in certain tribes indicate that the proportion of invaders carrying the gene to the invaded was high.

This relation between the invaders and the original population probably varied from place to place as communities became established; and the variation, together with the influence of genetic drift, could, we suggest, account for the widely different incidences that we have found from tribe to tribe. These differences would persist only if relative isolation continued, and it is generally believed that intermarriage is now common and probably always occurred to some extent.

With these facts in mind, it is of interest to note the suggestion of Lehmann (1953) that the sickle-cell condition may have been introduced in Africa and the Mediterranean region by migrating Veddic peoples.

Inter-marriage would tend to reduce the variability caused by genetic drift: although variations in A and B frequencies were also found they did not present the sharp contrasts in which were also found they did not present the sickling trait, and this may contiguous areas shown by the sickling trait, and this may suggest that the A and B genes were introduced earlier than the sickling one. The spread of the B gene in Western Europe has been described by Candela (1942), and similar postulates may apply to the diffusion of the sickle-cell trait in Africa.

Conclusion

At present there is little to suggest that the possession of the sickling gene has any selective value, and the A and B blood groups which show similar though unrelated variations to those of the sickling frequency are also believed to have no survival value, although it has recently been shown (Aird *et al.*, 1953) that some correlation exists between carcinoma of the stomach and the A blood group, and between carcinoma of the stomach and group O (Hunt and Lucia, 1953). It is not impossible that sickling may be related to hookworm or malaria or other tropical condition, but so far as our studies have gone we have not been able to show any such relationship. Until some such factor is demonstrated it would seem to us that genetic drift is the most probable explanation of the variations in both sickling and the ABO blood groups in Africans.

Summary

The incidence of sickle-cell trait and the distribution of the ABO blood groups in certain tribes in East and Central Africa are reported.

Considerable variation was found in different tribes and even between subgroups of the same tribe, indicating that surveys done on large heterogeneous groups of Africans are unlikely to give useful information.

Possible explanations for this are considered, and genetic drift is suggested as the most likely.

The question of the introduction, maintenance, and spread of the sickling gene in Africans is discussed.

We have to thank the Directors of Medical Services of the Sudan and Kenya for all the facilities that were put at our disposal. We are also grateful for the assistance given to us by the District Commissioners in the areas in which we worked.

ACUTE RESPIRATORY INFECTIONS IN EMPHYSEMA

AN ACCOUNT OF 118 CASES

BY

T. SIMPSON, M.D., M.Sc., M.R.C.P.

Physician, Chase Farm Hospital, Enfield, Middlesex

The advances in the physiological and pathological understanding of emphysema have not been paralleled by equal success in its clinical management. There may be three reasons for this. First, chronic bronchitis, without doubt the most important single factor in the production of emphysema, is, because of its ubiquity and apparent benignity, regarded as a tolerable evil; secondly, as a result of this the patients are unlikely to consult the physician in the early stages; and, thirdly, as it is a disease which would seem to be both irreversible and progressive, treatment is unrewarding. Because of these considerations the emphysematous patient in a general hospital is usually seen for the first time when suffering from incapacitating dyspnoea, congestive cardiac failure, or an acute respiratory infection. The latter, responsible for about 4% of the total admissions to my wards, may cause sudden and serious illness which is eminently treatable. This paper is concerned mainly with this aspect of emphysema. Similar cases have been studied at necropsy by Spain and Handler (1946) and Scott and Garvin (1941). Fulton (1953) emphasizes that chronic pulmonary disease is an important cause of mortality and morbidity in middle-aged men in the industrial area of Manchester. The diagnosis and treatment of acute respiratory infection in emphysema have been discussed by Cardon *et al.* (1951).

Material

Between March, 1947, and May, 1952, 118 patients with long-standing bronchitis and emphysema have been under my care because of acute respiratory illness. In all but one, progressive dyspnoea was a prominent feature. This one patient, a man aged 63, said that he was not short of breath as a rule, but physical examination, response to oxygen therapy, and respiratory function tests all indicated emphysema.

Of the 118 patients (100 men, 18 women), 48 died—41 as in-patients and 7 within one year of leaving hospital. The remainder were alive and well in the summer of 1952.*

Age Groups.—The ages of the patients were 30-39 years, 3; 40-49, 12; 50-59, 39; 60-69, 49; 70-79, 15.

Previous Medical History

A history of bronchitis of more than 10 years' duration was given by 100 of the 118 patients. There can be no doubt, therefore, of its importance in the evolution of emphysema.

Most patients said that their bronchitis began insidiously in the past and guessed at its duration. Some were more definite and chose as landmarks either the first world war or a previous attack of pneumonia. Sixteen males fixing upon the first world war attributed their bronchitis to gassing, yet only one had been admitted to hospital because of it. Their memory was probably playing them false. The same criticism might be applied to those who dated their bronchitis from a long-distant pneumonia. There were, however, others whose pneumonic illness was more recent, but here again caution must be exercised in relying on the patient's memory, as is illustrated by the following case of

*Since this article was submitted for publication a survey made in December, 1953, reveals that 75 patients are now dead, 25 are alive and well, and 18 have not been traced.

RAISED INTRACRANIAL PRESSURE IN EMPHYSEMA

BY

E. KEITH WESTLAKE,* M.A., M.D., M.R.C.P.

Medical Registrar, Chase Farm Hospital

AND

MICHAEL KAYE, M.B., B.S.

Medical Registrar, Royal Victoria Hospital, Montreal

The cerebrospinal-fluid pressure is usually normal in emphysema, but during intercurrent acute respiratory infections symptoms and signs of raised intracranial pressure—headache, blurred vision, papilloedema—not infrequently develop (Simpson, 1948). The observations recorded in this paper throw light on the aetiology of the raised intracranial pressure found in these circumstances. The relationship of intracranial hypertension to mental disturbance occurring during oxygen therapy is discussed.

Experimental Subjects and Method

Lumbar puncture was performed in a series of 12 emphysematous patients (including 3 with papilloedema) suffering from an acute respiratory infection: in 8 immediately following admission to hospital, and in 4 after 4 to 80 hours of oxygen therapy in a tent. In these four patients relief of anoxia was maintained during lumbar puncture by inhalation of 100% oxygen via a B.L.B. mask. In view

Raised Intracranial Pressure in Emphysematous Subjects with Acute Respiratory Infections

of the observations of Friedfeld and Fishberg (1934) and Pickering (1934) of the effect of increased jugular venous pressure and severe hypertension in causing raised intracranial pressure, none of the patients studied had either of these complications. The C.S.F. pressure was measured in the horizontal position with a glass manometer (internal bore 2 mm.) calibrated up to 700 mm. The effect of muscular tension and apprehension was eliminated so far as possible by recording pressures at intervals of 30 seconds for 10-30 minutes until a stable basal level was obtained. It was found that when the C.S.F. pressure was within normal limits fluctuations were seldom greater than 20-25 mm. (Fig. 1), but when it was elevated spontaneous

*British Medical Association Ernest Hart Memorial Scholar, 1952.

fluctuations of much greater magnitude could occur, and a true estimate of the basal pressure might be obtained only after 30 minutes' recording (Fig. 3). Blood was obtained for measurement of oxygen saturation and carbon dioxide content by arterial puncture immediately before lumbar puncture.

Details of the C.S.F. pressure, arterial oxygen saturation, and arterial plasma carbon dioxide content are recorded in the Table. In 10 of the 12 subjects C.S.F. pressures above the normal upper limit of 200 mm. were observed, with pressures of over 350 mm. in five. Arterial anoxaemia was present in all cases (O₂ saturation 40-89%) and hypercapnia (plasma carbon dioxide content >66 vols.%) in all except one.

Effect of Anoxia and Hypercapnia on C.S.F. Pressure

The exclusion of patients with raised venous pressure and hypertension narrowed the possible causes of raised intracranial pressure. The almost invariable presence of anoxia,

FIG. 1.—Effect of breathing high CO₂ and low oxygen mixtures on C.S.F. pressure in a patient with syphilitic aortitis.

hypercapnia, and dyspnoea suggested that a study of the effects on C.S.F. pressure of breathing pure oxygen, low oxygen and high carbon dioxide mixtures, and of hyperventilation might prove fruitful.

Fig. 1 illustrates the effect of breathing various gas mixtures in a 49-year-old patient with syphilitic aortitis. With 3, 5, and 7% carbon dioxide in oxygen inhaled for five to seven minutes the C.S.F. pressure rose by 27, 133, and 310 mm. respectively. With 10% oxygen in nitrogen the inhalation was terminated before the pressure had finished rising, as the patient became deeply cyanosed and complained of severe headache. Voluntary hyperventilation will consistently produce a fall of 30-50 mm. in C.S.F. pressure (presumably due to washing out carbon dioxide), and if muscular movement has any effect in raising the pressure it is completely outweighed by the effect of hypocapnia and alkalosis. The combined results of inhalation of various combinations of

carbon dioxide in 29 subjects is presented in Fig. 2. The scatter of individual observations is considerable, especially with the higher concentrations of carbon dioxide. For 3, 5, and 7% CO₂ the mean increases in pressure were 50, 130, and 280 mm. There was no correlation between the magnitude of the rise in C.S.F. pressure on inhaling carbon dioxide

FIG. 2.—Increase in C.S.F. pressure breathing 3, 5, and 7% CO₂ in 29 emphysematous subjects.

and the respiratory response to the same concentration. For example, Case 1, whose ventilation increased by only 4 litres per minute with 7% CO₂, showed an increase of 500 mm. in C.S.F. pressure.

These observations demonstrate that both oxygen lack (low pO₂) and carbon dioxide excess (high pCO₂ and increased H-ion concentration) cause an increase in C.S.F. pressure, and the magnitude of their effect is enough to account for the considerable elevation in intracranial pressure observed in emphysematous subjects during respiratory infections.

Effect of Oxygen on the C.S.F. Pressure in Emphysema

In 10 experiments on normal subjects we have found that inhalation of pure oxygen for 10-15 minutes has no significant effect on the C.S.F. pressure. Davies and Mackinnon (1949) observed that inhalation of oxygen in cases of cor pulmonale with congestive failure caused an immediate and striking increase in C.S.F. pressure. Studies on Case 6 have confirmed their observation and provide an adequate explanation for this phenomenon.

This patient was admitted to hospital in October, 1950, with acute bronchitis. He had been dyspnoeic on exertion for four years and had suffered from severe throbbing headaches for the preceding 18 months. He was found to have advanced emphysema, cor pulmonale with early congestive failure, and bilateral papilloedema with retinal haemorrhages. The blood pressure was 160/100 and the maximum breathing capacity fluctuated between 16 and 30 litres a minute. On the second day after admission the C.S.F. pres-

sure was 270-300 mm. and on the 18th day 420-440 mm. On the 27th day, when the signs of congestive failure had disappeared, the basal C.S.F. pressure breathing air was 220-260 mm. (Fig. 3). The minute-volume of ventilation was 8.03 litres (rate 21 × tidal air 382 ml.), the arterial oxygen saturation 89%, and the plasma carbon dioxide content 83 vols.% (normal level 60 vols.). At the 30th minute pure oxygen was administered via a rubber mouth-tube, and over the next 30 minutes a dramatic rise in C.S.F. pressure occurred, reaching a peak of 670 mm. The respiratory minute volume recorded over the last 5 minutes of oxygen inhalation had fallen by 30% to 5.77 litres (rate 20 × tidal air 288 ml.), the plasma carbon dioxide content had increased by 9 vols. to 92 vols., and the oxygen saturation had risen to 100%. At this point the patient felt drowsy but did not complain of headache. When inhalation of oxygen was discontinued, C.S.F. pressure fell rapidly and the respiratory minute volume rose to its pre-inhalation level of 8.11 litres

FIG. 3.—Influence of inhalation of oxygen on the C.S.F. pressure, pulmonary ventilation, and arterial CO₂ content in an emphysematous subject.

(22 × 368). Subsequently papilloedema subsided completely without residual visual impairment. The patient was still alive in July, 1953, and, although completely disabled by dyspnoea on exertion, no longer suffered from headaches and the C.S.F. pressure was normal.

