Many authors have stressed the importance of controlling gastric acidity. Nicol (1939) and Douthwaite (1939, 1947) showed that full doses of belladonna and the usual antacids, given by mouth, have no great effect on the diurnal gastric acidity, and Douthwaite and Thorne (1951) showed that hexamethonium was equally ineffective by day. Nocturnal acid secretion is, however, largely governed by neural mechanisms, and night acid can be controlled by hexamethonium (Kay and Smith, 1950) and full doses of belladonna (Riddell, 1951). Diurnal acid secretion can be controlled effectively by a continuous milk drip (Winkelstein, 1932) and by the continuous sucking of milk-alkali tablets (Douthwaite and Batty Shaw, 1952).

Regarding the prognosis of peptic ulceration most authors are gloomy. Nicol (1942), in a four-year follow-up of 389 cases, found that only 17% remained symptom-free, although a further 41% were well enough to remain at work on a diet. Martin and Lewis (1949) in a 10-14 year follow-up found 44% of gastric ulcers and 33% of duodenal ulcers inactive (no ulcer dyspepsia for the preceding five years). Barsby (1951) followed up her gastric ulcer subjects with the gastroscope until complete healing had taken place, but found that 43% had a recurrence at the original site and a further 9% at other sites.

It is therefore not surprising that many clinicians are sceptical of the value of many of the traditional

drugs and regimes used in the treatment of peptic ulceration. Todd (1949, 1951, 1952) cast doubt on the value of rest in bed, absence from work, strict dieting, sedation, and the avoidance of alcohol and tobacco. He advocated the liberal use of antacid tablets.

The possibility that in peptic ulcer subjects a "mucosa protecting" substance might be lacking has excited the interest of clinicians for some years, and recently "robaden" has been claimed by many Continental authors to possess ulcer-healing and mucosa-protecting properties (Neumann, 1948; Barfred, 1950; Schmassmann, 1951; Burghartz, 1951; etc.). Robaden is described by the makers as protein-free extracts obtained from the stomach and small intestine of freshly slaughtered young animals. The water-soluble part of the extract is used by injection and the water-insoluble part is taken by mouth in tablet form. The British literature contains few references to robaden. Hubacher (1946) claimed very good results in a 16-months follow-up of 54 patients treated with robaden whilst ambulant on a normal diet. There was, however, no control series. Stolte (1950) gave, impartially, robaden or a placebo to 101 patients with gastric or duodenal ulceration whilst they carried on with their normal work and diet. He found that, from the clinical and radiological points of view, there was no difference in the percentage of success. A possible criticism of this work is, however, that the injections and tablets of robaden were not given concurrently, as recommended by the makers.

In 1948 I decided to investigate the value of robaden in treatment and also whether strict dieting together with the usual gastric drugs whilst the patient was on strict rest in bed in hospital had any advantages over treatment in hospital on a light diet and partial ambulation.

Material and Method

I had the use of a male gastric ward of 10 beds, into which I admitted proved or suspected ulcer cases from the out-patient department. Those considered to be in need of surgery when first seen were not included in the series. The final diagnosis of peptic ulceration was made on radiological evidence supported, in a few cases, by gastroscopy. On admission, if not already done in the out-patient department, a barium-meal x-ray examination and an alcohol-histamine fractional test meal were performed, and during the fourth week in hospital three consecutive stools were examined for occult blood and the barium-meal examination was repeated. Almost all the radiology in the series was done by one radiologist.

The series comprised 27 patients with gastric ulcer, of whom five were female and three also had a duodenal ulcer, and 87 patients with a duodenal ulcer, of whom two were female and three also had a gastric ulcer.

On the patients' admission their names were put on a rota which decided by which of four methods they were to be treated. The four methods were: (i) strict gastric diet plus drugs, on strict rest in bed (bathroom freedom allowed once a day); (ii) as above, with the addition of robaden; (iii) post-ulcer diet whilst allowed up and about two hours daily; and (iv) as in (iii), with the addition of robaden. (Details of the diets and drugs used are given in the Appendix.)

Patients on robaden were given each morning for 21 days 1 ml. of the appropriate injection (for gastric or duodenal ulcer as the case might be) intramuscularly into the lateral aspect of the thigh, together with one robaden tablet three times a day before meals for seven weeks and then one tablet daily for the first ten days in each month for three

months. Patients on robaden whose pain persisted for longer than a few days after admission had their daily injection increased to 2 ml. for a week. Cases not on robaden were given placebo injections and tablets on the same schedule as the robaden cases. After four weeks' in-patient treatment the patients were sent home on their allotted regime (see Appendix) for three weeks, following which they were seen by me personally. If all was well they were then advised to return to work while keeping to their treatment. They were asked to come and see me every three months, and were encouraged to come up earlier if they had a recurrence of symptoms.

The following study deals with those patients whom I followed up for at least six months. The final information about the patients was obtained by interview in half the number. The remainder, who did not respond to an invitation to attend, replied to a questionnaire (see Appendix).

It is thought that the patients in each therapeutic group are comparable, as can be seen from Table I.

TABLE I

Treatment Group	No. of Cases		Average Length (Years) of Ulcer Symptoms		Average Age (Years)	
	G.U.	D.U.	G.U.	D.U.	G.U.	D.U.
1. Robaden + strict diet	6	20	7	5½	49	39
2. Strict diet	10	28	5	6	46	40
3. Robaden + post-ulcer diet	7	19	5	8	46	43
4. Post-ulcer diet	4	20	5	9	46	46

The history of previous treatment and complications, and also the alcohol and tobacco habits, were comparable in each of the groups.

Results

A. Patients with Gastric Ulceration

Comparison of the results between the four therapeutic groups was made in a number of ways. The disappearance of pain and tenderness was not found to be helpful, as these almost always disappeared within a few days of admission, whilst the absence of occult blood during the fourth week in hospital (at least two specimens examined) and the return of the radiological picture to normal were not of much value in assessing the prognosis. Thus, of those followed up for at least six months, only five had negative occult blood tests, and two of these had a recurrence of ulceration after 30 and 32 months (average follow-up time in those with no recurrence, 29 months), while 20 patients returned to radiological normality, of whom 5 relapsed (average time to relapse, 14 months; average follow-up time, 28 months). It is, however, of interest that of the 20 patients who returned to normal, 9 were on post-ulcer diet and robaden or post-ulcer diet alone, and none relapsed (average follow-up time, 30 months).

The figures in Table II give no indication that robaden expedites healing.

TABLE II.—Details of Radiological Results

Treatment Group	No. Followed until Healed Radiologically	Average Healing Time	Average No. of Barium-meal X-ray Examinations
1. Strict diet + robaden	4	9 weeks	4
2. Strict diet alone	8	9 "	4
3. Post-ulcer diet + robaden	6	19 "	3.2
4. Post-ulcer diet alone	3	7 "	2.3

1. Clinical relapse rate amongst the cases followed up for at least six months, severe enough to need dieting while they were off work (Table III). Those who were referred for surgical treatment during their initial admission to hos-

pital, and also those who, because they did not respond to the allotted regime, were given stricter treatment, are excluded.

The figures in Table III can be treated in another way—dividing the cases into four further groups: (A) those treated on diet alone (strict diet alone and post-ulcer diet alone);

TABLE III

Treatment Group	No. of Cases Followed Up at Least 6 Months	No. of Cases which Relapsed	Average Length of Follow-up in those Not Relapsing	Average Time to Relapse	Relapse
1. Strict diet + robaden	5	3	20 months	7 months	60%
2. Strict diet alone	7	3	26 "	12 "	43%
3. Post-ulcer diet + robaden	5	0	34 "	—	0
4. Post-ulcer diet alone	4	1	25 "	23 months	25%

(B) those given robaden (strict diet+robaden and post-ulcer diet+robaden); (C) those treated with a strict ulcer diet (strict diet+robaden and strict diet alone); and (D) those given a post-ulcer diet (post-ulcer diet+robaden and post-ulcer diet alone) (Table IV).

TABLE IV

Group	No. of Cases Followed Up at Least 6 Months	No. of Cases which Relapsed	Average Length of Follow-up in those Not Relapsing	Average Time to Relapse	Relapse
A. Diet	11	4	26 months	15 months	36%
B. Robaden	10	3	29 "	7 "	30%
C. Strict diet	12	6	23 "	9½ "	50%
D. Post-ulcer diet	9	1	31 "	23 "	11%

2. Two patients were given stricter treatment because they were not responding to their allotted regime. One was in group 2 and the other in group 3. Two cases came to surgery during their initial admission—one in group 1 and the other in group 3.

3. It is considered fair to compare each therapeutic group on the number of "failures" in each group. By failures is meant those who had a clinical relapse, those who came to surgery during their initial admission, and those who, because they were not responding to the allotted treatment, were put on to a stricter regime (Table V).

TABLE V

Treatment Group	Average Length of Follow-up	"Failures"	
		No.	%
1. Strict diet + robaden	20 months	4 out of 6	67
2. Strict diet alone	26 "	4 " 8	50
3. Post-ulcer diet + robaden	34 "	2 " 7	29
4. Post-ulcer diet alone	25 "	1 " 4	25

Treating these figures in a different way gives the results shown in Table VI.

TABLE VI

Group	Average Length of Follow-up	"Failures"	
		No.	%
A. Diet	26 months	5 out of 12	42
B. Robaden	30 "	6 " 13	46
C. Strict diet	24 "	8 " 14	57
D. Post-ulcer diet	31 "	3 " 11	27

The average gain in weight from the first to the last interview among those treated on a strict diet was 3 lb. (1.4 kg.) (average of 16 cases), whilst those treated on a post-ulcer diet gained 13 lb. (5.9 kg.) (average of 10 cases).

Comment.—These figures suggest that, of the regimes tested, a post-ulcer diet at rest in hospital gives the best results, and no evidence was found that robaden was of value in treatment. It is realized, however, that the series is a small one.

B. Patients with Duodenal Ulceration

1. Very strict radiological criteria were used before pronouncing a duodenal ulcer as having healed—namely, a cap normal in shape and with no demonstrable spasm or ulcer crater. Table VII gives details of the radiological results.

TABLE VII.—Details of Radiological Results

Treatment Group	No. who had Repeated Barium Meal X-ray Exams	No. Followed Until Healed Radiologically	Average Healing Time	Average No. of Barium Meal X-ray Exams
1. Strict diet + robaden	18	3	6 weeks	3.2
2. Strict diet alone	23	10	15 "	2.6
3. Post-ulcer diet + robaden	17	3	10 "	3.0
4. Post-ulcer diet alone	16	5	8 "	2.9

2. **Clinical Relapse Rate.**—Amongst the cases followed-up for at least six months, severe enough to need strict dieting while they were off work. Those who were referred for surgical treatment during their initial admission and also those who, because they did not respond to the allotted regime, were given stricter treatment are excluded.

TABLE VIII

Treatment Group	No. of Cases Followed Up at Least 6 Months	No. of Cases which Relapsed	Average Length of Follow Up in those Not Relapsing	Average Time to Relapse	Relapse
1. Strict diet + robaden	13	6	27 months	21 months	46%
2. Strict diet alone	17	4	27 "	9 "	24%
3. Post-ulcer diet + robaden	9	2	35 "	7 "	22%
4. Post-ulcer diet alone	15	7	25 "	16 "	47%

Treating these figures in a different way, by dividing the cases into the four groups: (A) "diet" (strict diet alone and post-ulcer diet alone), (B) "robaden" (strict diet + robaden and post-ulcer diet + robaden), (C) "strict diet" (strict diet + robaden and strict diet alone), and (D) "post-ulcer diet" (post-ulcer diet + robaden and post-ulcer diet alone), the results shown in Table IX are obtained.

TABLE IX

Group	No. of Cases Followed Up at Least 6 Months	No. of Cases which Relapsed	Average Length of Follow Up in those Not Relapsing	Average Time to Relapse	Relapse
A. Diet	32	11	26 months	13 months	34%
B. Robaden	22	8	31 "	17 "	36%
C. Strict diet	30	10	27 "	16 "	33%
D. Post-ulcer diet	24	9	29½ "	14 "	37½%

The figures in Tables VIII and IX do not demonstrate a clear-cut advantage of any of the four therapeutic regimes used.

3. Ten patients, because they were not responding to their allotted regime, were given stricter treatment (strict diet + continuous milk drip): one was in group 1, two were in group 2, five were in group 3, and two were in group 4.

In this series the prognosis in cases given continuous-milk-drip treatment was poor, but these patients, together with the nine described below, represented the hard core who did not respond at all to their allotted treatment.

4. Nine cases, owing to lack of response to treatment, came to surgery during their initial admission: three were in group 1, three in group 2, one in group 3, and two in group 4.

5. **Failures in Each Therapeutic Group.**—The figures comprise those who relapsed clinically, those who came to surgery during their initial admission, and those who, because they were not responding to the allotted treatment, were given a stricter regime. If in the last four groups in Table X the follow-up time is increased to 31 months the estimated failure rates (simple arithmetical proportions) are: diet, 58%; robaden, 56%; strict diet, 56%; and post-ulcer diet, 59%. As regards efficacy of treatment, these figures suggest that there is little to choose between the four therapeutic regimes.

TABLE X

Group	Average Length of Follow-up in Non-failures	Failures	
		No.	%
1. Strict diet + robaden	27 months	10 out of 17	59
2. Strict diet alone	27 "	9 " 22	41
3. Post-ulcer diet + robaden	35 "	8 " 15	53
4. Post-ulcer diet alone	25 "	11 " 19	58
A. Diet	26 "	20 " 41	49
B. Robaden	31 "	18 " 32	56
C. Strict diet	27 "	19 " 39	49
D. Post-ulcer diet	29 "	19 " 34	56

6. The absence of occult blood in the stool during the fourth week in hospital was not found to be of great prognostic importance, but the return of the duodenal cap to normal carried a good prognosis. With a follow-up of at least six months a total of 18 of the duodenal ulcer cases returned to a normal cap on radiology at some period (average follow-up time, 29 months), and only three of these had a clinical relapse after an average of 25 months' freedom, although there were four radiological relapses (symptomless) after an average of 14½ months.

7. The average gain in weight from the initial interview to the last one among those patients treated on a strict diet was 3.9 lb. (1.8 kg.), whilst the post-ulcer diet group gained 4.9 lb. (2.2 kg.).

Conclusions

These results support the findings of Nicol (1939), Ronald (1939), and Lawrence (1952) that rest in hospital on a light diet gives results as good as those achieved by rest in hospital on a strict "ulcer" diet with belladonna and antacids. As Doll and Pygott (1952) have found that cases treated on a "gastric" diet in hospital did better than those on ambulatory treatment and a "convalescent" diet, the conclusion can be drawn that the important factors in any successful therapeutic regime are mental and/or physical relaxation, together with the natural tendency for clinical remissions to occur in peptic ulceration.

In this country, at present, most people can best obtain this beneficial relaxation in a hospital ward where suitable food is provided, there is freedom from domestic tension, and financial worries are in most cases absent, owing to the National Insurance. It is felt that small gastric wards are an advantage: the patient has a feeling of individuality, whilst at the same time a community spirit is fostered. An occasional patient, of course, never settles down to ward life, and in these instances it is doubtful whether it is worth persevering with in-patient medical treatment.

My present routine is to treat patients with peptic ulceration in hospital on a "post-ulcer" diet. They spend most of their time in bed, but are allowed bathroom freedom and are up and about for two to three hours daily. Each patient has a supply of magnesium trisilicate on his locker, and he is encouraged to help himself to a dose whenever he has pain or discomfort. He spends a month in the ward, after which he continues resting at home on the same diet for a further

three weeks. He is then seen again and almost always advised to restart his work.

The occasional patient who fails to respond to this regime will need stricter treatment, such as a continuous milk drip or the continuous sucking of milk-alkali tablets, but my experience is that most of these refractory cases will need surgery within a few months.

Regarding after-care, it is suggested that the patient continues with his post-ulcer diet while back at work, avoiding excessive smoking and alcoholic indulgence. He should be encouraged to cultivate a calm and philosophical attitude to the stresses and strain of life, and he should, when he has discomfort, take freely of one or other of the harmless antacids as suggested by Todd (1952). In view of the high relapse rate in peptic ulceration, whatever medical treatment one gives, resort to surgery should not be delayed unduly. My practice is to advise surgery (provided there are no contraindications) if the patient relapses after one or at most two courses of medical treatment.

If this simple treatment of peptic ulceration gains favour much labour will be saved in preparing complicated diets and there will be saving on the cost of drugs. A good library, wireless, facilities for card games, and television will help to pass the time. Conventional occupational therapy is, I find, not popular with peptic ulcer patients.

Regarding robaden, I could find no clear evidence of its value. However, the patients treated with robaden were given it for only five months, and it is possible that if it had been given for a longer period beneficial effects might have been seen.

Summary

A total of 111 patients with peptic ulceration were treated in hospital and divided impartially into four therapeutic groups: (1) strict ulcer diet + robaden; (2) strict ulcer diet alone; (3) post-ulcer diet + robaden; and (4) post-ulcer diet alone. As a result of a follow-up study it is concluded that treatment on a post-ulcer diet gives results as good as those obtained with the other three regimes, and it is suggested that the important factors in any successful therapeutic regime for peptic ulceration are mental and/or physical relaxation, which assist the natural tendency for remissions to occur.

My thanks go to Dr. Stanley Nowell for the radiology; to Dr. John Forbes, who originally worked out the diets, for advice; to Professor Scarborough for advice; to the house-physicians who have kept such scrupulous notes; and to Sister J. Roberts, who instilled the right spirit into the ward and saw that the patients kept to their allotted regime.

APPENDIX

Regime followed by those patients treated on "strict diet."

Regime A: Strict Rest in Bed (Bathroom Freedom Once Daily)

On waking.—A glass of milk to be sipped slowly.

8 a.m.—A lightly boiled, poached, or scrambled egg. Four thin half-slices of toast or bread-and-butter. A cup of milk flavoured with tea and sugar.

10 a.m.—A glass of milk to be sipped slowly. Two digestive biscuits or rusks.

12 noon.—A small portion of boiled or roast chicken; or of steamed, boiled, or grilled white fish; or of tender steak or chop; or of tripe, calf's heart, or liver. Two heaped tablespoonfuls of mashed creamed potato. A glass of milk.

2 p.m.—A glass of milk to be sipped slowly. Two digestive biscuits or rusks.

4 p.m.—A cup of milk flavoured with tea and sugar. Four half-slices of thin bread-and-butter. A portion of plain sponge cake.

6 p.m.—A moderate amount of rice, macaroni, cornflour, arrowroot, or some other milk pudding. A glass of milk.

8 p.m.—A glass of milk to be sipped slowly.

10 p.m. (if awake).—A glass of milk to be sipped slowly.

During the night the patient should be given a drink of milk or cocoa if he wakes up.

No condiments are allowed. All food must be chewed carefully and the month rinsed afterwards and kept clean.

Drugs (No other drugs are to be given without the doctor's orders).—(1) Phenobarbitone, 1 gr. (65 mg.) b.d. (2) Laevohyoscyamine, 1/120 gr. (0.54 mg.) b.d. (3) Olive oil, 1 dr. (3.5 ml.) t.i.d., after the 8 a.m., noon, and 6 p.m. feeds. (4) Soluble amylobarbitone (sodium amytal) 3 gr. (0.2 g.) nocte p.r.n. (if patient awake). (5) Liquid paraffin or an enema may be given for constipation. (6) A teaspoonful of magnesium trisilicate two-hourly, half an hour after each feed, and two teaspoonfuls last thing at night.

After three weeks the patients went on to the following diet:

Regime B: Bathroom Freedom and Up and About Two Hours Daily

Breakfast.—Small portion of porridge with milk or cream and sugar if desired. Bread or toast with butter and marmalade. A lightly boiled, poached, or scrambled egg. A cup of weak tea with milk and sugar.

10.30 to 11 a.m.—A glass of milk with biscuits or rusks.

Dinner.—4 oz. (113 g.) of fish, chicken, game, beef, chop, steak, mutton, or lamb. Boiled, baked, or mashed creamed potato. A small milk pudding. Milk or water to drink.

Tea.—A cup of weak tea with milk and sugar. Bread-and-butter. Jelly or plain cake.

Supper.—Cold meat or tongue, boiled or grilled fish. Bread-and-butter. Puree of prunes, apples, or other fruit, flavoured with milk and sugar. Milk or water to drink.

8 to 9 p.m.—A glass of milk.

Drugs.—As in Regime A.

The patient should eat slowly, chewing all food carefully.

After a week on this regime, sieved vegetables should be added to the midday meal, and, after a further week, ordinary cooked vegetables allowed.

Similarly, after the first week, the fruit at the evening meal need not be sieved, but the patient should avoid all skins and pips.

After a further week the patients went home with a copy of this regime, which they were asked to follow until seen at the out-patient department three weeks later, when they were given a copy of the following "post-ulcer diet," which they were advised to keep to whilst working. This diet is also the one followed from the start by the groups treated on "post-ulcer diet" (one month in hospital and then three weeks at home, spending most of the time resting in bed but from the beginning allowed bathroom freedom and to be up and about two hours a day).

Regime C: Ordinary Food Should be Taken with Certain Reservations

1. **No roughage.** Avoid all pips and skins of fruit, unripe fruit, nuts, currants, raisins, figs, raw vegetables, fibrous vegetables (celery, etc.), and gristly meat.

2. *No irritants.* Avoid such things as hot gravies, spices, vinegar, lemon juice, pepper, mustard, curry, pickles, chutney, and strong hot tea or coffee. Take salt in strict moderation. Take alcohol in strict moderation only. Avoid all drugs and patent medicine, especially aspirins and strong purgatives (see below). Smoking should be indulged in only after meals and in strict moderation (five cigarettes, or three small pipefuls daily).

3. *Overeating at one meal is as bad as going for long periods without food.* Both are harmful, and it is important to supplement the three principal meals by taking a milk drink with chocolate biscuits or bread in the middle of the morning and in the afternoon and last thing at night. All food must be carefully chewed before swallowing.

4. *It is a mistake to avoid certain foods* (with the exceptions mentioned above) on principle because they are supposed to be indigestible. Narrowing the diet down too much leads to a loss of weight and malnutrition, which will tend to cause a recurrence of the indigestion. Eat any food that is available, unless it is found that a certain food always disagrees, in which case it should be avoided.

5. *If constipated* take a teaspoonful of milk of magnesia at night or a dessertspoonful of liquid paraffin morning and evening.

6. *Try to avoid mental and physical overstrain.* Keep regular hours, regular habits, and, above all, regular mealtimes. During unavoidable periods of extra work, intensive activity, or excitement, or when worried or upset, take extra care with diet: avoid beef, pork, pastry, and greasy foods.

7. *If indigestion is felt* take a dose of alkaline powder (magnesium trisilicate if possible), but do not take powder as a routine. Otherwise avoid all medicines, unless ordered by your doctor. If the indigestion is severe and does not clear up in a few days go and see your doctor.

8. *Do not spend all your time worrying about your stomach* and about your diet and about your health generally. Stick to these instructions, but otherwise forget about your stomach and enjoy life.

The following is a copy of the questionnaire sent to each of the patients who failed to keep his final follow-up appointment:

"I am very interested to hear how your indigestion has been since I last saw you, as we are doing some investigations on the subject.

"I should be most grateful if you would write to me in confidence (envelope enclosed) telling me in detail about any symptoms you have noticed, and also whether you have had any further treatment or operations, the date and results of any further barium-meal x-ray films of your stomach, and any complications that have occurred.

"Are you keeping to a diet, are you working, and how much tobacco are you smoking?"

During the last quarter of 1953 the City Analyst of Birmingham carried out a survey of five popular brands of "pocket inhaler." These articles consist of a conical plastic outer case with a smaller inner chamber containing absorbent paper soaked in amphetamine, or a closely related compound, together with menthol and essential oils. Sixty-four inhalers were examined, an average of 13 of each of the five brands. The first of these brands to be put on the market showed a remarkably consistent amphetamine content. Three other brands were very similar, but their content of amphetamine was less constant, sometimes showing an excess of up to 30%, and sometimes a deficiency of as much as 22%. The last brand examined, however, presented a very different picture: of 13 samples examined every one was deficient in amphetamine by amounts varying from 31% to 90%, with an average shortage of nearly 60%. The City Analyst then wrote to the makers, who suggested that the loss was due to evaporation consequent on long storage. However, no particular relationship could be discovered between age and the strength of the samples. As a result of this investigation the firm in question agreed to recall all inhalers issued before last year. In Mr. Bagnall's view, this appears to be yet another case where certain pharmacists have retained stocks of a preparation long after the time when they should have been destroyed or returned to the suppliers.

A PLEA FOR THE LONGER TREATMENT OF CHRONIC PYELONEPHRITIS IN CHILDREN

BY

J. M. STANSFELD, M.D.

Consultant Paediatrician, Durham Group of Hospitals

AND

J. K. G. WEBB, B.M., M.R.C.P.

Late Registrar, Children's Department, Royal Victoria Infirmary, Newcastle-upon-Tyne; formerly at the Churchill Hospital, Oxford

Acute pyelonephritis in children responds to sulphonamides so well that its treatment rarely presents a problem. Sixteen cases in infants and children were treated in the Radcliffe Infirmary during 1948 and 1949; all cleared up rapidly and only one relapsed. The latter responded to a second course of sulphonamide, and there was no recurrence.

In chronic pyelonephritis the results are very different. In the same two-year period there were 16 chronic cases at the Radcliffe. Symptoms had been present for at least two weeks, and in most cases for very much longer when treatment was started. They were all given a sulphonamide in full dosage for five to fourteen days. In every case the infection relapsed. In four of these cases further investigation showed lesions requiring surgery, but the other 12 remained essentially medical problems. Our experience since then suggests that these results are in no way exceptional, and it is with the treatment of chronic pyelonephritis without surgically treatable lesions that this paper is concerned. In most cases the infection is due to a coliform organism sensitive initially to all the readily available antibiotics except penicillin. The question to be decided is which antibiotic should be used, in what dose, and for how long.

General Considerations

In 1939 Weiss and Parker reviewed the post-mortem findings in 100 cases of chronic renal tract infection. In only one was inflammation confined to the renal pelvis and ureters; in 99 inflammation involved the renal parenchyma, and the disease was rightly called pyelonephritis. Birchall and Alexander (1950), in a review of the medical aspects of pyelonephritis, accepted this view of its pathology. They pointed out that in treatment it is the concentration of antibiotic in the plasma which is significant, and not the concentration in the urine. Therefore only full doses of a sulphonamide or antibiotic should be given in the initial treatment of pyelonephritis. Furthermore, there is no particular merit in a sulphonamide such as "urolocosil," which has been recommended because of the high concentration of the non-acetylated form obtained in the urine. Birchall and Alexander also draw attention to the fairly general experience that, with streptomycin, organisms become resistant very rapidly. They suggested, for this reason, that streptomycin should never be given for more than five to seven days. They also pointed out that as mandelic acid and related compounds are effective only in an acid medium, which cannot be attained in the interstitial tissues of the kidney, these drugs are unlikely to be of value in pyelonephritis, and should be reserved for infections of the lower renal tract. For the treatment of chronic pyelonephritis they recommended a 21-days course of a sulphonamide in

full dosage, together with intramuscular penicillin and streptomycin during the first week.

At the time their article was published we had no experience of this combined therapy, but we had already been using 14-days courses of a sulphonamide in full dosage, and had had four quite severe drug reactions. Two children on sulphadimidine developed rashes with generalized lymph-node enlargement on the seventh and eighth days of the course respectively. One child on "sulphatriad" developed fever and a rash on the eleventh day, and another on a rather large dose of sulphatriad—0.15 g. per lb. (0.33 g. per kg.) a day; body weight 20 lb. (9 kg.)—developed on the thirteenth day fever, generalized lymph-node enlargement with splenomegaly, and agranulocytosis with complete disappearance of polymorphs from the peripheral blood for nearly a week. This experience made us reluctant to give even longer courses of sulphonamides in full dosage. Furthermore, we already had, in one child, evidence of the value of a small dose of a sulphonamide continued over a very long period. We therefore decided to start treating all cases of chronic pyelonephritis with an initial 10-days course of sulphadimidine in full dosage, followed by a further variable period on a small dose.

It is clearly important to know whether this method of treatment gives better results than the orthodox short course. Only a planned investigation could give this information with certainty, and no such investigation has been made. However, during the last three and a half years we have treated over 40 infants and young children with chronic pyelonephritis in the Babies' Hospital, Newcastle-upon-Tyne, during the first half of this period with short courses of a sulphonamide or antibiotic, and during the second half with long courses. From among these infants it has been possible to form reasonably similar groups, and a comparison of the results of treatment in the two groups follows.

An Investigation

During this investigation the general management, nursing care, and follow-up of infants remained the same; only the length of treatment changed significantly.

Infants admitted before October, 1950, were treated with sulphadimidine, streptomycin, or chloramphenicol for five to fourteen days, seven days being the most usual. Dosage was standard—that is, sulphadimidine, 0.1 g. per lb. (0.22 g. per kg.) a day; streptomycin, 20 mg. per lb. (44 mg. per kg.) a day; and chloramphenicol, 50 mg. per lb. (110 mg. per kg.) a day. If the infection relapsed, a second similar course of appropriate antibiotic was given, and in some cases third and fourth courses. "Mandelix" was used in three cases after antibiotics had failed. If infection still persisted infants were kept on sodium citrate (average 90 gr. (6 g.) a day) for long periods.

After October, 1950, sulphadimidine was given in full dosage for an initial period, usually 10 days; the subsequent period on a reduced dose varied from only 10 days in two cases to over six months. If the infection did not respond to sulphadimidine or if the organism seemed unlikely to be sensitive—for example, *Staph. aureus*—chloramphenicol was used. Rather illogically, in the first case we treated with chloramphenicol (No. 17) this was given for only 16 days. The infection relapsed. Whenever we used chloramphenicol in subsequent cases we gave an initial course, usually of fourteen days, in full dosage and then a reduced dose for a period varying from six to sixteen weeks. Streptomycin was given in most cases during the first week of sulphadimidine. Alkalis were not used.

Only infants with a indisputable pyelonephritis who were under 1 year at the onset of symptoms, whose symptoms had been present for at least two weeks before the start of treatment, who had no evidence of renal acidosis or of hypercalcaemia, and who had no other illness which might have affected the course of the pyelonephritis have been included for analysis. Twelve infants in the early group and 11 in the later group satisfied these criteria.

The duration of symptoms before treatment is probably the most important single factor in determining prognosis. This was similar in the two groups. The results of treatment proved extremely difficult to assess. It was out of the question to use the urinary findings alone as an index of cure, and we therefore had to depend very much on the infant's general progress. Failure to thrive is so constantly present in infants with an active infection that a normal weight gain is a dependable sign of recovery. All weights were therefore graphed, and these, the mother's account of the infant, and the urinary findings were all taken into consideration. To express the results quantitatively, we tried to decide on a definite day, counting from the start of treatment, from which progress was uninterrupted and after which no significant pyuria was found. This was easy when there was a good immediate response to treatment with no relapse. Although there were minor variations in response, for the sake of clarity all such cases have been graded as 10—that is, progress uninterrupted from the tenth day of treatment. It was still fairly easy in the cases which relapsed but made a good recovery after further treatment, and all these have been given a definite grading. It was impossible in those cases in which, after months of ill-health with slow or fluctuating weight gains, gradual and possibly incomplete recovery occurred: in these no attempt has been made to be precise.

The results of this analysis are given in the Table. There is no doubt that the results of treatment are very much better in the later group. Six of the 11 made an uninter-

rupted recovery, against 4 out of 12. The average time from the start of treatment to recovery was less than half, and there was only one case with an indefinite end-point against three in the early group. However, in 5 of the 11 cases in the later group recovery was slow and interrupted. In two of these the reasons for this are obscure, but in three it is instructive to examine the treatment given in detail.

Case 17.—This child was in hospital at the same time as several infants with a gastro-enteritis due to *Bact. coli* D 433. He passed some loose stools shortly after admission, and it was because of the possible intercurrent gastro-enteritis that he was treated from the start with chloramphenicol rather than sulphadimidine. He responded well to a 16-days course, but the infection relapsed within a week. The infection then failed to respond to sulphadimidine given for 28 days when he was an out-patient, presumably because the organism was insensitive; so he was readmitted to hospital. A coliform organism sensitive to chloramphenicol was cultured from the urine, and he was given chloramphenicol, 250 mg. four-hourly for 14 days, 250 mg. twice-daily for 42 days, and 250 mg. once daily for 84 days. The infection responded promptly and has not relapsed in over a year's follow-up. He was given this very long course

because a persistently raised blood urea and no visible excretion of dye in an intravenous pyelogram suggested severe kidney damage.

Case 16.—This male child was treated initially with sulphadimidine, 0.25 g. four-hourly for ten days, with streptomycin during the first seven days. This was followed by sulphadimidine, 0.25 g. twice daily for seven days. The pyelonephritis had responded to this, but he then developed an abscess at the site of a streptomycin injection. Pus from this cultured *Staph. aureus* resistant to penicillin and streptomycin. Sulphadimidine was stopped and he was given chloramphenicol, 250 mg. eight-hourly for eight days. Total treatment was for only 25 days: the shortness of this course was due to a mistake, and was not in keeping with the general policy. The pyelonephritis relapsed after one week. His urine cultured coliform organisms still sensitive to chloramphenicol, and he was given chloramphenicol, 250 mg. eight-hourly for 21 days, and 125 mg. twice daily for 56 days. The infection responded promptly to this, and has not relapsed in nine months' follow-up.

Case 20.—A female child was treated initially with sulphadimidine, 0.5 g. six-hourly for 10 days followed by 0.5 g. twice daily for 21 days (total treatment 31 days). The infection responded promptly, but symptoms recurred a week after stopping treatment. They were at first attributed to a mild otitis media, for which penicillin was given for a week, but pyuria was found later. Urine culture revealed a chloramphenicol-sensitive coliform organism, and she was given chloramphenicol, 500 mg. eight-hourly for 14 days, and 250 mg. twice daily for 56 days. The infection responded, and there was no relapse in three months' follow-up.

In these three cases it seems probable that relapse could have been prevented by giving a longer course of treatment on the first occasion.

Conclusion and Discussion

From the evidence of this investigation it is clear that the plan of treatment followed in the later group offers a good chance of cure even in very long-standing infections. If the infection responds to the initial course of sulphadimidine or chloramphenicol in full dosage, relapse is most unlikely during the subsequent period on a reduced dose. We have in fact never seen this. The difficult question is how long the reduced dose should be continued. The results in Cases 16 and 20, which relapsed after 25 and 31 days of treatment respectively, suggest that the period must certainly be longer than a month, but we do not know how often we have used unnecessarily long courses.

It is perhaps worth considering at this point why the long period on a reduced dose prevents relapse. The following explanation seems reasonable. It is certain that in every case of long-standing pyelonephritis there is widespread disorganization of renal tissue. It is unlikely that this damaged tissue can be restored to normal in a period as short as two or three weeks, and while it remains incompletely healed it is presumably more liable to infection. The initial course of antibiotic in full dosage must kill most of the infecting organisms, but a few may survive in isolated foci. We imagine that the small dose of antibiotic is enough to protect the damaged tissue from infection spreading from the surviving foci. As the organism found in relapse is nearly always the same as in the original infection, relapse must usually occur by spread of infection from surviving foci rather than by reinfection with fresh organisms.

If this is the correct explanation the protective dose of antibiotic must be continued for as long as the damaged kidney will take to heal, and this will depend on the duration and severity of the infection before treatment was started. There can therefore be no final answer to this question of how long treatment should be continued. The length of history, the extent to which one or both kidneys have already been damaged, and the possible risk of toxic effects from the long course of antibiotic will all have to be taken into consideration.

Sulphadimidine is so cheap and safe that we are sure it should be used first whenever it is likely to be effective. For the same reasons, wherever the initial course in full dosage has proved effective it would seem wise to anticipate relapse and to give the reduced dose for a long period. As an approximate guide we would suggest eight weeks when infection has been present for less than two months, and up to six months or occasionally more in longer-standing infections.

When we have had to turn to another antibiotic we have used chloramphenicol, and our experience with this suggests that the same manner of dosage is needed as with sulphadimidine. We have used it in this way with good results and without any serious ill effects. However, reports (Hodgkinson, 1954) of aplastic anaemia following chloramphenicol suggest that it would be most unwise to make a practice of giving long courses. A final verdict on this question is not possible yet, but for the present it seems preferable to use aureomycin. It is most unlikely that aureomycin will prove effective in a significantly smaller dose or shorter time than chloramphenicol or sulphadimidine, and our very limited experience confirms this view. However, it is more expensive than sulphadimidine and its long-term toxic effects are less well explored. For both these reasons we are reluctant to advise giving really long courses unless they are absolutely essential. In the great majority of cases we believe they will be, but as a small proportion of cases clear up after a short course of treatment (see Cases 3, 4, 5, and 8) it may be wise to start with a 14-days course. If the infection relapses it is still likely to respond to a longer period of treatment as suggested for sulphadimidine.

Although most of those we have treated for pyelonephritis have been infants, limited experience with older children suggests that our conclusions are valid for them too. In older children, however, histories tend to be longer, and one occasionally meets with infections which are distressingly intractable. In such cases persistent treatment with frequent change of antibiotic as bacteriology indicates offers the only hope of cure.

Summary

All cases of pyelonephritis in infants and young children treated during 1948-9 at the Radcliffe Infirmary, Oxford, and in a 3½-year period (1949-52) at the Babies' Hospital, Newcastle-upon-Tyne, have been studied.

Attention is drawn to the possible chronicity of these infections and to the frequency of relapse after orthodox seven- to fourteen-days courses of a sulphonamide or antibiotic.

A new scheme of treatment has been described with an initial ten-days course of sulphadimidine or an antibiotic in full dosage, followed by a long period (two to six months) on a reduced dose.

Two similar groups of cases—one treated in the orthodox manner and the other according to the new scheme—are compared, and the superiority of the long course of treatment is shown.

The wisest plan of treatment to adopt in future is discussed.

We are grateful to Professor Sir James Spence and Dr. V. Smallpeice for permission to use their cases and for encouragement and help at different stages of this work, also to many colleagues in discussion with whom these ideas have developed.

DEEP X-RAY THERAPY IN SPONDYLITIS

BY

E. C. EASSON, M.B., Ch.B., D.M.R.T., F.F.R.

Consultant Radiotherapist, Christie Hospital and Holt
Radium Institute, Manchester

Since late 1947 a joint clinic has been conducted at the Rheumatism Centre and at the Christie Hospital and Holt Radium Institute for the investigation of cases of ankylosing spondylitis and their treatment by x rays. This paper concerns 332 cases seen under this joint arrangement and the changes observed in 275 of these following x-ray therapy.

The clinical picture of ankylosing spondylitis has been fully described in several recent publications (Polley and Slocumb, 1947; Mowbray *et al.*, 1949; Parr *et al.*, 1951), and notably in those of Hart *et al.* (1949, 1950). During the course of the present study patients whose disease conformed to the classical picture were labelled "typical" spondylitics, but there were some patients whose illness differed in various ways from this and who were classed as "atypical" spondylitics in the absence of a satisfactory alternative diagnosis. Some of the patients seen in the spondylitis clinic were found on further investigation to be suffering from conditions unrelated to spondylitis, such as bone disease, disk prolapse, and spinal cord lesions, but these have been excluded from this study. During the analysis of the spondylitic cases a "borderline" group was also introduced between the "typical" and "atypical" groups. X-ray therapy was not advised in a number of the atypical cases although many had been referred for this, and one of our purposes was to find out if that policy was in fact justified. X-ray treatment was also not given to typical cases in which the spondylitis appeared to be inactive.

Of the 332 cases, 242 were considered to be typical, 59 atypical, and 31 borderline. Some of the features of these cases are set out in Table I.

About one-quarter of the patients in each group gave histories of rheumatic complaints among relatives: in the typical group 35% of these were of fairly definite or probable ankylosing spondylitis, compared with 19% in the atypical group, but the difference is not significant ($P>0.16$). The incidence of iritis in the three groups did not differ significantly. The true incidence of involvement of the hands and feet in ankylosing spondylitis may be somewhat higher than is indicated owing to the inclusion of some typical cases in the borderline group, but if these groups are combined the incidence of 34 in 273 cases (12.5%) contrasts with the incidence of 52.5% in the atypical group. Tendinitis and tendon nodules were noted very rarely in typical spondylitics but were found in 12% of the atypical patients. Ball's modification of Rose's serum differential agglutination test (Ball, 1950) gave strongly positive results in 12% of the 50 atypical patients tested. Ball (1952) reported positive results with this test in 44.2% of 642 unselected cases

† Grade I—Sacro-iliac joints only involved. Grade II—Sacro-iliac joints involved + slight or moderate change in spine or elsewhere. Grade III—Sacro-iliac joints involved + severe and extensive change in spine or elsewhere.

of rheumatoid arthritis attending hospital. This suggests that the atypical group is not largely composed of patients with rheumatoid arthritis affecting the spine in spite of the high incidence among them of involvement of the hands and feet.