Discussion

Anoxia and hypercapnia might increase C.S.F. pressure by any of the following mechanisms: (1) increase in volume of C.S.F. due to more rapid formation or slower absorption; (2) increase in brain volume due to cerebral oedema; (3) increase in intracranial blood volume due to cerebral vaso-

dilatation; or any combination of the three. If the rate of C.S.F. formation was increased during the period of gas inhalation it would be expected that the pressure would remain elevated on discontinuing the gas mixture until absorption of the excess had restored normal volume and pressure. In fact, the pressure falls extremely rapidly—usually to 10–50 mm. below the pre-inhalation value (see Fig. 1). Raised venous pressure is thought to slow the rate of C.S.F. reabsorption via the arachnoid villae, and is the presumed cause of intracranial hypertension in congestive failure due to rheumatic heart disease. Inhalation of carbon dioxide does not, however, cause any significant change in venous pressure (Goldensohn *et al.*, 1951). This leaves mechanisms 2 and 3 as possibilities.

Wolf and Lennox (1930), by direct observation of the diameter of the pial blood vessels and measurement of the cisternal C.S.F. pressure in the cat, showed that inhalation of high carbon dioxide and high carbon dioxide plus low oxygen mixtures caused immediate vasodilatation with rise in C.S.F. pressure. Anoxia alone caused cerebral vasodilatation, but this effect was often offset by hyperventilation causing a fall of blood pCO_2 . White *et al.* (1942) made quantitative studies on changes in brain volume, cerebral blood volume, and C.S.F. volume in cats. With low oxygen inhalation, brain volume increased considerably, but the cerebral blood volume remained unchanged. This was attributed to the effect of anoxia in causing cerebral oedema by increasing the permeability of cerebral vessels. When carbon dioxide was added to the low oxygen mixture vascular dilatation with increase in cerebral blood volume occurred, but there was no further increase in brain volume. The effect of hypercapnia alone was not studied.

Thus it seems probable that raised intracranial pressure in emphysematous subjects with acute respiratory infections is due to the combined cerebral vasodilator action of anoxia and carbon dioxide retention. The antagonistic effect of low pO_2 and low pCO_2 may explain why the C.S.F. pressure in Case 8 was within normal limits—the vasodilator effect of moderate anoxaemia (O_2 saturation 69%) being offset by the lowered level of plasma carbon dioxide (7 vols. lower than the patient's normal level). The rise of C.S.F. pressure breathing oxygen in Case 6 may be explained as follows: in this patient resting ventilation was largely maintained by the stimulus of anoxia—as is shown by the fact that ventilation decreased by 30% on breathing oxygen. Although relief of anoxia *per se* would tend to produce cerebral vasoconstriction and a fall in C.S.F. pressure, this was more than counterbalanced by the increase in blood carbon dioxide content resulting from the fall in pulmonary ventilation. The net effect was a further increase of cerebral vasodilatation and rise in C.S.F. pressure. On breathing air once more ventilation increased, retained carbon dioxide was washed out, and C.S.F. pressure fell to its original (though raised) level.

An increase in blood carbon dioxide content invariably occurs during oxygen therapy in emphysematous subjects (Westlake, 1953) and accounts for the fact that the C.S.F. pressure often remains elevated (cf. Cases 9, 10, and 11) despite relief of anoxia. It is only on full recovery from the acute respiratory infection—when normal or near normal gas tensions are restored—that the C.S.F. pressure also falls to normal.

Is Raised Intracranial Pressure the Cause of Mental Disturbance During Oxygen Therapy?—Oxygen therapy in emphysematous subjects is often complicated by mental disturbance and neurological symptoms—acute mania, disorientation, profuse sweating, salivation, myoclonic twitching, stupor, and coma (Barach, 1937; Davies and Mackinnon, 1949; Coombs, Bahnsen, and Coates, 1950; Westlake, 1953). These symptoms are often attributed to raised intracranial pressure, but careful analysis of the mechanism involved makes this view untenable. In cerebral tumour (or other space-occupying lesion) raised intracranial pressure causes drowsiness and coma by decreasing cerebral blood flow, with consequent cerebral anoxaemia. In the emphysematous subject the rise in C.S.F. pressure that occurs dur-

ing oxygen therapy is due to increased cerebral blood volume from pial vasodilatation. Cerebral blood flow, far from being diminished, is greatly increased (Kety and Schmidt, 1948; Patterson *et al.*, 1952). In the absence of any evidence that raised intracranial pressure *per se* (when unaccompanied by reduced cerebral blood flow) has any deleterious action on the function of cerebral neurones, we prefer to regard mental symptoms as manifestations of the direct action of hypercapnia and acidemia on the brain (carbon dioxide narcosis) and do not believe that lumbar puncture has any therapeutic value.

Summary

Raised intracranial pressure in emphysematous subjects suffering from respiratory infections is attributed to the vasodilator action of anoxia and hypercapnia on cerebral vessels. During oxygen therapy the C.S.F. pressure may remain raised (despite relief of anoxic vasodilatation) owing to further rise in blood carbon dioxide content. Mental disturbance accompanying oxygen therapy cannot be directly related to raised intracranial pressure.

We wish to thank Dr. T. Simpson for permission to study cases admitted under his care, and for his continued encouragement and advice.

EARLY TREATMENT OF CLEFT-LIP AND CLEFT-PALATE

BY

W. G. HOLDSWORTH, F.R.C.S.

Surgeon, Rookdown House Plastic Surgery Unit,
Basingstoke

The effective closure of congenital clefts of the lip and palate has presented a challenge which has been taken up by most of the great surgeons of the past century, and considerable ingenuity and daring have been evoked. Many lips and palates were closed without anaesthesia of any kind. To-day, with the help of anaesthesia, electric lighting, suction, and fine instruments and sutures, the surgeon works under improved conditions. Fewer babies with this deformity die than formerly, and actual closure of the clefts can be achieved with certainty. Fairly general agreement has been reached in this country on what procedures are desirable, but there is uneasiness concerning their shortcomings. Any surgeon who operates on these conditions realizes that some of his cases do not turn out as well as he would like. He knows that some will improve with the passage of time, but he will also have the fear that some may become worse. Little is known of the effects of operation on the development of the facial skeleton, and these may be serious enough to prohibit procedures otherwise commendable. Investigation along these lines requires the construction in each case, and with unoperated controls, of a series of models of the dental arches covering the period of growth, and no such survey is likely to be available for a number of years.

Bearing the above in mind, and also the inadequacy of any classification based on personal appraisal of cases, it has nevertheless seemed worth while to attempt to assess the effectiveness of treatment in a series of 100 consecutive patients with cleft-lip and/or cleft-palate admitted to Rookdown House, the plastic surgery unit for the eastern area of the South-western Metropolitan Hospital Region.

Causation

As long ago as 1757 Trew mentioned heredity as a factor in the formation of congenital clefts, and since then many writers have pointed out the frequency of a family history of the condition: Muller (1886) and Haug gave 12%. Birkenfeld (1927) 20%, and Hinrichsen (1935) 24%. In 85 cases of the present series the parents had a reasonable knowledge of the child's forebears, and in 16 (18.8%) there was someone in the family with a cleft. Affected relatives were equally divided between the fathers' and mothers' families; they included the father's brother, sister, uncle, and great-aunt, and the mother's brother, uncle, great-uncle, and great-aunt. Few of us know much about our families two generations back, and the true figure would be greater than that given. From an examination of 703 family histories in cleft given. From an examination of 703 family histories in cleft cases occurring in Denmark, Fogh-Andersen (1942) concluded that there was no genetic connexion between isolated cleft-palate and cleft-lip with or without cleft-palate. The positive family histories obtained in our series support this view.

Little is known of the manner of formation of clefts of the lip and palate, but they lie in the line of approximation of the nasal and maxillary processes and are presumably the result of failure in development and fusion of the mesoderm of these parts. Normally this fusion is first seen in the region of the nostril floor, and thereafter successively in the upper and lower portions of the lip. A little later union spreads through the hard and soft parts of the palate to the uvula. Failure to join may be complete, in which case a cleft extends through lip, alveolus, and palate; or incomplete, only part of the line of fusion being open. The nostril floor is the part least often cleft, and partial lesions extend towards this site from the lip border or from the uvula.

Table I shows that in 51 cases the cleft extended through the lip and palate, though in several there were small skin bridges in the region of the nostril and in 10 the alveolus

TABLE I.—Extent of Clefts and Sex Incidence

	No.	Male	Female
Cleft lip and palate	51	38 (41.1%)	13 (16.4%)
Cleft-palates	36	20 (6.9%)	16 (13.6%)
" Lips	13	8 (14.4%)	5 (7.6%)
Total		66 (62.4%)	34 (37.6%)

Figures in parentheses are, for comparison, from Fogh-Andersen's analysis of 703 patients.

was intact. In 36 the cleft was confined to the palate, and in 13 the lip was cleft and the palate intact, though in 4 of these 13 the alveolus was cleft.

The preponderance of the condition in males has been mentioned by numerous writers. Fogh-Andersen remarked on the greater incidence of cleft-palate in girls, among whom in his series it was twice as common as in boys, but in the present series the incidence was greater in boys (5:4).

Table II shows that clefts on the left side of the lip greatly outnumber those on the right and double clefts; this fact has been noted by many observers.

TABLE II.—64 Cases of Cleft-lip: Extent

	Lip Only	Complete Cleft	Lip and Palate
Left	10	22	7
Right	2	8	2
Double	1	11	1
Total	13	41	10

Associated Abnormalities.—Six children had associated abnormalities (Table III). It will be noted that none of these were situated in the extremities, although in the past these have been noted as the sites of most frequent allied

TABLE III.—Associated Abnormalities

Mental deficiency, nystagmus, and optic atrophy	2
Hydrocephalus	1
Otitis media	1
Blindness; right eye absent, left cornea opaque	1

anomalies (v. Vershuer, 1938). Fogh-Andersen estimates the incidence of such anomalies as 10%. This would be in approximate accordance with our figure, which takes no account of neonatal deaths or abnormalities becoming manifest later in life.

Treatment of Cleft-lip

With a large lip a good operative result is more readily obtained, but, in view of the unsightliness of the deformity, delay to allow growth of the parts is unwarranted, and the majority of these babies were operated on between the third and sixth months of life. One complete cleft was closed on the day of birth, and a partial lesion was treated for the first time at the age of 23 years. By the third month the parts have grown sufficiently for the surgeon to be able to make a shapely lip and nostril, and the child has a good enough hold on life to withstand the anaesthetic and the operative hazards.

On the whole, the general health of the children on arrival at hospital has been excellent. It seems now to be recognized that the existence of the widest cleft is no threat to life from the point of view of interfering with feeding or permitting nasopharyngeal infections, and no case has been referred for urgent closure for either of these reasons. Operation has occasionally been postponed because the child had a cold, or was underweight, or because the haemoglobin level was low (under 10.5 g.%), but in no case has operation proved impossible or injudicious. In 15 cases palate closure was carried out when haemolytic streptococci had been grown from the throat swab, and in none were there complications. No transfusions have been given, before or after operation, and in only one case, with post-operative gastro-enteritis, was intravenous fluid required. The absence of any mortality is explainable partly by insistence on absolute fitness for operation and partly by the care given by experienced anaesthetists and nurses.

In treating single cleft of the lip there are two methods of approach. The first is simply to pare the cleft edges at the primary operation, joining the lip in layers with minimal tension so as to spare the maxillary arches from pressure where the cleft is complete. This postulates the necessity for a scar excision in all layers at a later date, when the construction of a lip of normal shape will be facilitated by the growth which has taken place in the interim.

The second method is to attempt at the outset to make the lip and nose perfect. In the minute lip of the infant this is not easy, and any mistakes will be magnified by growth. On the other hand, the scar obtained early in life, even when the gap is wide, can be less noticeable than any made subsequently.

This series includes 10 cases of single cleft which had been closed on the former principle at other hospitals, and a further 17 children were treated similarly at Rookdown House. With varying success, the attempt was made in most of these to adjust the nostril floor and alar base at the first operation.

In 22 others an attempt was made to perfect the lip and nose at the initial operation. Since the deficiency of lip tissue is most marked towards the margin, no simple paring of the cleft can produce a lip which pouts like that of a normal child, and it is necessary to cut into the lip and design complementary flaps. The Barrett Brown (Brown and McDowell, 1945) procedure was used in eight cases,

the Blair (Blair and Brown, 1930, 1931) in five, the Hagedorn in five, the Le Mesurier (1952) in three, and in one concavo-convex incisions as used by Vaughan and others. All of these cases, when reviewed, were found to have some fault which seemed worthy of surgical correction, and in this regard the primary operation failed in its objective. However, all such adjustments were minor, and there was no call to alter the original scars, which proved less obvious than those resulting from the two-stage method. A perfect result, though infinitely desirable, is not to be expected, and the tendency to seek perfection through a series of trimming procedures has been resisted. Even if the particular defect under consideration were corrected, each such operation takes something from the part and leaves it smaller. To quote Veau and Borel (1931), "Les petits détails de la lèvre qui souvent retiennent toute notre attention, n'ont pas la même importance que la forme générale du visage qui nous préoccupe moins."