Technique of X-ray Treatment

The x rays were generated at 250 kV with a half-value layer of 1.63 mm. of copper, the focus-skin distance being 50 cm. It has been our practice, even when symptoms were confined to one level of the back, to treat the whole spine and the sacro-iliac joints through rectangular applicators 7.5 cm. in width, the length being adjusted so as to ensure close apposition of these to the skin.

Previously, smaller fields were used to treat local painful regions of the spine, but this method was abandoned because, although the treated area might be painless after treatment, further lesions in the vicinity often developed or were disclosed during treatment. The sacro-iliac joints were treated through a single applicator, 15 by 12 cm., contiguous with the lowermost spinal field.

Almost all these patients were treated as out-patients, a dose of 150 r (measured with back-scatter) being given to the skin surface of each field at each weekly visit for ten weeks. Serious radiation sickness occurs infrequently with this low dosage, having caused curtailment of treatment in only four of these patients. It was also hoped that this dosage would decrease the likelihood of haematological complications, particularly in patients requiring retreatment at a later date.

Peripheral joints were treated through parallel opposing fields, a maximum skin dosage of 150 r being delivered to each field weekly for ten weeks. In treatment of the carpus and tarsus, as in the spine, large fields covering the whole of these groups of small joints proved most successful. For the tarsus, fields approximately 25 by 12.5 cm., to include the whole foot and ankle-joint, were used.

Localized painful lesions over bony prominences such as ischial tuberosities, adductor tubercles, and iliac crests, and painful costochondral junctions, were given single exposures through small fields to a dose of 500 or 600 r.

Method of Assessment

For analysis, the patient's status was assessed in terms of constitutional disturbance, pain, range of movement, and general functional capacity. In order to obtain some quan-

tative expression of disability before and after treatment for statistical analysis as a check on the general clinical assessment of the case, the patient was given a numerical score for each of these features, scores of from 0 to 2 being awarded for increasing degrees of constitutional disturbance, of from 0 to 3 for pain of increasing severity, and of from 0 to 3 for increasing impairment of spinal movement. Functional capacity was scored in five grades—from grade 1, in which the patient was fully employed or employable in normal work and able to undertake normal physical recreations for his or her type, to grade 5, in which he was confined to bed unable to look after himself. The total or "disability score" was taken to represent a measure of the patient's disability.

Patients considered to be "much improved" had complete or almost complete freedom from pain after treatment, the associated constitutional disturbance was abolished or significantly decreased, and they usually gained weight. The general functional capacity of the patient was increased, and in cases without extensive radiological changes the range of movement often, but not invariably, improved. Photographic records of the range of back movement done in some cases gave valuable objective evidence of this (Figs. 1 and 2).

FIG. 1.—Before x-ray treatment.

FIG. 2.—Two months after x-ray treatment

"Slightly improved" signified less improvement in these respects, usually implying persistence of pain of significant degree in the treated area. A smaller number of cases were included in this category, since, although the treated areas were much improved, the beneficial effect was overshadowed by the development of new lesions elsewhere. Improvement was usually first noted about the middle of the course, and maximum improvement within the first two months or so after treatment, though a few cases continued to improve for about six months.

The patients were assessed before and one month after completion of treatment and at intervals thereafter, in the first instance one year, but before this when necessary. They were in all cases instructed to report to the clinic should relapse occur before their appointments fell due.

Results

The numbers of patients treated in the three groups and their status after treatment are shown in Table II.

TABLE II

	Typical		Borderline		Atypical	
	Male	Female	Male	Female	Male	Female
Total No. of cases	197	45	28	3	45	14
No. treated	175	37	26	2	27	8

Slightly improved after treatment	41	10	6	0	9	2
No change after treatment	3	1	2	0	5	3
Unable to assess	7	1	2	0	4	1

As the proportions of males and females much improved after treatment do not differ significantly in either the typical or the atypical groups ($P=0.69$ and $=0.64$ respectively) the figures for males and females have been grouped together in the subsequent analysis.

The proportion of patients much improved after treatment is very significantly higher in the typical than in the atypical group ($P<0.00001$). The distributions of the disability scores in the two groups before treatment tested by the χ^2 method do not differ significantly ($P<0.96$), but a highly significant difference in these is apparent after treatment ($P<0.0008$). This difference is due to a significant increase in the proportions of patients in the typical group in the lower disability classes after treatment, whereas in the atypical group the proportions are not significantly altered.

In Table III a further analysis is made of patients in the typical group much improved after treatment.

Elevation of the blood sedimentation rate above 20/200 mm. Westergren is no guide to whether a patient will be improved after x-ray therapy. Hart *et al.* (1949) came to a similar conclusion. We recommend x-ray treatment only in cases in which the ankylosing spondylitis

*Eleven of these patients were treated, and eight were considered to be much improved after treatment.

appears "active," as we have been unimpressed by the results of treatment of patients with little pain, either spontaneous or on movement, or constitutional disturbance, though they may have severe limitation of movement and extensive radiological changes typical of the disease. This means that judgment of the "activity" of the disease must be largely based on clinical criteria.

As might be expected, the probability of improvement after treatment is higher in patients whose symptoms are of short duration. That the duration of symptoms rather than the age at which treatment is given is the factor concerned is suggested by the observation that among patients with symptoms of more than five years' duration the proportions much improved after treatment in the age groups above and below 45 years are almost identical. In keeping with this is the finding that significantly fewer patients were much improved after treatment when radiological changes were also present in the spine or elsewhere than when changes were confined to the sacro-iliac joints—a finding similar to that of Smyth *et al.* (1941a). It should be added that no such relationship between duration of symptoms and improvement after treatment can be shown in the atypical group, in which improvement appeared to be related to the age of the patient and unconnected with duration of symptoms, but this impression was not confirmed statistically.

Seventeen patients in the typical group have been given second courses of treatment to previously treated areas, 15 of these to the spine and sacro-iliac joints. Seven of these 17 patients were much improved after treatment, a significantly smaller proportion than after the first course ($P<0.02$).

We do not yet know how long the improvement after treatment will be maintained in most of these patients, but up to February, 1953, 56 of the typical cases had relapsed, and in 44 of these relapses areas treated in the first course were involved.

Thirty-two of the relapsed patients had been regarded as much improved after treatment, and of these none relapsed in the first six months after treatment, whereas five of the slightly improved patients relapsed during this period. Of the seven patients much improved after a second course of treatment, one has so far relapsed in the second six months after its completion; four of these patients have not yet been seen six months after treatment. It is unlikely that many more patients have had major relapses without our learning of these, as relapsed patients have usually been anxious to have further x-ray treatment, which in this region is entirely controlled from the Christie Hospital and the Holt Radium Institute.

Complications of X-ray Treatment

These relate to 301 courses of treatment given to 275 individuals. Twenty-five patients received two courses, 21 of these to the spine, and one patient has had three courses to the spine.

The only serious haematological complication encountered was in a man aged 44 whose haemoglobin prior to x-ray treatment was 64% (9.5 g. per 100 ml.). After seven weekly treatments to the spine and sacro-iliac joints profuse bleeding occurred from a rectal polyp and he rapidly became severely anaemic, requiring repeated transfusion. Sternal marrow examination revealed an aplastic picture, and no improvement in either the blood count or marrow appearances occurred with A.C.T.H. treatment. His spondylitis was little if any improved after treatment, and he was maintained in indifferent health by regular blood transfusions, to which he showed gradually diminishing response, dying with extensive haemochromatosis two and a half years after treatment.

In one patient inactive pulmonary tuberculosis seemed to be reactivated by treatment to the spine, and on being informed of his extensive pulmonary disease he committed suicide in a fit of depression. Since this occurrence routine radiographs of the chest have been taken before x-ray

therapy to the spine, and seven other known cases of inactive pulmonary tuberculosis have been treated without complication.

Two other patients have died. One was a woman aged 57 with atypical spondylitis and features of Cushing's syndrome. Hypertension was present before treatment, and after nine weekly treatments to the spine and a single exposure of 600 r to the sternum and sterno-clavicular joints she complained of increasing weakness, tiredness, anorexia, and loss of weight. Albuminuria, azotaemia, and greatly reduced renal function were detected. She died at home in heart failure two months after treatment.

The other was a man aged 39 whose arthritis appeared typical of spondylitis. He had an associated inactive chronic pyelonephritis with hypertension and azotaemia, and, though much improved in respect of his spondylitis after treatment, he died in uraemia eight months later.

It is possible that in both these patients x-ray therapy may have accelerated the renal failure, although the radiation dosage to the kidneys in these cases was considerably less than that found to produce permanent renal drainage in man by Kunkler *et al.* (1952).

Permanent amenorrhoea after treatment occurred in 13 of the 47 females treated, and probably also in three further cases; 13 of these were below the age of 45. Temporary amenorrhoea lasting up to one year occurred in three other cases, all below 35. Since this high incidence of post-treatment amenorrhoea was disclosed by analysis of these cases, a tangential field method of treatment of the sacro-iliac joints in females has been adopted. Radiation to the ovaries should be less by this technique, but too few cases have so far been treated to assess how often it results in amenorrhoea.

No other serious complications were noted.

Other Treatment

The patients were encouraged to lead as normal lives as possible within the limits of their disabilities. They were instructed in the performance of breathing exercises and simple measures aimed at correction of deformity, such as sleeping supine on a firm bed and gradually decreasing the number of pillows, and were advised to avoid prolonged stooping and heavy lifting in a flexed position. Some of the more severely disabled patients with potentially correctable deformities were also given a more intensive course of reablement as in-patients of the Devonshire Royal Hospital in Buxton. Eight patients, all with severe bilateral involvement of the hips, were referred for hip surgery, and one was referred for spinal osteotomy.

Immobilization

Spinal supports were rarely advised, as we have not been impressed by their value in preventing spinal deformity or relieving pain due to established deformity, although a number of patients had been provided with such supports before coming to the clinic. Patients were confined to bed only in exceptional circumstances. The few patients who had been immobilized, particularly those in whom the lower limbs and spine had been immobilized in plaster sometimes because of a mistaken diagnosis of tuberculosis, were as a group strikingly more disabled than the rest of the patients. A similar experience was reported by Swaim (1939). Nineteen patients in our typical group had at some stage been immobilized in bed, in plaster, or on frames for periods of months to years; of these, five were virtual statues with rigid dorsal and lumbar spines and fixed or grossly limited hips, and two of them had practically fixed knees. Only six similar cases were encountered among the remaining 223 patients in the group, and there was no indication from the histories of the immobilized patients that as a group they were examples of more severe disease than the rest of the cases. On the contrary, whereas all six of the patients who had not been immobilized had completely fixed cervical spines, in those cases in which only the lower limbs and lower spine had been immobilized neck

movement was full or only slightly impaired, the gross loss of movement being confined to the parts immobilized.

The case histories of the five patients mentioned illustrate this point.

Case Reports

Case 1.—Man aged 24. In January, 1944, at the age of 18 he developed pain in the right buttock and milder pains in the left shortly afterwards. In October, 1945, tubercle bacilli were found in his sputum, and in January, 1947, lobectomy was performed. In 1949 he began to lose ground, pain in the right buttock increased, and the sputum was again found to be positive. In September, 1949, tuberculosis of the right hip was diagnosed and he was immobilized from the upper dorsal region downwards in an abduction frame. On removal from this after one year, the dorsal and lumbar spines were fixed, the hips ankylosed, and the knees and ankles very limited in movement. Neck movement was full apart from slight restriction laterally, and there was a normal range of movement in the upper limbs. The patient subsequently underwent Girdlestone's operation on the right hip with good results.

Case 2.—Man aged 20. In 1943, when 15 years old, he developed fleeting pains in the low back, knees, and left heel, and left-sided sciatica. After unsuccessful treatment with salicylates and physiotherapy, ankylosing spondylitis was diagnosed in December, 1945. At this time the lumbar spine was straightened, dorso-lumbar extension was absent, and other movements were about three-quarters of normal range. Neck movements were full. There was minimal painful limitation of hip movement, all other limb joints being normal. He was immobilized in plaster beds from the upper dorsal region downwards from January to August, 1946, and again from January to November, 1947. At the end of this period the lower dorsal and lumbar spines, both hips, and both knees were fixed. Neck movement was full, and, apart from some limitation of external rotation of the right shoulder and slight fusiform swelling of finger-joints, the upper limbs were normal.

Case 3.—Man aged 42. In 1934, at the age of 27, he developed pain in the buttocks, which persisted in spite of physiotherapy and spread to the low back. In 1943 a plaster spica was applied to the right hip for two to three months, and reapplied for a further six months in 1944. On removal of this, the left-sided pain increased, and in January, 1945, he was immobilized in a Pearson bed and later in an abduction frame, and then for nine months from the head downwards on a plaster bed. Contrary to instructions, he continued to move his neck, though the plaster prevented extension. On removal from the plaster bed his lumbar and dorsal spines were stiff; extension of the neck was absent, but he had a useful range of other neck movements. Both hips were fixed, the knees had a full range, and the upper limbs were normal apart from minimal limitation of the shoulders. He still suffered pain of moderate severity, but by perseverance he regained a little movement in the spine and left hip. Deep x-ray therapy to the spine, sacro-iliac joints, and left hip early in 1950 resulted in complete relief of pain, which has been maintained.

Case 4.—Man aged 28. In 1938 at the age of 16 he noted pains in the feet followed shortly by pains in the interscapular region and neck, which spread during the following three years to all levels of the spine and to the hips. He was told nothing could be done, and took to bed for three years. At the end of this time his spine was completely fixed, apart from a trace of cervical movement, and his hips were ankylosed in flexion with severe total flexion deformity. Both shoulders had about half the normal range; the remaining joints appeared unaffected.

Case 5.—Man aged 41. In 1940 at the age of 26 he developed persistent low back pain and his back began to stiffen. After some months he was admitted to hospital and kept in bed for six months. Subsequently he wore a spinal brace for one year; his pain eased during this period. In 1943 the left knee became painful, and after some weeks in bed both legs stiffened, although previously the right

knee had been normal. For the next 18 months he remained on traction without any exercises, and at the end of this time the dorsal and lumbar spines were rigid and he had about half the normal range of neck movement. Both hips were ankylosed and the knees severely limited; movement of the upper limbs was normal. Later he was transferred for cup arthroplasty of both hips.

Discussion

Clinicians dealing with large numbers of patients with ankylosing spondylitis are generally agreed that x-ray therapy is of some value in this disease (Kahlmeter, 1930; Hare, 1940; Smyth *et al.*, 1941a; Scott, 1942; Hilton, 1943; McWhirter, 1945; Kuhns and Morrison, 1946; Hart *et al.*, 1949; Parr *et al.*, 1951), and at least two controlled trials have confirmed this clinical impression (Smyth *et al.*, 1941b; Desmarais, 1953), but x-ray therapy does not completely arrest the ankylosing process. The best long-term results are therefore achieved by combining this with systematic exercises, positioning in bed and at work, and other physical measures designed to retain mobility and prevent or correct deformity.

In Desmarais's trial the effects of various doses of x rays and mock therapy were compared in ankylosing spondylitis, rheumatoid arthritis, and osteoarthritis, and it was found that patients with ankylosing spondylitis showed the greatest improvement, those with osteoarthritis derived some benefit, but the course of patients with rheumatoid arthritis was not significantly different from that of untreated controls. The similarity in behaviour after treatment of peripheral joints treated alone and those treated concurrently with the spine in our typical cases favours the view that the beneficial effect of x rays in ankylosing spondylitis is due to a local action on irradiated tissues and not to an indirect effect mediated through an endocrine or other mechanism, and that the failure of rheumatoid joints to improve is due to a difference in tissue responsiveness to x rays.

The proportion of treated patients with symptoms of over five years' duration is slightly less in the atypical than in the typical group, so that the poor response to treatment in the atypical group cannot be ascribed to longer duration of symptoms, and the similarity of the mean disability scores and the distribution of these scores in the two groups before treatment argue against the results being due to a preponderance of unusually severe cases in the atypical group. The failure of many patients in the atypical group to benefit from x-ray therapy may therefore be due to inclusion in this group of a number of other conditions which resemble ankylosing spondylitis clinically but are unaffected by x-ray therapy.

Conclusion

The results of this study suggest that only patients suffering from typical ankylosing spondylitis benefit from x-ray therapy. It would therefore be desirable to have well-defined clinical and radiological criteria by which typical spondylitis could be distinguished from other conditions which may simulate this disease. Such a differential diagnosis is also desirable, since immobilization usually aggravates typical spondylitis, while it may be helpful in some of the atypical conditions. We are therefore studying the various arthritic conditions which may simulate ankylosing spondylitis with a view to elaborating a satisfactory differential diagnosis.

Summary

On clinical and radiological grounds 332 cases of spondylitis were divided into three groups: 242 "typical" cases conforming to the classical picture of ankylosing spondylitis, 59 cases classed as "atypical" in the absence of a satisfactory alternative diagnosis, and an intermediate group of 31 "borderline" cases. A family history of rheumatic complaints and a history of iritis were found with

CONGENITAL VALVES IN THE POSTERIOR URETHRA

BY

D. INNES WILLIAMS, M.D., M.Chir., F.R.C.S.
Genito-urinary Surgeon, the Hospital for Sick Children,
Great Ormond Street

A valvular formation of mucosal folds in the posterior urethra is the most often encountered example of the group of congenital anomalies which cause urethral obstruction. A full pathological and clinical description of the condition was given by Young, Frontz, and Baldwin in 1919, yet the lesion has never been widely recognized nor has a satisfactory routine for diagnosis and treatment emerged. I have had the opportunity of operating upon 14 of these valve cases, and the present observations are based upon the study of this series, and of the records of 21 further cases in which the diagnosis has been confirmed by post-mortem examination at the Hospital for Sick Children. All but one of the 14 cases have been treated during the past two years, and it may be of interest to record that during the same period eight cases with other forms of congenital urethral obstructions and four cases of bladder-neck obstruction in young children have come under treatment.

Their Origin

In the characteristic form (Young's type 1) a valve is formed on either side of the urethra by a double fold of mucous membrane, the two meeting in the midline sagittal plane of the urethra, leaving only a small channel anteriorly (Fig. 1). The free edges of the valves are continuous above and posteriorly with ridges connected with the verumontanum; below and anteriorly they fade out on the urethral wall at approximately the level of the external sphincter.

Faint ridges with a similar disposition are evident in the normal male urethra, and I have observed that in the embryo they first appear at approximately the 50-mm. stage. The ridges were exceptionally well developed in a 99-mm.

embryo which I have examined; they have no discernible function, and after this stage they appear to shrivel spontaneously, but it is clear that it would require only a slight exaggeration of the normal formation with some adhesion of the free edges to bring about the development of an obstructive valve. We are thus dealing with only a minor deviation from the normal, and we should not therefore expect a high instance of multiple congenital anomalies in this disease. In fact, the accompanying abnormalities are chiefly those consequent upon the obstruction.

From this evidence of their origin, it will be manifest that congenital valves will constitute an obstruction to the urinary passages almost from the time that urine is first formed and long before the complete differentiation of the nephrons. A free flow of urine is not, of course, essential

FIG. 1.—Diagram showing the disposition of urethral valves in their most characteristic form. The urethra has been drawn as if it had been opened by a vertical incision of the anterior wall, so that the anterior extremities of the valvular folds are held apart.

equal frequency in the three groups. In spite of a high incidence of involvement of the hands and feet in the atypical group, the comparatively low proportion of patients in this group giving positive results with Ball's modification of Rose's serum differential agglutination test is evidence that the atypical group is not largely composed of patients with rheumatoid arthritis affecting the spine. The adverse effect of prolonged immobilization in typical ankylosing spondylitis is emphasized.

A total of 275 patients received deep x-ray therapy; the proportion much improved after this in the typical group was very significantly higher than in the atypical group. In the typical group, the age or sex of the patient and level of the blood sedimentation rate gave no indication of the probability of improvement after therapy; better results were obtained in patients whose symptoms were of five years' duration or less and in whom radiological changes were confined to the sacro-iliac joints. No significant difference was observed in the behaviour of peripheral joints treated alone and those treated concurrently with the spine, suggesting that the effect of deep x-ray therapy in ankylosing spondylitis is a local one on irradiated tissues.

Complications of x-ray therapy included one case of aplastic anaemia, reactivation of pulmonary tuberculosis in one case, permanent amenorrhoea in 13 of the 47 females treated, and possible acceleration of renal failure in two cases.

Reasons are given for ascribing the poor results from x-ray therapy in the atypical group to inclusion of patients with other diseases simulating ankylosing spondylitis.

We are grateful to the many consultants in this region who have allowed us to study their cases during the investigation; to Professor J. H. Kellgren for much advice and helpful criticism; to Dr. Ralston Paterson for provision of facilities for x-ray treatment and follow-up of the patients; to Dr. O. Janus, who saw many of these patients originally in the clinic; and to Miss Marion Russell for help with the statistics.

Bracken Hill House, The Woods, Northwood, Middlesex, the pioneer hostel of B.R.A. Homes Ltd. (under the aegis of the British Rheumatic Association), is now open. It is designed to meet the needs of industrial workers with early and serious rheumatic conditions for whom bed accommodation at hospitals with rheumatic units is unlikely to be available in the near future. All medical services are provided by Mount Vernon Hospital. Industrial medical officers or the patient's family doctor can apply for accommodation. Cost of beds ranges from £4 15s. to £7 7s. Further details may be obtained from either Bracken Hill House or the British Rheumatic Association, 11, Beaumont Street, London, W.1.

to the general development of the foetus, and growth can proceed almost normally in the complete absence of kidneys: nevertheless, despite conflicting views, it does seem that urine secretion is a normal foetal activity and that urinary obstruction produces hypertrophy of the detrusor, sacculization of the bladder wall, dilatation of the ureters, and hydronephrosis whether it occurs in the foetus or in old age. The urinary tracts of infants dying from this disease during the first few days of life show all the changes associated with long-standing retention of urine, but it is characteristic of the very early obstructions that they cause relatively less bladder distension with relatively greater dilatation of the ureters, and that differentiation of the nephrons is interfered with so that the cortex of the kidney may contain cysts which show no evident connexion with the renal pelvis.

FIG. 2.—Sagittal section through the bladder and urethra of an infant dying on the third day of life (from the Museum of the Hospital for Sick Children, Great Ormond Street). The enormous dilatation of the posterior urethra is clearly shown, and there is a well-marked valvular fold. A, valve; B, bladder neck; C, verumontanum.

These observations apply to all types of congenital infra-vesical obstruction, but the situation of the valves leads to certain peculiar features. The posterior urethra becomes dilated and considerably elongated (Fig. 2), but the bladder neck remains as a well-defined constriction until a very late stage. The internal sphincter is essentially a condensation of detrusor muscle fibres, and it appears that a general hypertrophy of the bladder muscle must be inevitably associated with bladder-neck hypertrophy.

Clinical Features

On the clinical side, urethral valves present either because of disorders of micturition—incontinence, frequency, haematuria—or because of a deterioration of renal function—failure to thrive, dwarfism, or renal rickets.

Valves scarcely ever cause acute retention. Some urine is always able to dribble away, even though the rapidity of onset of bladder distension may have been sufficient to cause pain. Failure to pass urine during the first few days of post-natal existence is, of course, usually due to dehydration and oliguria, but if the bladder is found distended it is much more likely that the obstruction is an obliteration of the urethra rather than a valve. Overflow incontinence is in fact the most characteristic disturbance of micturition: urine is never passed in a good stream, but the frequent and difficult passage of small quantities or a continuous dribbling makes the child always wet. An infant who is found never to be dry has always some organic disease, and if we can be sure of the truth of this history a most careful investigation is imperative. In older children the incontinence is less easily distinguishable from functional enuresis, though it is usually diurnal as well as nocturnal, and its tendency is to become progressively more severe.

The onset of infection leads to an exacerbation of the obstruction and in the presence of already damaged kidneys

may prove overwhelming. The newer sulphonamides and antibiotics can, however, sometimes sterilize the urine even in the presence of an obstruction, and the rapid amelioration of symptoms may then suggest that no further investigation is required. In two of my cases the bladder and kidneys had been palpably distended during an episode of urinary infection at the ages of 1 month and 2 years respectively, yet because apparently normal micturition was re-established after sterilization of the urine the clinician in charge had felt that no organic obstruction could be present. As a result the children were left, one for three months, the other for seven years, before receiving surgical treatment, and in the latter irreparable renal damage had occurred.

Valvular obstruction is for the most part a slowly progressive disorder; sometimes, as in prostatic disease, there is an exacerbation of obstruction for no very obvious reason, and in such cases pain may be a feature. One of my cases was sent to hospital as a possible case of intussusception, and another, who had a large diverticulum, suffered abdominal pain before micturition.

Renal failure manifests itself in a variety of ways, and it is a curious fact that the cases with the most severe signs are often those with comparatively minor disturbances of micturition. During the first few weeks of life vomiting is much the most common presenting sign, and the infant is often suspected of pyloric stenosis until examination reveals distension of the bladder and a continuous dribble of urine. In later infancy and childhood general ill-health and susceptibility to infection or dwarfism may lead to investigation of renal function. Hypovitaminosis-D rickets is now such a rare disease in this country that the presence of a rachitic deformity must always suggest the need for urological investigation.

Diagnosis

Often the observation of an overdistended bladder and of a dribbling incontinence leaves little doubt concerning the presence of a urinary obstruction, and in a few cases the rectal palpation of a full posterior urethra gives assistance in locating the lesion, but the exact diagnosis of urethral valves can never be made on purely clinical grounds. Certain other causes of chronic bladder distension may, of course, be eliminated by clinical examination: the neurological disorders, for instance, are almost invariably accompanied by a recognizable spinal lesion, by sacral anaesthesia, and by paralysis of the anal sphincter. A meatal stenosis, or occasionally a diverticulum of the anterior urethra, may be seen on examination of the penis, but there remain many other obstructive lesions which can be identified only by radiological and endoscopic methods. Recently encountered examples of such lesions include a congenital stenosis of the membranous urethra, a diaphragmatic obstruction above the verumontanum, a duplication of the anterior urethra, and a ureterocele prolapsing through the bladder neck. Bladder-neck obstruction (Marion's disease) is perhaps the disorder most likely to cause confusion, particularly since hypertrophy of the bladder-neck muscle is the usual concomitant of any congenital obstruction lower down the urethra. This difficulty is illustrated by the following case.

A boy of 3½ years was transferred from an orthopaedic hospital, where he had been receiving treatment for a suspected tuberculous lesion of the left femoral neck. He was immobilized on a frame, with traction on the left leg, and a wide-bore needle had been inserted suprapubically to drain a chronically distended bladder.

His blood urea was 68 mg. per 100 ml. and an intravenous pyelogram showed no shadow in either renal area. His position on the frame rendered endoscopy impossible, and the replacement of the needle by some more satisfactory form of drainage seemed imperative. In performing the cystostomy, however, I palpated the bladder neck, which was clearly hypertrophied and resisted dilatation. A generous wedge of tissue was therefore resected from the posterior lip upon the tentative diagnosis of Marion's

FIG. 3.—Micturating cystogram in a boy of 8 years with a palpably distended bladder and incontinence of urine by day and night since age of 5. The dilated posterior urethra is evident; urethroscopy confirmed the presence of urethral valves. Treated by endoscopic resection with satisfactory results.

FIG. 4.—Micturating cystogram (oblique view) in a boy of 7 with lifelong dribbling incontinence of urine. Residual urine 6 oz. (170 ml.). Endoscopic resection has eliminated the residual urine and he is now continent.

renal function although some dilatation of the upper urinary tract remained.

The most important radiological investigation is the micturating cystogram. A catheter is passed, and the residual urine is drawn off and replaced by a rather larger volume of a 15% diiodone solution. The catheter is then withdrawn and exposures are made during micturition (Figs. 3 and 4). These films may show trabeculation of the bladder, the presence of vesical diverticula, reflux into dilated ureters, and dilatation and elongation of the posterior urethra. It should be noticed that unless micturition is actually taking place the urethra may be shut off from the bladder by the hypertrophied internal sphincter, so that it

is either not filled at all or contains only a trickle of opaque fluid, giving no true idea of its dimensions. In the young baby in whom micturition is not possible, manual expression of the bladder contents under anaesthesia is often an adequate substitute, but this does not hold good for the older children (Fig. 5). The cysto-urethrogram shows the exact site of the obstruction, and occasionally the actual outline of the valvular folds can be seen, but often the differentiation of the valves from congenital stenosis is impossible.

Cystoscopy and urethroscopy give more detailed information but require special instruments and much more experience for their interpretation. In the infant the instruments must be introduced via a perineal urethrostomy, but, provided this is performed, no particular difficulty should be encountered. I have recently urethroscopied a male infant of 10 days in this way. The cystoscope alone will reveal trabeculation of the bladder and the presence or absence of diverticula. The urethroscope, and preferably one which gives a view directly ahead, is required to identify the nature of the obstruction.

FIG. 5.—Expression cystogram in a boy of 10 months with a blood urea of 212 mg. per 100 ml. Dilatation of the posterior urethra is clearly present, but urethroscopy showed only a congenital stenosis of the membranous region, and there has been a steady improvement, with continuing fall of blood urea, on intermittent dilatation.

Management

The problems encountered in management vary according to the manifestation of the disease. In the infant with a palpably distended bladder, dribbling micturition, and a degree of renal failure, an operation for relief of urinary obstruction will clearly be required, but considerable caution must be exercised in preparing for this operation. It should be realized that drainage of the bladder is not the most urgent need in such a case; the dangers to life are from supervening infection and from a sudden biochemical disturbance, both of which may in fact be precipitated by catheterization. As in the elderly prostatic, the catheter, even when passed with stringent asepsis, may introduce an infection which initiates a rapidly fatal pyelonephritis. Particularly it is dangerous to empty a chronically distended bladder and then allow it to fill up again with a large residual urine. A clear idea of the degree of renal failure and of the presence or absence of other biochemical disturbances is the first essential. The blood urea is the most helpful single investigation, but deceptively high values may be observed if the child is dehydrated, and the estimation should be repeated after adequate fluid has been given.

The range of specific gravity of the urine often gives a useful indication of renal function; commonly the kidneys in severe cases are only capable of producing urine with a specific gravity of 1001 to 1006. Estimations of the bicarbonates, chlorides, sodium, and potassium are important in regulating the fluid and electrolyte requirements, and in long-standing cases with bone changes calcium and phosphorus studies are also required. Once instrumentation has been resorted to, adequate drainage of the urinary tract must be established and, if possible, a definitive treatment carried out. My present routine in such a case is therefore to perform a cystogram and a urethroscopy under anaesthesia, and then, unless the general condition of the child renders it dangerous, to proceed at once to operative removal of the

valve, leaving in a perineal urethrostomy catheter as drainage. In small children an indwelling urethral catheter is scarcely ever an adequate form of drainage: even apart from the danger of stricture formation in the penile urethra, the lumen of the catheter is so small that it easily becomes obstructed.

In the older child who is being investigated for incontinence but who has no serious renal damage, micturating cystography may safely be performed without preparations for immediate operation, provided prophylactic chemotherapy is employed, and full biochemical study may be omitted. The difficulty here is often to know which incontinent boys to investigate, since there is no infallible rule by which they can be segregated. Children with a palpable bladder, those with a continual dribbling incontinence, and older boys who are wet by day as well as by night will clearly be selected, but all enuretics who show no improvement after a fair trial on ordinary treatment should at least be submitted to urethroscopy.

Routine micturating cystography may also be performed during the investigation of recurrent or mild chronic urinary infection. An acute infection complicating an obstruction requires the immediate administration of an antibiotic, and it has seemed wise to give streptomycin while awaiting the bacteriologist's assessment of the susceptibility of the organism. Should there be no response to the antibiotic and if the blood urea is considerably raised, drainage of the urinary tract must be established without delay, and for this purpose a bilateral nephrostomy is far more effective than a suprapubic cystostomy which does not satisfactorily empty the dilated and tortuous ureters.

Operation

Regarding the technique of operation, I believe that the old method of attempting to rupture the valves by passing instruments downwards from the bladder should be discarded: it involves an open bladder, it allows no opportunity for confirmation of the diagnosis, and, as shown by post-mortem examination, often fails in its purpose of destroying the valves. The retropubic operation, in which the urethra is opened by a vertical incision prolonged downwards from the bladder neck to a point well below the verumontanum, can give a beautiful exposure and allows a deliberate surgical removal of the valvular fold, but it is often a prolonged and always a major procedure, it may involve considerable blood loss, and it is a severe tax on a uraemic child. In four cases I have employed an approach through the perineum: the bulb of the urethra is opened up through a longitudinal incision, the membranous region dilated up, and a miniature gorget inserted anteriorly. Then with a flat retractor posteriorly, a sucker, and a headlight the operator is able to get a view of the verumontanum and the valves coming down from it. They can be picked up with a blunt hook and burnt off with the diathermy.

Endoscopic resection, however, constitutes the most satisfactory approach employed so far. The instrument which I have used is an infant version of a simple McCarthy diathermy loop resectoscope, and with it the valvular folds can be scooped off the urethral walls. This type of operation is a comparatively minor procedure which does not place any serious strain on the child, but of course it is never a negligible matter to operate on a case of chronic retention, and the use of the resectoscope must always involve some risk of perforating the urethra, which would lead to a dangerous extravasation of urine, or of damaging the external sphincter and causing permanent incontinence.

Discussion

In discussing the results and complications of the treatment of urethral valves it must again be emphasized that the majority of these children are suffering from long-standing urinary obstruction with severe renal damage. Indeed, those which present during the first month after birth have scarcely ever sufficient functioning renal tissue for survival. In borderline cases it is too often the surgical intervention

which precipitates a rapid deterioration of renal function, either through the introduction of infection or through some other mechanism which we do not understand. Post-operative dehydration is always a danger, since the damaged kidneys put out urine of very low specific gravity and require a large volume of fluid in order to excrete the necessary load of solute.

In one case of congenital obstruction, not in fact a valve, an operation which successfully restored normal micturition was followed some weeks later by the development of a severe renal electrolyte loss of sodium and potassium—a type of salt-losing nephritis—which was ultimately the cause of death. One neonatal case of retention had on admission a biochemical pattern resembling Addison's disease, and it could not be determined for certain whether a renal or an adrenal cause was responsible. Another patient, in whom the electrolyte losses had been carefully followed and found normal, died unexpectedly on the third day with cerebral oedema but without any obvious precipitating cause. The biochemical problems involved in treating the obstructive uropathies are therefore complex and as yet poorly understood. It is in this sphere that we hope to make further progress in the future.

Just as the removal of the obstruction cannot lead to an immediate recovery of renal function because of irreversible changes in the kidneys, so too the urinary passages cannot at once regain their normal function. The ureters are tortuous and elongated, and cannot contract down to their former dimensions; in some cases the kinks and adhesions lead to obstruction in the ureter itself, and in several cases drainage of a dilated and obstructed ureter, or nephro-ureterectomy, has been required after the operation for relief of urethral obstruction. The bladder may be atonic, so that it is unable to empty without residuum even after an otherwise successful operation, and if free reflux into the dilated ureters has been established the bladder contractions will serve to fill these ureters rather than to expel the urine. Thus after micturition urine again flows down into the bladder, and catheterization will demonstrate the presence of an apparently large residuum. The loss of normal sensation in the chronically overdistended bladder is also a troublesome feature, since the child does not notice the filling of his bladder and urine may actually be leaking away before micturition is attempted. This is a matter which is capable of improvement by training, however, and should not be a permanent handicap.

Case	Age	Blood Urea (mg./100 ml.)	Operation	Result
1	19 days	66	Cystotomy and passage of sounds from above	Died next day. Grossly diminished renal parenchyma
2	1½ months	53	Retropubic valvulotomy	Satisfactory recovery from operation, but died of jaundice on 19th day
3	3½ "	74	Perineal valvulotomy and diverticulectomy	Well one year after operation, but blood urea remains at 66 mg./100 ml.
4	4 "	94	Perineal valvulotomy	Died on 7th day with multiple abscesses in kidney
5	4 "	86	Retropubic valvulotomy	Died on 2nd day—mongol
6	4½ "	51	Perineal valvulotomy and right nephrectomy	Well one year later
7	2½ years	134	Endoscopic resection	Died on 3rd day—oliguria
8	3 "	162	Retropubic valvulotomy	Died on 2nd day—oliguria
9	3 "	67	Endoscopic resection	Well 3 months later
10	3½ "	63	Retropubic valvulotomy	" 1 year "
11	7 "	26	Endoscopic resection	" 6 months "
12	8 "	41	" "	" 3 " "
13	9 "	40	Perineal valvulotomy and diverticulectomy	" 9 " "
14	11 "	150	Bilateral nephrostomy and endoscopic resection	Improved, but residual urine still present. Recent case

The Table summarizes the 14 cases of urethral valves which have been operated upon: clearly, the results leave a great deal to be desired. The older children are much more likely to survive than the infants, but this merely indicates that the older children are suffering from a less severe obstruction and in no way contradicts the view that earlier diagnosis will lead to improved results. More careful attention to the urinary abnormalities of the "under-threes" is required if a significant proportion of children with this disease are to grow up to be healthy adults.

ADDENDUM.—In the eight months which have elapsed since this paper was completed the survivors in the series reported have continued to thrive and five additional cases have been treated. Of these, two, aged 9 days and 11 weeks, died of renal failure before operative treatment of the obstruction had been completed; three, aged 3 weeks, 9 months, and 6 years, have made a satisfactory recovery.

My thanks are due to Mr. Twistington Higgins and to other members of the staff of the Hospital for Sick Children, Great Ormond Street, for allowing me to treat their cases, and to Mr. N. Stidolph, of the Whittington Hospital, for inviting me to see the last of the series. Thanks are also due to Mr. Derek Martin and Mr. P. Cull for their assistance with the illustrations.

CONTINUOUS CAUDAL ANALGESIA EXPERIENCES IN THE MANAGEMENT OF DISORDERED UTERINE FUNCTION IN LABOUR*

BY

G. TREVOR JOHNSON, M.B., M.R.C.O.G., D.A.
First Assistant, Department of Obstetrics and Gynaecology,
King's College, Newcastle-upon-Tyne

Prolonged labour which results from incoordinated action of the uterus or cervix is a serious problem which confronts every obstetrician from time to time. The occasional grave consequences to both mother and foetus have resulted in an increasing tendency to terminate such labours by caesarean section when vaginal delivery is delayed after 36 to 48 hours of established labour (Munro Kerr and Chassar Moir, 1949).

The purpose of this paper is to record the experience gained from the therapeutic application of continuous caudal analgesia to the management of this problem. The comments and conclusions are based on a study of 74 cases of disordered action of the uterus or cervix which had prolonged the first stage of labour beyond 48 hours. The clinical types treated included hypotonic inertia, hypertonic lower uterine segment inertia, and primary cervical dystocia (Jeffcoate, 1950). The material has been collected from the Department of Obstetrics and Gynaecology at Newcastle-upon-Tyne General Hospital during the past three and a half years, and 22 cases of cervical dystocia reported in a previous publication (Arthur and Johnson, 1952) are included.

Caudal analgesia was originally devised for minor pelvic operations and described simultaneously by Sicard (1901) and Cathelin (1901). The method is therefore not a new one, but Hingson and Edwards (1943) are largely responsible for describing the modern continuous technique and for applying it to obstetric practice, chiefly as a pain-relieving measure. The in-

trinsic difficulties and possible complications of the method, in its present form, however, prejudice its widespread adoption for obstetric analgesia, especially when adequate results are obtainable by simpler means. On the other hand, the satisfactory results achieved by its therapeutic use in the management of disordered uterine function justify a wider trial (Nixon, 1952).

The principle of caudal analgesia in the labouring patient is to block the sacral plexus with a suitable local analgesic agent as it lies within the confines of the sacral canal, and to extend the level of analgesia upwards in the extradural space to the level of the tenth dorsal segment.

By this means both the motor and the sensory connexions to the pelvic floor and perineum arising from the sacral plexus are effectively blocked, together with the visceromotor parasympathetic connexions to the cervix. The upward extension of analgesia to the tenth dorsal segment in the extradural space interrupts the sensory connexions to the fundus uteri which enter the cord at this level, and the uterine action becomes painless. The sympathetic visceromotor fibres of the fundus uteri arising from the cord higher up, in the region of the fifth dorsal segment, are uninfluenced by caudal analgesia, while the opposing parasympathetic fibres from the sacral plexus below are paralysed.

Successful caudal analgesia in the labouring patient is therefore aimed at securing unopposed and painless contractions of the uterine fundus, acting upon a completely paralysed and insensitive cervix and birth canal. These conditions seem very suitable for dealing with the problem of either inert uterine function or cervical dystocia, or a combination of these two conditions, and the principle has been adopted in the management of the labours described below.

Methods Used

The technique of continuous caudal analgesia used in this series closely followed that described by Hingson and Edwards (1943). With the patient lying in the left lateral position, a malleable caudal needle was introduced into the sacral canal and connected by a length of fine pressure-tubing, with a 10-ml. syringe and two-way tap interposed, to a bottle of 1.5% piperocaine hydrochloride ("metycaine") in Ringer-Locke solution. The malleable-needle technique was adopted in preference to the indwelling-catheter method for several reasons. In the first place, suitable nylon catheters were not easily obtained, and complications have been reported from time to time with "polythene" catheters. The risk of introducing infection seemed greater with any catheter technique, together with the added risk of tubing fracture. Furthermore, it is doubtful whether polythene catheters can be sterilized with sufficient certainty to insert into the extradural space with complete safety.

The malleable-needle technique proved completely satisfactory, and the requisite apparatus can now be obtained from Messrs. Thackray, Ltd. It was always ready for use, being autoclaved in a small drum together with the necessary drappings.

Analgesia was induced when labour had been prolonged beyond 48 hours owing either to an intrinsic failure of uterine function or to cervical dystocia without any evidence of cephalo-pelvic disproportion.

A preliminary vaginal examination was always made before caudal analgesia, to assess carefully the stage to which labour had progressed and to ensure that the cervix had reached at least one-third dilatation. Hingson and Edwards state that this degree of dilatation is essential, and failure to observe this rule may result in the inhibition of uterine contractions. It is also emphasized that this method

*Condensed from a paper presented to the Newcastle-upon-Tyne Obstetric Society on December 5, 1952.

should not be contemplated if there is any evidence of cephalo-pelvic disproportion, or non-engagement of the head from any other cause whatsoever, for fear of dangerously overdistending a paralysed lower uterine segment.

An initial dose of 40 ml. of piperocaine, injected down the pressure-tubing described above, gave satisfactory analgesia to the tenth dorsal segment for approximately one and a half hours. Thereafter, maintenance doses of 15 ml. were administered at half-hourly intervals. These injections were given by a midwife specially trained in the technique, and the patient was turned on to her opposite side via the abdomen after each half-hourly dose to maintain a bilateral effect. The blood pressure was recorded after each injection, and 20 mg. of methylamphetamine hydrochloride was administered intramuscularly at the onset of caudal analgesia to prevent any severe fall in blood pressure. Analgesia was maintained for approximately six hours in each case, and was then followed by a second vaginal examination to assess progress in cervical dilatation. The subsequent management of each individual case depended upon the progress made.

The comparative findings of the two vaginal examinations enabled each patient to be placed in one of three categories. Group 1 included all those with fully dilated cervixes who were immediately delivered with forceps. Group 2 comprised those patients who showed definite progress, but who had not achieved complete dilatation of the cervix after six hours of caudal analgesia. Treatment was continued with half-hourly injections of piperocaine in the confident anticipation of complete dilatation of the cervix, which was achieved in an average of nine hours in all the cases in this second group. The longest caudal block lasted fourteen hours. Group 3 included those who failed to respond at all after the six hours, and delivery was completed by a lower uterine caesarean section without further delay.

Results

The results in the 74 patients subjected to the treatment are given in Table I.

Group 1.—Forty-five patients were found to have completely dilated cervixes when the second vaginal examination was performed after four to six hours of treatment. Twenty-seven required simple outlet forceps to complete delivery, the foetal skull lying in the pelvic outlet and the

TABLE I

Method of delivery	Group 1 (45 Cases)			Group 2 (19 Cases)			Group 3 (10 Cases)
	Low Forceps	Anterior Rotation and Forceps	Breech Extraction	Low Forceps	Anterior Rotation and Forceps	Normal Delivery	Lower Segment Caesarean Section
Method of delivery	27	16	2	9	9	1	10
Stillbirths and neonatal deaths	1	0	1	0	0	0	1

occiput anterior. Sixteen required anterior rotation of the occiput in the mid-cavity of the pelvis from a transverse or posterior position before forceps delivery was completed. The two remaining patients were delivered by breech extraction. There was one stillbirth from an intracranial injury following a difficult breech extraction, and one infant died on the fourth day from pneumonia. In this latter case the membranes had been ruptured surgically for severe pre-eclamptic toxæmia arising two weeks before term. The blood pressure was 210/120 at the time of the rupture of the membranes, and the urine contained 5 g. of albumin per litre.

Group 2.—Nineteen patients showed progressing but incomplete dilatation of the cervix when the second vaginal

examination was carried out after six hours of treatment. Analgesia was continued until full dilatation of the cervix was reached. This was achieved in an average of nine hours, the longest duration being fourteen hours. Nine patients were delivered by a simple outlet forceps with an anteriorly presenting occiput, and nine more required anterior correction of the occiput before forceps delivery was completed. One patient delivered herself spontaneously. There was no stillbirth or neonatal death in any patient included in this second group.

Group 3.—Ten patients showed no further cervical dilatation after six hours of caudal analgesia, and all these were selected for lower uterine caesarean section and delivered successfully. One infant was delivered in a state of white asphyxia and died within a few minutes of delivery, but the remainder survived and did well. This death is attributed to an error of judgment, for caudal analgesia had been unwisely employed when the head remained above the pelvic brim from partial extension of an occipito-posterior position. A strong contraction ring developed in the uterus, and the infant presumably died from partial obstruction of the placental circulation. This case occurred early in the series and served to emphasize further the importance of avoiding caudal analgesia when the greatest diameter of the foetal skull still remains above the pelvic brim.

Table II shows, by comparison with other published data, that in the present series of 74 cases there was no increased incidence of prolonged labour—that is, labour exceeding 48 hours—despite a local interest in this problem.

TABLE II

	Total Labours Exceeding 48 Hours	Stillbirths and Neonatal Deaths		Maternal Deaths		Average Duration of Labour

Queen Charlotte's Hospital, 20,000 deliveries	631 (3.1%)	77 (12%)	—	3	—	74.9 hours	—

N.-C. = Non-caudal.

Discussion

The number of patients selected for the treatment gradually increased as technical ability improved and confidence in the method developed. Failures of technique were frequent in the early stages, but, with increasing experience, types of patients—for example, the obese or uncooperative—who had previously been regarded as unsuitable subjects were successfully treated. My recent experience agreed with Hingson's statement that successful caudal analgesia could be achieved in approximately 80% of cases attempted, and the presence of a pilonidal sinus or local sepsis became the main contraindication to the method.

To judge from the results obtained so far, there was a great improvement in the foetal salvage rate in the 74 cases studied. This was doubtless attributable to the overall diminution in the length of labour as shown in the last column of Table II, but a noteworthy observation in the series was the surprising lively condition of the infants at birth (with the exception of the three cases quoted above) despite unmistakable evidence of foetal distress in no fewer than 29 cases before analgesia was started. A suggested explanation of this phenomenon, which is under further investigation, is the dilatation of the uterine arterioles, which might result from blocking their autonomic connexions, thus enhancing the maternal blood supply to the placenta.

Conclusions

The application of continuous caudal analgesia to the management of prolonged labour which resulted from primary failure of uterine function or cervical dystocia has

proved a most valuable addition to the obstetrician's armamentarium.

In many cases the method resulted in speedy dilatation of the cervix to permit earlier delivery of the patient than might have otherwise been expected. Patients showing no response whatever to the treatment were selected for lower segment caesarean section, which was performed on patients who were refreshed by a respite from labour pains. It was deduced from the results obtained that caudal analgesia should be tried when caesarean section might otherwise be seriously regarded as the only satisfactory solution to prolonged and non-progressive labour. By its use many patients will be spared abdominal operation, but, on the other hand, if by failure of response caesarean section is subsequently thought to be necessary, its successful outcome will not have been prejudiced by the previous management.

There were no serious untoward sequelae attributable to caudal analgesia, and this series concludes a pilot study before a more careful statistical investigation is undertaken into the value of the method described in the management of labour exceeding 48 hours.

Summary

The results obtained by employing continuous caudal analgesia as a therapeutic measure in the management of 74 cases of uterine inertia and cervical dystocia, or a combination of these two conditions, are described.

Sixty-four patients were successfully delivered vaginally, with two neonatal deaths, after a period of analgesia lasting from four to fourteen hours.

Ten patients showed no further progress whatever after six hours of caudal analgesia, and were delivered by a lower segment caesarean section.

Continuous caudal analgesia accelerated the progress of labour in a high proportion of cases, and considerably diminished the foetal hazards of this perplexing obstetric problem.

My thanks are due to the nursing staff for preparing the apparatus and managing the patients, and to those obstetricians who have given caudal analgesia a fair chance to see what it can achieve. I am also indebted to Mr. Linton Snaith for his permission to publish the clinical data, and to Professor Harvey Evers and Mr. Hugh Arthur for much helpful criticism and advice in the preparation of this report.

Medical Memorandum

Supernumerary Pectineus Bursa Causing Femoral Vein Compression

Supernumerary pectineus bursa is a rarity. In the following case recurrent attacks of bursitis had led to femoral vein compression with consequent swelling of the affected leg.

CASE REPORT

A housewife aged 41 was referred to the out-patient department on December 31, 1951, complaining of severe pain in the right thigh which had kept her awake for one night. Her doctor stated that the thigh was greatly swollen and had made a diagnosis of possible venous thrombosis. Two months earlier she had complained only of swelling of the right thigh; there was no pain or tenderness, or any sug-

gestion of a deep vein thrombosis, nor were any inflammatory changes seen in the limb. The doctor thought it was possibly a case of angioneurotic oedema.

On examination her general condition was good. No abnormality was found in the respiratory system, cardiovascular system, or abdomen. The circumference of the right thigh was 2 in. (5 cm.) greater than the left, and the right calf 1 in. (2.5 cm.) greater than the left. There was, however, no evidence of actual oedema. The pulses of the two legs were equal and good. No pelvic abnormality was found on rectal or vaginal examination. There were no varicose veins. X-ray examination of the chest, pelvis, lumbar spine, and femora showed nothing abnormal. No cause could be found for this swelling in the limb and she was asked to report again should she get any further attacks, so that she could be seen during an attack.

She reported back on June 17, 1952, stating that during the previous week a lump the size of a walnut had appeared in the right groin. It had been present for two days and had then disappeared. On examination there was no sign of the lump in the groin, and in view of this she was again asked to attend when the lump reappeared.

Her third attendance, on September 22, 1952, showed a swelling the size of a walnut in the right groin situated below and lateral to the pubic spine. It was cystic and tender; the skin was mobile over it, but the swelling was fixed to the underlying muscle. An irreducible femoral hernia was diagnosed and operation undertaken.

At operation by a Lotheissen approach, dissection below the inguinal ligament revealed a cystic swelling which was found to be lying on the pectineus fascia and intimately adherent to the femoral vein. It was realized that this was not a femoral hernia but a bursa arising from the pectineus fascia. It was excised with the exception of a small portion adherent to the femoral vein.

Pathological Report.—The bursa contained gelatinous fluid and had a smooth lining. On histological examination the material was shown to consist of oedematous and congested fibro-vascular tissue, moderately infiltrated with chronic inflammatory cells, eosinophils predominating. In one edge the material was lined by flattened endothelial cells.

The patient made an uneventful convalescence, and on discharge from hospital on October 7 there was no significant difference in the circumference of the two limbs after exercise. When seen on December 15 she was symptom-free and there was no difference in measurement of the left and right lower limbs.

COMMENT

Supernumerary pectineal bursa is a further lesion to be considered in the differential diagnosis of swellings in the ileo-femoral region. In the case recorded the patient presented with swelling of the thigh, the cause of which remained undiagnosed until the bursa became large enough to appear in Scapa's triangle, when it was diagnosed as a femoral hernia.

Perrigard (1947) recorded this condition under the title of supernumerary bursa of pectineus muscle simulating hernia in the inguinal region. In his patient the bursa was adherent to some of the smaller tributaries of the long saphenous vein, whereas in our patient the bursa was firmly adherent to the femoral vein. In Perrigard's patient there were no symptoms referable to venous obstruction, and the bursa seemed to have been more superficial in its situation. We can find no other reference to this condition in the literature.

A similar condition which may lead to some confusion is the ileo-psoas or ileo-pectineus bursa which lies lateral to the femoral artery and may overlap the arteries and veins to lie anterior to them.

We should like to express our thanks to Dr. K. P. Ball and to Dr. Isobel Finlayson for the detail given in her original letter.

Reviews

CLINICAL ENDOCRINOLOGY

Clinical Endocrinology. Volumes 1 and 2. By Lewis M. Hurxthal, M.D., F.A.C.P., and Natalija Musulin, B.S., M.D. (Pp. 1,599; 482 figures, 146 charts, 1 coloured plate. £9 9s. the set of two volumes.) Philadelphia and London: J. B. Lippincott Company. 1953.

This is a remarkable compilation. It comprises two large volumes totalling some 1,600 pages, all of which are packed full of facts, charts, tables, and illustrations covering the whole wide field of modern endocrinology. It is a difficult work to classify. It is certainly not a textbook; it is not an illustrated dictionary, and it is not an encyclopaedia. It is primarily a work of reference, but one of unusual and indeed impressive type. All who feel that the traditional form of textbook of medicine leaves much to be desired should give this book serious and careful consideration, for it seeks to establish a new form in a most ambitious and comprehensive manner.

The whole work consists of the systematic tabulation and classification of the known facts of endocrinology. After a short chapter on normal growth and development, which contains 19 charts, diagrams, and photographs, there follow six long chapters which together cover 1,000 pages and which deal with the functions and disorders of the traditional endocrine glands. Each of these chapters consists of a preclinical or physiological part and a more extensive clinical section. Throughout, the emphasis is on the systematic classification and tabulation of facts. The text consists almost exclusively of lists under headings and subheadings. The multiple facts seem to have been chosen and sorted with a mature judgment and are supported by a wealth of excellent illustrations, diagrams, and up-to-date references. Indeed, the clarity and profusion of the illustrations and charts are an important feature of this work. Thus the section on cretinism is followed by 39 photographs of high quality and by five charts. The section on gigantism is likewise followed by 33 equally good photographs and radiographs and by four charts. No less thorough are the series of references. For example, those relating to the anatomy and physiology of the pituitary gland number over 1,100—a classified list which alone covers 30 pages. These references appear to be well chosen and include a representative series from European and British authors. Though mainly modern, the historical references are not neglected, for Galen and even earlier authors are referred to. Later chapters in this work are more assorted. They include a comprehensive one on sterility, and others on the pineal gland, dwarfism, hirsuties, the endocrines in hypertension, gastro-intestinal hormones, antihormones, and steroids.

The advantages of a work of this type are the ease with which any particular fact may be found and the ease of access to the wide bibliography. At a test we had no difficulty in finding an answer to the question, Is the thymus enlarged in Turner's syndrome? But there are real disadvantages in a work of this type. It is not always easy to find out what to do in a given clinical situation. Thus we had difficulty in deriving a plan of investigation of the hirsute woman from the data given in the chapter on hair growth. It is also often difficult to learn from the text what is common and what is rare. A good example of this is in the list of toxic effects of antithyroid drugs used in hyperthyroidism. This list gives equal prominence to skin rashes, headaches, jaundice, and agranulocytosis among others, and does not indicate which are common and which rare. The treatment for all these complications is listed as penicillin. Ambiguities of this type can be found in other places.

A stern test of the judgment of a modern author on endocrinology is perhaps in his handling of that controversial subject, the "general adaptation syndrome." A short chapter on this concept shows commendable restraint in avoiding the many speculative developments in this field. He confines

it to the more orthodox aspects of adrenal behaviour under stress, and gives a very fair survey of established facts.

This is an outstanding work conceived in the grand manner. All who have an active interest in endocrinology will find it worthy of a place of easy reference on their own shelves. It should prove particularly valuable also as a reference guide to endocrine literature in all medical libraries.

C. L. COPE.

INTRODUCTION TO PATHOLOGY

Basic Pathology and Morbid Histology. By D. B. Cater, M.A., M.D., F.R.C.S. (Pp. 330; 266 illustrations, including 20 coloured plates. 42s.) Bristol: John Wright and Sons Ltd. 1953.

The author of this book has made a valiant attempt "to help the student who has just begun the study of pathology and finds the subject difficult." He believes that the beginner in pathology, with his inadequate clinical background, comes to regard pathology as a dead science, finds that the microscopical appearances of diseased tissues are meaningless to him, and may eventually be "tempted to abandon the effort to master the subject." To rectify this sorry state of affairs, which is familiar to all those who teach pathology, the author has striven "to graft on to the student's knowledge of Physiology sufficient clinical information to make Pathology live." He tells us that the book, which is based on a one-year course of instruction, "was written for students and not for professors."

Dr. Cater's book is bursting with information, and he may be wrong in expecting the average student to acquire so much detailed knowledge in a year's preclinical course. It is possible that he would be less distressed about his students abandoning pathology if he investigated their attitude to it after three years of bedside experience, during which time they would have built up their knowledge of human pathology on the foundations provided by a preclinical course of general pathology, the success of which is usually considered to rest on the teacher's facility for skilful omission.

There are some omissions in Dr. Cater's book, and a harsh critic might consider it to be unbalanced. The word "tetanus" does not appear in the index and could not be found in the text. Syphilis is allotted a chapter of fourteen and a half pages; diphtheria is dismissed in half a page. Repair surely deserves more consideration than a detailed account of teratomata, hamartomata, and mixed tumours, and even the elementary student would like the account of fracture healing to be longer than nine lines. Regeneration is discussed in eight and a half lines. Hyperplasia does not appear in the index, and a long search in the text produced no more than a definition occupying one and a half lines. On the other hand, the pathology of tumours is most liberally treated and described with a wealth of detail and illustration, as are hypertension, renal disease, heart failure, and the anaemias and leukaemias.

In the early chapters of the book Dr. Cater makes the fullest possible use of analogy in order to fix his facts in the reader's memory, but when the story of leucocyte *versus* bacteria is compared with a full-scale battle, complete with demobilization centres, prisoners, engineers, front-line defence works, and commandos, this superficial analogy becomes rather overstrained. The author changes his literary style about a third of the way through the book, and his writing thereafter becomes quite conventional and less dramatic. One feature of this book deserves the highest commendation; the book contains a series of coloured histological drawings which are not only clear and instructive but have considerable artistic merit.

The perfect introduction to pathology has yet to be written. It may be that Dr. Cater's book will, by popularizing pathology, help in its understanding by undergraduates of average intelligence. They, after all, constitute the final court of appeal, for they alone are able to decide if they have been materially assisted by reading it.

GEOFFREY HADFIELD.

CHROMATOGRAPHY

Practical Chromatography. By R. C. Brimley and F. C. Barrett. Foreword by E. C. Bate-Smith. (Pp. 128; 34 figures. 15s.) London: Chapman and Hall. 1953.

The authors of this book describe in simple terms the various types of chromatography—adsorption, partition, and ion-exchange—and the various ways in which such chromatograms may be used—namely, elution, displacement, and frontal analysis. They then discuss working details at length, with brief references to some of the more common applications of the methods. The book ends with a chapter giving descriptions of the accessory apparatus required, such as fraction collectors and desalting apparatus.

The book fills a gap in the literature and will be found useful for those many medical research workers whose interest lies only in a particular limited application of chromatography. The literature on such a subject usually takes for granted a basic knowledge of chromatography, and without this the unfortunate potential chromatographer is forced to wade through a multitude of earlier papers gleaned little bit by bit here and there as he goes along. It is fortunate that two experienced workers have been persuaded to put aside their filter paper and columns and give us the benefit of their wide knowledge and experience.

C. E. DENT.

FATIGUE

Symposium on Fatigue. Edited by W. F. Floyd and A. T. Welford. The Ergonomics Research Society. (Pp. 196; 47 figures. £1 4s.) London: H. K. Lewis. 1953.

Some of us seem to be less worried by fatigue now that we can eat a steak at home without thinking of the protein starvation awaiting us for the rest of the rationing week. But no doubt this mixed psychological and physiological stimulus will soon pass, and we shall then have to think up other excuses for ourselves. This symposium provides a mass of solid facts on this problem, but some of the contributions are such difficult reading that they are apt to produce the very phenomenon under discussion. This is because they are highly specialized and technical contributions to already specialized aspects of a somewhat confused general problem. It is clear that some of the simplest findings remain unexplained. Psychological aspects tend to be blamed for discrepancies in physiological findings, but physiological changes may ultimately be found responsible for many of the psychological phenomena observed. As the introduction points out, the trouble lies in our present lack of knowledge of how the nervous system really works.

This book will be useful to industry, and the meeting reported was organized by a society interested in bringing together medical research workers and designers of modern machines and equipment. But little basic progress can be expected until psychological factors can be better understood in terms of altered function in the nervous system. Then there will be less need for a dualism of approach which destroys any chance of getting to the roots of the problem.

One contributor stressed the proved physiological value of limbering up before real work is begun. This symposium has the air of being this type of preliminary exercise despite the immense amount of work reported in it. Now we need another Pavlov to stimulate some sort of experimental synthesis.

WILLIAM SARGANT.

ANTIBODY RESPONSE

The Nature and Significance of the Antibody Response. Edited by A. M. Pappenheimer, jun. Symposium held at New York Academy of Medicine, March 21–22, 1951. (Pp. 227, 32s. 6d.) Columbia: University Press. London: Geoffrey Cumberlege. 1953.

This book contains fourteen articles which were presented at a symposium held at the New York Academy of Medicine in March, 1951. The science has advanced rapidly, so that there is a big gap between 1951 and 1953;

but some of the authors have brought their articles up to date—Kabat, for example, quotes papers published in 1952. Chapters 1–5 are on production of antibodies, Chapters 6–9 on kinds of antibodies, and the final chapters on antigen-antibody reaction in tissues. Each article is by an authority on the subject and together they give a most valuable picture of the present state of knowledge and the problems that remain unsolved. Some of the views expressed may be criticized, but the authors have as good a right as anyone to their opinions. As Pappenheimer writes in the preface, "One positive contribution I feel confident the symposium does make: that is to demonstrate how fruitful the application of quantitative immunochemical methods can be in throwing light on the mechanisms of immunological reactions."

J. R. MARRACK.

TREATMENT OF SPINAL INJURIES

Injuries of the Spinal Cord. Edited by George C. Prather, M.D., F.A.C.S., and Frank H. Mayfield, M.D. (Pp. 396; illustrated. 63s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

This book, with seven sections written by different authors, is essentially a manual of treatment of patients with spinal injuries and is based largely on experience of military casualties. In the neurosurgical section little is said about the physiology or the evolution of the clinical condition after complete transections of the cord. This omission is disappointing, for studies of these patients now that infection is better controlled might have added important information to knowledge of the physiology of the divided cord. The two most interesting sections are those on the urological aspects and on the nutritional problems. In the former there is an excellent account of the physiology of the "spinal" bladder and a critical account of the various methods of treatment, the author preferring a tied-in catheter or suprapubic cystostomy, either being connected to a closed drainage system with provision for manual or automatic irrigation. The importance of adequate nutrition, particularly of protein intake, has been increasingly recognized in recent years, and the chapter on nutritional aspects contains valuable information. Writers of other sections discuss in detail the plastic repair of decubitus ulcers and methods of rehabilitation and the treatment of associated injuries, and there is an interesting if somewhat discursive account of the psychology of the paraplegic. This book is a useful manual of treatment.

J. W. ALDREN TURNER.

ELECTRICAL HEART PICTURE

Das Elektrische Herzbild. By Dr. Wilhelm Ernsthausen. (Pp. 231; 227 figures. M.48.) Munich: Verlag für Biophysik, Hermann Rinn. 1953.

"The electrical picture of the heart," to translate the title of this work literally, will in all probability be outside the range of the average clinician. A mathematical equipment beyond the ordinary is needed to follow the arguments. Here and there, however, the reviewer has managed to glean some interesting information. The second chapter on the chemical elements concerned in the contraction of the muscle cells is interesting and illuminating, for there are some good illustrations which give a clear conception of the chemical structure of a muscle cell. The author puts forward the theory that relaxation is really an active process. In the next chapter he describes the movement of ions and the formation of energy. The control of metabolism is discussed from the aerobic and anaerobic aspects. From now on the subject-matter becomes very difficult, not only in itself but in the German. No doubt someone interested in advanced physiology will find it intelligible, but the complexity and multiplication of the hundred or so cardiograms which go to make up the "electrical heart picture" may well prove too obscure for the ordinary cardiologist for a long time to come.

THE MEDICAL TREATMENT OF PEPTIC ULCER

No matter how well the cause of a disease may be understood, nor how self-evident the rational treatment may appear to be, the proof of the efficacy of that treatment remains the observation that in practice it works. When, on the contrary, as is the case with peptic ulcer, knowledge of causation is rudimentary, it is all the more essential that treatment should be firmly based on the results of scientific trial. Yet the current medical treatment of peptic ulcer is more dependent on tradition, clinical impression, and armchair speculation than any other branch of therapeutics.

The reason is not difficult to understand. It lies essentially in the natural history of the disease, which is one of a continual succession of relapses and remissions, spread over a lifetime and punctuated on only rare occasions, if at all, by the complications of haemorrhage, perforation, or obstruction. Hence any form of treatment may readily be shown to be followed by improvement in a large proportion of cases. And if it can be shown that the treatment may in certain circumstances neutralize or reduce the secretion of gastric juice, a theoretical explanation for its efficacy has been obtained which may serve to establish it firmly in the body of customary teaching. Physical rest, the avoidance of mental conflict, the ingestion of frequent and bland meals, alkalis, antispasmodics, secretory depressants, and sedatives are all regularly advised as essential parts of a regime which must be adhered to, more or less strictly, if the symptoms are to be kept under control—and this, as Todd¹ has pointed out, despite the recognition that polypharmacy is nearly always a cloak for ignorance.

With increasing appreciation of the natural history of ulcer and of the ease with which therapy may

obtain the credit properly due to time alone, it has become accepted in this country that a fresh treatment must run the gauntlet of a planned clinical trial before it can reasonably be adopted for routine use. Consequently, although more than a score of new treatments (some entirely new,^{2,3} some variants of older methods^{4,5}) have been put forward since the war, none has gained general acceptance. Moreover, the justification for standard therapy is now increasingly often being questioned.

Elsewhere in this issue Dr. P. R. C. Evans reports the results of a trial of the proprietary product "robaden" and of the value of a strict dietetic regime accompanied by a number of conventional drugs. Robaden is a Swiss preparation extracted from the stomach and small intestine of animals: it is free from lipoids and proteins, and is therefore distinct from enterogastrone. It has been claimed that robaden can bring about the healing of ulcers produced by histamine injection in guinea-pigs even when the injections are continued, and numerous enthusiastic reports of its value in man have appeared in the Continental literature (the makers advise the use of robaden for out-patients in conjunction with a normal diet). The conclusions derived from controlled trials have, however, been distinctly different. Bubb⁶ obtained better results with bed rest and standard diet, and Stolte,⁷ in a model investigation, obtained equally beneficial results from an inert placebo. Evans's results are in complete conformity; out of a total of 45 patients given robaden he assessed 24 as failures (53%), while of 53 patients given similar injections and tablets known to be inert 25 were failures (47%).

Evans's more important, and possibly more surprising, observation was that 51% of patients (that is, 27 out of 53) had eventually to be classified as failures after a course of four weeks' hospital treatment on a strict gastric diet, with bed rest and administration of phenobarbitone, hyoscyamine, olive oil, and magnesium trisilicate. In comparison there were 49% of failures (22 out of 45) among those who were given four weeks' in-patient treatment on a simple convalescent regime, allowed up two hours daily, and given no drugs other than magnesium trisilicate when necessary to relieve pain. The comparison is perhaps not quite fair to the stricter treatment, since "failures" included patients who relapsed at any time during the follow-up period of (on the average) two to three years, and for the greater part of the follow-up both groups of patients were given similar treatment regimes. Comparison of the results immediately after the end of the in-patient treatment might have shown a different picture, but so far as

the practical implications are concerned this is of little importance, since within a short interval any presumed advantage was already lost.

Surprising though this result may seem, it is not out of line with other recent work. Rae and Allison,⁸ for example, studied 63 patients with ulcers who were all in the Royal Navy and who were provided with the most suitable environmental and dietetic conditions for a period of a year as part of an experimental scheme for the rehabilitation and employment of men with peptic ulcers. They reinvestigated the group five years later, when all but one had returned to civilian life, and concluded that "in this series of patients the natural history of the disease was not materially influenced by the prolonged medical treatment." In a series of 140 patients Lawrence⁹ found no advantage in strict dieting compared with the use of ordinary hospital food. Among 125 patients with duodenal ulcer treated ambulant with various drugs, including hexamethonium, methantheline, and olive oil, Friendlander¹⁰ was unable to detect any significant beneficial results; and Doll and Pygott¹¹ could find none among gastric ulcer patients treated with phenobarbitone. The last-named workers did, however, observe more rapid healing among patients who were treated in bed in hospital than among those who continued at work, while Lawrence confirmed the value of alkalis for the relief of pain.

On the evidence, therefore, it would seem that the value of any form of dieting or of any drugs other than alkalis (and these only for the relief of pain) must be considered unproved. Even continuous milk-drip has not been shown to accelerate the rate of healing significantly, though it is probably of value for the alleviation of persistent pain. Nevertheless, until further evidence accumulates, the weight of clinical impressions should not altogether be disregarded any more than should the patients' oft-reiterated statement that fried foods (or cheese or apple as the case may be) aggravate their pain.

ION-EXCHANGE RESINS

In 1935 Adams and Holmes¹ published their methods for the preparation of ion-exchange resins. These consist of a highly insoluble organic matrix containing as many centres as possible at which cation or anion exchange can occur. In the cation-exchange resins used in medicine these centres are of two kinds, carboxylic (COOH) and sulphonic acid (SO₃H) groups, the latter being active over a wider range of pH though having a lower exchange capacity than the former.^{2,3} Their affinity for cations decreases in

the following order: Ca⁺⁺ > Mg⁺⁺ > K⁺ > Na⁺ > NH₄⁺ > H⁺.⁴ They yield hydrogen ion in exchange for the cation which they absorb; and, since this tends to cause buccopharyngeal ulceration, when they are used for clinical purposes ammonium is usually substituted for the hydrogen ion, the resin then being said to be in ammonium phase or cycle. Whichever cycle the resin is in, the metabolic effect is the same. Acidosis is produced by the absorption of hydrogen ion in the one case, or in the other results from the absorption of NH₄ and the subsequent conversion of NH₃ to urea in the liver, leaving hydrogen ion to be covered and excreted. The exchange capacity of different resins *in vitro* is conditioned by a number of different physico-chemical factors,⁵ and it has been disappointing to find that *in vivo* they exert only about 25 to 40% of their *in vitro* binding power for cations.^{5,6} There have been various theories to account for this.⁷⁻⁹

In the *Journal* this week at page 603 Drs. A. G. Spencer, E. J. Ross, and H. G. L. Lloyd-Thomas describe their experiments on the uptake of isotopic sodium and potassium by a cation-exchange resin *in vivo*. Their results indicate that the uptake of sodium greatly exceeds that of potassium in the small gut except in the jejunum, where the presence of dietary potassium, especially when this exceeds the sodium intake, favours the uptake of potassium. Lower down in the small intestine the absorbed potassium is displaced by sodium; but in the colon the process is reversed, and sodium is lost from the resin in exchange for potassium. This is more marked in patients on a low sodium intake, partly at least because of the enhanced efficiency of the normal reabsorptive function of the colon which occurs in sodium depletion. The authors liken the presence of a resin in the gastro-intestinal tract to that of an artificial electrolyte-containing compartment in the organism, a compartment which is constantly exchanging its ions with those of the rest of the organism in a continuing series of dynamic equilibria. This emphasis on the dynamic aspects of

the mode of action of resins contrasts with the somewhat static part they have been assigned in many of the theories which have been advanced hitherto.

In the nine years immediately following their discovery the properties of ion-exchange resins were applied solely to chemical laboratory processes. A cation-exchange resin was first used in a medical laboratory to prevent blood clotting *in vitro* by exchanging sodium for the calcium of the blood.¹⁰ Later, anion exchangers were found to neutralize the free acid of the gastric secretion and were used therapeutically in cases of peptic ulceration¹¹⁻¹⁴; more recently complexes of anion-exchange resin and fatty acids have been used for the treatment of intestinal moniliasis.¹⁵ Cation exchangers yielding quinine for hydrogen ion have been used to detect the presence of free acid in the gastric secretion in tubeless gastric analysis,^{16 17} and to deplete body potassium in cases of hyperkalaemia due to renal failure.¹⁸ Following a suggestion by Dock¹⁹ that resins could divert from absorption most of the sodium ingested by patients with oedema, they have been used mostly for this purpose.

On page 597 of this issue Drs. Spencer and Lloyd-Thomas describe their experience with the use of cation-exchange resins in the treatment of 39 patients with oedema, 30 having cardiac and 9 renal disease. Seven patients had only minimal oedema, and of the 32 with gross oedema 65% showed marked improvement after resin treatment. The authors point out, however, that the resins were given as adjuvants to other measures, such as rest in bed, a low sodium diet, and fluid restriction, which in themselves are often sufficient to cause improvement and delivery of the oedema. 67% of the patients complained of discomfort, which was mainly gastrointestinal, and it was more marked in patients treated with the hydrogen-cycle resin given in the early stages of the investigation. A unique complaint of alopecia was made by one patient. 48% of patients developed clinical signs of potassium depletion, some with characteristic electrocardiographic changes and sensitization to digitalis. This was directly related to potassium intake, and occurred less often in patients who received 25% of the resin in the potassium cycle. Apart from this, biochemical distortions were common though rarely serious and included a compensated increase in plasma chloride, which rose to hyperchloraemic levels in only six patients with early renal failure, who developed clinical signs of acidosis, whereupon resin treatment was stopped.

In their renal cases Spencer and Lloyd-Thomas found that resin treatment was not contraindicated so long as there was no impairment of the kidney's

capacity to form ammonia to cover the excretion of acid, but that where initially there was uraemia and renal impairment resin treatment was contraindicated. There are many reports of the favourable effects of adjuvant treatment with resins on the oedema of the nephrotic syndrome,²⁰⁻²³ but most warn of its dangers in patients with a low renal reserve. The dangers are four: first, of causing an acidosis in patients whose ability to form ammonia is impaired; secondly, if an admixture of resin in potassium-cycle resin is given, of causing hyperkalaemia; thirdly, of contributing largely to the nitrogen intake with ammonium from ammonium-cycle resins; and, fourthly, of causing or aggravating structural damage in the kidney, for even healthy subjects taking resins have been shown to pass granular casts transiently in their urine.²⁴ Since Type II nephritis is the most common form of the nephrotic syndrome, and since it is a stage in progressive nephritis, it is questionable whether resin treatment should be used at all in this disease.

It is clear that treatment with ion-exchange resins requires careful biochemical control, and this raises the question whether they can be used safely in domiciliary practice. Spencer and Lloyd-Thomas found that they could, provided the necessary chemical estimations could be carried out every two to four weeks, and the answer really hinges on whether these can be done within a reasonable distance of a patient's home. Without such facilities, resin treatment for oedema, whether of cardiac or renal origin, would be dangerous.

WHOLE-TIME SPECIALIST APPOINTMENTS

The large majority of the medical profession has been consistently opposed to a whole-time salaried service: the plebiscite of the whole profession in 1948 left no doubt about that. Medical men and women entered the Service only on the promise—subsequently written into the Amending Act of 1950—that a salaried service would not be brought in by regulation. It is fair to say that the profession's opposition to a salaried service has been non-political, in so far as that is possible in an issue forced into the political arena, and came from a conviction that such a service would be bad for the public and the profession. The Royal College of Physicians in its evidence to the Guillebaud Committee, which we publish in this week's *Supplement* (p. 69), sums up the pros and cons of whole-time service and clearly presents what is the viewpoint of most doctors. It is the measured answer to Opposition questioners who in the house last week sought to persuade the Minister of Health—and, no

doubt, Mr. Guillebaud too—that a whole-time hospital specialist service would be more efficient and economical (see "Medical Notes in Parliament," p. 653).

Discussing the advertising of whole-time vacancies, the *Lancet* recently remarked on the preference of some boards for whole-time appointments and the preference of most consultants for part-time appointments, and went on to say that, "until a coherent policy has been adopted, there seems to be no reason why a board should not be able to advertise a full-time post if it has 11 sessions which it wishes to be undertaken by one consultant."¹ But, while opinions may differ about individual appointments, the policy on matters of principle has been settled. In 1948 the Ministry sent a circular to hospital authorities in which it was said that in assessing their staffing needs authorities should take into account so far as possible the individual consultant's wishes about his terms of service and that whole-time appointments should be made only where the requirements of the Service made such appointments necessary. This directive, as the Minister made clear in the House last week, has remained the policy of the Ministry ever since. However, in 1952 the Representative Body of the British Medical Association, meeting at Dublin, resolved that advertisements for new whole-time consultant or S.H.M.O. posts should not be accepted for publication in the *Journal* except with the approval of the regional consultants and specialists committee. This resolution rose out of a belief that some regional boards were wilfully misinterpreting the terms of the 1948 circular and were advertising more whole-time vacancies than were strictly necessary for the needs of the Service. It was later agreed between the Joint Consultants Committee and the Ministry that where there was objection by the local consultants to the advertisement of a new whole-time post it should be referred to the Ministry through the Joint Committee for discussion before the Association finally rejected the advertisement.

That is how the matter stands at the moment. Obviously the needs of the Service vary somewhat in different regions, and the boards must have some discretion in the administration of their area. At the same time they should realize that the staffing needs of their hospitals are best known by the hospital specialist staffs themselves. The profession has long sought to establish that hospital administrative bodies at all levels should seek the advice of representative professional committees on specified matters. This position has now

been achieved with hospital management committees and boards of governors but not with regional boards. Regional consultant committees would be suitable bodies to advise boards on such matters as staffing requirements, but, as they are not called into consultation, the present policy of refusing advertisements of whole-time posts at their request is the only way of making their voice heard effectively on a matter of importance. If it checks certain boards in their trend towards creating a whole-time specialist service, it is a check which the majority of the profession would support.

IMMUNIZATION AGAINST POLIOMYELITIS

Recent reports in the daily press that the Queen and the Duke of Edinburgh have been given injections intended to protect them against poliomyelitis in an epidemic area of Australia may have caused a widespread impression that there is now some effective method of active immunization against this disease. We are given to understand that the material used was gamma globulin, which is calculated to afford passive protection for the limited period of the royal visit to the area in question. In these very special circumstances no one will question the wisdom of taking this quite harmless precaution, even though absolute proof of its efficacy does not exist. In a disease with so low an attack rate as poliomyelitis, and one of which the dissemination is so mysterious that we cannot know whether or when any given individual has been exposed to infection, it is not surprising that extensive use of gamma globulin in the United States has failed to afford this proof. On the other hand experimental, as distinct from clinical, test is reassuring. Bodian² found that gamma globulin possessed a high degree of neutralizing power against all three types of virus, as judged by infectivity for monkeys, even though the blood from which it was derived was collected mainly in a part of the United States in which the Leon type of virus has never been isolated.

Active immunization presents the most formidable difficulties, greater perhaps than those for any other infectious disease. There are three immunologically distinct types of virus; they can be propagated only in tissue culture and thus on a very small scale. The use of animal cord suspensions, the only ready source of virus, is not altogether without risk of causing secondary changes in the central nervous system. Moreover, according to McHammon^{3 4} even in an epidemic area it would be necessary to inoculate 11,000 children to prevent one fatal or paralytic case, and in a non-epidemic perhaps 50,000. Many will remember the disaster of twenty years ago when two vaccines were

introduced in the United States in which the virus was supposed to be attenuated by chemical means, in the Kolmer vaccine with 1% sodium ricinoleate and in the other with 0.1% formalin. A report by the medical director of the United States Public Health Service⁴ describing twelve cases of poliomyelitis apparently resulting directly from injection of one of these vaccines, five being fatal, led to the abandonment of both.