Double clefts of the lip are usually associated with a serious deficiency of tissue, and their treatment presents the biggest problem in the field of lip and palate surgery. The method used in the 11 cases in this series was to close the lip in stages, first one side and a month later the other. The edges of each cleft were pared with care to preserve as much tissue as possible, closure being effected with three layers of sutures. In this way the soft tissues were draped in front of the prominent premaxilla, which was thereby subjected to a measure of tension and brought nearer alignment with the maxillae. While the appearance is improved by these operations, a number of secondary operations are needed, and a result comparable to that available in single clefts is extremely difficult to achieve.

Where a cleft is complete, closure of the anterior part of the palate at the time of lip closure is a convenience, since this region is relatively inaccessible later. With three

FIG. 1.—Alternative methods of closing the anterior palate.

manner recommended by Dorrance (1933) for closing the hard palate. Closure was successful in four of these. This is easier than direct suture of the nasal mucosa, and the saving in time is important when there is so much to do.

Treatment of Cleft-palate

The primary reason for operating on the cleft-palate is to permit normal speech. The aim is to produce a palate which is long enough to be able to meet the posterior wall of the pharynx when in the elevated position and sufficiently mobile to achieve this with rapidity. Eighty-five operations were performed, six different techniques being used.

1. *Two-flap Method* (Fig. 2) (24 cases).—This resembles the original operation of Langenbeck (1861), but differs in that the nasal mucosa is not divided transversely. Closure is with two layers of sutures—one in the nasal mucosa, the other in the buccal mucoperiosteum. In the soft palate these buccal sutures approximate the muscles. Catgut was used in the first four; thereafter silk (2/0) was preferred

because it seemed less irritating to the mucosa. These sutures do not require removal, since they come away by themselves.

2. *Three-flap Method* (Fig. 3) (33 cases).—This method differs from the above in that the mucoperiosteum is divided obliquely, a step which permits lengthening of the palate.

3. *Four-flap Method* (Fig. 4) (15 cases).—This is similar to the three-flap method, but employs two small flaps based in front for closure of the anterior part of a long cleft as described by Wardill (1933).

FIG. 2.—The two-flap operation.

FIG. 3.—The three-flap operation.

FIG. 4.—The four-flap operation.

FIG. 5.—The X operation.

4. *X Operation* (Fig. 5) (11 cases).—Here the transverse division of the buccal mucoperiosteum is made further back, over the horizontal plates of the palate bones. As with the above operations, the nasal mucosa is not divided transversely, and is carefully sutured in the midline. This operation has only one advantage: it does not disturb the distribution of the greater palatine vessels and the blood supply of the transverse palatine suture, which may be a growth centre.

5. *Cuthbert (1951) Operation* (Fig. 6) (1 case).—Swinging across the left mucoperiosteal flap breaks the longitudinal suture line, which is an undesirable feature of the above procedures. To allow the flaps to move, the greater palatine vessels must be divided. Transverse section of the nasal mucosa opposite the posterior border of the hard palate favours increase in length.

FIG. 6.—The Cuthbert operation.

FIG. 7.—The Gillies-Fry operation.

6. *Gillies-Fry (1921) Operation* (Fig. 7) (1 case).—Here the soft palate is united after division of its elements from the hard palate. The latter, along with the aperture created behind it, is covered with an obturator.

In 39 cases, mostly early ones, the greater palatine vessels were divided at the point of emergence from the palatine foramina so as to permit easier approximation of the mucoperiosteal flaps. This step is rarely required, and preservation of the vessels must promote the viability of the flaps.

In 51 cases the pterygoid hamuli were fractured as recommended by Billroth. This permits prolapse of the tensor palati tendons and reduces transverse tension on the suture line. In the majority of cases in which early palate closure fails one of the tensor tendons is found in place and undisturbed, and its action would inevitably jeopardize closure. After fracture this bony process moves medially and dorsally under the influence of the fibres of the superior constrictor which are attached to it. There seems to be a danger that displacement of the hamuli may weaken the formation of Passavant's ridge, a fold of mucosa which forms on the posterior pharyngeal wall at the time of elevation of the palate. This ridge results from the contraction of a band of muscle fibres the majority of which are attached to the hamuli, and it is difficult to see how the muscle can contract effectively if both its bony attachments are mobile.

The ridge is probably an important element in closing off the nasal from the buccal pharynx, as occurs constantly in speaking. In 34 cases, therefore, instead of fracturing the hamuli, tenotomy of the tensor tendons was performed.

Complications.—In two patients the operation failed, in that the entire soft palate broke down. One of these was a two-flap closure in which the hamuli had been fractured and the greater palatine vessels divided. In the other a four-flap closure had been done in conjunction with tenotomy of the tensors, the vessels being preserved. In neither case were haemolytic streptococci grown from the pre-operative throat swab, though in the second there was a staphylococcus. Fifteen cases, including 4 of the 11 X operations, developed small fistulae (Fig. 8) in the median suture line which required surgical closure. The 15 operations for obliteration of the fistulae were successful in all but two, and here the fistulae were close to the alveolus and therefore barely accessible.

In two cases otitis media developed within a week of operation. In both the pre-operative haemoglobin levels were high (13.8 and 11.9 g.%), and in neither were streptococci grown from the throat swab. One occurred in November, the other in April, and both followed three-flap closures.

Results

Many difficulties arise in attempting to interpret speech results, and in this series there is the further obstacle that many of these children are very young and have a lot yet to learn about speaking. In 15 cases no estimate of the result is possible, and for the other 70 the figures given below are published in the realization that subsequent review may indicate inaccuracies.

Speech has been classified as follows: class I, apparently faultless; class II, faults distinctly minor, so that no one has any difficulty in understanding even in moments of excitement; and class III, unsatisfactory.

The results for the various operations are given in Table IV, and, while there is little between them, the four-flap comes out best. It is interesting to note that of the 15 cases

TABLE IV.—Speech Results

	No. of Cases	Class I	Class II	Class III
Two-flap operation	22	46%	36%	18%
Three " "	25	48%	40%	12%
Four " "	12	50%	42%	8%
X operation	9	45%	33%	22%
All methods	68	47%	38%	15%

1 Gillies-Fry operation: speech improved.
1 Cuthbert operation: not yet speaking.

operated on for post-operative fistulae 5 developed first-class speech. The following previously published results are given for comparison.

Ritchie (1937) (100 cases): in 42 the speech was excellent, in 43 good, in 14 fair, and in 1 bad.

Oldfield (1949) (183 cases): in 87 the speech was excellent, in 79 good, and in 17 bad.

Bentley and Watkins (1947) (90 cases): in 46 the speech was perfect, 26 had minor faults, in 15 the speech was imperfect, and 3 were imbeciles.

Table V was made with a view to elucidating the respective merits of fracture of the pterygoid hamulus and tenotomy of the tensor palati. The results favour the latter, and

FIG. 8.—Location of post-operative fistulae. (All were in the midline.)

TABLE V.—Comparison of the Speech Results Following Fracture of the Pterygoid Hamulus With Those Following Tenotomy of the Tensor Palati

Speech	Fracture	Tenotomy
Class I ..	16	15
" II ..	18	9
" III ..	10	—
	44	24

of 31 patients who achieved class I, 16 had had fracture and 15 tenotomy, although almost twice as many were treated by fracture.

There has been considerable discussion about the optimal age for operation, with little in the way of statistics to substantiate the various views expressed. Wardill (1933) advocated operation early, in the expectation that the provision of an intact mobile palate before speech was attempted would permit this to develop in the normal way. Dorrance (1933) operated regularly at the age of 3 or 4 years, and claimed that speech was as good as with the early operation.

The results analysed in Table VI suggest that children operated on before the age of 9 months have a much better chance of achieving normal speech than those treated later.

TABLE VI.—Age at Which Palate was Closed

Age	No. of Cases	Class I speech in 77%
6 to 9 months	16	54%
10 to 12 "	17	53%
13 to 15 "	18	53%
16 to 18 "	12	22%
19 to 24 "	7	2 cases
2 years "	5	2 cases
3-4 "	3	—
5 to 10 years "	3	—
11 to 15 "	1	—
Over 15 "	3	—

and it should also be noted that no case operated on after the age of 3 years had a class I result.

Summary

In 100 cases of cleft-lip and/or cleft-palate both lip and palate were affected in 51, the palate alone in 36, and the lip alone in 13.

All lesions were more common in males.

In 18.8% there was known to be a relative of the child with a cleft.

Six children had associated congenital abnormalities, but in none was operation impossible.

Sixty-one operations were performed for primary lip closure and 85 for palate closure. There was no mortality.

Of the children born with cleft-palate, 47% are speaking without detectable abnormality, and a further 38% have only minor faults. Of the patients operated on under the age of 9 months, 77% speak normally.

PERSISTENT ADULT BED-WETTING TREATED BY SACRAL NEUROTOMY

BY

C. JENNINGS MARSHALL, M.D., M.S., F.R.C.S.

Senior Surgeon, Charing Cross Hospital

Definition and Aetiology

When the wide and varying group of cases loosely termed enuresis has been analysed and from it excluded all instances of precipitancy, defective control, and unintended bladder evacuation, diurnal or nocturnal, in which organic disease of the urinary tract (infections, developmental abnormalities of bladder and urethra) or of the nervous system has been demonstrated, there remains the clearly defined essential enuresis. This is a continuation of the irregular bladder action of infancy, commoner in the male than in the female, tending in most cases to be outgrown before puberty, though persisting in some cases until much later. It consists in bladder evacuation during sleep without awakening: in a great many cases there is an accompanying diurnal precipitate micturition amounting almost to incontinence and almost a strangury when it is attempted to hold back the urine. When in severe cases the enuresis finally ceases by degrees—as a rule with sporadic recurrences—the patient is left with a "weak" bladder with lifelong diurnal precipitate action.

During the years of active and frequent enuresis the life of the young patient is miserable; to go away from home is a recurring terror and shame, particularly as the most recent attitude appears to be that enuresis is a form of juvenile delinquency to be treated by "pep" talks and putting the young patient "on his honour"—the implications of which he greatly resents if he is at all sensitive and intelligent. Psychiatric thought regards it as an Oedipus matter—the boy, right on to adult life sometimes, wetting his bed to spite his mother and father for sleeping together. It is to the good that the time-honoured hunt for exciting causes (phimosis, worms, enlarged tonsils, etc.) has been abandoned, likewise the consequent operations, even as cures by suggestion. It is true that the patient can be "trained" to endure an uncomfortable bladder during the day for fairly long periods. This, however, is no more curative of the underlying condition than is inducing nocturnal anuria by fluid abstinence during the latter part of the day. The exceptionally good results claimed on hospitalization, when the patient is wakened every hour or so during the night, are open to similar criticism. Treatment by belladonna (as a parasympathetic inhibitor) and by amphetamine (partly a mild sympathetic stimulant, but acting mainly by producing light if any sleep) have equally transient effects.

The unsatisfactory position of treatment is reflected in the enormous literature by the vagueness of views expressed regarding the underlying cause. In the agreed absence of identifiable organic disease, recourse is had to mental and psychiatric defects, reflex factors, and so on; the most positive view was the old expression "pelvic neurosis." It is interesting to note that some fifty years ago Cathelin practised the flooding of pelvic nerves with saline or anaesthetic solutions by epidural injection into the sacral hiatus for the treatment of

"pelvic neuralgias, sexual neuroses, and incontinence." Development of the view that the condition is an inborn defect of nerve control of the bladder has been greatly hindered by the even now highly controversial opinions on the mechanism of the latter.

Innervation of the Bladder

Even here, though the source, deployment, and final distribution of the vesical and other visceral pelvic nerves are well known, the matter is further complicated by a variable and inconstant nomenclature.