A vaccine now undergoing clinical trial is that prepared by Salk and his colleagues.⁵ It is derived from roller-tube tissue cultures of monkey testicle or kidney, and includes all three types of virus, inactivated by treatment with 0.4% formalin. This has been found to induce antibody formation of similar degree to that resulting from natural infection. A perhaps more promising development, although only in an early stage, is the work of Koprowski and his colleagues^{6,7} on the use of an oral vaccine. It has been known for some years that antibody formation may result from the oral administration of certain strains of living virus in monkeys. Melnick and Ladinko,^{8,9} using the Y-SK variant of Lansing virus, obtained this consistently, although a few animals also developed paralysis. Koprowski and his colleagues have used the TN strain, which, having been adapted to the cotton rat, lost pathogenicity for monkeys. Successful trials in chimpanzees were followed by the administration of a suspension of infected cotton-rat brain and cord orally, first to one non-immune human volunteer and then to nineteen others, of whom fourteen were non-immune. No symptomatic effects of any kind resulted. Of the fifteen non-immunes, twelve had virus in their faeces more than four days after vaccination—that is, at a stage when passive elimination would not account for its presence—and neutralizing antibodies in high concentration appeared in the serum of these subjects and of three others in whose faeces virus was not detected. This trial was then extended to sixty-one non-immune mental defectives with similar results, in which the additional observation was made that virus does not appear in the blood. This method has obvious advantages, as well as the merit of imitating the process by which immunity is naturally acquired.

GREAT ORMOND STREET AND KAMPALA

It is now perfectly feasible for a patient to have afternoon tea in tropical Africa and have breakfast next morning in a London hospital. It follows from this that hospital staffs in this country will be the better equipped to answer any calls that may be made on their services if they possess, through personal experience, a knowledge of tropical conditions and the approach to tropical diseases which is at present largely confined to those who have served in our Colonial Medical Service. This is one of the several important reasons why active co-operation between hospitals in this country and those in the Tropics should be encouraged. Last week plans were announced of an admirable scheme for fostering close relations between the Hospital for Sick Children, Great Ormond Street, and the medical faculty

of Makerere College, Kampala, Uganda. Each year a member of the visiting staff of Great Ormond Street will spend some weeks in Uganda; a senior medical registrar will spend approximately two years in Kampala; and one or two nursing sisters will be seconded to staff the children's ward at Mulago Hospital, Kampala. This hospital is the teaching hospital for the medical school of Makerere College, and is reserved entirely for African patients. It forms part of the Uganda Medical Service, while Makerere College and its medical school are maintained by the three territories of Uganda, Kenya, and Tanganyika. This offers a close analogy to the teaching hospitals at home, which are now the property of the Minister of Health, while the medical schools conform to university standards: the same smooth relationship which exists between the teaching hospitals and the medical schools in Great Britain also animates the hospital and medical school at Kampala.

The study of what may widely be termed tropical paediatrics is still a young subject, to which the work on kwashiorkor carried out at Mulago has given a noteworthy stimulus. While there is no dearth of clinical material nor of paediatric problems in Uganda itself, Mulago Hospital, situated only eighteen miles from the airfield at Entebbe—an important junction on the London-South Africa air route—may well develop an increasing importance for large tracts of the African continent. When, a few years ago, the visitors of the General Medical Council made their report on Makerere medical school, they commented upon the lack of adequate facilities for paediatric education. Last summer, at the time of the Coronation, a meeting was held at the Hospital for Sick Children, Great Ormond Street, between representatives of that hospital and the Uganda Medical Service and Makerere College medical faculty, at which the birth of an association between the hospital in London and the paediatric services at Mulago was planned. Later two members of the Great Ormond Street staff visited Kampala, and were able to give a favourable report on the gestational progress. The liaison is now complete, for already a sister has left London for Mulago to take charge of the children's ward, and in the autumn the first of a flow of senior registrars is to be seconded for a period of two years to take part in the work and teaching of the paediatric department. This association between a London teaching hospital, the East African university, and the Uganda Medical Service will be warmly welcomed.

The Council of the B.M.A. at its meeting on March 9 unanimously decided to award the Gold Medal of the Association to Dr. S. Wand in recognition of his outstanding services to the Association and to the profession. Dr. Wand is chairman of the Representative Body. A member of the Insurance Acts Committee from 1937 to 1948 and of its successor, the General Medical Services Committee, since 1948, he was chairman of the committee during 1948-52. During these years he gave untiring and distinguished service in the negotiations on behalf of general practitioners which culminated in the Danckwerts award.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

TESTS FOR VENEREAL DISEASE—II

BY

I. N. ORPWOOD PRICE, M.R.C.S., D.P.H.

Pathologist, Whitechapel Clinic, the London Hospital

The method of taking serum from a suspected syphilitic primary sore has been described in Part I (March 6, p. 575), and the finding of *Treponema pallidum* by dark-ground examination is proof of the disease. One negative finding is not conclusive evidence that the patient is not harbouring the parasite, and it may be that three or four attempts at daily intervals may be necessary for success. During this time the lesion should be protected and bathed with normal saline as opportunity serves. Should any difficulty arise it might be wise to send the patient to the pathologist.

Blood Tests for Syphilis

Blood tests for syphilis include the standard serum tests and Nelson's treponemal immobilization test. The former tests are usually reported as being negative or positive, with neat serum or dilutions thereof. The strength of a reaction (the higher the serum dilution the stronger the reaction) is no indication of the "amount" of the infection, but rather a reflection of the reaction of body tissues to the disease. Time should never be wasted in taking specimens of blood from the umbilical cord of infants. Such specimens when they arrive at the laboratory are nearly always infected, thus vitiating precipitation tests, or are anti-complementary to such a degree that they cannot be tested by a complement-fixation test.

Standard serum tests for syphilis and their modifications are legion, but all come under two headings: (1) complement fixation—for example, Wassermann tests, using standard or cardiolipin antigens; and (2) precipitation tests (including the clarification tests) such as the Kahn, Meinicke, Venereal Diseases Research Laboratory (Chamblee, U.S.A.), and Price's precipitation reaction.

Most laboratories employ a Wassermann reaction as the standard test, and a precipitation test as a check. It is important to seek the advice of the serologist concerning the relative sensitivity of the tests on which the report is based before attempting to assess the results. Fig. 1, in

FIG. 1.—Relative sensitivities of five serum tests for syphilis.

which five serum tests for syphilis are depicted, illustrates this point. There is little difference during the rising phase in the sensitivity of any of these tests. Thus in the early stages of the disease one is not likely to become positive much earlier than the others. In the static and declining phases marked differences are evident. Thus test 1 stays static for the shortest time and becomes negative before any of the others. It is followed by tests 2, 3, 4, and 5. If, therefore, a blood were tested by these five reactions at time point A, the report would read: tests 1 and 2 negative, tests 3, 4, and 5 positive. Lack of knowledge of the rela-

tive sensitivities of the various tests would make the interpretation of such a report difficult.

It must be made clear that in the absence of any clinical signs a diagnosis of syphilis should never be made on the strength of positive tests obtained with one blood specimen. When such an occasion arises, it is unwise to inform the patient that he or she is suffering from syphilis. The history and clinical condition should be reinvestigated, and the possibility of a non-treponemal reaction (so-called biological false positive) discussed with the pathologist before any action is taken.

Non-treponemal Reactors

In Britain non-treponemal reactions (approximately 0.3% of all bloods tested) are most commonly obtained with bloods from patients suffering from atypical pneumonia and bronchial infections, from antenatal patients, and from those who have been vaccinated recently for smallpox or inoculated with T.A.B.C. vaccine. It follows therefore that when standard serum tests are being performed for emigration purposes the blood specimen should be taken before vaccination or inoculation is performed. Rarer causes of non-treponemal reactions are haemolytic anaemia and some cases of lupus erythematosus. In my experience glandular fever was possibly responsible for only one non-treponemal reaction when sera from 92 patients suffering from this disease were tested. In the conditions listed above the serum may, on serial testing and in the absence of any antisyphilitic treatment, remain positive at a low titre for a relatively short time (three months) before gradually fading in strength until it becomes negative.

The real difficulty arises in the case of antenatal patients, for time is short. Here Nelson's treponemal immobilization test may be of value, but the pathologist should be consulted before asking for this investigation. The test is so complex and time-consuming that it cannot be regarded as a routine test; it must be reserved for special "problem" sera. At least 10 ml. of blood taken with aseptic precautions into a sterile container is required, and the results are reported in percentage terms of immobilization. Thus 100 to 50% immobilization is a positive reaction, 50 to 20% a doubtful reaction, and 20 to 0% a negative reaction. Because the living *Treponema pallidum* is used as an antigen the test is said to be specific, and so far few non-treponemal reactions have been substantiated. One other serum test can be used with the blood of suspected non-treponemal reactors—the Kahn universal serological reaction. The serum is tested by a series of quantitative reactions using different solutions of saline. The results are read immediately as well as after 4 and 18 hours at 4° C. Different serological patterns are thus obtained, one of which is said to be typical of a syphilitic serum.

Chronic non-treponemal reactions are more difficult to deal with because serial blood testing may consistently yield positive results for years before the test returns to negative, and this in the absence of any family or clinical history, signs, or treatment of the disease. In fact it may be almost impossible to decide whether a patient is suffering from latent syphilis or whether he is a non-treponemal reactor. In such cases the treponemal immobilization test and Kahn's universal reaction may be of help. The decision to treat or not to treat can be extremely difficult, and if confronted with such a dilemma the practitioner is strongly advised to consult a venereologist.

Serological Patterns in Syphilis

Interpretation of serum-test reports depends, therefore, on the knowledge of the methods of reporting and the sensitivity of tests as well as on the behaviour of the tests during the course of the disease. Fig. 2 depicts a typical sero-

FIG. 2.—Typical serological pattern in a case of untreated latent syphilis of four years' standing, discovered on routine testing at beginning of treatment for gonorrhoea. The black rectangle indicates period of antisyphilitic treatment. P.P.R.=Price's precipitation reaction. W.R.=Wassermann reaction.

logical pattern of a patient with a positive serology tested throughout by means of the standard Wassermann reaction and Price's precipitation reaction. It will be noted that the latter returns to negative four months earlier than the Wassermann reaction in the absence of any further treatment.

Another but more complicated serological pattern of a patient is depicted in Fig. 3. Here, in spite of treatment, two sero-relapses occurred during the course of the disease before the blood tests returned to negative.

FIG. 3.—A case of late secondary syphilis with a healed pustular rash. Two sero-relapses occurred in spite of treatment.

"Oscillatory" phenomena, mentioned in connexion with the gonococcal complement fixation test, occur also with the standard serum tests for syphilis, and Fig. 4 depicts this phase of syphilitic serology. These types of reactions usually mean that the positive result is well on its way to becoming negative.

FIG. 4.—"Oscillatory" phase in the serology in a case of early latent syphilis of less than one year's standing.

A serological relapse may be said to have occurred when a series of three consecutive rises in titre are obtained by routine tests at short intervals during the course of management of syphilis. An example of this is shown in Fig. 2. Such a pattern may precede a clinical relapse.

"Carry-over" reagin is the term given to reagin which has passed from a sero-positive mother's blood to that of her newborn infant. Usually the serum titre of the mother is higher than that of the child, but the latter's positive serum reaction rapidly returns to negative in the course of six to eight weeks. Therefore if a child born of a syphilitic mother has no signs of the disease it should not be treated merely on the strength of a positive blood reaction. Quantitative serial blood testing at fortnightly intervals will soon reveal the course of events.

In general, once a diagnosis of syphilis has been made it is necessary to perform routine blood tests at suitable intervals in order to obtain a clear appreciation of the serological pattern, which indicates the response to treatment. The timing of blood tests must be left to the clinician, but it is suggested that the blood should be tested at monthly intervals for three months after treatment; thereafter, provided the clinical condition is satisfactory and the serum tests are negative or the titres are on the down grade, at three-monthly intervals for a year, followed by six-monthly intervals for another year. If all has gone well, a final blood test one year later should be performed. Variations in this scheme must depend on the response of the patient both clinically and serologically.

Cerebrospinal Fluid in Syphilis

All cases treated for syphilis should have their cerebrospinal fluid examined at least twice before being discharged as cured. In primary and secondary syphilis the usual times are at the end of the first six months of treatment and just before final discharge. Patients who come for diagnosis at a later stage of the disease should have their cerebrospinal fluid tested before treatment is given. Tests thereafter are taken at times which will depend on the diagnosis and the clinician's assessment of the effect of treatment.

Earle Moore's Classification of Spinal Fluid Patterns in Syphilis

Group	Cell Count	Protein Content (mg. 100 ml.)	Wassermann Reaction	Lange Test
Normal	9 or less, usually 5 or less	40 or less	Negative	0000000000 to 2111000000 or 0112100000
1	10 or more, usually less than 50	40 or more, usually less than 100	"	As in normal fluid, or, e.g., 3210000000
2	10 or more, usually less than 200	40 or more, usually less than 100	Positive	Variable readings
3	10 or more, usually (except in acute syphilitic meningitis) less than 500	40-200 or more	"	First zone or "paretic" curve, 4321000000 to 5555554321

If the Wassermann reaction is negative, the total protein estimation below 30 mg. per 100 ml., the cell count less than 10 per c.mm., and the Lange colloidal gold test normal, the result can be regarded as satisfactory. Any deviation from these standards may merit a close re-examination of the patient's mental and physical condition. It has been stated, however, that minimal amounts of reagin can leak through from the blood stream into the cerebrospinal fluid (possibly through the choroid plexus) with the result that a patient with a positive blood test may have a weakly positive cerebrospinal fluid (Wassermann reaction positive with neat fluid) in the absence of any clinical signs or increase in the total protein and number of cells. The interpretation of cerebrospinal fluid reports can be extremely difficult, and Earle Moore's* classification will be found to be helpful (see Table).

*J. vener. Dis. Inform., 1949, Suppl. 23, p. 66.

Group 3 is a "paretic formula" and is usually obtained with the cerebrospinal fluid of all untreated cases of paralytic dementia. This pattern can occur with other clinical forms of neurosyphilis, or even with asymptomatic neurosyphilis. When this happens the report should carry a warning to the clinician that unless the patient is treated adequately there is a grave risk that he may develop paresis. It should be realized that the cerebrospinal fluid can be normal in untreated neurosyphilis, especially in tabes dorsalis (20%) or in vascular neurosyphilis. In interpreting the results of the examination of cerebrospinal fluids, it is a good working rule to remember that the degree (or absence) of active inflammation in the nervous system (usually the meninges) is measurable by the cell count and protein content. If either or both remain high after treatment for neurosyphilis the patient should be treated again. On the other hand, if the cells and protein content recede to and remain normal, this is evidence of improvement of the inflammatory condition even if the Wassermann reaction and Lange test remain static. However, the findings in the cerebrospinal fluid of some cases of neurosyphilis (especially tabes) can show improvement in both cell count and protein, even in the absence of any treatment.

In cerebrospinal syphilis, therefore, the pathological report must be appraised with the following facts in mind: (1) the Wassermann reaction is used to exclude or confirm syphilis as the cause of an inflammatory condition; (2) the cell count and protein estimation are used as measures of the inflammation; and (3) the Lange colloidal gold reaction detects changes in the globulin/albumin ratio of the cerebrospinal fluid which occur not only in neurosyphilis but also in other infections of the central nervous system. In neurosyphilis three well-defined types of reactions are usually described—namely, the paretic curve 5555432100, the tabetic 0014321000, and the meningeal 0001234320.

Lymphogranuloma Inguinale (Lymphogranuloma venereum)

Lymphogranuloma inguinale is a disease due to a virus, in the diagnosis of which the laboratory can render considerable help. Of the two tests employed, the Frei skin test is the more important. The antigen (0.1 ml.) is injected in intradermally in the forearm so that a wheal is raised. In positive reactions an inflammatory infiltration or nodule measuring 6 mm. in diameter with a surrounding zone of erythema is present within 48-72 hours. The antigen used is a standardized culture of infected yolk of chick embryo, whilst the control test is made with material from uninfected yolks. The other test is a complement-fixation reaction, and a titre of 1 in 16 or more obtained with the serum of patients who have a positive Frei reaction is strong evidence of infection. Standard serum tests should always be performed to exclude a coexisting syphilitic infection.

Granuloma Inguinale

Granuloma inguinale is a rare disease in this country, and the diagnosis is permissible only when Donovan bodies are found in the smears or when pathognomonic cells are demonstrated by biopsy. If the practitioner suspects that a patient may be suffering from this condition it is suggested that a venereologist should be consulted.

Addenda

Before leaving the subject of tests in venereal diseases one other investigation should be mentioned—namely, that of vaginitis due to the parasite *Trichomonas vaginalis*. This relatively common and distressing condition, so prone to relapse, often coexists with gonorrhoea. The discharge should be inoculated into Stuart's transport medium and delivered to the laboratory as soon as possible. Smear preparations have not proved to be satisfactory in my hands and therefore are not recommended.

Finally, it must be pointed out that the importance of routine blood tests for all antenatal patients should not be overlooked. A recent investigation carried out in London showed that out of a total of 6,809 antenatal patients 44

(0.64%) were found to have positive Wassermann reactions. There should be little objection to this procedure, as serological tests for venereal diseases can be carried out with the same specimen as that used for Rh grouping.

Next article on Clinical Pathology.—"Tests of Thyroid Function," by Dr. Russell Fraser.

Reports of Societies

LOCAL MEDICAL SOCIETIES

Liverpool Medical Institution

Speaking at a symposium on mitral disease held on February 11 at the Liverpool Medical Institution, Mr. F. Ronald Edwards said that the danger of recurrent rheumatic fever after valvotomy for mitral stenosis had been exaggerated. However, if any considerable mitral regurgitation was present before operation valvotomy appeared to be of little value. Mild aortic stenosis and regurgitation did not contraindicate mitral valvotomy unless the regurgitation was causing lowering of the systemic diastolic pressure. Neither was auricular fibrillation a contraindication to operation, although these cases had a higher mortality. Valvotomy in pregnancy should be undertaken only if the previous obstetrical history indicated it, and then it should be done early. The other contributors to the symposium were Dr. Ronald Ellis, on the medical aspects, and Dr. R. J. Keating, who spoke on radiological diagnosis.

Preparations and Appliances

ST. GEORGE'S MODIFICATION OF SIMS'S VAGINAL SPECULUM

Mr. IAN A. DONALDSON, first assistant, Department of Obstetrics and Gynaecology, St. George's Hospital, writes: A disadvantage of the standard Sims's duckbill vaginal speculum is the relatively short blade, which makes demonstration of the cervix in some patients difficult. The sister of the gynaecological ward at St. George's Hospital designed a modified speculum which has been made by Messrs. Charles F. Thackray Ltd., who have supplied the following technical information about the new speculum.

The whole instrument is shaped from thin material to reduce the total weight, and the overall dimensions of the two blades are: larger blade, 4½ in. (12 cm.) long and 1½ in. (3 cm.) wide; smaller blade, 4½ in. (10.8 cm.) long and 1¼ in. (2.9 cm.) wide. Varying sizes of the modified speculum have been made. The longer and narrower blades and the marked decrease in weight make them far more convenient to use. The accompanying illustration of the largest examples of the specula shows the difference in dimensions.

Correspondence

Diagnosis of Thyrotoxicosis

SIR.—Professor E. J. Wayne, reviewing various methods of assessing thyroid function in his Bradshaw Lecture (*Journal*, February 20, p. 411), refers to the determination of the serum creatine level in such terms as to give the impression that this test has little diagnostic value; this impression is reinforced in the leading article on toxic goitre in the same issue (p. 443). I should like to state that this view is contrary to the experience of my colleagues and myself in more than 400 patients originally diagnosed on clinical grounds as suffering from some form of hyperthyroidism, and to answer the criticisms levelled at the test.

A normal fasting serum creatine level of less than 0.6 mg. per 100 ml., in both men and women, excludes all but the mildest, relatively symptomless, cases of hyperthyroidism and differentiates sharply the anxiety states from true thyroid disorders. A serum creatine in excess of this upper normal limit, if it occurs in association with the signs and symptoms of hyperthyroidism, though not necessarily with a raised B.M.R., is convincing evidence of thyroid disease; if the B.M.R. is also increased the diagnosis is, in my opinion, beyond doubt. When, as may sometimes happen, especially if the B.M.R. is within normal limits, the diagnosis remains uncertain notwithstanding hypercreatinemia, a therapeutic test with Lugol's iodine or thiouracil, given for a few days, will result in a fall in the serum creatine if the increase is due to thyroid dysfunction; other forms of hypercreatinemia remain unaffected.

The method is as clear-cut as is possible with tests of this kind, and the features of other diseases in which the metabolism and serum creatine are raised are sufficiently distinctive to obviate confusion. Contrary to Professor Wayne's statement, overlap of the creatine levels between normal and thyrotoxic men rarely, if ever, occurs; that some apparently normal women may exhibit hypercreatinemia does not detract from the value of the test if the situation is intelligently assessed and a therapeutic trial performed. Peters' method of estimation is capable of a high degree of accuracy given a good photo-electric absorptiometer and using cells of 2 cm. depth; it seems to be immaterial whether all the substance estimated is creatine or not.—I am, etc.,

London, S.E.1.

Weber-Christian Disease

SIR.—As Dr. H. R. F. Macdonald reports (*Journal*, February 13, p. 377), the Weber-Christian disease is not very commonly encountered.

I should like to mention two patients because of the apparent effect of treatment. The first, a woman of 50, married and at the menopause, suffered from typical recurring lesions, mostly on buttocks and thighs and occasionally breasts, over a period of seven years. Several lesions had been excised by a surgeon and the histology was typical. The administration of diphenhydramine hydrochloride, 50 mg. three times a day, cleared the affection within a few days, and there has been no relapse now after three years. The second patient, a female aged 44, had numerous characteristic lesions, mostly over the abdominal wall and breast and occasionally elsewhere, of about six months' duration. The condition was thought by a physician possibly to be leukaemia, but removal of a nodule showed the characteristic picture. This patient was put on promethazine hydrochloride, 25 mg. nightly, and on diphenhydramine hydrochloride, 50 mg. three times a day, while in hospital for a

week. On discharge from hospital the promethazine hydrochloride was continued for several months with some slight improvement but no marked clearance. The administration of cortisone, 25 mg. by mouth four times a day for three weeks, cleared the affection in this period, and there has been no relapse after nearly 12 months.

The results in these isolated cases may be no more than coincidental, but it will be interesting to hear the experience of others.—I am, etc.,

Leeds.

JOHN T. INGRAM.

SIR.—Like most G.P.s, I tend to become fuddled by the rarities that succeed each other in your columns, but the memorandum on Weber-Christian disease (*Journal*, February 13, p. 377) has solved a five-year-old headache for me.

A cheerful, healthy, obese housewife, then aged 42, developed painful nodules in the legs in November, 1948. She was febrile ($\rightarrow 102^\circ$) for three weeks, and there was considerable constitutional upset. Indurated swellings, some as large as bantam's eggs, continued to develop in the subcutaneous tissues of the extremities as far up as the deltoids and buttocks. There was no suppuration. Courses of penicillin and sulphadiazine had no effect. At the end of this time she spent a fortnight in hospital, but nothing significant was discovered. She was now afebrile, and slowly resumed her normal life, but further swellings developed in decreasing numbers every few weeks. In February, 1950, she had a typical lesion in the right breast, the only one to occur on the trunk. In June, 1950, she had a cholecystectomy for multiple stones; this had no influence on her other condition—large, usually solitary nodes appearing at slowly lengthening intervals. On February 5, 1954, she presented herself with one about 5 cm. in diameter on the left calf: previous specimens had been negative, but I decided to send one more for culture. Incision produced blood, and curious amorphous yellow globules.

On February 13 I read your memorandum and telephoned Dr. S. Faulds at the Cumberland Infirmary, to whom, and to his colleagues at the pathological laboratory, I am most grateful for the following report, which seems to clinch the diagnosis: "Wet films show large numbers of fat globules and occasional macrophages. This would fit with Weber-Christian disease as you suggested."—I am, etc.,

Appleby, Westmorland.

PETER DELAP.

Lilliputian Hallucinations

SIR.—Dr. J. Todd's account of Lilliputian hallucination in a case of trichlorethylene poisoning (*Journal*, February 20, p. 439) recalls to my mind two cases of methyl bromide poisoning in which similar phenomena appeared. One was a youth of 17 with mild symptoms who complained of his feet looking very small, and as if they were a long distance away; his environment was unaffected. The other was a severe case, with epileptiform convulsions, in a man of 25. The ward appeared of normal proportions, but the nurses were horizontal. When later on they appeared to assume the vertical position they were less than half their normal size but "fat and squashed, as if you saw them in a mirror at a fun-fair." Visitors had the same appearance and gave him considerable amusement. He recognized the nurses afterwards as the same people who had appeared in caricature. Inquiries of several other patients with the same condition led to the conclusion that microptic phenomena are uncommon features of methyl bromide poisoning.—I am, etc.,

Hornchurch, Essex.

H. WYERS.

Controlled Hypothermia

SIR.—It is pleasant in controversy to find grounds for agreement, and we would certainly support Dr. H. C. Churchill-Davidson's plea for simplicity (*Journal*, March 6, p. 583); not, however, at the price of accuracy. That a general anaesthetic agent may interfere with the thermoregulatory mechanism is unquestioned, but the dose required reduces the patient to a state of deep anaesthesia in which depression of this autonomic function is accom-

panied by depression of every other function, nervous, cardiovascular, and metabolism.

We must insist that thermo-regulation is an autonomic activity. Therefore, if chlorpromazine, or any other drug, proves to have a predominant action on the central synaptic connexions of the autonomic nervous system, including those associated with thermo-regulation and vasomotor tone, for the sake of accuracy, and ultimately of simplicity also, it should be described as producing "central autonomic block." It will then be clearly differentiated from the peripheral acting "autonomic ganglion blocking drug." After all, the general anaesthetics produce widespread muscular relaxation, but that does not invalidate the term "relaxant drug" for substances such as tubocurarine.—We are, etc.,

Anaesthesia in Out-patient Departments

SIR.—In your leading article (*Journal*, February 27, p. 305) you did not bring out clearly what I sought to show at the Royal Society of Medicine. You said that I drew attention to the low potency of nitrous oxide, which was well known, and to the hazards that may follow attempts to obtain "more than light anaesthesia" with it. "Even light anaesthesia" would have been nearer the mark, for I showed that, of an unselected sample of adults, less than half could be anaesthetized at all without anoxia, sometimes gross; and I contended that when a "gas" was given the main agent of anaesthesia was, in fact, not nitrous oxide but anoxia—a contention which, in the discussion that followed, was not challenged. In assessing danger, therefore, it is with anoxia, used as an agent of anaesthesia, that cyclopropane has to be compared.

It is true that with cyclopropane there is a risk of explosion which must be constantly borne in mind. But with ordinary care and with the anti-static rubber now available explosions should not occur. But the notion, commonly held, that I wish most to dispel is that cyclopropane is dangerous because it is a powerful anaesthetic. "Overdose" and "respiratory arrest" seem to spring to the mind of anyone who considers its use in the out-patient department. Whilst with nitrous oxide, because of its inevitable anoxia, these are an ever-present menace, with cyclopropane they are far distant and not, in practice, encountered. It is, in fact, precisely because of its power, which enables it to be used throughout with 50% or more oxygen, that cyclopropane, though not perfect, is probably the safest of all existing anaesthetics to administer easily and effectively to out-patients.—I am, etc.,

London, S.E.1.

J. G. BOURNE.

Dental Anaesthetics

SIR.—In a paper recently read before the Anaesthetic Section of the Royal Society of Medicine (*Journal*, February 20, p. 452) Dr. J. G. Bourne advocates the use of cyclopropane in dental anaesthesia. During the discussion that followed, attention was drawn to the possible danger of explosion when using this gas. That this is no mere theoretical objection is well borne out by the following incident which may be of interest to any of your readers who may contemplate trying out the suggested mixture of cyclopropane-oxygen.

A short time ago a dental colleague was engaged in a rather difficult extraction on a patient under nitrous oxide anaesthesia. The forceps accidentally slipped from the tooth, giving rise to a shower of sparks, which, in spite of a well-lit surgery, was plainly visible to myself and the nurse in attendance. Had I been using cyclopropane I am afraid that the result might have been very unpleasant for all concerned.—I am, etc.,

Hove.

H. NEWTON-ANDREWS.

Methylpentynol

SIR.—I was interested to read Dr. A. G. Boag's letter in which he draws attention to the use of methylpentynol for premedication (*Journal*, February 13, p. 393). In addition to the ward procedures that he mentions, I have found this drug of value in allaying anxiety before the administration of a barium enema. Radiological examination is facilitated by the patient's fuller co-operation.

Methylpentynol also seems to be helpful in attacks of asthma. It may be given four-hourly in doses of 0.5 to 1.0 grammes as long as an attack lasts. The reduction of anxiety permits a better response to the usual treatment.

May and Ebaugh¹ reported very favourable results from the use of methylpentynol as a sedative in aged patients. There is no completely satisfactory sedative for such patients and it is well known that barbiturates may induce or increase mental confusion and restlessness. Methylpentynol seems to be effective in certain cases and has advantages over paraldehyde, which is more commonly given. The dose used must often be large. As your annotation (*Journal*, August 22, 1953, p. 435) states, there is no analgesic action in methylpentynol and probably it fails to act in those elderly persons whose insomnia and restlessness are dependent on physical discomfort or pain. Nevertheless, the drug is worthy of further assessment, especially in patients with cerebral arteriosclerosis.—I am, etc.,

London, N.9.

A. N. EXTON-SMITH.

REFERENCE

J. Amer. med. Ass., 1953, 152, 801.

SIR.—I share Dr. A. G. Boag's interest in methylpentynol (*Journal*, February 13, p. 393), as I myself am testing this as premedication for children having tonsillectomy. It is my wish to find a drug with qualities that include production of sleep so that the children know nothing of their visit to the theatre, simplicity and acceptability of administration, minimal depression and cough reflex and respiration, no vomiting, and no post-operative restlessness. Quinal barbitone ("seconal") and pentobarbitone ("nembutal"), of which I have considerable experience, were less than perfect in the fifth of these requirements; rectal thiopentone in the second.

Till now I have used methylpentynol for 62 cases, and have found the requirements generally satisfied except for failure to produce sleep. Instead, however, the children, almost without exception, have arrived in the anaesthetic room calm, quiet, happy and co-operative, and sometimes sleepy. It has proved wise to give the elixir one to one and a half hours pre-operatively in a dosage of 500 to 750 mg. Even so, it is unlikely to be sufficient premedication for undisciplined children and those who are frightened of hospitals. Results with methylpentynol appear so encouraging as to warrant completion of the investigation.—I am, etc.,

London, W.10.

CHRISTINE M. RENDELL.

Cortisone and Manipulation of Knee-joint

SIR.—The report entitled "A Comparison of Cortisone and Codeine Medication as an Adjuvant to Manipulation in Rheumatoid Arthritis" (*Journal*, January 30, p. 233) demonstrates an immense amount of careful work, especially in co-ordination between groups as widely separated as Bath, Sheffield, and the London area. The administration involved to produce this report must have been considerable. But what has it achieved? In the summary to this report it is stated, "A controlled trial has been made of the value of cortisone as a cover to manipulation of the knee-joint in patients with rheumatoid arthritis. . . . In the dosage given there was no evidence that cortisone was in any way superior to tab. codein. co. for the purpose at issue." Yes, certainly, there is much ground for their actual findings, and negative findings are often of real value. Apart from this, my impression on first reading this report was to answer my question by an emphatic "Exactly nothing." But on my second and third reading other thoughts came to me that are, I trust, worthy of consideration.

The first of these is to note that the graph (unnumbered) at the top of page 235 shows steady improvement during the pre-therapy period, rudely interrupted by the treatment, and then further days elapse before the curve initiated during the pre-therapy period resumes its quiet progress. This point can be seen readily by casting the eye across the gap caused by "the trauma of this operation." My second is to note with interest from Table V of the "contralateral knee-joints (non-manipulated)," that the pain, range of movement, and timing tests all show a nearly smooth curve of improvement—thanks probably to a combination of hospitalization, enforced rest, and by "every endeavour was made to get the patient walking as early as possible."

Now I come to two quite different thoughts. It is stated: "In a proportion of cases these contractures cannot be corrected by conservative methods, and manipulation under a general anaesthetic is required." What evidence does this paper produce for the clinical accuracy of this *ex cathedra* statement? Absolutely none. Again, there is no description of the method or extent of the manipulation. Anyone with the smallest experience of manipulating joints in active cases of rheumatoid arthritis, such as those treated in this survey, knows that the technique is critical. Indeed there are many physicians and surgeons who would hesitate to manipulate (presumably under an anaesthetic, though this is not stated) a knee in a patient whose E.S.R. averaged 20 mm. Since when has it been a good form of therapy in joint disease cases to subject an actively ill patient to a form of therapy that increases their pain and diminishes their mobility as shown by the authors' graph?

Is it not time that a halt was called to these so-called methods of research, where every care is taken to leave no loophole for criticism of the methods employed or the deductions made? To cease, also, this unnatural way of regarding patients as so many pieces of machinery or guinea-pigs, and return to those methods of simple clinical judgment and observation where results are gauged by the method of presentation and by the individual's reputation for accurate and humane genuine medicine. Harvey, Lister, Mackenzie, Banting, Fleming, and many others secured the real advances that stand for ever to their credit by the very individuality of their work.—I am, etc.,

Chipping Campden.

C. B. HEALD.

Changes in Skin Response in Asthma

SIR.—I have read with great interest Dr. A. G. Ogilvie's article on changes in skin response in asthma (*Journal*, February 13, p. 370). These variations have for long been recognized, but have been all too little discussed.

A positive skin response merely demonstrates that specific antibody is present either in the epidermal cells or in the blood contained in the capillary loops. It is probably true that specific antibodies can at times be concentrated in other tissues—e.g., the bronchial or gastric mucosa—without being present in either skin or blood, in which case there will be no "immediate" weal and flare reaction when the sensitizing agent is applied to the skin. Conversely, it is well recognized that some patients give positive skin reactions to allergens with which they are no longer in contact, and which therefore cannot be the present cause of their attacks. In such cases the causative factor or factors must be sought elsewhere, and they may be found to be other than allergic. For these reasons I think that it is unsound to accept positive skin reactions as the criterion of a dominant allergic aetiology, without reference to the history, environment, and physical examination of the patient.

A number of diverse factors—hormonal, psychogenic, infective, for instance—can affect the concentration of antibodies, and therefore the intensity of the skin reaction. Dr. Ogilvie found that all his cases that had been "desensitized" gave negative reactions at the end of their courses of injections. This is a common finding, and is presumably due to the production of a blocking or inhibitory antibody. With regard to the development of fresh sensitivities, one has often found this to occur, sometimes dramatically. It has usually been demonstrated in the course of a reinvestigation when a case has relapsed. There are therefore several comprehensive reasons why there may be variations in the skin reactions in the same patient over a number of years, and I quite agree with Dr. Ogilvie that it is futile to attempt to

assess clinical progress solely on the basis of these reactions without consideration of the case as a whole.

Nevertheless, skin testing is a procedure without which it is impossible to make an adequate aetiological diagnosis in the majority of cases of asthma. It should, of course, be properly carried out by an experienced person, with negative and positive controls, using extracts of individual allergens (rather than groups) of known concentration and of reliable origin.—I am, etc.,

York.

HAROLD ROYLE.

SIR.—Dr. A. G. Ogilvie's observations in his paper on "Changes in Skin Response in Asthma" (*Journal*, February 13, p. 370) are so much at variance with general experience that an attempt must be made to explain them. I should like to comment under the following headings.

Technique of Testing.—The technique of skin-testing has now been more or less standardized for many years. The quantity of extract usually injected in the intradermal method is 0.01–0.02 ml., just five to ten times less than the amount injected by Dr. Ogilvie. The disadvantage of using relatively large volumes of extract is well recognized. I quote from two well-known textbooks. Cooke¹ states: "The common practice of injecting as much as 0.05 to 0.1 ml. in the performance of an intracutaneous test should be condemned. The initial trauma resulting from the injection of such a large amount of fluid into the skin is sufficient to produce non-specific wealing. This is not only misleading in itself but impairs the diagnostic value of many tests which produce only slightly positive reactions but which, nevertheless, are specific and of diagnostic significance." Vaughan and Black,² in discussing the technique of the intradermal test, say, "... Then press on the plunger introducing 0.01 or 0.02 cc. of the extract into the epidermal layer."

It is small wonder that many of Dr. Ogilvie's patients quailed at the thought of a second assault by his "energetic young skin-testers," and he may be accounted fortunate that this procedure was not followed by any serious results. A number of deaths have been recorded following skin tests with smaller quantities of extract than he employed. Presumably, the frequency of false positive reactions obtained by this technique explains his criterion for a positive reaction—namely, "a definite weal of at least the size of a silver threepenny-piece with pseudopodial irregularities and surrounding erythema." This would exclude many significant reactions and would explain why he has been unable to confirm sensitization in patients with strongly positive histories. It would also probably account for the apparent change from negative to positive and vice versa, when patients were retested after several years: many of those considered negative were probably still positive but not up to threepenny-bit standard—in other words the responses may have varied in degree rather than changed from positive to negative or negative to positive.

Variation in Potency of Extracts.—Dr. Ogilvie does not state whether fresh extracts were used from time to time, but, since the potency of few, except perhaps the pollens, would have remained unaltered during the time of his investigations, one assumes that he has done so. Unfortunately, we still have only rough methods of standardizing our extracts so that no two preparations made at different times can be regarded as identical in potency or quality. This applies especially to mixtures of extracts as used for "group testing." I habitually employ commercial extracts and find that they vary considerably in potency: this is not a reflection on the firms who put them up but an indication of the crudity of our methods of preparing extracts. I am at present using an extract of cat hair which gives a high proportion of positive reactions, many of which cannot be justified from the history: a short time ago the cat hair extract from the same firm rarely caused reactions. In other words, a change in the extract rather than a change in the patient may account for some of Dr. Ogilvie's observations.

Site of Test.—The site at which skin tests are carried out is important: if the forearms are used larger reactions are obtained near the bend of the elbow and smaller ones near the wrist using the same amount of the same extract. If the arm was in fact employed as the testing site, were precautions taken to ensure that the same relative positions were used for each test substance at the time of the original and subsequent tests?

Effect of Drugs.—Dr. Ogilvie does not state if precautions were taken to ensure that drugs such as adrenaline, ephedrine, or anti-histamines were not taken on the day the tests were carried out. These drugs are well known to cause reductions in skin sensitivity.

My own observations³ have shown a remarkable consistency in the skin responses of a small group of pollen-

sensitive patients tested repeatedly over three years. The reactions invariably diminished immediately after treatment and when the scratch test was employed sometimes disappeared, but they had almost returned to the pre-treatment level four months later: there was little variation from year to year. No one would deny that changes in skin responses do occur sometimes apparently "inconsequently"—new sensitivities develop and old sensitivities fade away. Like Dr. Ogilvie, I have always been sceptical of the value of skin-tests, but in investigating their vagaries one must stick to the rules. The really odd thing about his paper is his final comment (with which I am in full agreement) that "skin-testing . . . in the individual case may give valuable information if used with discretion."—I am, etc.,

The Prevention of Pulmonary Embolism

SIR.—Your annotation on pulmonary embolism (*Journal*, January 23, p. 202) prompts me to report a method designed to prevent this post-operative complication.

At the conclusion of the operation the surgeon and his assistant raise the patient's legs through an angle of 80 degrees. The powdered palm of the hand is then used to massage the patient's calves from the tendo achillis to the popliteal fossa. The patient's feet are then passively flexed and extended at the ankle. The legs are lowered on to an inclined plane of 45 degrees, which is placed on the stretcher canvas on the operating table; the tendo achillis rests on a sorbo-rubber bridge—a rubber loop fixed to the top of the inclined plane is slipped over the feet to prevent the legs from rolling off. When the patient is returned to bed the legs are kept at an angle of 45 degrees by a wider inclined plane which is slipped in under the mattress until active toe and foot movements are possible.

This treatment is based on the belief that most cases of post-operative pulmonary embolism result from clots which have their origin in the veins of the calf, and which begin to form during and shortly after operation; although the coagulability of the blood is altered, the venous stasis and endothelial trauma are all-important. By making use of gravity, massage, and the venous pumping action of the calf muscles it is ensured that no early thrombotic changes occur in the veins of the lower limbs before the patient regains consciousness, after which active toe and foot movements are possible.

The writer has been impressed with the incidence of pulmonary embolism among patients who have been in bed for any length of time pre-operatively, and, although it is not intended to list other prophylactic measures in general use, the precaution of keeping patients who are admitted to hospital for pre-operative treatment or investigation ambulant, whenever possible, will bear repetition. In passing, it may be mentioned that following operations in the lithotomy position, particularly in middle-aged and more elderly patients with atheromatous changes in the cerebral vessels and in whom a sudden lowering of blood pressure predisposes to cerebral thrombosis, and following obstetric operations in the lithotomy position when a lowering of the legs to the horizontal is not immediately desirable, the inclined plane has proved its value.

In conclusion, Sir, this simple piece of apparatus will help to reduce the incidence of post-operative venous thrombosis and its sequelae, and the complications resulting from a sudden fall in blood pressure, and will later form the subject of a more detailed communication.—I am, etc.,

Chelmsford.

ANTHONY PEARSON.

International Nomenclature for ABO Groups

SIR.—Before the adoption of the international nomenclature for the ABO groups, considerable confusion between the British and Continental literature occurred between groups I and IV as a result of using Moss and Jansky

terms respectively. It was hoped that the international notation would avoid all future errors; nevertheless, this has not proved to be the case. Before the international terms were instituted sera for grouping were issued as II and III, whereas for a time after the inception of ABO, the sera issued were labelled A and B. Some time ago the labels on sera for grouping were altered to anti-A and anti-B, the contents of which were respectively B and A, an apparent reversal to the uninitiated. Why this change took place, apparently without international agreement, is not clear.

Arising out of this change we have recently had a young house officer who previously held an appointment in the U.S.A., where, she stated, the previous method of labelling—that is, A and B—continues. One night recently, as an emergency, she grouped a patient preparatory to blood transfusion, and made the group B instead of A as a result of the labelling anti-A and anti-B. It was entirely new to her, and she had not seen this notation before. The mistake was corrected in time to avoid any possible transfusion disaster. Surely, however, the whole circumstance raises an important question of principle; the labelling of material of this kind should be a matter of international agreement. This will avoid confusion in the literature and, further, avoid possible disasters to patients. It seems to me to be entirely wrong that any change of nomenclature should be permitted unilaterally in one country. In short, an international agreement, once accepted, must not be broken by any individual country without due notice to all affected by such a decision.—I am, etc.,

London, S.E.18.

W. SMITH.

Improved Hearing by Re-education

SIR.—I feel it important that everyone interested in deafness, and especially otologists, general practitioners, and the lay hard-of-hearing public, should be careful about accepting unreservedly the claims made for improved hearing by re-education methods without hearing-aids. The claim is made concerning persons ranging from the hard-of-hearing (but not requiring an aid) to those with marked high-tone deafness, and even for some too deaf for an aid to help at all. An increase of ability to listen is denied; it is considered a definite improvement by releasing "latent" hearing. This may be so, but the principle needs medical and scientific investigation before the practice is recognized as of true value.

At present, the sponsors assess improvements only with a "live" voice and uncalibrated "complex" sound tests; any change in pure-tone audiometry is disclaimed and speech audiometry is not used. The value of the gain in hearing is also gauged by letters from grateful patients and clients, which, though enlightening, are in fact unscientific evidence and all too reminiscent of advertisements for patent medicines or "cures" in the Hunterian era.—I am, etc.,

London, W.1.

IAN G. ROBIN.

Atelectasis as a Complication in Artificial Pneumothorax

SIR.—In the first paragraph of Dr. R. L. Sadler's article on atelectasis as a complication of artificial pneumothorax (*Journal*, February 13, p. 359) we read: "... Some authorities seem to regard it as a dangerous procedure which should be used only in exceptional cases (Harris *et al.*, 1952 . . .)." We are at a loss to understand how Dr. Sadler can interpret anything we wrote in our paper¹ which can even remotely resemble the sentiments he attributes to us. If we may quote a sentence of our paper which appears to be relevant: "We think that the over-all results are good. With better selection, chemotherapy, and thoracoscopy, we believe that the artificial pneumothorax still has an important role to play provided that it is well maintained and that it is looked upon purely as a temporary collapse measure."

Does Dr. Sadler really suggest that he understands from that that we regard an artificial pneumothorax as a dangerous procedure? Even in our review of the literature we quoted no authority to suggest that the procedure was dangerous, although we did suggest that it was losing favour in many centres.—We are, etc.,

A Naval Occasion

SIR,—I was greatly entertained by your reviewer's reaction to my book *Our National Ill Health Service: An Essay on the Preservation of Health* (*Journal*, February 20, p. 441). Of course it is generally the author's lack of perspicacity if he fails to get a reviewer to follow his thesis. My subject was social health, in which, I tried to explain, I did not include clinical medicine. Therefore I hope you will not mind correcting the suggestion of Dr. Ffrangcon Roberts that the care of social health in the Royal Navy "had to be buttressed by the appointment of civil consultants who were given the rank of [rear] admiral." One is truly grateful to the eminent consultant clinicians who have given their services to the sick and wounded seamen, in peace as well as war. During the war the Navy expanded sevenfold, which, of course, needed a proportionate increase of "doctors" of all sorts. In fairness to the regular naval medical officers, it was not necessary to buttress their health duties by entering a single high rank consultant in social or preventive medicine, or give any "hostilities-only" medical officers of health a relatively higher rank than their permanent colleagues.

I can only cry *Touché* to my slip about the authorship of *Ecclesiastes*. It was deplorable; and not to be excused by the bad old custom of casually attributing all the "wisdom books" of the Hebrew scriptures as a matter of course to Solomon.—I am, etc.,

Leamington Spa.

SHELDON F. DUDLEY.

Myelomata of Bone

SIR,—With reference to the article by Mr. A. Naylor and Dr. F. E. Chester-Williams (*Journal*, January 16, p. 120) I should like to make some observations about the use of electrophoresis in demonstrating abnormal proteins in serum or urine.

In the past seven months at Kingston Group Laboratory, eight cases of multiple myelomatosis have been diagnosed by pathological investigations, and the part shown by electrophoresis of serum and urine is shown by the following chart. Dr. K. G. Cuming of this laboratory has confirmed some of these cases by marrow puncture and Dr. J. C. Lees by necropsy and tissue section. Although for final and undisputed diagnosis several criteria are necessary, those of first importance during life are positive marrow biopsy and the demonstration of an "abnormal" globulin in the blood or urine. The cases show that where an "abnormal" protein is not present in the serum it may be demonstrated in the urine. (I am indebted to Dr. F. V. Flynn, of University College Hospital, for urine electrophoresis in some of these cases). The case of J.O. suggests that in spite of the presence of a small round-celled solitary neoplasm of the femur, the failure to demonstrate "abnormal" proteins indicates that plasma cell myelomatosis is unlikely.

Since electrophoresis is an easy laboratory technique it would be important to know if cases exist of proved plasma cell myelomatosis where no protein abnormality can be demonstrated by this method. There is no doubt that electrophoresis may demonstrate what may be called false positives, since there has been one case in this hospital where a typical γ -globulin band has been seen with no other evidence of myelomatosis. The three-tube heating test for Bence Jones protein in urine has been demonstrated to be inadequate in the above cases, especially in the hands of

 ■ = MODERATE HEAVY BAND

PROTEIN IN URINE WITH MOTILITY β γ — BENCE JONES

more junior technicians. In no case has the test been absolutely typical of the text-book criteria—e.g., disappearance above 80° C. and reappearance on cooling. I would suggest that urine electrophoresis should always be done in cases of proteinuria and anaemia with back or leg pain over the age of 40 if cases of myelomatosis are not to be missed. Even the mode of death, sometimes in uraemia, does not necessarily suggest marrow dyscrasia.

The excretion of these abnormal globulins is interesting in relation to Professor Squire's recent article on protein excretion and reabsorption in the normal kidney. What is the normal method of metabolizing and excreting the very large γ -globulin molecule? The relation of plasma cells to globulin antibodies may be investigated in these cases of myelomatosis, since it can be demonstrated that several different globulins of different electric charge and molecular size are formed. The so-called neoplastic cells seem to form abnormal substances, but it is possible that an excess may accumulate (or be excreted) in response to an unusual antigen, or because of failure in the normal metabolism and excretion. With these new methods of diagnosis more cases of plasma cell multiple myelomatosis are found, and it can no longer be considered to be a rare disease.—I am, etc.,

Kingston-on-Thames.

PHYLLIS DAGNALL.

Press Publicity

SIR,—As a public representative I have been very interested in the letters and comments in your columns on the subject of press publicity about the Health Service. It is unfortunate that some persons in authority still fail to appreciate that the Service belongs to the community and that ordinary citizens are entitled to know all about its progress and problems. The attitude of "Theirs not to reason why" dies hard, and it remains a cause of deep resentment to intelligent citizens wherever they come in contact with it.

The average layman is certainly reluctant to complain about or to experts with professional qualifications. He is not quite so reluctant to complain to his Member of Parliament. A study of Parliamentary Questions and of M.P.s' correspondence would, I know, reveal numerous ex-

amples of the failure of boards, councils, and committees to let the public know what they are doing and why. By neglecting the regular supply of information, such authorities not only create suspicion and mistrust but lose the potentially powerful support of public opinion for the greater funds and resources they often need.

It is in the interests of all who work in the Service, as much as of those who require its facilities, that every citizen should feel a full sense of responsibility for its efficiency. But this relationship cannot develop unless the administrative and medical powers—that take the public into their confidence, stop being secretive about their decisions, and improvements and reforms. The best are doing this already, and I am confident that all who have tried this approach have found that there is a substantial fund of goodwill for the Health Service on which to draw.—I am, etc.,

House of Commons, S.W.1.

STEPHEN SWINGLER.

Infant B.C.G. Vaccination

SIR,—Dr. H. M. Purser's account of 2,500 B.C.G. vaccinations in newborn infants (*Journal*, February 13, p. 368) is of special interest in view of the exclusion of this age group mentioned in Memorandum 324/B.C.G., British Ministry of Health, November 5, 1953). As B.C.G. vaccination has been part of the Local Authority Anti-tuberculosis Service in Dublin since October, 1948, and 4,507 newborn infants have been vaccinated here, perhaps we may be permitted to comment on our experience.

When our scheme commenced attention was concentrated on contacts. From study of the annual childhood tuberculosis mortality in Dublin, we realized that children under 5 years of age had the highest mortality. For this reason it was decided to make B.C.G. vaccination available for all infants born in the maternity hospitals irrespective of contact. By kind permission of the Master of the Rotunda and Dr. W. R. F. Collis, paediatrician, the scheme for B.C.G. vaccination of the newborn began at the end of September, 1950. The scheme was later extended to the Coombe Maternity Hospital with the kind consent of the Master and Dr. W. Kidney, paediatrician, and each month has shown an increase of the number of vaccinations. Dr. Purser has raised the question of congenital tuberculosis, and we agree that a pre-vaccinal test is desirable if the mother is an open case, otherwise we dispense with pre-vaccinal testing in newborn infants.

We have not used the double dose of vaccine in infants—we use the same technique and method of administration as in the older age group. We subdivide 0.1 ml. of Danish vaccine into three intradermal injections made slightly apart over the middle of the left deltoid. The subdivision of the dose minimizes the risks of ulceration and adenitis. Dr. Purser refers to multiple adenitis. It is not clear if these occurred in both axillae as a result of both deltoid areas being used. This appears to be one of the disadvantages of the double dosage. The incidence of axillary adenitis and abscesses is somewhat less in our series using the single dose technique.

Incidence of Regional Adenitis—Comparison Belfast and Dublin

	Total Vaccinations New-borns	Total Regional Adenitis	Simple Adenitis	Abscesses
Belfast	2,500	46 (1.84%)	28 (1.12%)	18 (0.72%)
Dublin	3,429	52 (1.51%)	31 (0.9%)	21 (0.61%)

The above Dublin figures relate to vaccinations completed to the end of June, 1953, as complications occurring in vaccinations carried out since July, 1953, may not show until 1954. Many cases of adenitis do not appear until six to nine months following vaccination. The complication figures in the above table are at variance with those reported by Gaisford and Griffiths,¹ who reported 50 abscesses in 1,461 vaccinations—i.e., 3.4%. These workers used two different vaccines, and varied the dose with the object of expediting the conversion time. Many of their vaccinations were made in the buttock—we have avoided the use of the napkin area, and our invariable site of injection is into the skin over the left deltoid.

Dr. Purser has omitted to state what post-vaccinal tests were used, and at what time tests were applied by the practitioners on infants domiciled outside Belfast City area. In Dublin we prefer

to use a post-vaccinal Mantoux of 0.002 purified protein derivative in infants. Jelly or ointment tests are liable to be washed off, and, due to the sensitivity of the skin of infants, erythema without papules may give rise to misleading results when read by various readers. We find that the conversion rate depends on the time allowed to elapse between vaccination and post-vaccinal tests. A number of mothers fail to bring their infants in eight weeks' time for these tests. This entails much follow-up work, but has the advantage that the longer the delay to do post-vaccinal testing the better the conversion rate. We agree with Dr. Purser's findings on annual tests. In a random sample of 203 annual tests of newborn infants vaccinated prior to 1952 only one had become negative, so it would appear better to retest at school entry.

In this total of 4,507 vaccinations in Dublin and 2,500 in Belfast, little of the distressing complications envisaged in Memorandum 324/B.C.G. have appeared. Because of the conflicting attitudes to B.C.G. vaccination of newborn infants and the rarity of reports in the literature, Dr. Purser's article is worthy of study.—I am, etc.,

Dublin.

M. DUNLEVY.

Prolonged Hypotension Following Hibernation Anaesthesia

SIR,—The papers in the *Journal* of December 5, 1953, by Dundee, Gray, *et al.* (pp. 1237 and 1244), and Smith and Fairer (p. 1247) have been most interesting and stimulating. One of the complications of hibernation anaesthesia not mentioned by either groups has been that of "failure to rewarm," as discussed by Huguenard.¹ This complication, he states, is commoner in the older patient. One of the associated features of failure to rewarm may be that of prolonged and possibly progressive hypotension. We should like to quote the following case as an example.

A female of 78 years, weighing 120 lb. (56.3 kg.), was admitted to hospital with a closed fracture of the upper third of the shaft of the femur. It was proposed to carry out an open reduction of the fracture with fixation of the fragments by cross-screwing. The patient's condition was fair for a woman of her age. The blood pressure was 150/100 mm. Hg, pulse 100/min., regular in character, haemoglobin 13.5 g.%, and the red cell count 4,320,000 c.mm. The heart sounds were of good quality and the chest clear. Premedication consisted of morphine gr. $\frac{1}{4}$ (11 m.g.) and atropine gr. 1/100 (0.65 mg.) given one hour before operation. It was decided, however, later to use hibernation technique in this case.

Accordingly, the patient was given 10 ml. over a period of 10 minutes of a mixture of pethidine, 50 mg., promethazine, 25 mg., and chlorpromazine, 25 mg., which had been diluted to 20 ml. in saline. At the end of 10 minutes the patient was asleep and she was intubated with ease. She was then given a mixture of 4 litres of nitrous oxide and 4 litres of oxygen, using a semi-open circuit. At this stage the blood pressure had fallen to 80/45 mm. Hg, and the pulse had risen in rate to 120/min. Bleeding was minimal throughout the operation, despite the fact that severe surgical handling of a difficult fracture took place. In all some 40–50 ml. of blood was lost. The blood pressure and pulse rate remained steady throughout the operation. One hour later at the end of the operation the patient objected to the endotracheal tube as soon as the nitrous oxide-oxygen mixture was withdrawn and the tube was removed and replaced by an ordinary airway.

On return to the ward the blood pressure had fallen to 70/40 mm. Hg, and two hours later, despite elevation of the foot of the bed, to 50/20 mm. Hg, the pulse remaining steady at 120/min. The colour at this stage was not good, the skin being waxy-white in appearance. The ears, however, were quite pink on rubbing and the arteriolar-capillary refill time seemed satisfactory. The respiratory rate and depth seemed adequate at this stage. A clinical thermometer placed in the rectum did not register, the temperature having fallen to under 95° F. (35° C.). As suggested by Huguenard, the intravenous administration of atropine gr. 1/50 (1.3 mg.) followed by neostigmine 5 mg. was carried out without much success. Except for slight fibrillary twitching of the fingers and eyelids, little was observed, and the blood pressure remained at 50/20 mm. Hg and the pulse rate at 120/min. The foot of the bed was now raised to a twenty-degree tilt and hot-water bottles were applied cautiously to the trunk. An intravenous transfusion of 1/250,000 solution of L-noradrenaline was now set up. After a few ml. of this solution

was run in, the blood pressure rose to 120/80 mm. Hg, and the pulse slowed to 80/min. The patient now began to warm slowly and there was a marked return of muscular tone. She answered to her name some 10 hours after her return to the ward and was wide awake in 12 hours. Altogether some two pints (1.1 l.) of the L-noradrenaline solution was given over a 10-hour period. Recovery has been uneventful and the patient is now well, but of course not yet walking due to her orthopaedic condition. The temperature was slow to rise, and after two days was still only 96° F. (35.6° C.) rectally, although she felt well and did not complain of cold.

The administration of atropine and neostigmine, which, according to Laborit,² induces the liberation of adrenaline, had little effect in this case. Atropine blocks the cholinergic muscarinic effects, while neostigmine elicits a stimulation of the pre-ganglionic fibres. Recourse therefore had to be taken to supportive adrenergic therapy as hibernation was obviously reaching an irreversible phase.—We are, etc.,

Utero-tubal Insufflation

SIR,—Despite Dr. A. Sharman's statement ("Some Lessons from 4,000 Utero-tubal Insufflations," *Journal*, January 30, p. 239) that no harm arises from insufflation of the fallopian tubes with carbon dioxide in the pre-menstrual phase of the cycle, it seems likely that more patients will be found to have patent functioning tubes on first investigation if kymography is carried out about mid-cycle or before.

The annotation on this subject (p. 265) repeats the assertion that the variations on insufflation may be due to other factors than tubal patency and motility; all the work of Rubin and Sharman is based on the proven fact that the information obtained is definitely attributable to the fallopian tubes alone, and, if this is not assumed, then our conclusions from kymography at present are based on a false assumption.—I am, etc.,

Cheltenham.

STANLEY A. BOND.

SIR,—Mr. Albert Sharman in his interesting survey of utero-tubal insufflations (*Journal*, January 30, p. 239) refers to the question of failure of passage of the gas resulting from tubal spasm, and describes failure of action of spasmolytic drugs. In this unit we have, for the past three years, used amyl nitrite in all cases where the gas has failed to pass at a pressure of 200 mm. This is administered in the usual way by inhalation from a fractured glass capsule, and in a large proportion of cases has led to relaxation of tubal spasm and the passage of the gas, with subsequent demonstration of normal peristalsis at low pressures. In such cases the use of diphenhydramine before intercourse at mid-cycle has subsequently been recommended and a number of pregnancies have followed.

Amyl nitrite has also been used where difficulty has been encountered in passing a biopsy curette for endometrial biopsy, and in many cases relaxation of cervical spasm has been demonstrated which has enabled the biopsy to be completed. The action of amyl nitrite in these cases is similar to that seen in retained placenta with contraction ring. I would recommend the use of this drug in all cases of apparently negative insufflation, since it may avoid repeated interventions and also the false diagnosis of tube blockage. I may add that we have generally used it without anaesthesia, but that it appears to be equally effective with anaesthesia.—I am, etc.,

Worcester.

J. A. CHALMERS.

The Cerebrospinal Fluid in Diagnosis

SIR,—In his article on the cerebrospinal fluid (*Journal*, February 20, p. 449) Dr. J. N. Cumings has made several statements about the C.S.F. protein which are not supported by modern work.

He states that the protein is almost all albumin with only a trace of globulin. This is not true. Merritt and Fremont-

Smith, using chemical methods, found an A:G ratio of about 5:1. They probably measured only the γ globulin present. Kabat *et al.*,² using an immunological technique, found a similar value for the albumin: γ globulin ratio. However, Schneider and Wallenius³ found that cerebrospinal fluid subjected (after concentration by dialysis) to paper electrophoresis gave patterns similar to normal sera with A:G ratios of 1-2:1. Parallel examination of C.S.F. and serum from the same patient showed the protein components of the two to be similar.

Dr. Cumings gives the value of the C.S.F. protein for children as 10-15 mg.%. As long ago as 1928 Stewart,⁴ in 50 normal children, found an average value of 35 mg.% (S.D. 11), using a turbidimetric method. Dr. Cumings also gives the normal values for adults as up to 30 mg.%, although he admits that in elderly people values of 50-60 mg.% are sometimes found. Kabat gives a mean for adults of 37 mg.% (S.D. 8), also measured turbidimetrically. It is now well known that all turbidimetric methods are unreliable. When turbidities are read visually against standards, a common method, considerable errors occur sometimes of the order of 50% or more. Greater accuracy is got by using a photo-electric absorptiometer to read the turbidity, but when compared with Kjeldahl protein determinations on the same normal samples, the turbidimetric method gives an answer lower by about 10-20% (Hall, 1954, in press).

During the past five years I have used a biuret method employing a modified Weichselbaum reagent for C.S.F. proteins. The method gives excellent correlation with Kjeldahl determinations. Protein values for adults and children are a little higher than reported by previous workers, the average value being 40-50 mg.%. Values of 60-70 mg.% are not uncommon.—I am, etc.,

Prevention of Bovine Tuberculosis

SIR,—We were surprised to read Drs. R. W. Kind and M. C. Brough's suggestion (*Journal*, February 13, p. 372) that their cases of bovine tuberculosis emphasize the need "either for ensuring that the milk supply throughout the country must eventually come from accredited tuberculin-tested herds or the general pasteurization of milk." Surely the boiling of milk offers the only certain preventive measure and pasteurization but a reasonably safe alternative. Tuberculin-tested milk carries no guarantee; only in the past few months have we seen a larger but similar outbreak to the one in Leicestershire occur amongst children given milk from an accredited herd, the damage commencing shortly after a routine check of the cows.

We beg to suggest as an immediate preventive measure that, wherever possible, only pasteurized milk be issued to schools. In those instances where this is impractical parents should be notified so that those who wish may make alternative arrangements.—We are, etc.,

Depression Treated by E.C.T.

SIR,—I was most interested in the article entitled "Prognosis of Depression Treated by Electric Convulsion Therapy" by Dr. Hugh F. Jarvie (*Journal*, January 16, p. 132), and agree most strongly with his enunciation on the importance of critical assessment of the long-term results of this treatment. From his study of 114 cases of depression, Dr. Jarvie concludes that E.C.T. is an effective form of treatment in most cases of depression, but adds the rider that "its limitations in some 30 to 40% of cases should be recognized." He therefore shows himself to be far from an uncritical advocate of E.C.T. and it may therefore seem somewhat tendentious to submit his study to criticism. Nevertheless, the data on which he bases his conclusions

show one serious omission in that he has no adequate control group wherewith to compare his results. He has therefore, in my opinion, failed to prove how E.C.T. has altered the rate of recovery and prognosis, since he does not take into account the tendency to spontaneous recovery in depression—a factor unfortunately often suppressed or forgotten by many advocates of this form of therapy.

Dr. Jarvie's report is based on 114 cases of various types of depressive illness, but his conclusions on the effectiveness of therapy are drawn from 97 of these 114 patients, whom he regards as his "treated group." The number of convulsions administered to individuals in this series of 97 patients varied from a minimum of 2 to a maximum of 14 convulsions. The remaining 17 patients do not, however, provide an adequate control series, since Dr. Jarvie, in describing them, states that they "either did not receive E.C.T. or received such small amounts that it was regarded as not affecting the course of the illness" (italics are mine). One at least of these 17 received four convulsions before cardiac complications during administration dictated discontinuation of treatment. Four convulsions represent double the minimum number given in his "treated" series, and the elimination of such unsuccessful cases from the treated group obviously tends to weight the evidence in favour of E.C.T. as a form of treatment. Dr. Jarvie also does not give the time relationship between treatment with E.C.T. and recovery. Many patients submitted to E.C.T. do not show any amelioration of symptoms till some weeks or months after cessation of treatment, which gives rise to the suspicion that their recovery is not directly attributable to such treatment.

Some years ago I carried out a survey of 923 patients with a depressive illness admitted to the Royal Edinburgh Hospital for Mental and Nervous Disorders between the years 1930-48.¹ This period covered both the era preceding the introduction of E.C.T. and that following its utilization as a method of therapy. Many of the patients had been admitted on more than one occasion with recurrent depressive episodes, so that the total number of hospitalizations reviewed was 1,611. Eighty per cent. responded to a follow-up questionnaire by a personal visit or letter. The results of this survey—which were quite contrary to those envisaged by me at the commencement of the study—showed that (a) the percentage rate of recovery did not vary greatly whether patients with depression were treated conservatively or by E.C.T. Such slight differences as did exist were not statistically significant; (b) the use of E.C.T. did not shorten the duration of the depressive illness; and (c) did not prevent its recurrence. (Space does not allow of the quotation of figures, for which the original article can be consulted.)

This investigation emphasized the importance of having good control groups in the assessment of any therapy for depression, since the figures for the pre-E.C.T. era showed that 80% of the patients recovered. Of all the major psychoses, depression is recognized as having the best prognosis. An interesting finding was the considerable number of patients discharged "recovered" or "improved" within two months of admission without being submitted to E.C.T. Had E.C.T. been given as a routine measure within the first few weeks of their hospitalization, the recovery of these patients would no doubt have been attributed to its use. The clinical evaluation of E.C.T. showed that in some there was symptomatic improvement, and that recovery occurred only if treatment coincided with spontaneous recovery.

In conclusion, the findings emphasized the high expectation of recovery in depressive states and in turn underlined the necessity for the application of stringent criteria in the evaluation of any form of therapy which claims to accelerate this process of natural recovery. The need for a critical review of all physical methods of treatment in psychiatry has been long overdue, and it is hoped the profession will soon undertake such a study.—I am, etc.,

Montreal, Canada.

Galactosaemia

SIR,—Dr. B. Laurance is quite right to emphasize the frequency and possible severity of umbilical haemorrhage in babies with galactosaemia (*Journal*, February 20, p. 459), but we have no reason to suppose that bleeding from other sites is common. This possible tendency need not in any case interfere with investigations, for all blood samples that are needed can be obtained from a heel prick. We cannot agree that the diagnosis of galactosaemia can be confirmed by urine examination only. We recently investigated a 10-day-

old baby with severe jaundice and a large liver. The urine contained 0.95 g.% of reducing substance, almost all being galactose. The blood sugar, however, was only 85 mg.%. Some galactose is often found in the urine of neonates; the frequency of this is at present being investigated.—We are, etc.,

Medico-Legal

CARBON DIOXIDE TEST IN MURDER INVESTIGATION

The use of carbon dioxide to cause abreaction in a murder investigation was described during medical evidence at the Old Bailey last week. The trial was of Raymond Harold Barker, aged 35, an operator, who on March 4 was found guilty but insane on a charge of murdering Mrs. Beatrice Elizabeth James.

On December 15, 1953, Mrs. James was found dead at her house suffering from 60 stab wounds. A bloodstained bent vegetable knife was found in a hall-stand drawer. Barker was arrested two days later.

Giving evidence for the defence, Dr. Arthur Paterson said that Barker was suffering from mania-a-potu, and Dr. A. Rossiter Lewis said he had formed the view that Barker was suffering from manic-depressive insanity.

Replying to defending counsel, Dr. Paterson said he did not think that Barker had any control over the measure of his anger. If he was only angry with the woman he would have stabbed her in the heart or if there had been any carnal lust he would have mutilated her.

The judge said he did not follow entirely, and Dr. Paterson said there were three possibilities for a killing. One was that it was done in a state of automatism, the second that it was a sadistic attack, and the third was that he was sane and wanted to kill her. If Barker was sane at the time and simply wanted to kill the woman, then he would probably have aimed at a vital part such as the heart or the throat. In a case of lust, a man would kill a woman out of jealousy, or in a case of sexual perversion it would not be uncommon for him to rip a woman or mutilate her. The most probable explanation of the attack was that he was in a state of automatism and did not know what he was doing, because he stabbed her 60 times, only three being in vital places. He thought the state of the man's mind was due to acute alcoholism combined with a hereditary history of mental instability.

Dr. Rossiter Lewis said he decided first of all he would try to restore Barker's memory by questions, but was unsuccessful in getting details. On February 21, in the presence of the medical officer at Brixton prison, he gave Barker a mixture of oxygen and carbon dioxide (30%). Its object was to create an abreaction. It was done in two parts, the first lightly and the second more deeply, bordering on actual unconsciousness. On neither test was he able to restore the memory for the actual stabbing or what had been carried out immediately after the stabbing. His conclusion from this was that Barker's mind was so deranged at the actual time that the memory was non-existent in detailed form. "Based upon that, I came to the conclusion that at the time this offence was committed he was suffering from a form of insanity." He took the view that Barker's was a case of manic-depressive insanity which had shown itself as a result of the effect of alcohol on his brain.

Dr. J. C. McI, Matheson, principal medical officer at Brixton Prison, was called by the prosecution to give evidence of rebuttal. He said he had seen no signs of any mental abnormality. In his opinion Barker was sane at the time he killed the woman and knew what he was doing.

Dr. Desmond Curran, psychiatrist, was also called by the prosecution in rebuttal of medical evidence given by the defence.

Obituary

N. G. HORNER, M.A., M.D., F.R.C.P., F.R.C.S.
Editor, *British Medical Journal*, 1928-46

We announce with deep regret the death at the age of 72 on March 7 of Dr. N. Gerald Horner, Editor of the *British Medical Journal* from 1928 to 1946. He had been in ill-health for some time.

Norman Gerald Horner was born on January 1, 1882, at Tonbridge, Kent. His father, Arthur Claypon Horner, after serving with a Red Cross ambulance through the Franco-Prussian war, had been surgeon and naturalist to two Arctic expeditions before settling down

to general practice in Tonbridge, where he was medical officer to Tonbridge School. In later years Gerald Horner used to maintain that to be born and bred in a working doctor's home was a most valuable foundation to the life and work of a medical editor. He showed an early taste for journalism, and in his schooldays at Tonbridge produced 156 numbers of a weekly comic magazine, largely written and illustrated by himself, for family circulation. From the scientific sixth form he went to Caius College, Cambridge, and graduated B.A. in the Natural Sciences Tripos of 1902. After three happy and successful years at St. Bartholomew's Hospital he qualified M.R.C.S., L.R.C.P. in January, 1906, and served a term as house-surgeon at the Westminster Hospital. On return-

ing to Bart's as house-physician to his godfather and good friend Sir Norman Moore, he became editor of *St. Bartholomew's Hospital Journal*, of which he had already been assistant editor. Some of the many light pieces he wrote for its pages are still remembered, including "A Vision of the Second M.B.," "The Night Dresser's Dream," "The Keen Man," and "An Echo of the Past."

About this time Sir Henry Burdett had the idea of making the *Hospital*, hitherto largely concerned with administration, into a weekly paper for general practitioners, and he persuaded Horner to write for it and to join him later as assistant editor. This occupation, with interludes of general practice in town and country,

and clinical assistantships at Bart's and the Children's Hospital in Shadwell, lasted for two or three years. The technical experience in weekly journalism proved useful and led to his engagement in 1911 as assistant editor of the *Lancet* under Squire Sprigge, who had succeeded to the editorship two years before. He thus entered upon whole-time work in the office of a leading professional journal at the opening of the long-drawn-out National Insurance struggle, and he attended every one of the stormy Representative Meetings of the British Medical Association that began with the introduction of the Bill. The indoor staff of the *Lancet* were then, as now, on friendly terms with their colleagues of the *British Medical Journal*, while the close association with Squire Sprigge was full of profit and entertainment. But the proprietorship of the paper was changing hands,

and the war upset things further, so that when Horner took a temporary commission in the R.A.M.C. early in 1915 he parted company with the *Lancet*. While waiting for his commission he joined the Special Constabulary and he did night duty at Buckingham Palace for a time. He served in France for two years—with No. 14 Stationary Hospital at Wimereux, with No. 36 Casualty Clearing Station and the 97th Field Ambulance on the Somme, and as registrar of No. 10 General Hospital at Rouen. In 1917 he returned to England as assistant editor of the *British Medical Journal* and began to share with Sir Dawson Williams the conduct of the paper through a period of stress and strain and of readjustment to changing circumstances. Perhaps the heaviest test during

those early years came in 1920, when for five months Sir Dawson was incapacitated by the first and worst of the heart attacks that troubled him at intervals for the remainder of his life. After the lean years of the war, with their shortage of space and staff, the *Journal* gradually expanded, the *Epitome of Current Medical Literature* started again, and the editorial staff had to keep pace with reawakened activities of every kind both at the centre and locally. By the middle of 1927 it had become painfully apparent to those whose business brought them to Headquarters that advancing age and precarious health were taking heavy toll of the editor's strength. Sir Dawson Williams had lived for the *Journal* for the greater part of half a century and

[Elliott & Fry, Ltd., London]

shrank from the prospect of idleness; but, in accordance with arrangements made by the Council at its December meetings, he retired formally on January 18, 1928, the thirtieth anniversary of his appointment as editor, and Horner was appointed in his place.

Horner had graduated M.B., B.Ch. at Cambridge in 1910 and took the M.A. in 1919. He proceeded M.D. in 1922 with a thesis on the growth of the general practitioner in England, and read a paper before the International Congress of the History of Medicine, which met that year in London. For two sessions he was secretary of the History of Medicine Section of the Royal Society of Medicine and afterwards vice-president. At the Centenary Meeting of the British Medical Association in 1932 he opened a discussion on medical journalism in the British Empire with a paper which his friends of the *Lancet* published in the following week. The ready pen of youth was severely disciplined as time went on, so that from being fluent he became rather a fastidious writer, more concerned with lucidity and precision than he had been formerly. Beyond two short poems published during the war and a few historical papers, he wrote little after the age of 30 outside his own journal. No doubt his approach to the craft of letters was influenced by daily intimate contact for over ten years with Dawson Williams, for whom he felt a deep regard and admiration. While never trying to mould himself upon a man so different in habit of mind and intellectual texture, he nevertheless followed "the D.W. method" in the literary and business sides of an editor's work, and strove to impart this to his junior colleagues. For a piece of writing or of editorial revision he could give no higher praise than the word "workmanlike," which stood for him, as for his great predecessor, as the sovereign quality. The *Journal* certainly gained from his wide reading and constant thought and care for the English language.

Dawson Williams had been such a strong influence in the counsels of the Association for so many years, and more than anyone had been responsible for establishing the *British Medical Journal* as the outstanding general medical journal in the English-speaking world, as to make it difficult for anyone to succeed him with a feeling of equanimity. Horner had for his predecessor a deep respect which amounted almost to veneration. For years he had been Dawson Williams's right-hand man, and in one sense it can be said that even after his chief's death he still felt the force of this relationship. Extremely diffident by nature, he was almost at times too conscious of his predecessor's pre-eminence. Apart from this, when Horner succeeded to the editorship in 1928 the editorial department was in his view much understaffed, and ill-health in the small staff that there was doubled a burden that was already heavy enough. Between 1928 and 1931, three of his medical assistants had to resign because of illness, and there is no doubt that Horner felt that he could not have taken over the reins of office under greater disadvantages. It is true to say also that, rightly or wrongly, he thought the Association did not fully appreciate the difficulties under which he was then working. From 1930 onwards conditions gradually became more stable and he could be assisted by a small staff, who, under his guidance, had to gain their experience while working on the job. In 1934 the Association was able to appoint a deputy editor—the first time in the history of the *Journal* that such an appointment had been made.

During Horner's long editorship a number of important changes were effected in the management and printing of the *Journal*, all of which benefited from his help and experience, though in fact he took little part in initiating them, being by nature inclined to see in change disadvantages rather than advantages. About 1934 criticisms were voiced in different quarters about the physical appearance of the *B.M.J.* There was, for example, the sham gothic type on the cover, the rather grey effect of the printed page, the preponderance of printer's rules and other typographical devices which some described as old-fashioned. After the Journal Committee had made a preliminary survey of the situation it sought, at Horner's suggestion, the help of Mr. Stanley Morison, who was typographical adviser to the *Times*, the Monotype Corporation, and the Cambridge University Press, and the designer of the *Times* New Roman type. Work on the typographical reform of the *B.M.J.* extended over a period of months, and under Mr. Morison's inspiration and guidance a complete change was effected and the *Journal* appeared in its new dress on January 2, 1937. The device which has appeared on the cover since that date was designed by Mr. Eric Gill. In the discussion that went on round this subject it soon became evident that this change of format brought obviously to the front the need for a change in the method of printing the *Journal*. Up to the end of March, 1937, the Association had had its own composing room on the fourth floor of the North wing of B.M.A. House, and each week the formes were loaded on to a van in Burton Street to be taken to Fetter Lane for the final machining to be done. The *B.M.J.* must have been one of the few remaining periodicals of any size or standing which still maintained its own separate composing room. After much debate in committee and Council, the Association finally decided to dismantle its composing room and to have the *Journal* composed and printed in one and the same place. Undoubtedly this made for economy and efficiency, and speed of production, though many of the older members of the Council and, indeed, Horner himself, viewed with much regret the disappearance of the composing room of which they had every reason to be proud. When the printing works of Messrs. Eyre & Spottiswoode, who were responsible for printing the *Journal* from 1937 to 1941, were destroyed in an air raid on May 10, 1941, those responsible for the conduct of the *Journal* were relieved not to have a composing room on their hands. Monday, May 12, 1941, was a memorable day in the experience of the editorial department and, in particular, of the editor. When Horner arrived at his office on that day he and his staff were faced with the fact that they were without a printer and that blocks and type which had been prepared for that week's *Journal* had flowed down Norwich Street in a flood of molten metal. Under Horner's guidance, he and his much-depleted war-time staff gathered together bits and pieces of copy by lunch-time and by the middle of the afternoon had secured the willing co-operation of the Temple Press in Clerkenwell. A *Journal* was "made-up" by the end of the afternoon and went to press on time on the Wednesday, every member receiving his copy that week by the usual post. Horner happily christened this issue the "Phoenix Number." The risks of continuing to print the *Journal* in London were vividly brought home by this event, which at the time it was the fashion to describe as an "incident," and a decision was quickly made to transfer,

if possible, the printing of the *Journal* outside London. Horner himself had always been used to having a printer near at hand, and he was indeed dismayed at the difficulties that might arise if the *Journal* was printed outside London while it continued to be edited from B.M.A. House. When a decision was finally taken and Messrs. Fisher, Knight & Co. agreed to print the *Journal* at St. Albans, Horner had no wish to follow the printing into the relative security afforded by a town nineteen miles from B.M.A. House. To the end of the war he continued his work as editor in London.

On top of the stress and strain inseparable from an experience shared by all other Londoners, Horner had the grave misfortune, in the winter of 1942, to suffer a detachment of the right retina. He decided not to take the chance of partial recovery of sight in that eye which operation might have given him. Thereafter his health suffered and he was compelled by illnesses to remain away from work for months at a time. Nevertheless, even when in hospital he still continued to do what work he could for the *Journal*.

In spite of these difficulties—if the evidence of outside observers is to be accepted—the *Journal* gained in support and prestige throughout the war years. Not only that, but during these years it was found possible for the Association to undertake the publication of new quarterly journals. In 1939 the Association was publishing the *Archives of Disease in Childhood*, the *British Heart Journal*, and the *Journal of Neurology*. During the war, in conjunction with the Association of Industrial Medical Officers, the *British Journal of Industrial Medicine* was launched in 1944. In 1944, too, in co-operation with the Empire Rheumatism Council, it began publishing the *Annals of the Rheumatic Diseases*. It laid plans for the publication of *Thorax*, the first issue of which was published in 1946. Before the war ended a scheme was worked out for establishing an abstracting service, and *Abstracts of World Medicine* and *Abstracts of World Surgery, Obstetrics and Gynaecology* as a result of this made their appearance at the beginning of 1947. Although because of ill-health Horner was able to take little part in the initiation of these, he gave all these various projects his help, encouragement, and guidance, and was the author, for example, of the title under which the abstracting journals were finally brought out. When he retired at the end of 1946 under the age limit, he was able to pass on to his successor a *Journal* that had grown in prestige and circulation, and an editorial structure that had stood the test of time. More important still, he handed on a sound tradition of responsible editorship which he himself had inherited and had maintained intact from the corrosion that is sometimes the result of the passage of time. He was scrupulous, perhaps at times over-scrupulous—if this is, indeed, possible—in the use of the English language, and nothing could ruffle him more than an infelicitous phrase, an apparent breach of etiquette, or work that was in any way slovenly or unfinished.