The bladder, seminal vesicles, prostate, and lower ends of the ureters, among other organs, are supplied by numerous filaments of the (inferior) hypogastric plexus, which lies in the lateral part of the true pelvis. The part of it

supplying the bladder is sometimes termed the extrinsic vesicle plexus; it is without any sharp demarcation from the rest of the plexus, however. In the sub-mucous and muscular coats fine intrinsic (vesical, urethral, etc.) plexuses are formed before the final distribution of fibres. On both the intrinsic and the extrinsic plexuses the fibres subserving opposing functions are indistinguishably mixed; no satisfactory inferences may be derived from disease in, or stimulation of, either of these situations.

is formed from: (a) The lumbar sympathetic. Branches from the lumbar ganglia pass to the presacral or superior hypogastric plexus; the innervation ultimately reaching the bladder is derived probably from the first and second ganglia. From the presacral plexus the fibres pass to the (inferior) hypogastric plexus via the hypogastric nerves, some possibly via branches to the pelvic parasympathetic chain. The site of synapse is open to dispute, but does not affect the question of function. (b) The sacral nerves. Filaments pass from the trunks of S2, 3, and 4 immediately on their emergence from the sacral foramina; the major contributor is usually S3, the least S4. Some of the fibres pass direct to the hypogastric plexus, others to the ganglia of the pelvic parasympathetic chain—a continuation of the lumbar chain passing under the common iliac vessels—to lie immediately in front of the sacrum slightly medial to the foramina. The sacral branches—short filaments 4-8 mm. long—pass, therefore, some slightly medially, to join the parasympathetic chain and others laterally to join the plexus. They are best displayed by lifting the cord forwards and outwards. The parasympathetic chain gives numerous branches throughout to the plexus.

Function

(a) Motor.—Since the classic researches of Learmonth there has been little or no doubt concerning the main function of the sympathetic component: stimulation causes con-

traction of the bladder neck of the prostatic and seminal vesicular musculature, and of the ureteral orifices, together with relaxation of the detrusor. This part of the innervation is capable of simulation (hypogastric nerves, presacral plexus) without overflow of stimulus into the sacral part; but a brief consideration of the anatomy shows that the effects of pure stimulation of the latter are practically impossible to obtain. That the function of sacral innervation is antagonistic to the sympathetic is inherent in the term parasympathetic: the nomenclature which applies this term to the cord continuing the lumbar sympathetic into the pelvis is unfortunate and misleading. The evidence comes from several sources: compression of sacral nerves by very low spinal disease; operative removal of parasympathetic trunks; and disease or operative damage—for instance, in abdomino-perineal resection of the rectum with a posteriorly adherent growth—all show that damage or removal of the sacral supply leaves a bladder now solely under sympathetic control, without emptying power, and with an obstinately contracted neck. This confirms the quoted effects of sympathetic stimulation and disproves the view that the sacral supply controls both emptying and retention.

(b) Sensory.—The question of sensation is more under dispute, and in particular whether the sympathetic supply is sensory in addition to motor. Several observations favour such a view. For instance, patients with a transverse cord lesion above the sacral level "have been aware of filling and emptying of the bladder"—the cautious and honest wording is to be noted. Stimulation of the presacral nerve in the conscious patient has caused an accurately localized pain over the bladder. On the other hand, presacral neurectomy gives very little relief of chronic bladder pain. The vesical sensation in cord lesions may well be peritoneal in origin. I incline to the view that it is vasomotor in origin, adducing my experiences with local analgesia of the bladder.

Local Analgesia of the Bladder

During the past 13 years I have performed some 700 prostatic and bladder-base operations under a local analgesic combination. The essential feature is sacral spinal anaesthesia. With the patient sitting, about 0.8 ml. of hyperbaric cinchocaine hydrochloride is injected without barbotage through the lowest interspinal interval, 12-15 minutes being allowed for fixation. The upper level of anaesthesia is S1, shown by paraesthesia of the Turkish slipper area. On the table the hypogastric abdominal wall is anaesthetized by a fan of infiltration with 0.5% procaine*; for vasectomy a further small injection into the cord, supplied from D12 to L1, is required. The method was adopted in order to undertake prostatic operations in even the worst cardiovascular risks: it was developed from the knowledge that transurethral diathermy and resection can be painlessly performed under low spinal analgesia alone, always provided that S1 shows clear signs of anaesthetization. Ordinary sensation—pain of cutting and burning, and, in the enucleation of adenomata, distension of the prostatic bed and the adjacent trigone—therefore travels purely via the sacral nerves.

It was originally intended that the sympathetic element, even in the lumbar region, should be unaffected, in order to avoid the least fall in blood pressure; it was not foreseen that the preservation of the sympathetic supply would result in a most helpful and favourable "fluke"—the removal of sacral inhibition giving virtually a sympathetic stimulation. After enucleation of adenomata the bladder base and prostatic musculature contract down, providing an active haemostasis lasting with cinchocaine some three hours. (This contrasts most favourably with the false haemostasis seen with high spinal analgesia, resulting often in severe reactionary haemorrhage.)

In cystoscopy it is observed that a low spinal analgesic is undesirable when it is necessary to catheterize ureters; the contraction of the bladder base, particularly of the

*Adrenaline should not be employed in elderly patients as there is a great risk of setting up fibrillation.

musculi ureterae, sharply angulates the intramural course of the ureter, making it impossible for the catheter to do more than just enter the orifice. Further, with sacral spinal anaesthesia there is retention as long as the anaesthesia lasts. These various experiences confirm—were it necessary—the retentive sympathetic control described by Learmonth; the effect is clearly not a purely vascular one as is sometimes held.

The Bladder-emptying Mechanism

There is evidence to support the view that two distinct types of sensory impulse derive from the bladder base—first, the discomfort and pain when distension begins to stretch the trigone, and, secondly, that of the prostatic urethra which is associated with the sensation of micturition (this is evoked clinically when the examining finger presses into the prostatic groove and in painful disease amounts to strangury). Physiologically, when urine enters and distends the prostatic urethra the sensory impulse via the sacral nerves sets off the detrusor-stimulating, sympathetic-inhibiting reflex of micturition, which then becomes automatic. The trigonal and the prostatic sensations are distinct and different; for long the increased frequency of "middle lobe" prostatic enlargement has been attributed to the carrying up into the bladder of this "trigger" prostatic mucosa and to its being subjected to urinary contact (better, participation in trigonal stretching).

Mechanism of Enuresis

An enticing explanation of the phenomena of enuresis would be an ectopic distribution of the innervation of the prostatic urethra, overlapping the bladder neck and extending on to the trigone: the upward growth of the prostate would engulf the ectopic area progressively, accounting anatomically for the amelioration in most cases, and particularly in some severe ones about puberty. Confirmation by cystometry is difficult to obtain, for observations made with a catheter in contact with the urethra clearly present fallacies, as would the use of any form of anaesthesia to remove the effects of stimulation by the instrument. The usual cystometric findings in enuresis are that distension of the bladder up to a considerable volume is tolerated normally, but then extreme intolerance, urgency, and precipitancy develop. There is therefore neither a mental basis nor a general trigonal hypersensitivity, for the volume tolerated implies a considerable degree of trigonal stretching; the specific reaction occurs when the stretching affects the bladder neck, the last place to be affected by the process. In the enuretic this seems to behave as if innervated like the prostatic urethra.

The alternative hypothesis is "parasympatheticotonia"—both motor and sensory; the former implying excessive inhibition of the retentive factor, the latter sensory hypersensitivity (that this does occur is shown by the occasional patient who is completely unable to permit even a soft catheter to remain in his urethra). The converse—sympatheticotonia—has been accepted as a cause of sphincter disturbances in, for instance, achalasia of the cardia and hydronephrosis, and it seems reasonable to extend the type of explanation to enuresis, in which it seems more satisfactory than the idea of an ectopic nerve supply. In either case, however, a surgical reduction of the nerve supply to the bladder base and prostatic urethra clearly offers itself as a radical, or at least a permanent symptomatic, treatment of enuresis.

Sacral Neurotomy

There being no information whether the sacral supply has a segmental character—for example, does S 2 supply the trigone and S 3 the prostatic urethra?—as might be expected on developmental grounds, an empirical reduction in the nerve supply should increase sphincter tonus, decrease detrusor tonus and sensitivity, and produce a normal balance. Division of the fibres from S 2 on both sides and crushing of those from S 3 on one side is a likely com-

promise, interfering temporarily only with part of the components of nervi erigentes. In the typical case the scales swing strongly to the side of retention for several days, a balance between the two functions being recovered in ten days or so.

Operation

With the patient in a moderate Trendelenburg position, the abdomen is opened in the midline below the umbilicus and the gut packed conveniently away. The pelvic peritoneum is incised posteriorly from the midline at the sacral promontory down to the right of the rectovesical pouch (Fig. 2). The edges of the peritoneum are lifted gently aside along the whole extent and the presacral fascia is similarly divided (Fig. 3).

Neither procedure is attended with more than the slightest bleeding. The edges of the fascia, held by forceps, are very gently and gradually raised and peeled outward by gauze dissection on the right side; the parasympathetic chain and the sacral foramina come into view. The former is easily seen; the latter are obscured by loose connective tissue, fat, and small veins. No attempt should be made to demonstrate them by dissection laterally to the parasympathetic chain until the latter has been elevated and drawn outwards; their branches are then seen, some going to the chain and some direct to the hypogastric plexus (Fig. 4). The temptation to define the foramina other than by touch must be resisted, for any dissection is almost certain to result in haemorrhage from fragile veins obscuring and staining the fine filaments and rendering accurate section uncertain.

With the chain well raised and drawn outwards, the branches from S 2 and S 3 can be fully defined by gentle open-and-shut forceps-tip movements. All branches from S 2, both to the chain and outwards to the plexus, are divided, and the foramen is covered with a small disk of wax. The branches from S 3 are crushed. The exposure is repeated on the left side, and branches of S 2 are divided and a disk of wax, in later cases a small sheet of aluminium foil, again is applied over the foramen. The presacral fascia, the peritoneum, and the abdominal wall are closed in the normal appropriate way.

FIG. 4

Case Reports

Case 1.—A man aged 23, admitted for interval appendicectomy; enuresis since infancy, also diurnal urgency; had to rush to leave class at school. Treated by medicines and tablets (amphetamine recently), fluid restriction in latter part of day, micturition very late at night, etc. Had given up all treatment as a bad job. Enuresis about four to six times a week; even in hospital, with very restricted fluid, enuresis occurred two nights in four when awaiting operation. No organic disease of nervous or urinary system. Cystometry: 4 oz. (113 ml.), pressure 16 cm.; 10 oz. (283 ml.), 18 cm.; 16 oz. (454 ml.), 21 cm.; 17 oz. (480 ml.), precipitate emptying of bladder. Admitted for interval appendicectomy, he gladly accepted the chance that a nerve section might at least improve his condition. At operation S 2 divided on both sides; S 3 crushed on the right. Appendicectomy. In this first case the procedure, above recommended, of elevating and drawing outwards the chains was not adopted, and the foramina were exposed and defined by blunt dissection. Exceedingly troublesome bleeding made accurate nerve section difficult and problematic. During convalescence he had complete retention for first 24 hours, and passed a great deal at a time; during the next eight days frequency gradually returned to normal. The urgency by day disappeared. He reported at intervals after discharge; enuresis recurred, but to a far less extent than before—twice a month, three times a month, even five or six times a month. This was without precautions about taking of fluid, getting up last thing at night, etc. The daily urgency has completely disappeared. This is the state at 28 months after operation; clearly only a partial success owing to the uncertainty in the operative procedure, and to regeneration.

Case 2.—Male aged 20; enuresis since infancy, treated with numerous drugs and tablets and restricted fluids with temporary and slight improvement, but always relapsing on cessation of treatment to nightly bed-wetting even with restricted fluid and late waking; enuresis in hospital five times a week (admitted for operation on tendo Achillis). No gross organic disease in nervous or urinary system. Cystometry: 4 oz. (113 ml.), pressure 14 cm.; 8 oz. (226 ml.), 16 cm.; 12 oz. (340 ml.), 21 cm.; 16 oz. (454 ml.), 21 cm.; 18 oz. (510 ml.), precipitate emptying of bladder. Sacral parasympathotomy performed; branches S 2 divided both sides; S 3 crushed on right. During three weeks' convalescence in hospital no enuresis, though none of previous precautions taken. During first four days large quantities passed at wide intervals; micturition, initiated only when bladder contained as much as 18 oz. (510 ml.), was easily controlled and quite effortless. Thirteen months later he reported enuresis now thrice a week since operation. No precautions had been observed; the diurnal urgency had completely disappeared; there was no abnormality of bladder or of sex function.

Case 3.—Female aged 23. Enuresis at least three times a week; daily frequency four or five times, always with great precipitancy. Unaffected by dexamphetamine sulphate or fluid intake. Cystometry: pressure 70 cm., volume 700 ml., intense and precipitate micturition (continuous flow); 40 cm. pressure, intense desire to micturate (interrupted flow). No organic disease of urinary or nervous systems. Operative division branches S 2 both sides, crushing S 3 on right. Post-operatively no precautions taken; during 18 days' convalescence she always woke at night when micturition was needed; had never done this in her life before. Reporting nine months later, stated bed wet thrice in each month without any precautions taken.

Case 4.—Male 22. Enuresis since childhood, now five or six times a week, great diurnal precipitancy. Had had treatment by medicines and tablets, restricted fluid, waking by alarm clock in early morning, etc. No organic disease by urinary or nervous systems. Cystometry: 5 oz. (142 ml.), 14 cm. pressure; 10 oz. (284 ml.), 15 oz. (425 ml.), 20 cm.; 17 oz. (480 ml.), precipitate emptying. Sacral parasympathotomy: S 2 divided both sides, S 3

crushed on right; fine filaments from S 1 on both sides also divided. Normal post-operative course. No enuresis in 16 days; diurnal precipitancy gone. Reported ten months later: no enuresis since discharge, though no precautions taken; still free from diurnal precipitancy.

Case 5.—Male 23. Enuresis six nights in seven. All the usual remedies have been tried. Great daily frequency with precipitancy. Cystometry: 5 oz. (142 ml.), pressure 15 cm.; 10 oz. (284 ml.), 16 cm.; 15 oz. (425 ml.), 20 cm.; 16 oz. (454 ml.), precipitate emptying. This was repeated after administration of a sacral spinal anaesthetic; similar pressures were recorded, but with 20 and 25 oz. (568 and 710 ml.) there were pressures of 24 and 27 cm. still without emptying. Sacral filaments from second divided on the right, from third on both sides; aluminium foil applied over the roots. There was complete retention for 30 hours relieved by catheterization; at the end of a week micturition occurred about every five hours. At the end of five months no recurrence of enuresis; precipitancy of micturition also had not recurred.

Comments

Whether the view taken of the essential nature of enuresis is correct or not, the cases treated by nerve section show one very partial cure over 26 months, no doubt owing to insufficient nerve division and regeneration, two very near cures of 14 and 16 months, and one nine-months cure. In all cases none of the previous restrictions and precautions have been observed; in all, the previous precipitancy had disappeared. The choice of nerve fibres for section is admittedly empirical; it would appear, however, that in the later cases a middle course has been successfully steered between the Charybdis of enuresis (an exaggeration but not entirely inapt!) and the Scylla of retention; the use of crushing only of S 3 was resorted to in case there was, so to speak, over-correction of the enuresis, when nerve recovery would correct this error. On the whole, the amount of nerve division is, if anything, on the timid side. Many more precautions are needed against regeneration. Any mention of an operation on the pelvic sympathetic seems automatically to evoke great concern for the nervi erigentes. There has been no complaint on this score, and, in any case, only a small part of their origin is put temporarily out of action. It might be argued that a temporary damping down of the function concerned in the adolescent male would not be entirely a bad thing.

The cases operated on have been of the severest type; it remains to be seen if the parents of a lad of 10 years or so, with nightly enuresis and the probability of years more of the humiliating condition before a problematic recovery ensues, will not seriously consider the prospect of cure afforded by an operation of little more than interval appendicectomy risk and inconvenience.

The application and extension of the procedure to other conditions is no part of the present communication; it is clearly a necessary adjunct to complete interruption of the sympathetic supply to the pelvis in order to obtain complete denervation for painful conditions, and is simpler than the wide and not entirely satisfactory excisions of hypogastric plexuses that have been used. It should afford at least symptomatic relief in cases of stress incontinence, and even in some cases of inexplicable habitual abortion.

The work of the speech therapist, an occupation open to both men and women but so far followed mainly by women, is described in a booklet recently issued by the Central Youth Employment Executive (*The Speech Therapist*, Choice of Careers Series, No. 51, H.M.S.O., 6d.). Details are given of the work in school clinics, which deal solely with children, and in hospitals, where both children and adults are treated. Information is given on the educational qualifications required, arrangements for training, employment prospects, and salaries. This booklet is one of a series intended primarily for boys and girls who are about to decide the kind of work to take up on leaving school.

CLINICAL APPLICATION OF PORTAL
VENOGRAPHY

BY

H. FULD, M.D., M.R.C.P.Ed.

Consultant Physician, Newsham and Sefton General
Hospitals

AND

D. T. IRWIN, M.B., D.M.R.D.

Radiological Registrar, Sefton General Hospital

The differential diagnosis and the full clinical assessment of splenomegaly can even to-day be an interesting and at times puzzling task. Conditions are met with in which the aetiology and pathogenesis of an enlarged spleen remain unexplained in spite of exhaustive bedside study and radiological investigations.

Modern advances in vascular surgery alone make it desirable that there should be a clear recognition of those cases of splenomegaly in which some of the symptoms can be remedied by vascular anastomosis for relief of portal hypertension. Attempts to demonstrate the portal system by injection of radio-opaque substances into a branch of the coronary vein, into veins draining the caecum, into the main portal branch, and into the branches of the splenic vein were carried out in recent years (Blakemore and Lord, 1945; De Sousa Pereira *et al.*, 1949; Moore and Bridenbaugh, 1950; Santy and Marion, 1951). The techniques employed were difficult, and not without risk to the patient, and, of course, only possible after laparotomy.

Abeatici and Campi (1951) were the first to describe a method of percutaneous portal venography in a dog via the spleen and splenic vein, and Leger (1951) applied the same technique in man for the first time. Soon afterwards, Boulvin and co-workers (1951) described their technique of portal venography by the same route in great detail. Their first patient suffered from cirrhosis of the liver and the second from an extrinsic obstruction of the splenic vein. These authors pointed out the potential value of the method for the differentiation of intrahepatic and extrahepatic block. Dreyer and Budtz-Olsen (1952) applied splenic venography in 11 patients with palpable spleens and again suggested the clinical application of the method. Milnes Walker and co-workers (1952) were the first in this country to publish their findings of portal venography by intrasplenic injection on 12 occasions, again in patients with enlarged spleens. Of particular interest was their demonstration of the flow from the portal vein into the left inferior vena cava nine months after successful end-to-side anastomosis between the portal vein and the inferior vena cava.

Konar and Sen Gupta (1953) related their experiences of splenic venography in 14 cases, which included cases of portal hypertension and of splenomegaly of unknown cause.

Present Investigation

We have applied the method of percutaneous intrasplenic injection on over 50 occasions, using a similar technique to that described by Boulvin and co-workers. Good contrast was obtained with 50% diodone, and this strength was used in all but one patient, who received a 70% solution. In some patients several films were taken at three-second intervals, but in most cases we were satisfied with the result of a single exposure after an injection of 18 ml. of the solution. A fine flexible lumbar-puncture needle with short bevel was used. The needle was entered in the left posterior axillary line just below the tenth rib with the patient on his

FIG. 1.—Unusual but not abnormal splenogram.

FIG. 2.—Splenogram in pernicious anaemia with splenomegaly.

back, but we have also obtained satisfactory pictures by injection into the tenth intercostal space in the scapular line, with the patient lying face down. The technique in normal people with healthy spleens is naturally far more difficult than in cases of splenomegaly.

Exact location of a healthy spleen by percussion was nearly always impossible, and we therefore had to rely on touch when the needle met resistance on entering the spleen. Several times we failed to hit the spleen and diodone was injected into the peritoneal cavity, and on at least one occasion into the splenic flexure of the colon. No ill effects followed. With growing experience we learned to appreciate the degree of resistance to the injection which is to be expected when the needle has pierced the spleen. We found the spleen a rather mobile organ, which may move about 2 in. (5 cm.) medially before the needle point enters the splenic capsule. In consequence the splenic vein appeared kinked, as shown in Fig. 1, which was the result of an injection into a healthy spleen through the scapular line. Tortuosity of the splenic veins was observed on several occasions in healthy people as well as variations in the size of the splenic and portal veins. In our experience no significant changes are to be expected after diodone injections into enlarged spleens without portal hypertension or extrahepatic obstruction. The dye did not spread to any extent within the spleen, and distinct filling of the splenic and portal veins and its intrahepatic branches was observed using no more than 12–18 ml. of diodone (Fig. 2). The intrahepatic distribution of the portal vein is shown up in a liver grossly enlarged due to melanoblastoma (Fig. 3).

Fig. 4 belongs to a series of eight splenograms taken in a patient with cirrhosis of the liver over a period of 14 months. The degree of portal hypertension as seen on portal venography varied in this patient, corresponding to changes in the clinical picture. A chronic hepatitis was originally confirmed by laparotomy and his liver

was complicated by right lower lobe bronchiectasis. Each acute attack of bronchial suppuration was followed by deepening jaundice and increasing ascites, which improved under streptomycin treatment. We obtained normal splenograms in this patient when the ascites and jaundice subsided, but could demonstrate anastomoses with gastric veins of varying degree during acute exacerbations of hepatitis, of which Fig. 4 is one example. A severe degree of portal hypertension in another patient with appearances of oesophageal veins is demonstrated in Fig. 5. We were able to demonstrate a fine trickle of the dye through an almost completely thrombosed splenic vein in a young male patient with cirrhosis of the liver. The pathology was subsequently confirmed at operation. Fig. 6 was taken in a case of carcinoma of the stomach with secondary deposits in the portal fissure. The abrupt cessation of the flow of diodone along the splenic vein confirmed an extrahepatic block. Similar pictures were obtained in a patient with advanced carcinoma of the head of the pancreas.

Discussion

We have found intrasplenic portal venography a useful help in the diagnosis of splenomegaly of unknown origin, in the differentiation of intrahepatic and extrahepatic venous block, and in the assessment of the degree of portal hypertension and the anatomy of the anastomosis between the splenic vein and gastric and oesophageal vessels.

The technique presents no difficulties in cases with enlarged spleens, in contrast to injections into normal

FIG. 5.—Severe degree of portal hypertension.

FIG. 3.—Melanoblastoma of liver.

FIG. 4.—Portal hypertension.

FIG. 6.—Carcinoma of stomach with secondary deposits in portal fissure.

spleens, when failure to enter the splenic tissue on account of the mobility of the organ is frequently to be expected.

We are indebted to Professor Charles Wells for permitting us to use the method on three of his patients who were about to undergo shunt operations.

NEOMYCIN IN PYOGENIC SKIN
DISEASES

BY

RONALD CHURCH, M.D., M.R.C.P.Ed.

Senior Registrar, Rupert Hallam Department of
Dermatology, Royal Infirmary, Sheffield

Pyogenic infections are the commonest cause of skin disease, and cure of the acute case can be simple, but even impetigo, when mishandled, may persist for many weeks. Although the local use of antibiotics has considerably shortened the duration of these illnesses, it presents two disadvantages which some have thought contraindicate their use: (1) the danger of sensitizing the patient and thus preventing future systemic treatment with the antibiotic in what might be a serious illness; and (2) the encouragement of antibiotic-resistant organisms.

A stable and effective antibiotic which is not used systemically, which causes little cutaneous reaction, and which has a low incidence of bacterial resistance would overcome the most valid objections to local antibiotic therapy. Neomycin appears to fulfil these requirements in infections with *Staphylococcus pyogenes*.

Neomycin was discovered by Waksman and Lechevalier in 1949. It is produced by a strain of streptomycetes related to *Streptomyces fradiae*. It is water-soluble and thermostable, and maintains its effectiveness in practically any vehicle, including both acid and alkaline aqueous solutions. The drug is bactericidal *in vitro* against a wide variety of Gram-negative and Gram-positive organisms. Toxic effects causing kidney damage and deafness have prevented the parenteral administration of the drug, and its present use is limited to oral administration as an intestinal antiseptic and to local application. The effectiveness of neomycin as a local application in pyogenic skin eruptions has been reported in America (Kile *et al.*, 1950, 1952; Livingood *et al.*, 1952; Kimberly, 1952).

Present Investigation

A series of 93 cases were treated. They included: impetigo, 48; sycosis barbae, 18; ecthyma, 10; infected eczema and dermatitis, 8; furunculosis, 5; infective eczematoid dermatitis, 3; and blepharitis, 1. In none of these cases was irritation or sensitization of the skin caused by the ointment.