Horner suffered from a sensitivity that made him vulnerable to the criticisms and attacks to which any editor of any responsible journal is always exposed. Extremely diffident by nature, he felt at times overburdened by the responsibility of his post. Yet to the outside world he showed little of this, his philosophy being, as he used to say, that of the stoic. Of the many tributes paid to him in his career he valued above all his election as F.R.C.P. (under by-law xxxix (b)) in

1939: he was made F.R.C.S. in 1942. His attachment to the B.M.J. and all its fortunes was deep and abiding, and though he knew he had to retire at the age limit, to leave his office even though his health was poor was a severe wrench. To his colleagues he was unfailingly courteous and helpful. His mastery of the English language was a continuing example to them. Whatever difference of opinion there might be, Horner always remained patient, and was, above all, just and fair in his dealings.

Outside the *Journal* Horner's other strong attachment was to his club, the Savile. To meet him there was really to meet a different person—to meet someone who was a kind and considerate host and a witty and light-hearted companion. Towards the end of the war he began to live at his club and there he remained until his last illness. Above all he used to enjoy meeting there men eminent in other walks of life. He had a wide interest in literature and art, and a skill in writing that was the envy of his colleagues. It is a matter for great regret that on his retirement ill-health made him, no doubt, disinclined to put down on paper his reflections on the medical scene of which he had been for so long a detached and judicious witness. For a time after 1947 he lent a hand in the compiling of the medical history of the war, thus returning to an early interest. His wife, Grace Malleon Fearon, died in 1950. He leaves one son.

Sir ROBERT YOUNG writes: Gerald Horner was appointed assistant editor of the *Lancet* when I was a member of its staff. It was quickly apparent that he was a man with great charm of manner and a kindly personality. I came to regard him as a friend, and he was always helpful in suggestions and ideas. He was an excellent sub-editor, and I know that Sir Squire Sprigge, who was at that time the very distinguished editor, had a high opinion of him and found him a valuable and reliable member of his staff. Horner had a wide knowledge of medical matters, a keen and incisive mind, and considerable literary gifts.

His work for the *British Medical Journal* is well known to readers and to the Association, which has been very fortunate in its sequence of editors. Horner was well worthy of his place in that distinguished roll. Ill-health had for some years handicapped his activities and allowed his friends the chance of meeting him but seldom. I saw him some months ago at the Savile Club, when he greeted me in his old friendly manner and expressed his pleasure at reviving old associations. He was a good friend, and I have happy memories of him.

Professor ALAN MONCRIEFF writes: Horner set and himself maintained a high standard of medical journalism. Nearly 30 years ago he purged my early efforts of clichés and got rid of superfluous or repetitive matter. He was always kind to juniors and encouraging, although as I got to know him better I realized that he could be almost blistering if he liked. He had a very subtle and caustic wit, and loved a good verbal quip. He had indeed a real interest in words and their use. I do not think he liked committee work. He preferred to get on with his direct editorial duties, but it was sometimes surprising to realize how little of the business side really escaped his notice. He had a difficult task to follow Dawson Williams, but I should judge that he left the *Journal* at a higher standard than when he took on, with a better standing in the scientific world.

Dr. HENRY ROBINSON writes: There is no doubt that Horner's apprenticeship under, first, the late Sir Henry Burdett, editor of the *Hospital*, and then under Sir Squire Sprigge, of the *Lancet*, taught him much about the technical side of newspaper production—type, paper, format, etc.—

which, together with what he learned from Sir Dawson Williams later, was to prove of great service to the B.M.A. and to the *Journal* later on. At the numerous meetings of (the late) Dr. Ronald Gordon's subcommittee in 1935–6 his advice was often sought, and never in vain: he rarely intervened in the discussions unless appealed to by Gordon, but whenever he did speak his contribution was always very much to the point. The outstanding success of the reorganization which followed was due, in part, to his sage counsel and loyalty.

Horner was never a robust man, physically or constitutionally, and his many friends at the Savile noted two years ago with deep concern a gradual but steady deterioration of his health. To celebrate his seventieth birthday the members entertained him at a complimentary dinner, where poems composed for the occasion were recited in his honour—one was entitled "An Ode on a Distant Prospect of Gerald Horner." But he was already too much indisposed to make a reply such as a few years earlier would have been full of *bons mots*. A notable characteristic of the Horner touch was that his wit was never malicious and never left a sting. Though impatient of anything slipshod in the use of the English language, he was not pedantic: his appreciation of a felicitous touch or allusion in the work of his contributors or subordinates was genuine and warmly expressed.

T. JENNER HOSKIN, M.D., F.R.C.P.

By the untimely and sudden death of Dr. Jenner Hoskin on February 27, the Royal Free Hospital has lost a well-loved senior physician, its staff and students a wise and kindly friend. He was 65 years of age.

Theo Jenner Hoskin was born into a medical family on December 12, 1888, and after receiving his early education at Charterhouse proceeded to Trinity College, Cambridge, and the Middlesex Hospital, from whose medical school he graduated in 1914. After a few pre-liminary house appointments he joined up and served with distinction throughout the remainder of the first world war, taking part in such historic events as the landing at Suvla Bay. At one time or another he served in Egypt, Gallipoli, German East Africa, and Sierra Leone, and he was mentioned in dispatches.

After demobilization he embarked on further post-graduate study and training, notably at the Heart Hospital, where for years he worked in association with the late Dr. Strick-

(Elliott & Fry, Ltd., London)

land Goodall. Success came with his appointments to the honorary staff of Queen Mary's Hospital for the East End and, very shortly after, in 1924, as honorary assistant physician to the Royal Free Hospital. Owing to a succession of retirements he rose unusually rapidly in seniority, and for the last 16 years of his life was senior physician to the hospital. Further appointments included that of cardiologist to St. Paul's Hospital for Genito-urinary Diseases, physician to the Royal National Throat, Nose, and Ear Hospital, and chief medical adviser to both the Pearl Assurance Company and the Friends' Provident and Century Life Office. He belonged to many learned societies: one he appreciated most was the Medical Society of London, of which he

was president in 1948. The climax of his distinguished career came in the latter part of last year, when he was elected to the council of the Royal College of Physicians, an honour which gave him unusual pleasure. Not a prolific writer, he contributed from time to time to specialist journals, his words carrying both good sense and authority. One of the first papers he wrote (entitled "Five Hundred Cases of Malaria in Pensioners") was published in this *Journal* in 1921. Beyond his professional sphere he enjoyed a full and active life, being a liveryman of the Skinners Company and at one time master of the Worshipful Company of Playing Card Makers. His interest in all forms of sport was well known, and until latterly he was himself an active and keen golfer.

One of the first to appreciate the need and value of specialist departments, he speedily succeeded in building up a cardiological department in the Royal Free, deciding at the same time, in his natural humility, to limit his private patients to the cardiological field in order to give the best, and only the best, advice to both family doctor and individual patient. His art—for medicine with Jenner Hoskin was always an art rather than a science—was perhaps best demonstrated by his management of patients. Ever more interested in people than in disease, and recognizing the futility and frustration of invalidism, he had a special skill in helping the handicapped back, if not to perfect health, to as full and active a life as was practicable.

In the Royal Free Hospital he found himself for the first time in the unfamiliar surroundings of a women's medical school and training hospital. After a few hesitant teaching rounds he speedily established that attitude of easy and genial informality that lastingly endeared him both to students and to junior medical staff, while losing him nothing in respect. From then on he identified his interests with those of the hospital which he was so long to serve. He taught assiduously and skilfully and was noted both for punctuality and for regular attendance. Nothing would have ever caused him to neglect his hospital duties for private concerns. It might have been thought that the Royal Free Hospital was his life if it were not known that he brought an equal interest and enthusiasm to the claims of his wide consultant practice and to his insurance work.

He was a man of complete integrity, of unswerving high standards, and a stickler for good taste. As a colleague he was all that anyone could want and more. Unfailingly loyal, disarmingly courteous, striving to promote harmony and to discourage acrimony, exerting always a moderating influence, he became the trusted counsellor to many who knew his quality and his wisdom. The reliance placed on his judgment and experience was illustrated in this last year by his re-election as chairman of the medical committee of his hospital. Possessing a remarkable memory for people, he had the reputation of being able to name every student who had ever passed through his hands. Equal to this splendid memory was an astute and almost faultless judgment of persons, by which he managed time after time to appropriate the outstanding student for his own house-physician, sometimes to the chagrin of his colleagues. All who ever worked for him became bound in affectionate respect and thereafter could count on his continued and wholehearted support. No effort was wasted, no time ill spent, that furthered the career of his protégées.

In his home life Jenner was singularly fortunate. His wife, Maisie—daughter of Mr. William Stewart, of Skelmorlie, Ayrshire—whom he married in 1920 and who survives him, was the perfect partner, and their happy and contented home life was not only an inspiration to all who enjoyed their hospitality but provided the peaceful background essential to his restless spirit. Maisie Hoskin devoted herself completely to his interests, and not a little of his success and the freedom with which he spent his gifts and energies depended on her. To Mrs. Hoskin, his daughters Margaret and Mary, and his son, Christopher, still at his own old school, we extend deep sympathy.—U. C. L.

We are indebted to Dame LOUISE McILROY for the following appreciation: The sudden death of Dr. Jenner Hoskin has come as a shock to all his friends, of whom he had very many. All who knew him had a great regard for him and an appreciation of his distinguished work as a physician. He devoted much of his time and skill in helping in the diagnosis and treatment of the cardiac conditions of women in pregnancy and childbirth in the Royal Free Hospital. I have always been grateful to him for the infinite trouble he took over patients not only in London but when he served on the consulting staff of the Officers' Wives Maternity Hospital at Fulmer Chase, Bucks, during the war. Dr. Hoskin always took a very personal interest in the teaching of students, and his influence on the training of young graduates was profound. His endearing personality will long be remembered. The sympathy of all his friends will go out to his devoted wife and family in their irreparable loss.

Dr. G. CATHERINE EVANS writes: Others will have written about Dr. T. Jenner Hoskin's professional and academic achievements, not only as an outstanding cardiologist, but as a physician whose breadth of vision and interests were unusually wide. Some will have mentioned his election a few months ago to the council of the Royal College of Physicians, an honour which gave such pleasure and satisfaction to his colleagues and friends. But I would like to pay tribute to his memory not only as an old student but as a patient of his for the last 34 years. Dr. Jenner Hoskin was an excellent teacher. His ward rounds were deservedly popular, for he had the happy knack of using a homely simile to impress some particular point, which consequently became indelibly printed on his students' minds. His devotion to his hospital work was unstinted, and he gave full measure in furthering the interests of the students and nurses. Every patient I sent to him without exception came back gratefully impressed by the scrupulous care and trouble he took in assessing their case. He had the gift of putting his patients quickly at their ease and giving them complete confidence in his judgment. Knowing him as his patient for so many years, I always found him to be not only a skilled clinician but a never-failing wise counsellor and kind friend.

T. W. MORGAN, M.B., B.S.

Dr. T. W. Morgan, a former member of the Council of the British Medical Association, died on February 27 in Westminster Hospital. His untimely passing at the age of 53 after a short illness is a sad blow to his many friends and patients.

Thomas Walter Morgan, who was born on June 20, 1900, received his medical training at Cardiff and at St. Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1927 and taking the London degrees of M.B., B.S. three years later. After a series of resident appointments at the Westminster Hospital, where he was also assistant surgical registrar and radium officer, he became a general practitioner and for twenty years conducted a large general practice in New Malden and district with

exceptional ability and skill. He gave himself unsparingly to the best interests of his patients, and throughout the years was the family counsellor and friend of many of them. His efforts to bring to the aid of his patients in all walks of life, at home or in hospital, the expanding resources of modern medicine and surgery occupied nearly the whole of his time and energies; and his patients, once the first encounter with him had been successfully achieved, stuck to him with fierce loyalty. His quick and discerning mind always sought to reach the heart of any problem brought to him.

Dr. Morgan had a ready grasp of medico-political matters. His clarity of thought and happy ability to speak well in public opened to him a wide field, in which he worked hard to preserve and maintain the highest ideals of medical ethics. His energy and organizing powers were remarkable, and with these he combined a sense of humour and good fellowship which won him many friends. These gifts he put generously at the service of the British Medical Association, his local hospitals, and National Health Service committees. He was a member of the Council of the Association from 1947 to 1952 and represented his constituency at all the Annual Representative Meetings from 1942 up to last year. Among the many committees on which he served, the Central Ethical, the Private Practice, and the Health Centre Committees benefited most, in length of time, by his membership. Locally, he acted as honorary secretary of the Kingston-on-Thames Division from 1945 to the time of his death; he was chairman of the Division from 1942 to 1945; and president of the Surrey Branch in 1951-2. His work for the Kingston Victoria Hospital, of which he was chairman of the medical board for many years, brought him into nation-wide prominence and will be remembered as long as the re-organization of the hospitals under the National Health Service Act is discussed. Although he did not succeed in saving the Victoria Hospital from absorption, when the decision that it should be taken over was made he showed his sterling qualities by immediately deciding to give of his best under the new regime. Largely owing to his efforts another general-practitioner hospital now exists in place of the old Kingston Victoria Hospital.

His influence on local medical affairs was great. At the time of his death he was a Treasury medical officer, medical officer to the Borstal reception centre at Latchmere House, Ham, member of the Surrey Executive Council, and a co-opted member of the Surrey County Council's health and ambulance committee. He served the Wimbledon Hospital as an honorary physician and as vice-chairman of the medical staff committee and was vice-chairman of the Surrey Local Medical Committee. He was a past master of the freemasons' lodge at Westminster Hospital and had recently joined the Malden rotary club. During the last war, as a member of the local air raid precautions service, he was one of the first medical officers to be called into action as a result of enemy air attacks.

At the memorial service held on March 4, Christ Church, Malden, was crowded by a gathering of all his associates, representative of every section of the community in which he lived and worked. In the address a remarkable tribute was paid by his old friend, the Rev. H. E. Baldwin, and for many the memorial service lightened the shock and sense of loss of his passing, leaving instead a feeling of gratitude and encouragement from his great example. He leaves a widow and two sons, to whom we extend our deep sympathy.—J. W. S.

Medical Notes in Parliament

Service in the Colonies

Mr. JOHN TILNEY asked the Secretary of State for the Colonies on March 3 what arrangements there were for seconding doctors from the National Health Service to the service of Colonial governments; and how many were at present seconded to Nigeria and the Gold Coast respectively.

Mr. J. G. FOSTER, the Under-Secretary for Commonwealth Relations, said that hospital authorities had power to second members of their medical staffs in suitable circumstances to overseas and other posts. In addition, Health Service hospital doctors might take up employment in the Colonial Medical Service for periods up to six years, with continuing participation in Health Service superannuation. The salaries and general conditions of service of doctors so employed were similar to those for doctors on the permanent establishment. On reversion to employment in this country a gratuity was payable. One doctor was serving in Nigeria and three doctors in the Gold Coast under these latter arrangements.

Mr. TILNEY said that in Northern Nigeria there was only one doctor for every 64,000 people. He asked the Minister to discuss with the Minister of Health what might be done to make seconding better known and more popular. Mr. FOSTER agreed, and said the trouble was partly due to the recent creation of the posts and partly to reluctance to accept a new idea.

Fowl Pest Infection in Men

Mr. DENYS BULLARD asked the Minister of Health on March 4 if his attention had been drawn to the danger that four men in Norfolk might have contracted fowl pest after helping with the slaughter of chickens among which the disease had occurred. Miss PAT HORNSBY-SMITH, Parliamentary Secretary, said the Minister was advised that this disease, although in a limited sense transmissible to man, was not readily passed on among human beings. The only known clinical form of the disease in man was a mild inflammation of the eyes without constitutional disturbance. In the instance referred to the men were back at work. She added that, while it was not unreasonable to attribute the eye condition in the men concerned to contact during work with diseased fowls, laboratory tests did not confirm the association.

Consultant Service

The MINISTER OF HEALTH, having told Dr. BARNET STROSS on March 4 that all regional boards, in suitable cases, allowed transfers from whole-time to part-time medical service, was asked for his own view about this. Dr. Stross had expressed the view that the service was not best served by full-time consultants transferring to part-time. Mr. MACLEOD suggested that no such generalization could be drawn. The policy that all boards allowed transfers, subject to the needs of the service, was based on the 1948 circular, and there had been no change in that. He believed that a part-time consultant service was a very good thing, and he certainly had no evidence to show that there was any deterioration in the service provided.

Mr. A. BLENKINSOP said that some regional boards were offering the maximum number of part-time sessions, as an alternative to full-time sessions, to the greater detriment of the service. Mr. MACLEOD replied that boards might well interpret circulars, and particularly the 1948 circular, in different ways. There were different trends in different regional boards, but he had no reason to think that boards were not applying their general policy to individual cases—which was what mattered—in a reasonable manner.

Answering another question by Dr. STROSS, Mr. MACLEOD said the financial effect of such a hypothetical circumstance as the abolition of the part-time consultant service and its replacement by a full-time service could not possibly be assessed.

Dr. STROSS suggested that the saving would be considerable. Full-time consultants, he said, were not allowed any of the perquisites, such as expense allowances, of part-time service. If there could be a switchover to full-time service, would it not be possible to make the service more attractive financially? Mr. MACLEOD pointed out that matters of remuneration went back to the Spens Report. Any suggestion of abolition of the part-time service would be a breach of faith with the profession. Mr. SOMERVILLE HASTINGS said the payment for travelling time and expenses inflicted great cost on the service. The withdrawal of these facilities, which applied only to part-time officers, would save a lot of money and give the opportunity to improve the service in other ways. Mr. MACLEOD replied that he understood the point, but did not agree with it.

Mr. BLENKINSOP asked if the Minister was aware of the financial advantages enjoyed by part-time specialists employed by hospital authorities in comparison with those employed full-time, and whether he would refer the matter to the Guillebaud Committee for their consideration in view of the heavy cost of payments for travelling time and domiciliary visits charged by part-time specialists. Mr. MACLEOD replied to this that he was aware of the arrangements which were agreed in 1949. It was open to the committee to consider the point made by Mr. Blenkinsop, but it would not be appropriate for him, as Minister, to ask them to inquire into particular topics. He added in a further reply that any adjustment in terms and conditions of service was far better left to the medical Whitley Council, where it could be fully discussed.

Consultants' Salary Claim

Mrs. JEAN MANN asked the Minister of Health on March 4 what negotiations were in progress regarding salary scales to consultants, S.H.M.O.s, and registrars.

Mr. IAIN MACLEOD replied that a claim was before the Whitley Council, and the hon. Member would not expect him to make a statement while it was under consideration.

Mrs. MANN said that it had been under consideration since the Spens Report a number of years ago. General practitioners had had their pay settled under the Danckwerts award more than a year ago. Could the Minister not do something to speed this matter up, or did he enjoy the delay? Mr. MACLEOD replied that it had not been under consideration for quite as long as that, although it had been under consideration for a very long time—some 16 or 17 months, which was a very long time indeed. "I had a meeting on this subject this morning. There will be no unnecessary delay, and I think we are now nearing conclusion on the matter. . . . This is a matter of the most profound importance, which will have repercussions in many other fields."

Cotton-wool for Cushions

Five questions, concerned with the use of cotton-wool obtained under a Health Service prescription for stuffing cushions, were addressed to the Minister of Health on March 4. Mr. GEORGE JEGE, who had tabled the first three, wanted to know: (1) what action was taken against doctors who prescribed medical and surgical material without inquiring for what purpose it was required; (2) what instructions were given to doctors to ensure that they ascertained that medical supplies were necessary before they prescribed them; and (3) if he was aware that a doctor in the East Midlands had prescribed cotton-wool in large quantities, without satisfying herself of the purpose for which it was requested, and that it was afterwards used for stuffing cushions, and if he would instruct the appropriate executive committee to investigate and take action.

Mr. IAIN MACLEOD answered that a practitioner should prescribe only what was necessary for proper treatment, and if the cost of his prescribing was in excess of the amount necessary on this basis a sum might be withheld from his remuneration. "I am sure that practitioners are co-operating

in an endeavour to avoid excessive prescribing. I see no necessity for any special action in this case."

Mr. JEGGER asked if the Minister would investigate this case, in which Lady Barnett, while acting as a doctor, prescribed cotton-wool in excess of the amount required; and whether any action had been taken, as she was a well-known Conservative worker, while other doctors who had prescribed cod-liver oil and malt had been fined for excessive prescribing. Mr. MACLEOD said that Mr. Jeger sought to show, on the basis of one case, that there had been abuse. What he had not said was that this happened in the autumn of 1948.

Mr. NORMAN SMITH said that this story was told by Lady Barnett a few weeks ago. Mr. HORACE KING said the Opposition had always taken the view that abuse in the Health Service could take place only with the connivance of doctors, dentists, and opticians. Was it not wrong that a Tory doctor should use her professional shortcomings as propaganda against the Health Service? Mr. MACLEOD said there was nothing in the reports he had read to justify the Opposition statements.

Dr. EDITH SUMMERSKILL asked whether the Minister did not think it would be in the interest of the Health Service for him to say that this case was unique, and that no similar case had been brought to his notice. Mr. MACLEOD said that certainly no similar case had been brought to his attention. Both he and the executive council had better things to do than inquire whether or not seven years ago a patient had or had not used appliances correctly.

Vital Statistics

Week Ending February 27

The notifications of infectious diseases in England and Wales during the week included pneumonia 869, scarlet fever 1,463, whooping-cough 2,098, diphtheria 11, measles 2,099, dysentery 910, acute poliomyelitis 24, paratyphoid fever 5, and typhoid fever 3.

Infectious Diseases

Infectious diseases were slightly more prevalent in England and Wales during the week ending February 20. The increases in the number of notifications included 183 for whooping-cough, from 1,916 to 2,099, 98 for measles, from 1,846 to 1,944, 85 for dysentery, from 669 to 754, and 62 for scarlet fever, from 1,161 to 1,223.

The largest variations in the incidence of measles were an increase of 58 in Norfolk, from 328 to 386, and a decrease in Cumberland, from 200 to 143. The largest fluctuation in the trends of whooping-cough was a fall of 47 in Kent, from 120 to 73. 19 cases of diphtheria were notified during the week, being 8 more than in the preceding week. The chief feature of the returns of diphtheria was a rise in Lancashire from 1 to 5. Only small variations were recorded in the local trends of scarlet fever.

19 cases of acute poliomyelitis were notified. These were the same number for paralytic and 2 fewer for non-paralytic cases than in the preceding week. The largest returns were Devonshire 4 and Yorkshire West Riding 3. The only administrative area with more than one case was Plymouth C.B. with 4.

The continuous rise in the incidence of dysentery during the present year has resulted in the notifications reaching a level that has not been exceeded for almost two years. The rise during the week reviewed was mainly contributed by established outbreaks, and no new outbreak of any size was reported. The largest centres of infection were Lancashire 185 (Bolton C.B. 43, Eccles M.B. 30, Preston C.B. 23, Preston R.D. 17), Yorkshire West Riding 114 (Leeds C.B. 37, Bradford C.B. 34, Keighley M.B. 19), London 90 (Islington 31, Hackney 21), Staffordshire 68 (Cannock U.D. 52, Cheadle R.D. 10), Kent 59 (Tonbridge R.D. 19, Sevenoaks

R.D. 18), Middlesex 50 (Ealing M.B. 15, Enfield U.D. 14), Norfolk 32 (Norwich C.B. 29), and Essex 25 (Waltham-stow M.B. 13).

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus ———, the figures for 1954 thus ———. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 20 (No. 7) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Medical News

A Great Benefaction to Nottingham University.—Boots Pure Drug Company Ltd. has given Nottingham University £100,000 to endow two new Chairs in honour of Lord and Lady Trent. The Chairs are the "Lord Trent Chair of Pharmaceutical Chemistry" and the "Lady Trent Chair of Chemical Engineering." Lord Trent, son of Jesse Boot, the founder of Boots, has only recently resigned from the chairmanship of the company, a position he had held for 26 years. When in 1948 Nottingham University College was raised to the status of a university, Lord Trent became its first Chancellor. Before that he had been in turn a member of the University College Council (since 1923), its chairman, and in 1945 President of the College. The two new Chairs commemorate the work which he and Lady Trent have done both for the company and for the City of Nottingham. On March 3, when the gift was announced, the Court of the University heard with very great regret of the resignation of their Chancellor because of ill-health.

Annual Meeting of Irish Medical Association.—The programme for the annual meeting of the Irish Medical Association, which is being held at Killarney this year, starts with the opening of the medical exhibition by the president of the I.M.A. at 3.30 p.m. on July 6. On the next day, after religious services, there are the annual general meeting itself and in the evening the President's Reception. On July 8 and 9 there will be papers and discussions on the subjects "Drug Eruptions: Old and New," "Genito-Urinary Emergencies in General Practice," and "Recent Advances in Paediatrics." The annual dinner will be held on July 8, and a dance in aid of the Royal Medical Benevolent Fund on July 9. On the last day of the meeting, Saturday, July 10, there will be clinical demonstrations at the Mental Hospital, Killarney. Further information may be obtained from the Medical Secretary, 10, Fitzwilliam Place, Dublin.

Exchange of Teachers.—The Foreign University Interchange Scheme provides each academic year for an agreed number of visits each way between members of university staffs in the United Kingdom and those in 13 other European countries. The purpose of the visits is to promote academic contacts and to facilitate the exchange of information about recent research. The cost is shared equally between the participating countries, and in Britain the scheme is administered by the British Council. Among the medical teachers visiting Europe this month under the scheme are Professor J. McMichael from the Postgraduate Medical School, London (to Vienna, Graz, and Innsbruck universities), and Professor J. H. Burn, professor of pharmacology at Oxford (to the universities of Louvain and Liège).

Special Number of "Family Doctor."—The March issue is a bumper number to coincide with the venture of taking a *Family Doctor* stand at the Daily Mail Ideal Home Exhibition. Apart from the bright reader-winning picture of a baby on the cover, there are 49 pages of text and 58 pages of advertisements in this issue, and the whole magazine shows a high professional finish which should put it on good competing terms with its rivals. The principal medical articles are those by Sir Allen Daley on preventive medicine, Dr. Walter C. Alvarez on "How to Live with Your Blood Pressure," Dr. Greville Park on rashes, Dr. T. Traherne on schizophrenia, and Dr. G. K. Selborne on the psychology of breast-feeding. Other attractive features are an opening article by Elizabeth Bowen, the novelist, and a useful six-page guide to the keeping qualities of various foods at room temperature or in the refrigerator, ice-chest, or deep-freeze. *Family Doctor* costs 1s. 6d., and is published every month.

Royal College of Surgeons in Ireland.—On the occasion of the Charter Day Dinner of the Royal College of Surgeons in Ireland on February 13, the President, Mr. M. P.

Burke, conferred the Honorary Fellowship of the College on Sir Cecil Wakeley, President of the Royal College of Surgeons of England. The introductory oration was delivered by Mr. William Doolin, Secretary and Councillor.

Chair of Biochemistry at Oxford.—Sir Rudolph Peters, F.R.S., is retiring from the Whitley Professorship of Biochemistry at Oxford at the end of September. Applications for the chair are invited, not later than April 29, in the March 4 issue of the *Oxford University Gazette*. Sir Rudolph Peters, who will be 65 next month, is particularly noted for his studies on vitamin B₁₂ which paved the way for his work on arsenic poisoning and the discovery of B.A.L.

Dr. Daniel Merlin Pryce, reader in morbid anatomy at St. Mary's Hospital Medical School, has been appointed to the London University chair of morbid anatomy tenable at St. Mary's. Dr. Pryce will take up his appointment on October 1 in succession to Professor W. D. Newcomb.

Basildon and District Medical Society.—This society held its inaugural meeting recently. Any doctor interested in joining the society should get into touch with the honorary secretary, Dr. John Z. Garson, 48, Worthing Road, Laindon.

Dr. T. M. Ling, who led the B.M.A. mission to Latin America in 1951 (*Journal*, April 5, 1952, p. 756), has been made a Member of the Order of Carlos J. Finlay by the President of Cuba.

COMING EVENTS

Professor Max Rosenheim will deliver the Oliver-Sharpey Lectures on March 16 and 18 at 5 p.m. at the Royal College of Physicians. His subject will be "The Treatment of Severe Hypertension."

Christian Medical Fellowship.—The Fellowship will hold an open meeting on March 16 at 8.15 p.m. in the hall of the Royal Empire Society, Northumberland Avenue, London, W.C.1. The chairman will be Sir James Paterson Ross and the speaker Dr. D. Martyn Lloyd-Jones. Further details may be obtained from the Secretary of the Fellowship, 39, Bedford Square, London, W.C.1.

London Marriage Guidance Council.—A course of five lectures on marital problems for postgraduate medical students is being held at the Royal College of Nursing, Henrietta Place, Cavendish Square, W.1, weekly on Wednesday evenings at 7 p.m., starting on March 17. The speakers are Dr. P. L. Backus, Dr. Ethel Dukes, Dr. Clifford Allen, Dr. Philip M. Bloom, and Dr. H. V. Dicks. The fee is one guinea, and applications for enrolment should be made without delay to the Secretary, London Marriage Guidance Council, 78, Duke Street, Grosvenor Square, London, W.1.

The United Hospitals' Festival Choir.—A special performance of the *Messiah* will be given at the Royal Albert Hall on March 23 at 7.30 p.m. Tickets at 10s., 7s. 6d., 5s., and 3s. 6d. are available from the Royal Albert Hall and the usual agents.

London Medical Orchestra.—The orchestra will give its first musical evening for members of the medical and dental professions, and their friends, at B.M.A. House on April 3 at 8 p.m. The programme will include a rarely heard oboe concerto by Haydn, a concert aria by Mozart, and Schubert's Unfinished Symphony. Admission will be by programme obtainable at the door, price 2s. 6d.

The Boat Race.—Messrs. Vitamins Ltd. announce that they have available a number of tickets for doctors who may wish to view the Boat Race on April 3 from the Bemax premises. Early application should be made to Dept. B.R.1, Vitamins Ltd., Upper Mall, Hammersmith, London, W.6.

Course in Child and Family Psychiatry.—The department of child psychiatry, Ipswich Group Hospitals, offers a refresher course for school medical officers and other medical practitioners from April 5 to 9 inclusive. There is no fee. Places in the course will be allocated in order of application to 11, Fore Street, Ipswich.

Brompton Hospital Association.—The third dinner of the association will be held on April 23 at the Waldorf Hotel, Aldwych, London, W.C.2, at 7.15 for 8 p.m. Dr. A. Hope Gosse, the president, will be in the chair. The cost of the dinner will be 25s., and as accommodation is limited early application is advised. Informal dress.

NEW ISSUES

Abstracts of World Medicine.—The March issue (Vol. 15, No. 3), which is now available, contains abstracts of important papers drawn from medical and other scientific journals published in some 20 different countries and in all five continents. The subjects covered range over the whole field of clinical medicine and include pathology, pharmacology, and chemotherapy; there are also sections dealing with public health, industrial medicine, forensic medicine and toxicology, anaesthetics, radiology, and the history of medicine.

Issued monthly; annual subscription £4 4s., single copy 8s. 6d.; a specimen will be sent free on request.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, March 15

●HUNTERIAN SOCIETY.—At Talbot Restaurant, 64, London Wall, E.C.4, 7 for 7.30 p.m., dinner meeting. Discussion to be opened by Professor L. P. Garrod and Dr. O. B. Mitchell-Heggs: The Misuse of Antibiotics.

Tuesday, March 16

HARVEIAN SOCIETY OF LONDON.—At Royal College of Surgeons of England, 8 p.m., Harveian Lecture by Dr. A. H. Douthwaite: Problem of Duodenal Ulceration.

ILFORD MEDICAL SOCIETY.—At King George Hospital, Ilford, 8.45 p.m., Dr. H. C. Faulkner: Group Practice.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. P. Wade: Treatment of Epithelioma of the Skin.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Oliver-Sharpey Lecture by Dr. M. L. Rosenheim: Treatment of Severe Hypertension.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE: EDINBURGH BRANCH.—At West Medical Theatre, Edinburgh Royal Infirmary, 5 p.m., annual general meeting. Dr. C. A. Hopkins, Ph.D.: Filariasis in the West African Rain Forest.

ST. MARY'S HOSPITAL MEDICAL SCHOOL.—5 p.m., Mr. Aleck W. Bourne: Restraint in Obstetrics.

SOUTH WEST LONDON MEDICAL SOCIETY.—At Bollingbroke Hospital, Wandsworth Common, S.W., 8.30 p.m., Dr. P. A. B. Raffe: Use of Medical Statistics.

WEST END HOSPITAL FOR NERVOUS DISEASE.—5.30 p.m., neurological demonstration by Dr. C. C. Edwards.

Wednesday, March 17

●FACULTY OF ANAESTHETISTS: ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Joseph Clover Lecture by Dr. T. Cecil Gray: Disintegration of the Nervous System.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Precancerous Conditions of the Skin.

INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. J. G. Sandrey: Vesical Neoplasms.

LIVERPOOL MEDICAL INSTITUTION.—At David Lewis Northern Hospital, Liverpool, 3 p.m., clinical meeting. Symposium on Diabetes.

●LONDON MARRIAGE GUIDANCE COUNCIL.—At Royal College of Nursing, 7 p.m., Dr. P. L. Backus: Psychology of Marital Adjustment.

MIDLAND MEDICAL SOCIETY.—At Birmingham Medical Institute, 8.15 p.m., Dr. H. F. Humphreys: Magic and Medicine.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Joseph Clover Lecture by Dr. T. Cecil Gray: Disintegration of the Nervous System.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Miss Isabel Macdonald, S.R.N.: Royal Nurses in History.

ROYAL MICROSCOPICAL SOCIETY.—5.30 p.m., Dr. F. J. Aumonier: Regeneration of Striated Muscle Following Coxsackie Infection.

●ROYAL SOCIETY OF ARTS.—2.30 p.m., Trueman Wood Lecture by Dr. E. D. Adrian, O.M., P.R.S.: Recent Developments in the Study of the Sense Organs (illustrated by lantern slides).

Thursday, March 18

BRITISH INSTITUTE OF RADIOLOGY.—8 p.m., Mr. D. Innes Williams: Urinary Obstruction in the Early Years.

●CHANCING CROSS HOSPITAL MEDICAL SCHOOL.—5.30 p.m., Huxley Lecture by Sir Lionel Whitby: Dynamics of Haemopoiesis.

EDINBURGH CLINICAL CLUB.—At 7, Drumshough Gardens, 8 p.m., Dr. John Thomson: Care of the Neonatal Infant.

INSTITUTE OF PSYCHIATRY.—5 p.m., Dr. G. M. Carstairs: Attitudes to Death and Suicide in an Indian Cultural Setting.

LIVERPOOL MEDICAL INSTITUTION.—8 p.m., discussion: Minor Injuries of Joints. Opener, Sir Reginald Watson-Jones.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Medical Society of London, 8.30 p.m., Dr. F. Avery Jones: Clinical Problems of Gastroenterology.

LONDON UNIVERSITY.—At London School of Hygiene and Tropical Medicine, 5.30 p.m., special university lecture by Professor A. C. Lendrum: Pulmonary Changes due to Cardiac Disease.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—5 p.m., Oliver-Sharpey Lecture by Dr. M. L. Rosenheim: Treatment of Severe Hypertension.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.—At Royal Army Medical College, 7.30 p.m., laboratory meeting. Demonstrations.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., psychiatry demonstration by Sir Paul Mollinson.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.—At Lecture Theatre, 5 p.m., Sydney Ringer Memorial Lecture by Professor G. L. Brown, F.R.S.: Studies on the Sympathetic Nervous System.

Any Questions?

Intradermal T.A.B.

Q.—An American textbook of preventive medicine refers to immunization with T.A.B. by the intradermal route. Is this an effective route for inoculation, and are there any special hazards? Is it recommended for routine use?

A.—Vaccination against the enteric fevers by intradermal inoculation of T.A.B. vaccine has been studied particularly by American investigators, who have shown that the antibody response is essentially equal to, or even greater than, that obtained following subcutaneous inoculation, even when the dosage is markedly reduced. However, it was considered that this method was more suitable as a booster injection in previously immunized persons rather than a method for primary immunization. The recommended dose is 0.1 ml., and there do not seem to be any associated risks. Intradermal inoculation is seldom used in this country, but may be useful for people who have reacted severely to previous subcutaneous injections.

Deep Anaesthesia for Domiciliary Midwifery

Q.—I use a standard gas-oxygen machine for domiciliary maternity work. For forceps deliveries a vaporizer is plugged into the gas circuit, containing either "vam" (25% vinyl ether with 75% ethyl ether, by weight) or trichlorethylene according to whether any source of ignition is present. Vam gives much more satisfactory operating conditions, but is often contraindicated owing to open fires; trichlorethylene has to be "pushed" for anything but easy outlet forceps deliveries, and then the recovery period is undesirably long. Is a small dose of intravenous pethidine (25 mg.) combined with gas and oxygen in any way contraindicated for this sort of situation? Alternatively, is any other technique recommended for use when there is a definite explosion risk? Positive pressure is available but no suction, so relaxants are too dangerous to use.

A.—Only the most simple obstetric operations should ordinarily be carried out in the patient's own home, and for these the type of anaesthesia mentioned in the question should be adequate. Any complication or situation calling for deeper anaesthesia is generally an indication for transferring the patient to a fully equipped maternity hospital. There are a few exceptions to this rule; manual removal of the placenta, for example, should be carried out wherever the patient is situated.

In the event of an additional anaesthetic agent being required in domiciliary practice, then the question arises as to its object. If more relaxation of the muscles of the pelvic floor and vagina is required, local infiltration or pudendal block with an analgesic solution followed by episiotomy is safe, effective, and easy. If, however, the object is to relax the uterus in order to rotate the foetal shoulders or to remove an imprisoned placenta, then the most suitable anaesthetic is probably open ether. Indeed, there is much to be said for using this as a routine rather than the gas, oxygen, and trichlorethylene mixture mentioned in the question.

The risk of fire and explosion should be eliminated not by recourse to an anaesthetic agent which involves other dangers, but by removal of the fire. If the practitioner is dealing with booked cases he might advise all his patients antenatally against having a fire (other than one easily extinguished) in the room during labour. If he is called to an emergency case in which he has had no opportunity to give this advice, then it is not a difficult matter to clear the fireplace with a shovel and bucket.

Women vary considerably in their sensitivity to pethidine, and even a small dose given intravenously can have a major effect, especially if other forms of anaesthesia are in use.

Friday, March 19

BRITISH INSTITUTE OF RADIOLOGY.—5 p.m., meeting of medical members. FACULTY OF RADIOLOGISTS: RADIODIAGNOSIS SECTION MEETING.—At Royal College of Surgeons of England, 2.15 p.m., Dr. Roy Astley and Dr. J. W. Gerard: X-ray Diagnosis of Coeliac Disease; Dr. R. E. Steiner and Dr. Ian Donald: Respiratory Diseases in the Newborn.

INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. L. Forman.

POSTGRADUATE MEDICAL SCHOOL OF LONDON.—2 p.m., Professor R. A. Willis: Metaplasia.

Saturday, March 20

BIOCHEMICAL SOCIETY.—At Department of Biochemistry, University College, 10.45 a.m., A.G.M. followed by scientific papers.

APPOINTMENTS

DRUMMOND, R. GORDON, M.B., Ch.B., D.P.H., Medical Officer of Health for the City of Durham, Durham Rural District, Brandon and Byshottles Urban District, and Assistant County Medical Officer, Durham County Council.

DUNN, MICHAEL J., M.B., Ch.B., Assistant County Medical Officer and School Medical Officer to the Isle of Ely County Council, March, Cambridgeshire.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—C. R. Savage, M.B., B.S., F.R.C.S., Part-time Surgical Registrar; Gwendolyn R. Tapp, M.B., B.S., D.C.H., Assistant Resident Medical Officer, Tadworth Court.

LIVERPOOL REGIONAL HOSPITAL BOARD.—A. V. Clemmey, B.M., B.Ch., D.O.M.S., Part-time Assistant Ophthalmologist to hospitals in the Warrington area; W. M. Owen, F.R.C.S., D.L.O., Part-time Consultant Ear, Nose, and Throat Surgeon, St. Helena area.

NORTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—J. W. Lewis, M.B., B.S., D.A., Part-time Anaesthetist (Consultant), Harris Hospital, Woodford Green; E. Hacker, M.R.C.P., D.A., Part-time Anaesthetist (Consultant), St. Andrew's Hospital, Bow, and St. George-in-the-East Hospital, Wapping; Sheila Millar-Danks, M.B., B.S., D.A., Part-time Anaesthetist (Consultant), St. Andrew's Hospital, Bow; C. D. Wilson-Sharp, M.B., B.S., D.M.R.D., Full-time Radiologist (Consultant), Colchester Group of Hospitals; A. Giordani, M.R.C.S., L.R.C.P., D.M.R.D., Part-time Radiologist (Consultant), King George Hospital, Ilford; Ella Preiskel, M.B., B.S., D.M.R.D., Part-time Radiologist (Consultant), St. Mary's Hospital, Plaistow, and Forest Gate Hospital.