Neomycin was used in a concentration of 5 mg. per g. in an ointment base consisting of

White mineral oil	25%
Wool fat	20%
White petrolatum	54.4%

For purposes of comparison of bases, the same concentration was used in a water-miscible base:

Emulsifying wax, B.P.	20%
White petrolatum	20%
Phenoxyethanol	2%
Borax	0.6%
Boric acid crystals	1.2%
Water	to 100%

The two bases were used on the impetigo cases, half the series being treated with the water-miscible base. In contrast to the experience of Forbes (1952), no appreciable difference in the clinical results was found.

The patients were instructed to apply the ointments three times daily, cleaning the affected areas and removing crusts with liquid paraffin. In the few cases of furunculosis the ointment was also applied once daily into the nostrils.

Bacteriology

The organisms were cultured from each case and their sensitivity to penicillin, streptomycin, chloramphenicol, aureomycin, and neomycin was estimated. From practical experience it was found that a *Staph. pyogenes* which was insensitive to less than 25 units of penicillin per ml. or to 50 µg. of chloramphenicol or aureomycin could be regarded as resistant to the respective drug as a local application.

Staph. pyogenes was found in 91 cases—46 were penicillin-resistant, 2 aureomycin-resistant, 18 chloramphenicol-resistant, and 1 was resistant to less than 16 µg. of neomycin. All other staphylococci were sensitive to less than 4 µg. of neomycin; in 70 cases the staphylococci were sensitive to less than 0.015 µg. of neomycin. A haemolytic streptococcus was found alone in two cases and in association with *Staph. pyogenes* in 20 cases. The only other organism isolated was *Pseudomonas pyocyanea* in one case of impetigo. This was resistant to penicillin, aureomycin, and chloramphenicol, but sensitive to streptomycin and neomycin.

In the 48 cases of impetigo a *Staph. pyogenes* was found alone in 37, a haemolytic streptococcus in association with *Staph. pyogenes* in 10, and a haemolytic streptococcus alone in 1. The staphylococci were resistant to penicillin in 34 cases and to chloramphenicol in 11.

The 10 cases of ecthyma yielded a *Staph. pyogenes* alone in three cases; in the remaining seven the infection was a mixture of *Staph. pyogenes* and a haemolytic streptococcus. The staphylococci were resistant to penicillin in one case and to chloramphenicol in two cases.

The 18 cases of sycosis barbae yielded pure growths of *Staph. pyogenes* alone. The staphylococci were resistant to penicillin in eight cases, to aureomycin in two, and to chloramphenicol in five.

The miscellany of eight cases of infected eczema, five cases of furunculosis, three cases of infective eczematoid dermatitis, and one case of blepharitis yielded a haemolytic streptococcus alone in one case, *Staph. pyogenes* in 14, and a combination of these organisms in two cases. Penicillin-resistant staphylococci numbered three and the organisms were sensitive to the other antibiotics.

Results

Impetigo.—Three cases were treated with base alone as a control; as expected, the impetigo spread rapidly. Of the remaining 45 cases treated with neomycin, 27 healed in less than one week, 11 in less than two weeks, and 7 took longer than two weeks, but were quite healed in three weeks. There were no failures. The cases varied in severity and duration. Twenty-one had resisted previous treatments by their own practitioners for over three weeks. Twenty-five cases were definitely known to have been treated with penicillin cream and six cases with chloramphenicol without response.

Sycosis Barbae.—The 18 cases are classified according to the severity and chronicity of the condition, those which had lasted less than nine months being referred to as folliculitis barbae. Eight cases of folliculitis barbae were seen whose duration varied from one week to eight months. Four of these cases are known to have been treated with penicillin cream, two with chloramphenicol cream, and one with aureomycin cream, all without success. On treatment with neomycin ointment four cases healed completely—two in less than one week, and two in a fortnight—and have remained healed for four months. One severe case improved to the extent of having only a few pustules left, and there was no response in three cases. The 10 cases of sycosis barbae varied in duration from two to 31 years. Six cases are known to have been treated with penicillin, five with chloramphenicol cream, and five with aureomycin cream, without cure. Four cases responded well to neomycin ointment, healing in periods ranging from two to four weeks, two of them having slight residual erythema but no pustulation while using the ointment. Two further cases healed in a fortnight, but relapsed

two and four months later while still using the ointment, although the organisms remained sensitive to the antibiotic. Two cases were much improved and two showed no response.

Ecthyma.—Of the 10 cases of pyoderma and ecthyma treated, 3 healed in less than one week; these were all cases in which *Staph. pyogenes* alone was cultured. The remaining seven cases had a mixed infection of staphylococci and streptococci, two healing in less than a fortnight and the other five showing no response.

Miscellaneous.—Eight cases of infected skin conditions, including seborrhoeic dermatitis, contact dermatitis, and eczema, were all treated without any sensitization reactions. Three cases healed in less than one week, four in two to three weeks, and one case showed no response. One case of chronic blepharitis healed in three days. Three cases of retro-auricular infective eczematoid dermatitis healed in less than two weeks. The five cases of furunculosis had resisted a variety of treatments for this condition, and only one case ceased to have boils on treatment with neomycin ointment.

Comment

In the treatment of impetigo contagiosa, neomycin ointment is effective and rapid in action. In view of the advantages of using neomycin as a solely local antibiotic it might with advantage be adopted as a routine treatment for this condition.

In this series 60% of cases of impetigo cleared in less than a week, and many of these took only three to four days. Forbes (1952) treated 67 cases of impetigo with neomycin, 62 clearing in less than a week; he remarks that the type of patient was of high standard, most of them being university students and able to follow instructions. It might be assumed that there is some difference in this capacity between American college students and the industrial population of Sheffield. In the treatment of impetigo, chloramphenicol cream (Newman and Feldman, 1951), aureomycin ointment (Solomons, 1951), and bacitracin (Miller *et al.*, 1949) all give comparable results, most cases healing in less than a week, though Solomons found two cases aggravated by aureomycin cream.

In the treatment of sycosis barbae, aureomycin cream seems to have given the best results. Solomons treated 22 cases, all of which responded, only three being left with a few scattered pustules. Chloramphenicol cream (Newman and Feldman, 1951) cured only one case in five, improved two cases, and gave no result in two. Bacitracin (Miller *et al.*, 1949) cured 5 of 16 cases, the other 11 showing no response. Neomycin ointment in this series cured eight cases, and improved five; there was no response in five. Neomycin therefore seems to be superior to all antibiotics except aureomycin in the treatment of this condition.

Prolonged local application of any antibiotic encourages the growth of resistant organisms, and in this series the only aureomycin-resistant staphylococci were found in two cases of sycosis barbae. The routine use of a purely local antibiotic would therefore seem desirable as the first line of attack in the treatment of this condition.

As a local application to infected skin conditions and infective eczematoid dermatitis, neomycin showed no tendency to irritate the skin. Over a large number of cases this harmlessness is unlikely to continue, but Kile *et al.* (1952) applied neomycin to 869 cases and obtained only one sensitivity reaction. In the same paper the authors remark that some patients with haemolytic streptococcal infections did not respond well to neomycin. This was also found in this series in the cases of ecthyma, though sycosis barbae which did not respond or which relapsed the organisms had not developed resistance to the drug. This state is unlikely to last, although it has been the experience of all other investigators of neomycin. Nevertheless, antibiotic therapy is literally becoming a process of hurrying to use the new drug before it ceases to cure.

Summary

Ninety-three cases of pyogenic skin disease were investigated bacteriologically; *Staphylococcus pyogenes* was isolated and found to be resistant to penicillin in 46 cases, to chloramphenicol in 18 cases, and to aureomycin in 2 cases. None were resistant to neomycin.

The cases were treated with neomycin ointment in a strength of 5 mg. per g. In the treatment of impetigo the drug gave results comparable to those of aureomycin, chloramphenicol, and bacitracin. In sycosis barbae the results were superior to those of all other antibiotics except aureomycin. In other skin conditions, with the exception of the deeper infections with haemolytic streptococci, infection was controlled and sensitization reactions were not encountered.

Neomycin ointment is suggested as a routine treatment for impetigo and as the first line of attack in sycosis barbae.

My thanks are due to Dr. J. Colquhoun for the bacteriological investigations. I am indebted to Dr. H. R. Vickers and Dr. I. B. Sneddon for permission to use their cases for this investigation, and to the Upjohn Company for the supply of neomycin and neomycin ointment.

STORAGE OF TESTICULAR TISSUE
AT VERY LOW TEMPERATURES

BY

A. S. PARKES, Sc.D., F.R.S.

AND

A. U. SMITH, M.B., B.Sc.

(From the National Institute for Medical Research,
Mill Hill, London, N.W.7)

The discovery that glycerol has the property of protecting the spermatozoa of certain species (Polge, Smith, and Parkes, 1949; Smith and Polge, 1950) and also red blood cells (Smith, 1950; Sloviter, 1951a, 1951b) against the otherwise fatal effects of freezing and thawing was extended by Smith and Parkes (1951) to ovarian tissue. The latter work was recently recorded in more detail (Parkes and Smith, 1953), and it is clear that rat ovarian tissue, soaked in glycerol-containing media and subsequently frozen slowly and stored in liquid air, suffers only slight loss of its capacity to form an endocrinologically active graft. Moreover, the loss is not increased by prolonging very greatly the period of storage.

Method

Analogous observations have now been made on the preservation and grafting of rat testis tissue. The testes were taken from male rats 7 to 9 days old, at which age the organ is firm and easy to handle. The tunica was slit and the contents were slightly teased out. The capacity of such preparations to form functional grafts, after treat-

Reviews

BRITISH SURGEONS

Lives of the Fellows of the Royal College of Surgeons of England, 1930-1951. By the late Sir D'Arcy Power, K.B.E., F.R.C.S., and continued by W. R. Le Fanu, M.A. (Pp. 889. 42s. Obtainable from Editorial Secretary at the College.) London: Published by the College. 1953.

Platt's *Lives of the Fellows* has for many years been a valuable work of reference and it is a pleasure to greet this continuation, which contains the lives of those Fellows whose death occurred between 1930 and 1951. Sir D'Arcy Power wrote the lives of those who died between 1930 and 1940, with one exception, and Mr. Le Fanu has written the remainder. Sir D'Arcy felt the loss of his friend Harvey Cushing so deeply that he thought he could not write an adequate life of this great man.

The volume contains the lives of 981 Fellows, among whom will be found the names of many of the most distinguished pioneers of modern surgery—Moynihan, Cushing, Grey Turner, Bland-Sutton, F. T. Paul, Arbuthnot Lane, Wilfred Trotter, James Berry, Tudor Edwards, Robert Jones, Thomson-Walker, G. H. Makins, and D'Arcy Power himself. There are also included a few physicians like Lord Dawson and Sir Humphry Rolleston, upon whom the Fellowship had been conferred.

This volume at once becomes the essential book of reference for most of the important British surgeons who moulded British surgery at a vital period of its growth. It gives the main facts of their lives, a list of their chief publications, and the sources from which further information can be obtained. Not only are their surgical deeds recorded but we are given illuminating details about what they did in their moments of relaxation, and it is interesting to note what were their pastimes. Many were fond of shooting and fishing, others were mountaineers, some were connoisseurs and collectors, some were musicians or photographers, some even worked embroidery, a few were ornithologists, one made a study of basking sharks, and several were yachtsmen, of whom one, Sir Alexander MacCormick, sailed his own craft from Australia to England with a crew whose ages were all over 60. Such activities have served to give relaxation from the surgical work that takes a heavy toll of these men in anxiety.

The reviewer spent the best part of a week-end reading a great number of the biographies and found them of engrossing interest. He had known, admired, and had an affection for many of these great pioneer surgeons, and his feelings of pride in their achievements were mingled with a sadness for their passing. Every Fellow of the College will surely wish to have a copy of this book upon his shelves.

ZACHARY COPE.

DIURESIS

Diuretic Therapy: The Pharmacology of Diuretic Agents and the Clinical Management of the Edematous Patient. By Alfred Vogl, M.D. (Pp. 248. £1 18s. 6d.) London: Baillière, Tindall and Cox. 1953.

An intelligent co-ordination of diuretic measures with proper attention to minor technical details may often restore an extremely dropsical patient to a reasonable state of health and comfort for a long time. Yet, though medical literature abounds in monographs on the pharmacology and therapeutic actions of digitalis, diuretic therapy, which is of almost equal importance, has received rather scant attention. The author of this scholarly but practical treatise was the first to observe the remarkable diuretic properties of the organic mercurials. It is of interest to note, as Dr. Arthur Fishberg points out in a foreword to the work, that the discovery of both digitalis and the organic mercurials was due to the prepared mind of the scientist being fructified by the observations of an attendant on the sick, or, to use the more modern language of bureaucracy, of a medical auxiliary—Withering's

discovery owing much to Mother Hutton's success in the treatment of dropsy, and Vogl's to the accurate coloured charts of intake and output kept by an anonymous nurse on a patient undergoing treatment for syphilis with "nova-surul." While this monograph is mostly concerned with the physiology, pharmacology, and clinical use of the organic mercurials in congestive heart failure, yet other diuretic measures such as treatment by acidifying salts, by low sodium intake, and by the xanthine and osmotic diuretics are not neglected, and the treatment of every type of oedema is discussed. The treatise is up to date, fully documented, and thoroughly readable, being written in good plain English.

D. M. DUNLOP.

PEPTIC ULCER

Peptic Ulcer: Pain Patterns, Diagnosis and Medical Treatment. By L. A. Smith, M.D., M.S. in Medicine, F.A.C.P., and A. B. Rivers, M.D., M.S. in Medicine, F.A.C.P. Foreword by George B. Fusterman, M.D. (Pp. 576; 208 figures. No price given.) New York: Appleton-Century-Crofts, Inc. 1953.

This book covers particularly the pain patterns, diagnosis, and medical treatment of peptic ulcer and is presented as a digest and evaluation of the experience of the Mayo Clinic in a series of 30,400 cases of peptic ulcer, ranging from the oesophagus to the ileum. The emphasis is particularly on the clinical aspects, with special reference to pain, and there are many illustrative diagrams and case histories. In addition, there are sections on the history of peptic ulcer and on the physiology of the stomach.

For those who are especially interested in peptic ulcer there are a number of interesting facets to the book, particularly in relation to ulcer pain, but it is a disappointing publication. It gives the impression that it was a long time on the stocks and was probably held up by the death of one of the editors (A.B.R.). Some of the chapters read as if they had been written some years ago. In the section on the treatment of bleeding, all of the 52 references are more than 10 years old, and in some other chapters too there is a paucity of recent references. Again, it is often difficult to get a clear picture of the personal opinion of the writers, which may become lost in a surfeit of reports from the literature.

Any book on peptic ulcer to-day must stand comparison with the recent monumental work by Ivy, Grossman, and Bachrach. This present publication lacks both the critical commentary and up-to-dateness which were so notable in that book.

F. AVERY JONES

ATLAS OF HISTOLOGY

Pathology in Surgery. By Edwin F. Hirsch, Ph.D., M.D. (Pp. 647; 388 photographs; 2 colour plates. 76s. 6d.) London: Baillière, Tindall and Cox. 1953.

This is one of a number of annotated atlases of morbid histology published in the U.S.A. in recent years. The reason for their compilation is not far to seek, for the useful information provided by the examination of tissue removed at biopsy has gained for histological diagnosis an assured place in the investigation of an increasing number of diseases. The resulting demand for expert morbid histologists was at first impossible to meet, and these books were obviously written to help the increasing number of pathologists who wish to acquire diagnostic proficiency in a rather difficult art. Such proficiency can be gained only by long experience under expert supervision, free access to all kinds of morbid material, and the cultivation of a peculiar sort of visual memory of microscopic structure. There is no satisfactory alternative to this arduous discipline. Morbid histology must be learnt from the actual section, which, during the period of training, can never be replaced by photomicrographs, however good their quality.

These atlases are valuable for reference purposes for those who have enough experience to be able to read and interpret photomicrographs. They are positively dangerous to

the inexperienced morbid histologist, who may be tempted to diagnose the disease process by matching his section against the "picture in the book." Dr. Hirsch's volume is open to this criticism but to no other. It is entirely concerned with surgical diseases. The profuse illustrations are of good quality, well reproduced, and skilfully selected. The text is clearly written, and, although in places almost telegraphic in its brevity, it is packed with sound information and not a little pathological wisdom.

GEOFFREY HADFIELD.

EDINBURGH LECTURES

Edinburgh Post-graduate Lectures in Medicine. Volume 6, 1950-53. Published for the Honyman Gillespie Trust. (Pp. 508; illustrated. 21s.) Edinburgh and London: Oliver and Boyd. 1953.

This is the sixth volume of lectures delivered in the Royal Infirmary, Edinburgh, under the auspices of the Honyman Gillespie Trust. The thirty-four lectures have been evenly distributed over the whole field of medicine and surgery, and it is difficult to pick out any themes for special mention. Tuberculosis and diseases of the chest are best represented, and there are lectures on such new topics as A.C.T.H. and cortisone and the use of isotopes in diagnosis. There are two lectures on genetic subjects and a delightful article by McCrie entitled "Reflections from a Provincial Deanery." The volume is well produced and well illustrated, and contains some coloured plates. From the publishing point of view the price of 21s. is therefore extremely low.

L. J. WITTS.

BALLISTOCARDIOGRAPHY

Ballistocardiography: The Application of the Direct Ballistocardiograph to Clinical Medicine. By Professor William Dock, B.S., M.D., F.A.C.P., Harry Mandelbaum, M.D., F.A.C.P., and Robert A. Mandelbaum, B.A., M.D. (Pp. 293; 153 figures. £3 11s. 6d.) London: Henry Kimpton. 1953.

Ballistocardiography has not received much attention on this side of the Atlantic. This method of studying the action of the heart depends on the sum of several forces, and these may overlap one another or oppose one another. Briefly, three main actions may be distinguished: that of recoil when the blood is being ejected from a chamber; that of the impact of the ejected blood on the peripheral circulation, particularly on such a structure as the arch of the aorta; and, thirdly, the motion imparted to an elastic tube as a wave of pressure moves along it. When the movements which these forces impart to the body, lying horizontally, are recorded by suitable apparatus, several waves appear in the record, some 15 in all for each cardiac cycle. This sounds rather formidable, but it would appear that only five or six are important; others are not concerned with ventricular systole. The physical causes for some of these movements are admittedly hypothetical.

By this method the clinician is seeking to fill an important gap in knowledge which is to some extent filled by the examination of the pulse and of the heart beat itself. But the ballistocardiograph is much more sensitive than the fingers or ears. The reader will find the most interesting chapters are those on the effects of coronary disease on the function of the heart as expressed by the ballistocardiogram. Particularly notable are the sections on infarcts and on the diagnosis of angina pectoris. Striking alterations in the curves are obtained by exercise. Another interesting chapter is on the surprising effect of nicotine on the ballistocardiogram. The authors maintain that these effects may be noticed before any signs of disease appear. They have a number of patients who reacted in this way and later developed frank coronary trouble. The arrhythmias and defects of conduction are not well shown by this method.

The writing of the book is on the whole good; occasionally the expression is obscure, and too many lines pile up without a single stop. The illustrations are clear, but there are two criticisms. First, to the uninitiated it is most important to label the waves, for they are not easily distinguished, and for many of them there is no label at all, which makes

it quite impossible to know which wave is which. Secondly, the timing is often given against pulse-tracings, and sometimes these hardly show up or do not appear on the record. It is much more satisfactory where the timing is done by the cardiogram. Anyone who wants to study this new subject will find the book useful. It is not really difficult, and there is something in it which might be well worth studying; but clearly a good deal of time will be needed to get the information. For instance, the suggestion is that on each occasion at least seven tracings will have to be taken, and some little time is required for the patient to settle down, and must also elapse after a meal. But if the claim is justified that "the ballistocardiogram gives information on the vigor and effectiveness of systole which no other technique can supply," then this information is certainly worth having.

TERENCE EAST.

SURGICAL HANDBOOK

Surgery of the Biliary Tract, Pancreas and Spleen: A Handbook of Operative Surgery. By Professor Charles B. Puestow, M.D., Ph.D.(Surg.). (Pp. 370; 72 plates. 68s. Subscribers to the whole series of Handbooks, 60s.) Chicago: The Year Book Publishers Inc. London: Interscience Publishers Ltd. 1953.

This is essentially a personal book and a practical book. The author addresses himself to surgical residents and to practising surgeons who may require guidance on procedures with which they are unfamiliar. He describes the methods he himself has found satisfactory and gives no bibliography.

It is inevitable that the views of a surgeon practising in another country should differ in some respects from those current in Britain. Dr. Puestow, for instance, favours needle biopsy in the diagnosis of cancer of the liver and of the pancreas. In biliary surgery he advocates division of the falciform ligament and use of the hepatic end as a tractor, and he displaces the liver medially in order to make the hilum more accessible. In exploring the common bile duct he seems to make a much longer incision in the duct than we should. He favours cholecyst-gastrostomy, which we have found unsatisfactory as a means of short-circuiting a biliary obstruction, and in pancreatectomy he seems to implant the gall-bladder rather than the common bile duct into the jejunum.

Common sense and practical experience mark his advice throughout. He points out the dangers of premature interference, and particularly of exploratory aspiration, in the treatment of subphrenic infections. He has found that the use of the bridge or the pillow in gall-bladder surgery does not improve access but is very apt to lead to troublesome backache afterwards. He reminds us that jaundice after an attack of gall-stone colic does not necessarily mean that a stone has entered the common duct. He devotes 150 pages in all to the surgery of the common duct, 40 of them dealing in an admirable manner with injuries and their repair. The surgery of cancer of the pancreas is discussed in a balanced manner, and the author has come to the conclusion, with which any experienced surgeon will agree, that in most cases only ampullary growths offer sufficiently good prospects of cure to justify the severe operation of pancreatico-duodenectomy.

The figures are all line drawings admirably chosen and executed, and showing the author's intention far better than the more elaborate half-tone figures that usually illustrate books on operative surgery. The experienced surgeon for whom this book is intended will find it interesting and useful.

HENEAGE OGILVIE.

In *Humanly Speaking* Dr. Eustace Chesser discusses fluently and provocatively sexual conduct in its social setting. He chooses for some of his main themes problems of adolescence, marriage and divorce, and society's attitude to the homosexual. Sir Cyril Burt contributes a foreword. The book is published by Hutchinson's Scientific and Technical Publications, price 8s. 6d.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 6 1954

SICKLING AND MALARIA

The sickle-cell phenomenon has almost since its discovery been the subject of controversy. Until recently records of observation had tended to multiply much more rapidly than well-founded theories. Hypotheses were mutually contradictory, and even some series of recorded observations appeared incompatible with others. In the past two years, however, a body of well-established and generally accepted facts has begun to arise and to give a firm basis for theory.

Great numbers of Africans and many persons from other continents in normal health have red cells which, under chemically reducing conditions, form bizarre "sickle" shapes. These persons are said to have the sickle-cell trait. Other persons with similar (usually more severely distorted) red cells suffer from a chronic haemolytic anaemia associated with a high mortality: these are said to suffer from sickle-cell anaemia. It is important that the distinction should be made clinically and not as a result of genetical theories.

The two conditions taken together without distinction between them behave as a Mendelian dominant—every person showing sickling in any form has at least one parent who also shows it in some form. There is, moreover, evidence to show that most or all of the clinically normal persons with the trait are heterozygous for the condition, while most of the persons with sickle-cell anaemia are homozygous. This is the opinion of most workers in America and of many but not all of those who have worked in Africa.

The immediate cause of the sickling phenomenon and of the haemolysis of sickle-cell anaemia is the replacement of part or all of the normal haemoglobin of the red cell by a form of haemoglobin which, in the reduced state, has a very low solubility and crystallizes inside the cell. The sickle-cell-trait carrier (who is usually heterozygous) has less than 50% of this abnormal kind of haemoglobin, while most of the anaemic persons (usually homozygotes) have nearly 100% of it, usually with some of the foetal type of haemoglobin as well.

Whatever view be taken of the precise relation between the chemistry, genetics, and clinical manifestations of sickling, it appears that in many parts of Africa considerable numbers of persons are dying of sickle-cell anaemia. The gene for sickling is thus being eliminated, and unless some compensatory influence is at work the gene should ultimately reach an extremely low frequency. Two main alternative hypotheses have to be considered: either that the gene is maintained by a high rate of mutation from its normal allelomorph, or that heterozygotes for sickling tend to have more children than normal persons. The rate of mutation demanded is, as Dr. A. C. Allison points out in an article appearing elsewhere in this issue, three thousand times as high as that known for any other human gene: this hypothesis is therefore a most unlikely explanation. If sicklers are on the average to have more children than normal persons, then either individual parents must have more children or more sicklers must survive from birth to the reproductive age. The former possibility must be regarded as a reasonable one, for it has been shown for several other congenital diseases that parents tend, where possible, to over-compensate by subsequent replacement for the deaths which take place. Such compensation does not, however, depend solely on biological mechanisms but is largely dependent on cultural traditions. Thus, even if the process has a share in maintaining the incidence of sickling, it may be effective only in certain tribes. Selective survival, on the other hand, being a purely biological process would, if proved, be of more general application.