ROTH, MARTIN, M.D., M.R.C.P., D.P.M., Visiting Director, Laboratory of Experimental Therapeutics, Allan Memorial Institute of Psychiatry, McGill University, Montreal, until September 1, 1954.

SOUTH-WESTERN REGIONAL HOSPITAL BOARD.—L. C. Bell, M.B., B.Ch., B.A.O., F.R.C.S., Senior Registrar, Department of Thoracic Surgery, Frenchay Hospital, Bristol; R. R. Knowles, M.B., B.S., D.P.M., Senior Registrar in Psychiatry, Bristol Mental Hospital; Beatrice E. Sleight, M.B., Ch.B., D.A., Anaesthetic Registrar, Frenchay Hospital, Bristol; E. A. W. Houghton, M.B., Ch.B., Medical Registrar, Southmead Hospital, Bristol.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Bauer.—On February 25, 1954, to Gitta, wife of Jacob Bauer, M.D., a son—Eran Nicodemus.

Donohoe.—On February 26, 1954, at The Firs, Mansfield Road, Nottingham, to Ursula Donohoe (formerly Wilkin), wife of Dr. T. W. G. Donohoe, a sister for Mollie.

Radecki.—On February 16, 1954, at the Middlesex Hospital, London, W., to Lois, wife of Carl Radecki, M.B., B.S., of the Repatriation General Hospital, Concord, New South Wales, Australia, a daughter—Carole.

DEATHS

Deane.—On February 20, 1954, Reginald Neville Deane, M.B., B.Ch., of 2, Canterbury Road, Croydon, Surrey.

Douglas.—On February 18, 1954, at Old Manse, Lockerbie, Dumfries, John Primrose Douglas, M.B., Ch.B.

Gibson.—On February 18, 1954, at The Gables, Grimsby Road, Cleghampton, Lincs, Robert Ernest Stewart Gibson, M.B., Ch.B.

Grills.—On February 16, 1954, at Craybrook, Whitbarrow Road, Lymm, Cheshire, Galbraith Hamilton Grills, M.D., aged 82.

Hues.—On February 13, 1954, at Lobden Cottage, Colwall, Malvern, Worcs, Herbert Walter Hues, L.S.A.

Jeffrey.—On February 11, 1954, at his home, Sandon House, Heywood, Lancs, Harry Foster Jeffrey, M.B., Ch.B., J.P.

Jeffrey.—On February 21, 1954, at 24, Stevenson Street, Dalmeir, Dunbartonshire, John Edward Jeffrey, M.B., Ch.B.

McKay.—On February 8, 1954, at the General Hospital, Burnley, Lancs, Charles McKay, M.B., Ch.B., of The Lindens, Manchester Road, Burnley.

Marradi.—On February 22, 1954, at the Cambridge Hospital, Aldershot, Hants, Arthur Trevor Marradi, D.S.O., M.R.C.S., L.R.C.P., Lieutenant-Colonel, R.A.M.C., aged 44.

Merrill.—On February 10, 1954, at 20, Hornsey Rise, London, N., William Spence Merrill, M.B., Ch.B.

Miles.—On February 11, 1954, at Bewdley, Worcs, Usher William Newton Miles, M.R.C.S., L.R.C.P., aged 82.

Mitchell.—On February 19, 1954, at 22, Warrander Park Terrace, Edinburgh, James Mitchell, L.M.S.S.A.

Nightingale.—On February 12, 1954, at Uppingham, Rutland, John Nightingale, M.D., D.P.H., Lieutenant-Colonel, R.A.M.C., T.D., retired.

Porter.—On February 4, 1954, at the City Hospital, Exeter, Arthur Edward Porter, M.D., D.P.H., late of Budleigh Salterton, Devon, aged 80.

Reid.—On February 8, 1954, at Dunmar, Tigh-na-brath, Argyll, Spence Reid, M.B., Ch.B., Colonel, late R.A.M.C., retired.

Rogers.—On February 9, 1954, at 4, Queensborough Studios, London, W., Frederick Colin Rogers, M.R.C.S., L.R.C.P., Lieutenant-Colonel, I.M.S., retired.

Sweet.—On February 16, 1954, at Westholme, 10, Victoria Drive, Troon, Ayrshire, Robert Sweet, D.S.O., M.B., Ch.B., F.R.F.P.S., Colonel, I.M.S. (retired), aged 66.

Webster.—On January 16, 1954, at 75, Sandon Road, Birmingham, Kathleen Mary Webster, M.R.C.S., L.R.C.P., D.P.M., late of Whitley Bay, Northumberland.

Wynne.—On February 7, 1954, at Midhurst, Avenue Gardens, Cliftonville, Kent, Albert Edward Wynne, M.D., F.R.C.S.I., formerly of 27, Westland Road, Dublin, aged 88.

at the same time. The margin of safety is increased if pethidine is given in dilute solution and in divided doses—or even in the form of a drip infusion. This sort of complicated procedure is, however, clearly unsuited to domiciliary midwifery. Likewise, as the questioner suggests, relaxant drugs have no place. Safety demands that these be given only by an expert working under hospital conditions. Moreover, their application to obstetric operations is limited. They promote relaxation of pelvic floor muscles, but this can be more safely achieved by local analgesia. They do not, however, relax the uterus, and for this reason they may hinder rather than help obstetric manoeuvres. Moreover, they appear to encourage silent regurgitation of stomach contents, probably by relaxing the diaphragm. Since they also suppress the cough reflex, they increase the risk of inhalation asphyxia and pneumonia.

It remains to be added that many obstetricians still hold the view that chloroform, if properly administered on an open mask with no gamgee to interfere with a generous intake of air, still has a place in domiciliary midwifery. Those who have been trained to use it will probably regard it as the obvious and simple solution to the problem posed in the question. It should not, however, be given for more than a short period of time, nor should its administration be repeated. It is also to be avoided if labour has been much prolonged and if the patient shows evidence of ketosis.

Mepacrine Stains

Q.—How can mepacrine stains be removed from clothes?

A.—Mepacrine stains are chemically similar to proflavine stains, and in his book on the acridines Albert¹ says that stains on fabrics can be lightened by washing with alcohol until no more colour is removed; the residual stain should then be smeared with oleic acid and immersed in alcohol containing a small amount of ammonia. Probably the simplest procedure of all, which might be tried first, is to rub the stain with 1% ammonia and then treat it with 80% alcohol. This should remove it.

Should Mothers Leave their Babies?

Q.—Is it psychologically harmful to leave a baby of 6 to 12 months with its grandparents while its parents are away for a month?

A.—Some interesting observations have been made, especially by Dr. John Bowlby, on the emotional reactions of young children removed from their mothers—for example, when they have had to go into hospital. These reactions not only occurred while the child was away but also after his return home. Apart from the anxiety and estrangement which one might expect, a variety of behaviour disorders were also seen. Bowlby found that the age of greatest susceptibility to such reactions was rather older than in the case described in the question, 18 months to 2 years being the peak. Control studies and more prolonged follow-up than has so far been possible are needed to show just how seriously these reactions are to be taken. Until further work brings greater understanding, practical problems are best solved in a common-sense way.

Thus in the case described it is unlikely that any harm would arise to the child. The period of parental absence is short, and the child should be able to get over it quickly. Furthermore it is very young, and at that stage of development, apart from being less aware and less discriminating than a child of 2, is unlikely to have the fixation on one person which it would normally have later. The most important psychological needs of a young child, affection and security, will presumably be supplied by the grandparents, and any severe emotional reaction during or after its stay with them is improbable. It is the anonymous atmosphere of a hospital or institution which appears to be deleterious.

Mercury Poisoning in Dentists

Q.—Is there any evidence that the habit of some dentists of mixing amalgam filling material in the palm of the hand may, in the course of years, cause symptoms of chronic mercurial poisoning?

A.—While theoretically the danger does exist, there does not appear to be any case reported where chronic mercury intoxication has arisen in a dentist in the way suggested by the questioner. The work of Storlazzi and Elkins¹ tends to show that some mercury absorption does occur from newly inserted silver-amalgam fillings. But the maximum temporary concentration is less than that found continuously in the urine of workers exposed regularly to quantities of mercury apparently too small to cause chronic poisoning. However, symptoms of mild chronic mercury poisoning are difficult to distinguish from irritability and anxiety due to other causes, and often have to be sought for specifically. In short, the risk to dentists, though theoretically real, must be very small indeed—if it exists at all.

Dry Heat Sterilization in General Practice

Q.—What are the disadvantages of dry heat sterilization in general practice? Is it suitable for sterilizing suture materials and dressings? Could a domestic electric oven be used for the purpose?

A.—Dry heat sterilization is unsuitable for either of these purposes; it is indicated only for syringes, glassware, powders, and oils. Any fabric (dressings or thread, the latter being presumably the form of suture material meant) is charred and rendered brittle. Any oven which attains throughout (temperature may vary by many degrees in different parts) a temperature of 160° C. will serve; 180° should not be exceeded. The melting point of the solder used on syringes and needles is about 200° C., so any higher temperature than this would cause the solder to flow and the mounts to separate. A suitable thermometer would decide whether the oven in question is suitable. Most cooking ovens normally attain too high a temperature, but when regulation is possible they may be used.

NOTES AND COMMENTS

Smoking Cures.—Colonel H. W. DAUKES (Bethnal Green Hospital, London, E.2) writes: With reference to your answer to the question on smoking cures ("Any Questions?" February 20, p. 471), I feel that the answer given, while correct, is not very helpful. I have found a really good way to cut smoking down easily and effectively without undue nervous strain. Having lived much abroad, I developed the habit of smoking about 35 cigarettes a day regularly over many years. On returning to this country I found I could not afford this, so I tried making my own cigarettes first with a "rizla"-type maker; then, when I found this was effective, with one of the box type in which the closing lid rolls the cigarette, using a filter tip (mainly to give a neat end to the cigarette) and only making a cigarette when I actually wanted to smoke one. I have cut down to half an ounce of tobacco a day, which, when added to the cost of the filter tips and paper, results in a saving of £70 per annum. The two most important points are: (1) Not to sit down and roll a whole batch of cigarettes but only to make one when actually wanted—this cuts out a large number. (2) When you can have a cigarette whenever you want it sufficiently to go to the trouble of making it, this cuts out any element of nerve strain.

Highest peak concentrations and sustained therapeutic effect with 'ESKACILLIN'

the palatable liquid oral penicillin

Some authorities stress the value of high, if intermittent, peak penicillin serum concentrations; others favour lower, but sustained, plateau levels.

With 'Eskacillin' the advantages of both patterns are available. A very high peak concentration is achieved within about one hour of the first dose, succeeded by a more than adequate therapeutic level sustained for several hours.

Children of all ages clamour to take the prescribed dose at VI-DAYLIN time.

It is clear, smooth-flowing, honey-coloured, and has a citrus-like flavour all its own.

VI-DAYLIN is miscible with milk, cereal and other infant foods, but most children prefer it straight from the spoon.

Each 5 c.c. teaspoonful of VI-DAYLIN contains :—
Vitamin A, 3,000 i.u.
Vitamin D (Vioosterol), B.P., 800 i.u.
Aneurine Hydrochloride, B.P., 1.5 mg.
Riboflavine, B.P., 1.2 mg.
Vitamin B₁₂, 3 mcg.
Ascorbic Acid, B.P., 40 mg.
Nicotinamide, B.P., 10 mg.

Available in 90 c.c. and 16 oz. bottles

PAUL EHRLICH*

BORN MARCH 14, 1854

BY

Sir HENRY DALE, O.M., G.B.E., F.R.C.P., F.R.S.

This week there was held, in Frankfurt-on-Main and in Marburg, a joint centenary commemoration of the births of Paul Ehrlich and Emil von Behring. They appear to have been born on successive days, March 14 and 15, 1854; but the combined celebration recognized also, of course, the fact that both had contributed to a great and historic achievement in medical science. Their direct association lasted, indeed, for only a few years; but their names will always be linked together by the fact that von Behring discovered the antitoxins against diphtheria and tetanus in the opening years of the 1890s, and that Ehrlich, in the immediately following years, was largely responsible for the rapid development of that discovery. Ehrlich's work, indeed, played a part of central importance, not only in the early production of the antitoxins as effective and exactly controlled remedial agents, but also in the rapid opening which ensued, of a new vista of fundamental knowledge concerning the nature and the mechanisms of the reactions of immunity in a much wider field.

An essential preparation for such a new science of immunology had, of course, been made earlier by the work of Pasteur, of Koch, and of those who immediately followed those great leaders—and even much earlier, perhaps, by the observations of Edward Jenner, nearly a century before that time. There can be no doubt, however, that the study of the nature of immunity to infections entered a new phase of rapid progress with the discovery and further investigation of the antitoxins. Von Behring himself was doubtless concerned to find an immediate application for his sera in practical treatment, especially of diphtheria. So far, however, he appears to have made little more than a qualitative and empirical, though a fundamentally

*A lecture delivered at a centenary celebration in Amsterdam, on March 20, 1954, to the Genootschap ter Bevordering van Natuur-, Genees- en Heelkunde.

important, observation. His first sera cannot have contained, in a cubic centimetre, more than a fraction of what was later defined as a unit of antitoxin, and he had not discovered the appropriate technique for so raising the acquired immunity as to obtain an antitoxin of a therapeutically useful potency. Ehrlich, on the other hand, was already in possession of at least some of the knowledge required for this next and immensely

important step. In work on which he had already been engaged quite independently, on the specific immunity acquired by animals which had been given sub-fatal doses of the poisonous plant proteins, ricin and abrin, from castor-oil and jequirity seeds, he had discovered that this immunity could be raised by stages to a high level if a suitably spaced series of increasing injections were given.

Collaboration with von Behring

When von Behring's discovery of the diphtheria and tetanus antitoxins was announced, it was natural, then, for Ehrlich and his co-workers to apply their method of progressive immunization to the production of these, with potencies likely to make them practically effective in treatment, or in prophylaxis. Such records as are available suggest that the first serum of this kind to be used with a convincing

remedial effect, in human diphtheria, was one which Ehrlich had prepared in a sheep or a goat, at a time when von Behring's attempts had not yet produced an antitoxin with a recognizable therapeutic action; a result which, indeed, was to be expected, if we can accept Ehrlich's statement that the serum from his immunized goats already contained up to 100 units of antitoxin per ml., while von Behring's still showed less than one unit. It is certain, in any case, that von Behring invited Ehrlich's collaboration, and that, as the result of their work together, antitoxin of good potency was soon

Ehrlich in 1905.

obtained from the horse—in all ways a more suitable animal—and was thus made ready for large-scale production in Germany, and then in other countries.

A position of this kind, in which one investigator has been responsible for a primary and fundamental though essentially an empirical discovery, and another for giving it a quantitative and scientific basis and thereby making it effective in practical therapeutics, must always be apt to cause some division of opinion on the proportion of credit due to each of these different contributions to a common result. We know that the collaboration between von Behring and Ehrlich did not last very long, and that misunderstandings of some kind arose between them. On an occasion like the present we may be well content, I think, to leave the matter of the personal relations between these great men of science where it was left some 20 years later by von Behring himself, when at the side of Ehrlich's grave he said:

Nun ruhest auch Du, Du lieber Freund . . .
Du hattest stets eine empfindliche Seele . . .
Und wenn wir Dir wehgetan haben—Verzeih!

For our present purpose I think that it is more important to recognize that the direct collaboration between men of such different aptitudes and ideals probably lasted as long as it could render its best service to science. It had left Ehrlich deeply engrossed for more than 10 years with the fundamental nature of the immunity reaction, and of the relation between the specific immune substances and the corresponding antigens, to the immeasurable gain of scientific immunology.

Von Behring, on the other hand, was less concerned with these deeper problems. His primary discovery of the antitoxins remained the only one of that status calling for a special centenary commemoration of his life and achievements. He made, indeed, in later years, another contribution to immunology which has acquired a comparable importance in practical medicine. This, however, may be regarded as an extension of the earlier one; it was his recommendation, as a safe and effective inoculum for producing an active immunity to diphtheritic infection, of a suitable dose of diphtheria toxin combined with the amount of antitoxin required to neutralize it. In this case, however, I think that we are bound further to recognize that the mere trial of such a method would not have become practicable until Ehrlich's work had made clear the complexity of the factors concerned in this neutralization of toxin with antitoxin, and especially the presence in any toxin of "toxoid," combining specifically with the antitoxin and able to evoke its production, but free from the toxicity of the unmodified toxin. It would scarcely have been possible, indeed, until Ehrlich had further established, for diphtheria antitoxin, the first of all the biological methods for measuring the specific activity of a remedy, and probably still the most accurate of any. He had based it, as all later valid methods of biological standardization have been based, on the definition of a unit of activity as that of an exact weight of a permanently dried, stable, standard sample of the active substance, in this case of the antitoxin itself.

Ehrlich knew from the first, what one or another worker in quantitative biology from time to time forgets, and falls into trouble by forgetting, that a biological measurement, like any other measurement, has no real meaning unless it is made in relation to a fixed, invariable standard. And it may be noted yet further

that von Behring's contribution to the practice of active immunization against diphtheria did not extend much beyond the initial discovery and recommendation; so that in any account of its practical and systematic application, now so widely successful, it would be necessary to mention also the names of a number of others who were responsible for its first trials on an extensive scale, for the methods of controlling its efficacy, or for the introduction, as the inoculum, of a toxoid prepared by treating the toxin with formaldehyde, and for the modifications of this which are now prevalently used, with greater success and safety than the toxin-antitoxin mixture which von Behring had suggested. I think, however, that we may be glad to have the opportunity which this occasion affords of saluting the memory of Emil von Behring, as a pioneer whose initiative played a very important part in the origin of an immunological therapeutics, which has now at its disposal the means for both passive and active immunization, used for a preventive or a curative purpose, with all that those resources mean for the effective control of infectious diseases, in any modern, scientifically developed community.

A Predominating Influence

In the case of Paul Ehrlich, whose personal and scientific career forms my real subject to-day, it seems to me that we are concerned with achievements of a different order, which for more than half a century have had a predominating influence upon almost every aspect of the medicinal treatment of infections, and upon its aims as well as its methods and materials. In 1896 Ehrlich was appointed to the directorship of a small "State Institute for the Investigation and Testing of Sera," in Steglitz, a suburb of Berlin; and his progress there, with the fundamental study of problems arising more or less directly from the fulfilment of this official duty of control, was certainly but little checked by the relatively small dimensions and meagre equipment of the Steglitz Institute. It was from there, in 1897, the year following his appointment, that he published his famous memoir on "Die Wertbestimmung des Diphtherie-heilserums und deren theoretische Grundlagen" ("The Standardization of Diphtheria Antiserum and its Theoretical Basis"), which remains to this day the classical treatise on the subject. It laid the foundation, indeed, not only for all future work on the standardization of the diphtheria antitoxin, but for standardization in general by biological methods, in practically all of its now multitudinous applications. Even when the more imposing Royal Prussian Institute for Experimental Therapeutics in Frankfurt-on-Main was opened three years later, in 1899, with Ehrlich as its director, it was planned essentially for an extension of the work at Steglitz, though the change in title suggested a somewhat broader conception of its functions. Its first responsibility, however, to the Government which provided the money for its support, continued to be the organization and control of the testing of the new antitoxins, in order to give a public guarantee of the potency and safety of every batch which was issued in Prussia for practical use. To Ehrlich this was no merely tiresome obligation of routine, as many an investigator might have regarded it; on the contrary, he eagerly seized the opportunity which it presented for new scientific enterprise in many directions.

And for more than 10 years, from 1893 onwards, the natural flow of his inventive and speculative genius followed the course thus given to it by the requirements of a public responsibility. It led him, in the first instance, into a detailed study of the diphtheria toxin itself, in which he recognized a series of components, with different affinities for the antitoxin, and contributing to different phases of the toxic action—components to which, characteristically, he liked to give a pictorial representation, in what he called

the "spectrum" of a toxin. This dissection of a toxin into its components was needed, of course, before a really scientific method could be elaborated for titrating against it the potency of an antitoxin, with an animal reaction to show the end-point. And such studies led Ehrlich naturally to examine the nature of immunity-reactions over a much wider range. In the later part of this period, and especially in conjunction with his principal colleague at that time, J. Morgenroth, Ehrlich extended these studies to the more complex immune lysins, formed in response to the injection of intact foreign cells, such as red blood corpuscles from an alien species, or bacteria; and in these lysins they found two components, both needed for the lytic action—a specific "amboceptor" and a non-specific "complement"—present also in normal serum. Bordet, who had studied the phenomenon independently and from a somewhat different angle, had also recognized these two components and had named them "substance sensibilatrice" and "alexine."

The Side-chain Theory

And when Ehrlich's brilliant scientific imagination had occupied itself actively for some years with the meaning of these variously complicated phenomena, the famous "side-chain theory" emerged. It would be far beyond the scope of my present purpose to deal with that theory in detail; it may be that some other contributor to this celebration will make it the main theme of his address. Others also will probably be noting that one principal feature of the theory, in which receptor-groups are pictured as forming side-chains of a protoplasmic macromolecule, figures also in Ehrlich's way of thinking about other reactions than those of immunity, and particularly about the specific localization of chemotherapeutic agents.

In no case, I think, could the side-chain receptors, in the form in which Ehrlich had conceived and pictured them, have retained all their first convincing appeal, or the stimulating influence on further investigations which they so long exercised. The theoretical background has, of course, since those early days been transformed by great advances in biochemical and physico-chemical knowledge. And in Ehrlich's rather rigid conception of an immune antibody, with its closely specific affinity for a particular foreign substance, as originating from preformed side-chain receptors, kept ready, as it were, to combine with an antigen which they had never yet encountered, must surely have become more obviously inadequate as evidence accumulated. For it was soon to become clear that the cells of the body would produce these intensely specific antibodies in response to a practically unlimited variety of natural antigens. Landsteiner was later to show that a really unlimited number of artificial antigens could be prepared, by attaching pure chemical substances, natural or synthetic, by diazo-linkages to large-molecule proteins. And so it became clear that the antibodies must be formed, not from pre-existent receptors, but from some indefinitely adaptable cell constituent, which would respond to contact with any antigen by acquiring a new surface contour, conforming to that of the antigen with the detailed precision of a cast fitting into its mould. And, since all the immune antibodies appear to belong to the group of the gamma-globulins, Linus Pauling has pictured the long molecules of these as coiled into skein-like macromolecules, presenting surfaces which can be moulded to fit those of any number of different antigens. Such an ideal will obviously correspond more readily with the present state of knowledge than Ehrlich's diagrammatic conception in its original form.

Ehrlich's mind, however, though tenacious and combative in the face of criticism which he regarded as unfair, was readily receptive and versatile, eager to welcome any real illumination of his problems from sources outside the range of his own knowledge and experience. And I feel sure that, if he could have lived to survey all the evidence now available about the reactions of immunity, he would have

been ready to incorporate any new and more elastic interpretation of their meaning into the general structure of his own theory, and even to assume, perhaps, that this would involve a modification only in detail, and not in principle, of his own conception of the source of the antibodies. I myself believe, indeed, that there would be a substantial justification for such a claim. For there was another and by no means a less important feature of Ehrlich's original theory, which no more modern conception of the protoplasmic precursors of the antibodies has been able to replace, or even to modify. That was Ehrlich's application to the special case of an immunity reaction of a more general pathological principle, first propounded, as he was always proud to acknowledge, by his own distinguished cousin, Carl Weigert.

Weigert had drawn attention to the regular tendency of a living tissue, in its repair of the effects of an injury, to produce new cells, and eventually new tissue, in excess of what is required for mere replacement; and Ehrlich conceived that the cell constituents—the protoplasmic side-chains, as he pictured them—which were first occupied and put out of action by specific combination with an antigen, would then, in accordance with Weigert's principle, be reproduced in such an excess that they would be shed freely into the body fluids as circulating antibody. And whatever more modern conception may now be acceptable to account for the initial specific union with the provocative antigen, the idea which would attribute to such a reparative overproduction, not only the first appearance of the antibody as a freely circulating constituent of the blood plasma, but also the rapid rise of its concentration there, in response to successive, appropriately spaced and graded injections of the antigen, seems to me to have lost none of its original validity. That idea was an original component, a central feature indeed, of Ehrlich's side-chain theory of the immunity reaction. And even to-day, after more than half a century, it still provides the only interpretation yet available for an essential aspect of the complex reaction of immunity, and still retains its power as a stimulus to further experimental inquiry. Will anybody yet discover, we may ask, why the metabolism of the body cells, when once it has been thus constrained to the overproduction of a protein with such a newly imposed specificity, should continue indefinitely to produce such a specific antibody, though in a diminishing quantity, even without further antigenic provocation? It is a question, I feel, which would have been congenial to Ehrlich's own alert and ingenious imagination.

And it seems to me that, whatever permanence we may be inclined to predict for the details of some of his theories and speculations, Paul Ehrlich's manifold permanent achievements in this field alone would give us an abundant justification for commemorating the centenary of his birth.

Although, however, the joint commemoration with that of von Behring has led me thus to deal first with Ehrlich's work on problems of immunology, and although this had, as we have seen, a great and intrinsic significance of its own, it had no such primacy of importance in his total scientific achievement. If we take a longer view of his scientific career as a whole, this concentration of his interest during a middle period on the phenomenon of immunity, and on its practical applications in therapeutics, assumes the appearance rather of a diversion, made first in response to a call of public duty, from the line of the researches which he had been following till then on his own natural initiative, and to which he was to return with an undiminished enthusiasm, and with an augmented equipment of knowledge and ideas, when this immunological phase was coming to an end. To obtain a more comprehensive and balanced appreciation, therefore, of Ehrlich's work in the medical sciences as a whole, we ought at this stage to go back to the beginning, so that we may consider his researches and his contributions to knowledge in relation to his life and career, and in their natural, chronological sequence.

Early Activities in Research

We should note then, in the first place, how early Ehrlich's activities in research began, and how, from the very first, he was led by the natural line of his interest to study the way in which chemical substances become distributed in the body, in accordance with their varying affinities for the different tissues. From a statement made by Ehrlich himself, in a still unpublished address which he delivered at the opening of the Georg-Speyer Haus in Frankfurt in 1906, we learn that his attention was first attracted to such problems during his first year as a student of medicine in Strasbourg, under Waldeyer, when at the age of 19 he read a book by Heubel on lead-poisoning. This described the distribution of lead in the body, as revealed by chemical analyses of the different organs. The young Ehrlich evidently began then to think of the possibility of following the unequal distribution of other substances in the body, due to their varying fixation by organs and tissues having different affinities for them. Lack of chemical methods for their detection would make an investigation of such distributive variations impracticable in the case of many substances. The distribution of dyestuffs, however, could be followed by direct observation, either with the naked eye or under the microscope; and the German industrial production of synthetic dyes, then in its early stages, gave the young enthusiast his opportunity.

His cousin, Carl Weigert, shared to some extent his interest in the new dyes, but was more concerned with their uses as conventional stains for microscopical specimens. Ehrlich appears from the first to have had in view the possibility of using them as selective, histochemical reagents; and there are incidents on record which suggest that he was apt to arouse comment from his teachers, by the amount of time which he spent on experiments of this kind with the new dyes, to the detriment of his studies of the more normal subjects of a medical curriculum, on which he would presently have to face his examiners.

Already in 1877, as an undergraduate of 23, he published a paper on the use of staining with aniline dyes in microscopical technique; and in the following year, 1878, he presented his graduation thesis to the medical faculty of the University of Leipzig. This has never yet been published, but, most fortunately, a copy of it in typescript has been preserved. It is entitled: "Beiträge zur Theorie der histologischen Färbung" ("Contributions to the Theory of Histological Staining"); and it is full of precocious speculations concerning the meaning of the selective staining of different tissue elements. Little imagination, indeed, is required to detect in this thesis by the 24-year-old Ehrlich the germs of nearly all the ideas which were to guide his scientific activities, and to lead him eventually to his great discoveries, during the whole of his active career.

By the next year, 1879, he had begun to use the dyes to classify the wandering white cells of the blood and the tissues, by the different and chemically significant staining-reactions of their granulations; and he had thus opened the way for his classical series of researches on the anaemias and the leukaemias, extending from then onward over many years, through which he became one of the principal founders of the modern science of haematology. As a student of physiology, I myself first heard of Ehrlich as the discoverer of the different types of leucocytes, with their oxyphil, basophil, and neutrophil granulations. In 1883, while holding a clinical appointment in Berlin, he discovered the acid-fast staining property of Robert Koch's then recently discovered tubercle bacillus, and the colour-reaction given by the urine in certain diseases with diazo-benzene-sulphonic acid.

And then, in 1885, came his remarkable treatise entitled: "Die Sauerstoffbedürfnisse des Organismus" ("The Avidity of the Organism for Oxygen"). This is truly a precocious classic of functional biochemistry, in which the comparative avidities for oxygen, of the still normal cells of the different organs of a living animal, are measured by their

power of converting one, both, or neither of two dyes with different reduction-potentials, indophenol blue and alizarine blue, into the corresponding, colourless reduction products. Even to-day, when oxidation-reduction potentials and the intracellular systems of oxidizing and reducing enzymes are matters of daily experiment and discussion in so many laboratories, this little book remains full of stimulating suggestions, and many have found in it, again, the germs of ideas which were to be given more definite form in the side-chain theory.

Work on Methylene Blue

In the same year, 1885, Ehrlich published his first observations on the biological uses of methylene blue, which was to play such an important part in more than one phase of his further investigations. He had observed that it also was readily reduced by some tissues to a colourless leucobase, and that it showed a selective affinity for nerve cells and nerve-fibre endings. Three years later, in 1888, he was experimenting with Leppmann on its possible use to interfere with nerve conduction, and thus to act as an analgesic. And from about this time, or more probably two years later—after his return from a longish absence due to a threat of tuberculous infection—there are undated copies of letters which he wrote to leading dyestuff chemists, inquiring about the possibility of obtaining analogues and derivatives of methylene blue for trial, and even suggesting the details for a possible synthesis of a cyano-derivative, with an astonishing knowledge of chemistry in this range for one who had had no formal training in any kind of chemistry beyond the mere rudiments.

The same letter, to Professor A. Bernthsen, contains a request of particular significance. Bernthsen had earlier supplied a specially purified sample of methylene blue, and Ehrlich reports that this has all been used by him with Leppmann in the clinical trials of its efficacy in neuralgia; and he now asks for a further supply, "which is again to be used for therapeutic experiments, but in this instance they are to be extended in a new direction." There can be little doubt of the nature of the new experiment which he had in view. As Ehrlich recalled in later years, in a paper dealing with his chemotherapeutic experiments with trypanosomes, Leopold Landau had already recommended him, about 1880, to try methylene blue as an internal antiseptic, since Ehrlich had himself shown it to be a specially good stain for bacteria. It was not, however, until his experiments with Leppmann had further encouraged him that he decided to try it on human malaria—the malaria parasites having also, of course, a strong affinity for methylene blue, as could be seen in a stained blood film. This clinical trial was actually carried out in 1891 with Professor Guttman, who had a patient suffering from malaria under his care; and the result was not, in itself, at all discouraging. Methylene blue appeared to have a definite remedial action on the malarial paroxysms, but not better than that of quinine, and not certainly even as good.

This clinical trial of methylene blue as an antimalarial remedy seems to me, however, to have been one of the decisive events in Ehrlich's scientific career, and one of the principal landmarks in the history of modern therapeutics. For it appears to have been the very first occasion on which an artificial substance, or, indeed, a medicinal substance of any kind, was made the subject of a deliberate test of its power to cure an infection by a direct action upon the infecting organisms. Here, then, Ehrlich adopted for the first time what he later claimed to be a new principle in therapeutic research, and called "chemotherapy"—a quest for remedies which would specifically kill or eliminate the parasitic organisms responsible for infectious diseases, without detriment to the patients; in contrast to the then current pharmacology, which only concerned itself, as he alleged, with the symptomatic or toxic effects which a supposed remedy produced on the patient or on an

experimental animal. Ehrlich's effective campaign on these new lines was not to begin till some 12 years later; but the delay is not to be attributed to disappointment with the result of this first trial. Methylene blue had shown, in fact, sufficient promise as a specific antimalarial agent to have qualified it for use as the starting-point of a systematic attempt to find better ones. And when, many years later, and long after Ehrlich's death, the research staff of the Bayer Company undertook such a campaign, using the transmissible malaria-like infections of birds to test their synthetic products, and were thus led to discover plasmoquine and atebirin (mepacrine), their starting-point was, in fact, methylene blue rather than quinine. There is even evidence on record of a successful use, as recently as 1946, of methylene blue itself for the treatment of certain cases of chronic malaria.

A Diversion

Ehrlich, then, abandoned further attempts at chemotherapeutic research for the time being, not because the result with methylene blue was unpromising, but rather because the experimental requirements were not yet available. He could not wait for opportunity on the chance of encountering another case of human malaria, or test an indefinite series of new compounds on human patients for curative efficacy and toxicity. The effective opening of his chemotherapeutic campaign had therefore to wait till the opportunity was presented by Laveran and Mesnil's discovery that trypanosome infections could be transferred to rats and mice, and maintained indefinitely in series by subinoculations.

We must remember, moreover, that it was not long after the trial of methylene blue in malaria that Ehrlich's activities were diverted, and fully occupied then for more than a decade, by the enlistment of his interests in the production and standardization of the new antitoxins, and by his eager pursuit of the fundamental problems of immunity with which he thus came into contact. I doubt, indeed, whether Ehrlich himself would have regarded this interlude as a diversion. For him, I believe, the antitoxins and other immune substances would already have presented themselves as the ideal chemotherapeutic agents: with maximal specific affinities for the parasites and their poisons, and none for the tissues of the host, they must surely have been for him the perfect realization of the "magic bullets" which had figured in his therapeutic dreams.

Systematic Chemotherapy

But when Laveran and Mesnil showed that trypanosome infections in small laboratory animals could be made available in any numbers required for experimental treatment, Ehrlich seized the opportunity to return to his study of the remedial effects of artificial substances, and in the first place of synthetic dyes, and thus to make an effective beginning of his systematic chemotherapy. For this he obtained the co-operation of Dr. Shiga, known to all the world for his work on bacillary dysentery, who was on a visit to the Frankfurt Institute from Japan; and they began to explore the possibilities of finding a synthetic dyestuff with the desired selective affinity and the consequent high toxicity for the infecting trypanosomes, and relatively little for the tissues of a mouse. Ehrlich's friend, Dr. von Weinberg, of the Cassella dyestuffs firm, was ready to place its resources at the disposal of the new enterprise; and when I myself was working in the Frankfurt Institute for a short period, in 1903-4, Ehrlich and Shiga had just reached an initial success with the discovery that trypan-red, a sulphonated benzidine dye, would definitely cure an artificial trypanosome infection in mice. In the event, it was not found to be similarly effective in the natural trypanosome infections of man and the larger animals, as they occur in tropical Africa; but its discovery had shown the potentialities of the chemotherapeutic approach to the problem and given great encouragement to further explorations by the same method.

All the world knows about Ehrlich's discovery of salvarsan, which has even been made the subject of a popular

film; and it has, indeed, a proper claim to such wide recognition, as the first great practical success of chemotherapy, and one which brought new hope of an effective campaign against what had been one of the most resistant of the microbial enemies to human health in all the world. But it seems to me that the debt of medicine, and of humanity, to Ehrlich's dedicated genius would have been but little diminished if he had never discovered salvarsan, or any other chemotherapeutic remedy with a comparable importance for practical treatment. For there are other important practical successes, achieved by Ehrlich's methods long after his death, the origins of which can be traced in fairly direct line to pioneer observations which he had made many years before, without any such directly practical results. We have seen already how the scientific pedigree of the first artificial remedies for malaria can thus be traced to Ehrlich's trial of methylene blue; and, similarly, trypan-red, though it was not itself effective as a practical remedy, can be recognized as the founding ancestor of the line leading to germanin (suramin). I am sure that other examples of such particular derivations could be found; but in addition to them all, and surpassing them by far in its claim upon our grateful recognition, we should remember how large a part of all the great and still expanding advance in the direct and specific treatment of infectious diseases can be traced at its beginning to the inspired vision, the brilliant initiative, and the invincible scientific enthusiasm of Paul Ehrlich.

An Unusual Personality

Paul Ehrlich was a man not only of rare scientific genius but of a very unusual personality. His waking thoughts and attention were concentrated upon his scientific activities and speculations with a burning intensity. Any visitor, if he could be thought to have some kind of contact with such interests, was likely to find himself abruptly plunged into a flood of enthusiastic and exclamatory exposition, though he could hardly fail to retain some stimulus and inspiration from the immersion. Within his special range Ehrlich's knowledge was profound and comprehensive, and his memory prodigious; but beyond the sharply drawn limits of that range he made no secret, but rather a parade, of the astonishing completeness of his ignorance. Anything electrical, for example, was entirely beyond his ken, and he would confess to, or boast of, his inability to remember the direction of the earth's rotation. Apart from his unremitting concentration on his scientific work, his small remainder of interests and activities had a remarkable simplicity.

He seemed to read very little outside his own scientific range. I have heard him speak with enthusiasm, indeed, of the Sherlock Holmes stories, and a portrait of Conan Doyle hung on his study wall; but that was because he prided himself on a supposed resemblance between Holmes's detective methods and those of his own researches. His tastes in the fine arts were those of a child; and there were many other child-like aspects of his character. He had no trace of the pomposity which men of his eminence in the Germany of those days were apt to display; and his freedom from many normal inhibitions could be endearing or exasperating, according to the circumstances. He seemed to be generous and petty, open-hearted and secretive, culpably careless of his own interests, and fiercely, explosively resentful of anything which he felt as an encroachment, or even as unfair criticism—all in turn and unpredictably. His character seemed, indeed, to have a heavy dose of what is commonly called the artistic temperament, but without any faculty of artistic appreciation.

With it all, nobody who had the privilege of knowing him, and of working at any level under his stimulating influence, can have had any doubt of his essential greatness. The world has abundant reasons of gratitude for his achievements and his inspiration, and for celebrating the centenary of the birth of one of its great benefactors.

The portrait is reproduced from *Paul Ehrlich*, by Martha Marquardt, by kind permission of the publishers, Wm. Heinemann (Medical Books) Ltd.

PAUL EHRLICH—MEMORIES OF 1905-7

BY

C. H. BROWNING, M.D., LL.D., F.R.S.

Professor Emeritus of Bacteriology, University of Glasgow

Paul Ehrlich merely as a figure of a man was not conspicuous; he was of moderate build and slightly under average height; but often, as the proverb goes, "good gear is small bulked." As I saw him first, his features are well conveyed by the frontispiece of Bolduan's translation of the *Collected Studies in Immunity* and the volume published under the title of his name to celebrate his 60th birthday (Jena, 1914)—the frontispiece of Miss Marquardt's book is like the latter. A Scottish friend on seeing these pictures remarked, "He might have been a Scotsman." In repose his expression had something finely spiritual, but the lean, stressed, and wistful face of later photographs was that of an ill and harassed man. What cannot be adequately reproduced is the intense alertness and animation which informed his looks, voice, and movements. His absent-mindedness, illustrated in so many stories, true or apocryphal, had no influence on his deepest interests, which comprised not merely his investigations in a restricted sense, but everything bearing even remotely on them. To direct his attention successfully to any matters which lacked this appeal required strenuous persistence. The preoccupation was intense; at whatever place or time he might encounter an assistant the talk quickly turned to experiments on hand or in the future.

Fellow guests casually met would be told about published work in a lucid and entertaining way which can be glimpsed from the formal lectures. For visitors to the "Institut" he would demonstrate with the stub of the broadest make of crayon pencil the structure of an antigen and antibody by bizarre shapes (somewhat modified, although still recognizable, in the hands of present-day investigators of the subject) or the constitution of a drug by benzene rings like irregular ovals. He was as a rule kindly and humorous, appreciative of help and quite tolerant of criticism provided it was not expressed polemically. But then, as the French say, he became "the savage beast; when attacked it defends itself." Some of the controversies, like that with Gruber, illustrate this, or an earlier reminder to an objector that but for his (Ehrlich's) discovery of the acid-fast method of staining the tubercle bacillus he would not recognize one on meeting it face to face.