It was first suggested by Raper¹ that sickling was protective against tropical parasites, and later Brain² made the definite suggestion that heterozygous sicklers might have a greater resistance to malaria than normal persons. If this were so it would, by the operation of natural selection, tend to raise the frequency of sicklers in populations exposed to a high intensity of malarial infection. Impressed by the clinical evidence of Beet³ and of Brain² and by the general correspondence between high malarial incidences in Africa and high sickling frequencies, Allison examined some hundreds of children of one homogeneous tribe for sickling and showed that the non-sicklers had a significantly higher rate of parasitaemia than the sicklers. In the course of the work he found important clues which suggested that sickling probably conferred a resistance which was specific to infection with *Plasmodium falciparum* rather than to malaria in general. He then infected with *Plasmodium falciparum* two carefully paired groups each of fifteen volunteers, one group consisting of sicklers and the other of non-

sicklers. The infection became firmly established in all but one of the non-sicklers, whereas only two of the sicklers became infected and then mildly.

In a problem where so many ill-defined variables are involved it is highly desirable that confirmatory investigations should be made by other workers and on other populations, but there can be little doubt that Allison has demonstrated that the possession of the sickle-cell trait gives considerable protection against *Plasmodium falciparum* infection, and that he has thus made clear the main mechanism whereby high frequencies of sickling are maintained in certain African, Indian, and Greek populations. Lehmann⁴ and Allison have independently suggested that the relative protection against malaria which is enjoyed by newborn infants is due to the foetal type of haemoglobin in their red cells; and Allison has now shown that the progressively increasing incidence of malaria during the first year of life runs parallel to the replacement of foetal haemoglobin by the adult form. It may therefore further be suggested that in the child with sickling, in whom the foetal haemoglobin becomes largely replaced by the sickling instead of the normal adult form, this protection is to a great extent maintained, so that infection, when it occurs, as it almost inevitably will, is modified.

From now on the probability of a relation between sickling and malaria must be considered in investigations into the epidemiology of malaria in all parts of the world. Conversely, malarial incidence must be considered in all studies of the incidence of sickling. There is still a great need for such surveys as that carried out by Dr. H. Foy and his colleagues (see p. 294). While these authors do not regard malaria as an important factor influencing the distribution which they find, there is no doubt that the points which they stress, such as racial ancestry and genetic drift, have an important effect on sickling frequencies. Allison's work would, however, suggest that, provided the sickling gene is present in the population, its frequency will in the long run be determined mainly by the incidence of malaria. Nevertheless the presence or absence of sickling will remain an important anthropological character and a guide in the assessment of such hypotheses as that of Lehmann,⁵ who suggests that the character was introduced into Africa by Veddoid immigrants.

Other widespread congenital abnormalities of haemoglobin synthesis are known—thalassaemia in the Mediterranean area, and the occurrence of haemoglobins C and D in American Negroes.⁶ It is important that the distribution of these too should be studied and their possible relation to malaria and other infections explored.

THE PITUITARY AND CARCINOGENESIS

In 1945 Li, Evans, and Simpson¹ described the isolation of an anterior hypophysial growth hormone, and during the succeeding years, as supplies have become more readily available for research, some remarkable properties have been ascribed to this pituitary extract. The prolonged administration of growth hormone to rats causes more neoplasms to arise than would be expected to do spontaneously. They may affect the pulmonary and lymphatic tissues,² adrenal glands,³ and reproductive organs.⁴ Most laboratory animals, subjected as they are to interbreeding, are apt to produce strains which are particularly liable to develop malignant tumours in certain organs. Thus experimental work on tumour formation carried out in one animal farm may be difficult or impossible to reproduce in another even with apparently identical techniques.

Moon and his colleagues,⁵ of the University of California, injected different strains of young mice for 194 days with up to 2.0 mg. of growth hormone daily. In only one strain did neoplasms arise. An interesting observation was that the females under this treatment grew larger than the controls, and developed larger viscera. Since the prolonged administration of growth hormone to rats produces tumours of various kinds in many different organs, it is clearly of interest to know what happens in such animals deprived of any growth hormone by hypophysectomy. These workers have shown that, after removal of the pituitary, rats do not develop spontaneous tumours, nor will the injection of growth hormone induce them to appear. In further experiments⁶ pellets of methylcholanthrene, which is a potent carcinogen, were implanted into the gastrocnemius muscles of rats which had been hypophysectomized. The removal of the pituitary effectively inhibited the carcinogenic effect of the methylcholanthrene.

Another group of workers, Griffin, Rinfret, and Corsiglia,⁷ studied the effect of hypophysectomy on the liver damage and hepatomas produced in rats by giving an azo dye with the food. They administered 3-methyl-4-dimethylaminoazobenzene to rats for ten to twelve weeks, and this induced a high percentage of liver tumours. Hypophysectomy effectively inhibited their developing. Further work⁸ by these investigators at Stanford University showed that, if hypophysectomized rats fed on the azo dye were given

A.C.T.H. or cortisone, no liver damage or tumour appeared, but, if they were given pituitary gonadotrophin, liver damage and cirrhosis were seen. It is possible that the pituitary factor or factors involved in this carcinogenic process are present in the gonadotrophic fraction. These recent experiments in carcinogenesis suggest very strongly that some pituitary factor must be present before a malignant change can be initiated in the body, though there must also be many other as yet unknown factors. It is striking that a known anterior pituitary fraction, the growth hormone, should induce malignant tumours in so many different organs of the rat when it is administered in excess.

Race, environment, diet, and injury mechanically or chemically induced have all been shown to be important in the causation of cancer in man. In addition, when malignant disease arises in prostate or breast it can sometimes be temporarily controlled by the administration of hormones. This hormone therapy consists in giving large doses of stilboestrol or testosterone, which inhibit the secretion of anterior pituitary hormones and possibly work by performing a "medical hypophysectomy." Since the initiation and also the continued growth of a neoplasm require the presence of a normally functioning anterior pituitary, and since many of the pituitary hormones are now available, hypophysectomy has become a possible method of treatment. This is borne out by a report in the current issue of *Time*,⁹ according to which a Cuban woman seriously ill with recurrence of a breast cancer had her pituitary gland removed just over a year ago. She has had hormone-replacement therapy, and it is now reported that 95% of the outward signs of her cancer have disappeared. A few years ago it would have been considered most improbable that bilateral adrenalectomy would ever be advocated for arresting the growth of malignant disease in man,¹⁰ but the introduction of cortisone has made this a feasible, if somewhat experimental, therapeutic procedure. Even if such drastic techniques as total adrenalectomy and hypophysectomy are restricted in the main to the experimental animal, they should in time help us to understand why malignant tumours grow in the way they do.

RESPIRATORY INFECTION AND EMPHYSEMA

It is an experience common to family doctors and hospital physicians alike that the winter months bring in their wake increasing numbers of patients with chronic bronchitis who, having developed an acute

respiratory infection, suddenly become seriously ill and not infrequently die. These patients have signs of bronchopneumonia, are deeply cyanosed, mentally confused, and suffering from varying degrees of right heart failure: deterioration quickly occurs because they are already afflicted with emphysema, and their respiratory insufficiency is greatly aggravated by the added infection. The outcome in such patients is always difficult to forecast, but clinical impressions strongly suggest that the prognosis has been materially improved by the introduction of antibiotics and the efficient use of oxygen.

Elsewhere in this week's *Journal* Dr. T. Simpson describes his observations on 118 patients with acute respiratory infection complicating emphysema. The patients were mostly men in the sixth and seventh decades of life. The common occurrence of this malady can be judged from the fact that it was responsible for 4% of admissions to the medical wards and its seriousness from the fact that roughly one-third of the patients died while in hospital. Most patients had long-standing bronchitis and showed signs of bronchopneumonia, often complicated by mental confusion and heart failure. Among the notable features of complicated emphysema in this series of patients were a poor temperature response to infection, a fall in the systolic blood pressure on inspiration, and a curious appearance of the optic fundi characterized by darkness of the retina, distension of the veins, and changes in the optic disk sometimes amounting to papilloedema. Simpson believes that any respiratory infection in the emphysematous patient should be treated as an emergency. Antibiotic therapy is of paramount importance: penicillin is usually all that is required, but if that fails and chloramphenicol is also ineffective sputum examination will show to which of the other antibiotics the particular organisms are most sensitive. Hospital treatment will almost certainly be needed for those patients whose fever fails to respond quickly to treatment, or in whom deep cyanosis, mental symptoms, or heart failure supervene.

The administration of oxygen to these patients raises certain difficulties. It is generally agreed that relief of anoxia helps the patient, but it is now also known that mental confusion, myoclonic movements, coma, and even death can follow oxygen therapy.^{1,2} The cause of these nervous symptoms has been investigated by Drs. E. K. Westlake and M. Kaye, whose observations are reported at page 302. They studied the effect of inhaling various

gaseous mixtures and found that the cerebrospinal-fluid pressure increased in response to both anoxia and carbon-dioxide retention (hypercapnia), the increased pressure probably being caused by increased cerebral blood flow. In most emphysematous patients with infection both anoxia and hypercapnia are present. The relief of anoxia, though in itself beneficial, also removes one of the stimuli to ventilation, and therefore further carbon dioxide retention takes place to offset the effect of oxygen therapy. Drs. Westlake and Kaye conclude that the adverse effects of oxygen therapy are due to the direct toxic action of carbon dioxide on the brain rather than to the raised intracranial pressure; and they do not believe in lumbar puncture as a method of treatment in patients with mental symptoms.

The use of oxygen in patients with respiratory infection must therefore be approached with a full knowledge of its dangers as well as its value. Simpson believes that Barach's method⁴ of giving oxygen has some merit: here oxygen is given initially by nasal catheter, the rate of oxygen flow is slowly increased, and later the patient is transferred to an oxygen tent. The modern oxygen tent is the most efficient method of giving oxygen, but for this very reason the patient may develop cerebral signs of hypercapnia more quickly. Since respiratory depression will increase the dangers of carbon dioxide retention, morphine is strongly contraindicated in the infected emphysematous patient, and other sedatives must be used with great discretion.

AEROSOL DETERGENTS

The value of a humid atmosphere in the treatment of some forms of respiratory disease has long been recognized. Humidity is usually produced by means of steam or, more correctly, warm water vapour from a bronchitis kettle. In the patient's home a pan of boiling water on a stove may be used. The vapour is often "medicated" with tinct. benzoin co., which probably has little therapeutic effect although it does impart a pleasant smell to the atmosphere. The use of hot water vapour is not without its dangers, and there is some risk of scalding the patient or of producing hyperpyrexia in a sick child. In order to overcome these dangers various forms of "cold steam" humidification were devised in which cold water vapour was atomized by means of a spray,¹ and this method was thought to give a better effect more quickly. Now a recent development has been the use of various synthetic detergents, or wetting agents, in the form of an aerosol mist in order to liquefy viscid secretions.²

Detergents contain two radicals—a hydrophobic or water-repellent group, consisting of a long hydrocarbon chain, and a hydrophilic group. In aqueous solution the

molecules arrange themselves so that the hydrophobic group is on the surface away from the water. The film which is formed lowers the surface tension and reduces the viscosity of the solution. In addition the hydrophobic group has some solvent action on fatty materials. A number of these substances in the form of mists have been tested both in experimental animals and in clinical practice. Hall tested four compounds for toxicity in guinea-pigs.³ He found that if they were used in a concentration of greater than 0.1% dyspnoea was rapidly produced, and with higher concentrations the animals died. Post-mortem examination showed degeneration and desquamation of the alveolar epithelium, invasion of the alveolar spaces by macrophages, and fibroblastic proliferation. In a later clinical study Hall⁴ investigated one compound—sodium lauryl sulphate—and recommended its use in concentration of 0.05% as an aerosol mist in exudative respiratory infections in infants. Small unpublished trials in this country have confirmed the absence of toxicity, but striking benefits have not been observed.