A Happy Period

The period I refer to was a happy one for Ehrlich; his reputation with scientists throughout the world stood very high (although, of course, his greatest fame with the general public was still to come): his work on the blood and on immunity and the discovery of trypan red had aroused the widest interest and respect, and there was a continuous stream of visitors distinguished in biology, chemistry, or medicine. Work went on actively and with an absence of the hurry and strain which developed later when the practical application, or in many cases misapplication, of salvarsan involved Ehrlich in worry and frustration. I had been received as a voluntary assistant at the Königliches Institut für Experimentelle Therapie on the recommendation of Professor Robert Muir after participating in his work on haemolytic sera, etc.; but I found that Ehrlich's interest in the subject of immunity had ceased to be active. However, Sachs was carrying on this line of investigation with distinction, and I took part with him for some months and

have warm memories of his kindness and impartiality of outlook. Stabsarzt Otto, a genial and able man, was in charge of the statutory control of antisera and also carried out fundamental research on the recently discovered Theobald Smith phenomenon of serum anaphylaxis in guinea-pigs.

Ehrlich was more concerned with cancer research, in which his co-operator was Apolant, a gifted musician as well as investigator, while Roehl, in a suite of two small rooms, continued what was fast becoming Ehrlich's chief interest, the chemotherapy of trypanosome infections, begun with Shiga and Franke. Berthelm, the organic chemist, who came almost at the same time as I, and then Miss R. Gulbransen, along with several visitors and the veterinarians Sticker and later Schöne, and Bechhold, a physical chemist, made up the research staff during the two years that I was in Frankfurt, except that when the Georg Speyer Haus, built adjacent to the Institut, was opened and the work on chemotherapy removed to it, additional chemists came there. As Ehrlich said, he did not like too many doves flying in and out. Max Neisser's bacteriology department, housed in the Institut, was largely self-contained.

Soon after my arrival Roehl was due to leave for another appointment, and to my great good fortune I was asked to succeed him, and became an official assistant. This entailed one or more talks with Ehrlich on most days and the receipt of at least one of the notes which he wrote, chiefly at home, whenever ideas struck him, on thin cards of the size of a single sheet of notepaper, usually of canary yellow colour. These "blocks" were copied and laid on the laboratory table first thing in the morning; they contained comments, suggestions, or requests arising out of the work and were signed with a sprawling E. When one could half-guess the contents it was possible to read them; but Sachs alone could decipher them at first sight. Conversations were held at unspecified times when Ehrlich made a round of the departments. Two exclamatory formulae invariably were associated with his entrance to a laboratory—"Fenster zu" (his dislike of draughts was intense; as a young man pulmonary tuberculosis had been diagnosed and he spent some time in Egypt, but the open-air cure had no place in his regime) and the famous "takko" (as it sounded to me), which, I imagine, was a portmanteau word composed of "guten Tag" telescoped into "nun was gibt es neues"—a courtesy greeting smothered by an impatient desire to learn at once the latest progress of experiments; his writing, too, consisted largely of abbreviations. On other occasions one was called to his narrow room in the Institut, with shelves, table, and chairs crowded with a disarray of books and papers, where visitors were received. It might happen that on arrival Ehrlich was dictating a letter to his secretary; then he fixed his eye on the newcomer and continued as if delivering a personal message to the latter.

His Liking for Aphorisms

The talks arising out of the researches were an intensely stimulating experience for any young assistant. They ranged widely over every aspect and were accompanied by comments on other investigators and their work in similar fields and filled with allusions the appositeness of which was a mark of Ehrlich's powers. Talk was enriched with lively and thought-provoking aphorisms which were unforgettable. I quote several as nearly as possible in the original words (translated), and, I feel sure, true to their spirit. "When taking a journey in a balloon you can't tell what the scenery will be like where you land, but you can keep your eyes open and see what is there" (he always insisted on the importance of observing what happened under fresh conditions). "My researches on the leucocytes were like a fisherman setting his net—something had to get into it." "Work like that of Emil Fischer [i.e., the synthesis of polypeptides] has the great disadvantage that the more amino-acids one successfully unites, the more difficult it becomes to add another." "The use of refined methods to measure something liable to uncontrollable variations is pseudo-

exactitude," or, put in another way, "If you succeed in eliminating 19 fallacies, there will always be a twentieth which you cannot get rid of." "The chemists remain riveted to their theories" (he was often at odds with the academic chemists and disapproved of their satisfaction with reactions which after months of work yielded only a few milligrams of product). "The pharmacologists have been content to chart only the dangerous shoals and sunken reefs of therapy, but never a safe haven" (his comment on the then prevalent toxicological studies of drugs).

Ehrlich was much given to thinking aloud and, I believe, whetted his mind on a listener. Such time as he had free for personal work in the laboratory was spent in performing chemical reactions, the apparatus being test-tubes and a Bunsen burner on a large table, which, like the shelves, was covered with bottles of chemicals and reagents, many of them without labels other than those he carried in his head. I guess that the elucidation of the constitution of atoxyl began when he found it could be diazotized and so was not an anilide as then supposed. A credible story was that a monkey which had the run of the laboratory could shake a test-tube over an imaginary flame with precisely the attitude of the master.

The work required of an assistant, at that time at least—investigations on the arsenobenzenes, including salvarsan and arsenophenyglycine, were only beginning when I left—was not heavy, and a great part of the day was free to use or waste at one's own discretion. Provided Ehrlich's moderate requests were met no questions were asked or available materials grudged. One lesson, however, was learned early—never to state the intention to carry out any line of experiment on one's own initiative, but to try it and if something of interest emerged to demonstrate the findings to him. In that event the highest reward came in seeing the satisfaction with which he accepted the result.

Some Personal Characteristics

Ehrlich was a sedentary man; he always drove in a cab to the laboratory in the morning and home again at a variable time after 3 p.m. There must once have been an accidental fire which had impressed him strongly, because he would come, even upstairs, before leaving, to say, "Lampen aus," although work was going to continue for several hours longer. His scientific reading was done with great rapidity and an unerring eye for the important points, and his memory was immense. His recreations, apart from the time passed with his family, included detective novels, Sherlock Holmes was a favourite, and H. G. Wells's *Food of the Gods* pleased him very much. Also, he worked mathematical exercises; he told his younger daughter's husband, a mathematician, "I do mathematics when I am tired." Then there was the inevitable succession of cigars throughout the waking day. Music and art made no great appeal, possibly because they would have taken up time required for thought on his own work, which was almost incessant.

Ehrlich's genius lay in his art of devising experiments which yielded important results, his faculty for correlating facts from his profound knowledge of biology and chemistry and thereby effecting syntheses unnoticed by others, and his capacity for getting things done. He seemed to be able to rid himself of preconceived ideas. As he said, "It is absurd, but we shall try it," meaning by absurd not foolish, but contrary to prevailing opinion. When new facts were discovered, they were stringently verified by repetition and modification of experiments. Publications were made in the light of added knowledge far in advance of that revealed; thus he was usually saved from the need to retract afterwards. While the facts might be largely contributed by his co-workers, the pattern of theory woven attractively round them was his own. He had the gift of holding attention and making what was highly complex sound clear and understandable to those less informed on the subject than himself, and, I believe, he obtained great pleasure from exercising this power. Some of his predictions were inspired, such as that of the side-chain (receptor) theory of nutrition,

recently established firmly by Whipple, according to which direct entrance of protein molecules into cells, as well as their exit, occurs. Like a diviner, he seemed to sense the presence of treasure, and a generation following him has been engaged in digging out a part of it. His self-reliance was supreme, but it was based on a vast amount of skilfully conceived work. Is it surprising if he occasionally missed something, made a slip, or spoilt an experiment? Truly he was a Master Builder.

PAUL EHRLICH
SOME REMINISCENCES

BY

MARTHA MARQUARDT

Secretary to Paul Ehrlich, 1902-15

I regard it as a great and most lucky episode of my life that I was allowed to work for Ehrlich as his secretary day by day for 13 years; and that, observing his actions and hearing him speak to his friends and colleagues, I was given an insight into the wonderful riches and greatness of his soul. Paul Ehrlich appointed me his secretary in November, 1902, "on approval," for he declared that he did not know whether he would get accustomed

In the laboratory.

to dictating his thoughts, letters, and scientific papers. Much later I learned the true reason: once, in Berlin, he had engaged somebody to help with his writings, but the typist, writing down all his interjections and repetitions, produced a strange sort of script. Finally, getting nervous, she was unable to take down his dictation and ran away. Of course, Ehrlich wanted to protect himself against another such experience.

Ehrlich liked to read detective stories, for they could "almost" distract his attention from his work; but even these, as all other books he read, bore on the inside and the covers his notes written in coloured pencil—a proof of not being distracted. He could not return borrowed books when asked for, but had to order new ones to replace them. Scientific articles sent to Ehrlich by their authors would, having been read, show in the margin or on the cover Ehrlich's judgment, such as "good," "important," "must be read carefully"; but sometimes quite frankly "miserable." Once somebody applied for a position and sent to Ehrlich a copy of one of his publications. Later on, having received no

answer, he asked a friend who was working with Ehrlich to say a word about him. When this friend spoke with Ehrlich about the applicant, Ehrlich merely pulled out of the piles of books on the big sofa a small reprint and handed it to him. In large letters there was but the remark on the cover: "Quatsch" (bosh). Both laughed heartily, and the case was dismissed.

"606"

In 1905 the discovery of the microbe causing syphilis was announced. This event was of great importance in medicine. The Kitasato Institute for Infectious Diseases was founded in Tokyo, on his return to Japan, by Kitasato, a friend of Ehrlich's since the time of their studies at the laboratory of Robert Koch in Berlin. And now, after the discovery of the syphilis spirochaete, one of the most talented of Professor Kitasato's pupils, Dr. Hata, started at once with experiments to produce syphilis in rabbits by inoculation, gaining great skill in his work. In the spring of 1909 Dr. Hata was sent to Ehrlich to continue work on these lines at the Speyer-Haus, producing infections in rabbits experimentally and then testing on these infected animals the curative properties of the preparations worked out by Ehrlich. Dr. Hata was delighted to do this work, took all the small bottles Ehrlich gave him, with inscriptions on the labels, and said proudly, with a nod, "418," "606." Dr. Hata, after his first trials of all the substances given to him, soon came to show Ehrlich his records, and said: "Believe 606 very efficacious." Ehrlich would not believe it, and Hata, untiring, did not shrink repeating the experiments again and again until a clear and definite result was obtained that 606 was best. Ehrlich then confessed that he always had had a strong feeling—yes, had been convinced for two years—that 606 must be good. Trial treatments of patients had now to be made again by those collaborators who had already been working with 418 successfully, and finally Ehrlich consented to announce the invention of 606 to the world, following a number of publications showing good results.

Ehrlich had to receive all medical visitors asking for 606, telling him personally what observations they had made, asking his advice about special cases; he had to listen to patients who wanted to be treated by him, and sent them to one of the clinics where treatment was given. Untiring, he had a kind word for everyone and helped wherever he could. Besides all the urgent work at the laboratories, in the chemical section, and in the biological section where continued series of animal experiments required his presence and help, he had to watch over the process of manufacture with every precaution, to safeguard 606 from the influence of oxygen. Later on Ehrlich said himself: "Without the strictest observance of all necessary precautions it would have been impossible to introduce 606 into human medicine."

In addition, something quite different required Ehrlich's attention: from everywhere crazy ideas for treatments and cures were sent in. In spite of all his urgent work, Ehrlich found time to answer inquiries politely. People seeking positions asked for work; many beggars implored his help; children told him that their birthdays were on the very same date as his; people with the same name inquired if they were not relations. To those who asked for help Ehrlich sent a sum of money; he was the kind of helper who did not let his left hand know what his right hand was doing. He simply wanted to help and could not say "no," for this "no" may have made unhappy somebody who urgently needed help. He was always ready to assist members of the medical profession or their families who were temporarily or really in want. Large sums were often involved, and it was understood that they were gifts, not loans.

During the seven months or so following the Wiesbaden Congress until the Congress in Königsberg in September, 1910, much experience with 606—which had been given the name "salvarsan"—had been gained, but Ehrlich did not cease to advise everybody at the Congress not to be content

with a momentary success, but to observe strictly all precautions in using 606.

In the meantime, as was also the case previously, trouble had arisen when using salvarsan, and when Ehrlich returned from Königsberg more unfavourable experiences were reported. Ehrlich now called out in distress: "Those wretched scoundrels are really going to smash salvarsan entirely, because they will not pay attention to any of my instructions," and, clenching his fists, he went on: "But I shall force my will upon them! I shall introduce intravenous injection and insist upon it for all treatment with 606, to put an end to this hoggish, dirty behaviour once and for all!" "They will all object to it," remarked Dr. Sachs critically, "they are not used to intravenous injection—it is given only in cases of extreme emergency." "Then they must learn it . . . I shall demand it and compel them to do it . . . the blood will get the better of all the dirt." And Ehrlich succeeded, though only after another grave incident.

In December, 1910, the chemical works completed big installations for the manufacture of 606, tried it out, and produced quantities sufficient to cover the requirements of all pharmacies for some time. Supplies from the Speyer-Haus were now no longer necessary. Since the announcement of the invention of 606 at the Wiesbaden Congress in April, 1910, more than 65,000 doses had been sent out free of charge.

Honours and Celebrations

On March 14, 1914, Ehrlich's 60th birthday, the daily papers had long articles about him and his wonderful work; some issued richly illustrated special numbers in his honour. The scientific periodicals also celebrated the occasion. Hundreds of telegrams and letters from all countries came in, and many of his friends from abroad arrived to take part in a simple friendly celebration, and all his family and relations were there. His assistants and former pupils had compiled a special book on his work, a volume of 668 pages (*Paul Ehrlich, Eine Darstellung seines wissenschaftlichen Wirkens*, Gustav Fischer, Jena). Dr. Arthur von Weinberg, a helpful and appreciative friend of Ehrlich's for many years, announced that, on his suggestions, the pupils and friends of Ehrlich planned, as a gift to him, to found a new wing to the Serum Institute, with a large laboratory, equipped in the most up-to-date way, and, adjoining it, a pleasant study with armchairs, large writing-desk, book-cases, and an office for me. Paul Ehrlich was deeply touched by these generous gifts and shook hands all round, with a few kind words for everybody. Of course, Ehrlich stayed in his old rooms, as nothing was as yet finished. Later on, the laboratory being almost ready, Ehrlich went over—but once—to see what it was going to look like. Taking a deep breath, he then went back to his old rooms which he loved and where he was happy to work.

In 1908 Ehrlich and Professor Metchnikoff, of the Institut Pasteur, Paris, were awarded the Nobel Prize for their successful studies in immunity. That was for work dating back almost 20 years. When Ehrlich, in December, 1908, went to Stockholm to deliver his lecture before the Nobel Committee, he spoke of "Chemotherapy." On his return to Frankfurt Ehrlich's friends organized a party to celebrate this honour. As his friends knew of his dislike for big official ceremonies, this party was arranged in a big hall in Frankfurt as a so-called beer-party, with much mirth and informal gaiety. Ladies were not admitted, but Ehrlich's wife and daughters, and those of his friends, were allowed to look on from the galleries above. Dr. Adickes, the Lord Mayor of Frankfurt, made an enthusiastic speech, saying that Ehrlich would be capable, if required, of working at and managing any number of institutes for research besides the two he already had. The audience showed their approval by great applause.

Wartime Activities

In August, 1914, war broke out. Newspapers came out with enormous headlines; crowds gathered round the news-

stands, some looking sceptical, some sad, some pugnacious; marching men were everywhere; there were endless goings to and fro. I shall never forget! In the Serum Institute there was great activity preparing serum for the army on a large scale. Every room was used for this work, and every worker. Ehrlich's new laboratory was immediately requisitioned as a control centre for all sera which the chemical works had to produce. In Ehrlich's "reception room" and my office in the new wing cases and chests were piled up, filled with sera ready for use, waiting to be dispatched. Ehrlich had really never liked the idea of leaving his old rooms and moving into the new surroundings. It seems he had a presentiment that he would never work there. Very exhausted from his labours and depressed by continuous attacks from his enemies, Ehrlich had once again gone to Baden-Baden for a holiday; and once again he had to come back to Frankfurt when war broke out.

I shall never forget the distressed look in his face as he put his hands up and cried out: "But this war is pure madness! No good can come of it!" Ehrlich felt quite lost and strange in the noisy bustle at the institute—people running hither and thither, and large cases being continually dragged along the corridor. Only in his old laboratory and his study could he find refuge and a quiet place to think. His staff had planned to take advantage of his absence on holiday to move all his collections and belongings into the new rooms. When he heard of this plan before he left he protested very decidedly: "In my absence nothing is to be touched; I want to take care of all that myself." If this plan had been carried out Ehrlich would not have been able to find anything on his return, and would have had no place to stay; it is impossible to imagine how unhappy he would have been. Once or twice he went into the new wing to see what they were doing there: I can always see how desolate he seemed on coming back, walking slowly down the long corridor into his old rooms, deep in thought, closing the door behind him with resignation.

There were many changes in the Speyer-Haus as well as in the Serum Institute as a result of the war, especially through the call-up for military service. Dr. Bertheim was summoned to his cavalry corps at once, and on the first day in Berlin, going down the stairs in the house where he was billeted, caught his spurs in the carpet and fell, fracturing his skull and dying instantly. Ehrlich now had only Dr. Paul Karrer, whom he had invited shortly before the outbreak of war to come from Zurich and work with him. Ehrlich could discuss all his test-tube experiments with him and entrust to him the detailed working out of his ideas. They were on friendly terms, and some articles on silversalvarsan were published. Later on Dr. Karrer returned to Zurich, and in 1939 was awarded the Nobel Prize for Chemistry.

Failing Health

During the first year of the war—the last of his life—Ehrlich's health grew worse, and he had to follow strict medical advice with regard to diet. Long years of heavy smoking of strong imported cigars, irregular meals, in fact almost complete disregard of proper food—these combined to produce a disastrous effect on his system. He had to give up smoking, and this he found very hard, though he always pretended that leaving off a habit was really not difficult. But with a complete lack of appetite he found it "an absolute torture" to take the prescribed amount of nourishment. He knew it was necessary, and tried the best he could. About Christmas, 1914, Ehrlich had a slight stroke, but recovered from the obvious effects in a few days. It was a first serious warning; his grave illness progressed imperceptibly, without giving him or those around him any suspicion that catastrophe was near.

Shortly before the war Ehrlich was at last persuaded by his friends to buy a car for more comfortable travel between his house and the institutes. War came, and immediately his car was requisitioned by the military authorities and he had to go back to his old custom of using a horse-drawn cab. In this last year of his life I used to call for Ehrlich

every morning at his house to accompany him to the institutes. In fine spring weather we went by cab only as far as the Hippodrome Riding-School, where the Paul Ehrlich-strasse begins, and then walked down the street. On one side there were no houses, only building sites, the plots surrounded by fences, with bushes of acacias and elder, grass and trees. Ehrlich was always very fond of gay flowers with bright colours and strong scents, and he would pause and breathe in the fragrance of a flower or bush in bloom, his eyes delighted. He paused and looked, and with a slight nod would pass on, saying simply: "Nice, isn't it?" In the car rumbling along the streets, passing the railroad station, over the Wilhelms Bridge, he often sat silent, and I did not venture to disturb him. He was depressed and discouraged by the war, which he said could not end well and ought to have been avoided. Also he was deeply distressed by the interruption of his scientific relations with all his foreign friends. He spoke affectionately of his grandchildren, who often came to see him; he would even laugh at a funny street scene or an odd notice at a shop in passing by.

Sometimes he talked quite cheerfully about his future scientific plans. Once he said to me: "You know, I need never work out anything new at all. If I followed up all the thoughts and problems I have noted down in 'blocks' and put aside in favour of other more urgent work, if I took up all that again, I could keep a dozen chemical assistants busy with work for years. Those 'blocks' are a real gold-mine of discovery." But Ehrlich was now more often in a depressed state of mind. His elasticity had never failed him in overcoming even the greatest difficulties; with tenacious perseverance he had always piled experiment upon experiment to find a really scientific foundation for his theories; his titanic, heaven-storming optimism had inspired all his collaborators and pupils; but now he was discouraged, tired out, and too weary to fight any more.

Last Days

At the beginning of August, 1915, Ehrlich went to Bad Homburg, near Frankfurt, for a holiday and treatment in the sanatorium of a friend, lovingly cared for by his wife, his daughter Marianne, and his grandchildren. It had been arranged that I should go there now and again, to avoid a too great accumulation of work during his holiday. When I was asked to come I was told on arrival the terrible news: Ehrlich had had a second stroke during the previous night and was sinking rapidly. He still recognized me and was able to exchange a few kind words. His elder daughter Stefanie and the two sons-in-law hurried to him when summoned by telegram. His wife, the true companion of his life, and all his family were with him when—on August 20—he drew his last breath and his eyes closed for ever.

Paul Ehrlich is buried in the Jewish Cemetery of Frankfurt. On top of the two high columns at the entrance of the box-edged tomb are, visible from afar, the Star of David and the Snake of Aesculapius. A large slab of marble from the quarries of his native Silesia covers the tomb, upon which only his name and the dates of the beginning and end of his remarkable life are engraved. On a high stone carved from a natural block of marble, at the head of the tomb, was a large vase of porphyritic rock containing trailing rose-bushes with an abundance of blossoms. His resting-place was covered with the falling petals. Despite the ravages of war Paul Ehrlich's resting-place has not been damaged.

Ehrlich dedicated and sacrificed his whole life to the welfare and healing of mankind, never failing in his idealism, his optimism, and his faith, until he finally broke down from exhaustion. Nothing on earth mattered to him except scientific research aimed to overcome suffering and disease, and to increase the happiness of mankind. His unshaking and unwavering faith in the progress of his work was like a warming flame which filled his whole nature and shone forth in all his actions.

Paul Ehrlich will never be forgotten.

EMIL VON BEHRING

BORN MARCH 15, 1854

BY

Sir ARTHUR S. MacNALT, K.C.B., M.D., F.R.C.P.
F.R.C.S.

Formerly Chief Medical Officer of the Ministry of Health

The Army Surgeon

Emil von Behring, "one of the greatest benefactors of humanity" (*British Medical Journal*, 1929), was the son of a schoolmaster, who had 11 other children. He was born at Hansdorf, Deutsch-Eylau, West Prussia, on March 15, 1854, the day following the birth of Paul Ehrlich. He took his doctor's degree at the University of Berlin in 1878 and passed the State examination in 1880. He began his career as a military surgeon, serving in the Army Medical Corps, first at Posen, then in 1887 at Bonn, as staff surgeon, and lastly in the same rank in 1888 at the Army Medical College, Berlin. His first published paper (1887) dealt with iodoform as an antiseptic.

While still an army surgeon Behring was impressed by the discoveries in bacteriology which were revealing the cause of a number of diseases, and especially by the great work of his compatriot Robert Koch. In the early 'eighties, therefore, he began a series of investigations which were the precursor of his main life-work. Bacteriologists had noted already that white rats were immune to anthrax, while wild rats were susceptible. Behring took the fresh serum of white rats and tested it on anthrax bacilli *in vitro*. In a short time the bacilli were killed. Nuttall had made similar observations on the bactericidal powers of the fresh sera of man and of several animals, and his observations, together with Behring's findings, led to the humoral theory of defence against the invasion of germs into the animal body.

Discovery of Diphtheria Antitoxin

By 1889 Behring had left the army and had become an assistant to Koch at the Institute of Infectious Diseases, Berlin, then a stimulating and productive centre of bacteriological research. In 1884 F. Loeffler had been deeply immersed in the study of diphtheria and had issued his exhaustive work on the bacillus of the disease, which he identified with the bacillus described by Klebs in the preceding year. Kitasato had discovered the bacillus of tetanus. Both diphtheria and tetanus were shown to be diseases caused by the local multiplication of the organism without

penetration into the body generally. The hypothesis was then advanced that these two bacilli secreted soluble poisons which, being absorbed, acted on the cells of the central nervous system and other organs of the body.

Loeffler's work had been subsequently confirmed by many observers, but particularly by Roux and Yersin at the Pasteur Institute in a series of three important memoirs (1888-90). They also announced that they had grown diphtheria bacilli in broth and removed the bacilli by filtration through unglazed porcelain; the resulting sterile filtrate on injection into animals produced the characteristic symptoms of diphtheria; this soluble poison they termed a toxin.

These important results aroused universal interest. Loeffler had also been engaged in searching for the hypothetical toxin, and in 1890 Brieger and C. Fraenkel prepared a toxic substance from cultures of the diphtheria bacillus in bouillon, which they called "toxalbumin." By injections of this toxalbumin into guinea-pigs, Fraenkel established an immunity, so that 14 days later the animals were resistant to a virulent living culture of *C. diphtheriae*. These results were published in the *Berliner klinische Wochenschrift* on December 3, 1890, and on the following day, December 4, there appeared in the *Deutsche medizinische Wochenschrift* Behring and Kitasato's classical paper, entitled "Ueber das Zustandekommen der Diphtherie-Immunität und der Tetanus-Immunität bei Thieren." One week later (December 11) Behring, alone, published another paper, in the same journal, dealing with immunity against diphtheria and enumerating five different methods by which this could be obtained.

These papers announced the great discovery that an animal immunized against tetanus and diphtheria by graduated injections of killed broth cultures of these bacilli produces in its blood substances which are capable of neutralizing the toxic action of these bacilli. It was also

shown that an animal previously injected with the serum of such an immunized animal was resistant to an otherwise fatal dose of bacilli or toxin; and, in addition, that an animal when treated with the serum, even if symptoms developed, could be cured. The substance in the serum of immunized animals was given the name of "antitoxin" by Behring and Kitasato. As the treatise on diphtheria of the Medical Research Council (1923) states: "In these papers we have the details of one of the greatest discoveries ever made in medicine. . . . History must assign unchallenged to E. Behring the merit of the discovery of antitoxin. It came at the end of a long period of research in which the bactericidal action of the blood had been very thoroughly studied."

These experimental results opened the gate of the new field of serum therapy for mankind. In quick succession many papers appeared confirming and amplifying Behring's discovery, including further papers by Behring himself and by Ehrlich.

Emil von Behring.

Treatment of Diphtheria in Man

The practical application of the discovery to the treatment of diphtheria in man was advanced by the further work of Behring and Baer and of Behring and Wernicke. The antitoxic serum was tested in children with favourable results. The first child treated by antitoxin was a patient in von Bergmann's clinic in Berlin, the injection being made by Geissler on Christmas night, 1891. The firm of Meister, Lucius, and Bruning began to immunize animals in their factory at Hoechst in 1892.

In 1893 Behring had the title of professor conferred upon him. In this year with Kossel and Heubner he recorded the first cases in man treated with the new remedy.

Emile Roux, with his fellow-workers Louis Martin and Yersin, was mainly responsible for bringing diphtheria immunization from the experimental to the practical stage. Roux and Martin were the first to immunize horses, and were thus enabled to produce antitoxic serum in large quantity. In the hospitals of Paris serum treatment of diphtheria was established by 1894. In that year Roux was able to announce in his famous address at the International Congress of Hygiene and Demography at Budapest that the case mortality in children suffering from diphtheria in the Paris children's hospital had already been reduced from 52 to 25%.

In England in the summer of 1894 E. W. Goodall first treated by the new method some 20 patients suffering from diphtheria with favourable results, in the Eastern Hospital, Homerton; he used serum supplied to him by Sir Joseph Lister, who had obtained it from Roux. Goodall stated in his book (*A Short History of the Epidemic Infectious Diseases*, London, 1934) that in the autumn of the same year Armand Ruffer prepared antitoxin at the British Institute of Preventive Medicine, now the Lister Institute, and this serum was first used at the Eastern Hospital on October 23, 1894. It has lately been put on record that Sir Charles Sherrington used the first antidiphtheric serum made in this country on October 15, 1894. The serum was prepared by Ruffer and himself at the Brown Institution. The patient, a boy of 8 years, was regarded as dying from diphtheria. He recovered. (See *Marginalia* contributed by Sir Charles Sherrington to *Science, Medicine, and History: Essays on the Evolution of Scientific Thought and Medical Practice* written in honour of Charles Singer. Oxford University Press, 1953, Vol. II, 550).

Ehrlich's Standardization

In 1895 a control station was set up in Berlin for testing antitoxin; in 1896 this became an institute for serum research and testing, first at Steglitz (Berlin), and from October 1, 1899, at Frankfurt under the direction of Paul Ehrlich. He produced a quantitative method for determining the antitoxic value of any sample in units defined in relation to a stable standard of reference; his method is still the most accurate of all such biological titrations, and, incidentally, he laid down the main principles for all standardizations by the use of biological tests, which subsequently provided a basis for the accurate dosage of many different types of new remedies (Dale, 1950). By Ehrlich's work a good antitoxin with a precise measurement of its activity was made available to mankind, and antitoxin could be given in an adequate dose at the onset of diphtheria. The mortality of the disease, in such cases, fell to insignificant proportions. Ehrlich therefore greatly extended the practical application of Behring's discovery to the cure of diphtheria in man.

International Recognition

Within a few years the administration of antitoxic serum to patients suffering from diphtheria became a routine method of treatment. In an address, "The Aims and Achievements of Serum Therapy," delivered at the Naturalists' Congress in 1895, Behring said: "I have no fear that the thought which forms the basis of serum therapy will ever disappear out of medicine!" He estimated that antitoxin treatment produced a reduction of 75% in the mor-

tality from diphtheria in Germany, an annual credit of 45,000 human lives. For this work Behring shared with Roux the 25,000 francs prize of the Paris Academy of Medicine and the 50,000 francs prize of the Institute of France. In 1901, when he received with Roux the Nobel Prize for medicine, he delivered an address at Stockholm on serum therapy. Orders and distinctions in the years following 1895 were showered upon him by learned societies of all European countries. Nor was the prophet without honour in his own country. In 1895 he received the title of Medical Privy Councillor and in 1901 a patent of nobility.

Researches on Tuberculosis

In 1894 Behring became Professor at Halle, and in 1895 was appointed to the Chair of Hygiene at the University of Marburg and Director of the Institute of Hygiene. Ill-health compelled him to give up systematic lecturing and teaching, and he gave only an occasional public lecture. After 1901 he turned his attention to the problem of immunization in tuberculosis. His premises were that human and bovine tuberculosis were but varieties due to the same organism; that infection in man and animals takes place in early life in the alimentary canal and pulmonary tuberculosis is a sequel to such intestinal infection; and that few human or bovine subjects escape infection before reaching adult life. The first two premises were not generally accepted. He attempted to immunize calves against tuberculosis with an attenuated strain of human tubercle bacilli, but the results were disappointing. His bovo-vaccine was largely used in Germany, Russia, Sweden, and America, and for a time aroused much interest. It has not withstood the test of time and prolonged experiments.

For the treatment of human beings von Behring prepared a form of tuberculin, named "tulase," by the action of chloral on tubercle bacilli. The exact method of preparation of tulase was unfortunately kept secret. It was eventually found not to be superior to any other form of tuberculin. He also did experiments on human immunization with killed tubercle bacilli.

As already mentioned, von Behring believed at first that human and bovine tubercle bacilli were identical, and, though there was a time when he favoured their dual nature, he returned in the end to his original belief. He also considered that tuberculosis was a lifelong affection; and contemporaries often quoted his aphorism that "phthisis is but the end of a lullaby sung at the cradle of the prospective consumptive." His experimental work in tuberculosis, although disappointing, was an introduction to the problem of immunization against tuberculosis in man and bovines.

Von Behring was financially interested in the manufacture of antitoxic sera by the great commercial firm of Farbwerke Höchst, which built and equipped laboratories on a well-planned and extensive scale for him. Here he conducted researches in which were used 7,000,000 oz. of cultures of tubercle bacilli. He was also interested in another commercial enterprise, the Behringwerke, which manufactured his bovine-vaccine. As a consequence of these interests von Behring rose to affluence and became the owner of a large estate on which grazed herds of cattle, which he also used for experimental purposes.

In 1905 he had investigated the collection of milk by aseptic methods and its preservation by formalin and hydrogen peroxide. He was the author of numerous articles on the experimental therapeutics of anthrax and streptococcal infections, the hygiene of the milk supply, water, and other subjects. He also wrote books on blood serum therapy (1892), the aetiological treatment of infectious diseases (1893), the history of diphtheria (1893), and the general treatment of infectious diseases (1898).

Discovery of Toxin-Antitoxin

In the study of diphtheria von Behring had achieved fame, and in 1913 he introduced his new preparation for protection against the disease. With Wernicke he had shown in 1892 that immunity to diphtheria was produced

by a protective dose of antitoxin. Later work by Goodman, Lohr, and others showed that such immunity does not persist after two to three weeks from the inoculation. It appears that Behring and Wernicke discovered in 1898 that immunity against diphtheria could be produced by doses of diphtheria toxin neutralized by antitoxin in experimental animals, but it was not until 1913 that von Behring gave his "new" preparation to the world. Theobald Smith in 1907, as the result of successful experiments upon guinea-pigs, had suggested that a toxin-antitoxin mixture might be used for preventive inoculation in man, but it was left to von Behring to achieve this. The preparation of his nearly neutral mixture of diphtheria toxin and antitoxin was varied from time to time, and gradually rendered less toxic.

Active Immunization in Diphtheria

Von Behring's toxin-antitoxin mixture was the forerunner of modern prophylaxis in diphtheria, and here again he must be acclaimed as a pioneer in immunization. The practical application on a large scale in New York City was due to the work of W. H. Park and to Bela Schick's skin test with a small dose of diphtheria toxin, which gave evidence of the need of the individual for immunization and of its success when applied. Sheldon Dudley's work and tests on young naval personnel assisted in establishing the value of the method in Great Britain. The immunizing reagent (toxin-antitoxin) has been modified in various ways—for example, the production of toxoid by treating the toxin with formaldehyde (toxoid-antitoxin mixture), etc. In Hamilton, Ontario, the incidence and mortality from diphtheria had shown little change for years up to 1925, when general immunization began. Thereafter, both fell so rapidly that there has been no death from diphtheria since 1930 and no case of the disease since 1933. Similar excellent results have been secured in other parts of Canada and in the United States of America. In this country successive Chief Medical Officers of the Ministry of Health have advocated artificial immunization since 1922, but, in spite of official memoranda and the co-operation of a number of medical officers of health, both incidence and mortality of diphtheria continued high. The incidence varied between 69,480 cases in 1920 to 46,281 in 1940 (England and Wales). At the end of 1940 the Ministry of Health undertook the free provision of prophylactics, the cost of which had been borne by local rates. This provision undoubtedly aided the campaign for immunization, which during the war years and subsequently has been vigorously pressed. In 1952 only 376 cases of diphtheria and 32 deaths in England and Wales were recorded, as compared with 23,199 cases and 934 deaths in 1944.

Such are the encouraging sequelae of von Behring's pioneer work in diphtheria immunization.

Von Behring in his later years was subject to severe periods of mental depression, which the advent of the first world war exacerbated. He died at Marburg of an acute attack of pneumonia on March 31, 1917.

The Significance of von Behring's Work

In the course of this paper reference has already been made to the significance of von Behring's work. In general terms it can be said that he was one of the founders of immunology as a science, and that Ehrlich's standardization of diphtheria antitoxin augmented its potentialities. Tetanus antitoxin, the discovery of von Behring and Kitasato, was another striking example of passive immunization, and its value has been proved in the prophylactic treatment of the disease. The specific sera which neutralized the other sporing anaerobic bacteria causing gas gangrene, together with tetanus antitoxin, helped to reduce these deadly complications of soil-contaminated wounds in two world wars. Antisera have also been used in dysentery due to the Shiga bacillus, and in the treatment of pneumococcal pneumonia and cerebrospinal meningitis. The use of all these antibacterial sera has largely given place to chemotherapy. In 1935 came the sulphonamides and later penicillin, streptomycin, and other antibiotics. It is of interest here to note that von

Behring at first attempted to produce a disinfection in the body by a great variety of chemical substances. With trichloride of iodine he partially succeeded in curing some cases of experimentally produced diphtheria in animals, and his comparison of their blood with normal blood may have aided him in the discovery of antitoxin.

It is a far better thing to prevent disease than to cure it. Active immunization against disease began with Jenner and was applied by Pasteur. Koch and von Behring were unsuccessful in tuberculosis, but Wright's typhoid vaccine has helped to abolish typhoid fever as a scourge of armies. The B.C.G. vaccine of Calmette and Guérin, involving the administration of a living culture of the tubercle bacillus rendered avirulent, has now become the subject of experimental trial in this country. The assessment of the real value of antibacterial vaccines is very difficult. Von Behring's initiation of toxin-antitoxin immunization and its later triumphs have already been described in this paper. Immunization with tetanus toxoid is a more modern instance of successful prophylaxis. Immunization against virus infections, of which the most successful is that against yellow fever, is another recent advance, and work is proceeding on vaccines designed to overcome the viruses of influenza and of poliomyelitis. Much of this successful work in the conquest of disease during the present century has followed from von Behring's pioneer researches, and his discovery of diphtheria antitoxin and toxin-antitoxin. Remembering the great boon he conferred upon mankind by these discoveries and the way he opened to the prevention of this killing disease of childhood, it is fitting, therefore, that the centenary of his birth should be honoured in Great Britain.

The spread of certain diseases from one country, and even from one continent, to another is facilitated by air travel. Insects such as mosquitoes, flies, fleas, and lice may carry diseases dangerous to man. Perhaps most serious are malaria, yellow fever, virus encephalitis, sleeping sickness, typhus, and plague. According to Dr. P. H. Bonnel, of the epidemiological services of World Health Organization, the behaviour of insects in aircraft in flight has been the subject of close scientific observation. Such observations have shown that altitude and changes in air pressure and temperature during long flights do not permanently affect the activities of the insects. The vibrations in modern aircraft are reduced to a minimum, and insects which penetrate into a plane can live there for as long as they can exist without nourishment—that is, if they cannot find what they need in the aircraft itself. It was noted that certain insects laid their eggs on the outside of aircraft, on the wings, the fuselage, the rudder, and even on the propellers. These eggs were found to be still there at the end of the journey: neither the wind nor the altitude nor yet changes in temperature had affected their capacity for survival. On one single plane thousands of larvae emerged from the eggs and swarmed over the surface of the aircraft. Strict surveillance of aircraft and of aerodromes is therefore absolutely essential. This passive defence can be effective, however, only if it is complemented by more active measures which remove all possibility of transporting live insects in aircraft. Active control measures consist in spraying aircraft with insecticidal aerosols containing pyrethrin or D.D.T., but countries vary in their methods and in when "disinsectization" is performed. The application to the interior of aircraft of certain new resinous varnishes in which are incorporated residual insecticides is perhaps the best and simplest means of control. This important aspect of international prevention of disease is one of the subjects dealt with by the W.H.O. committee on international quarantine.

INFECTIOUS MONONUCLEOSIS

A SYNDROME OR A DISEASE?

BY

S. SHUBERT, M.B., Ch.B.

Late Captain, R.A.M.C.; Senior House Officer,
Royal Infirmary, Manchester

J. G. COLLEE, M.B., Ch.B.

AND

B. J. SMITH, M.B., Ch.B.

Pathologist, General Hospital, Newcastle-upon-Tyne

The difficulty of defining any criteria for the clinical diagnosis of infectious mononucleosis is emphasized by the frequency with which the word "protean" occurs in accounts of the features of this disease. Tidy (1934) divided his cases into three groups—anginose, glandular, and pyrexial—and mentioned the frequent overlapping which occurred. This classification has been expanded to include those cases in which meningitis, haemorrhagic phenomena, jaundice, or nephritis is the main feature (Bernstein, 1940; Wechsler *et al.*, 1946). A respiratory form in which cough and nasal discharge predominated was mentioned by Vander Meer *et al.* (1945), while Chevallier (quoted by Bernstein, 1940) described an inguinal form in which lymphadenopathy was restricted to the inguinal region.

It is evident that the clinical criteria for the diagnosis of infectious mononucleosis are limited solely by the ever-increasing number of syndromes recognized as being caused by the disease. Halcrow *et al.* (1943) and Vander Meer *et al.* (1945) added the subclinical or asymptomatic form (*British Medical Journal*, 1947) which they encountered during a haematological and serological survey of apparently healthy contacts during an outbreak of the disease among military personnel. These authors also noted that, apart from these subclinical cases, many mild cases were seen which, if the presence of the outbreak had not been known and laboratory investigations not carried out, would have been diagnosed as colds, influenzas, or sore throats. The problem of diagnostic criteria is not limited to the clinical aspect, but is met in assessing the laboratory findings of suspected cases. Since the causative organism has not yet been isolated, confirmation of the diagnosis rests upon haematological and serological investigations.

In 1942 Paul and Bunnell discovered their non-specific test for the demonstration of heterophil antibodies. Soon after the introduction of this test it became apparent that many cases were occurring which, on clinical and haematological grounds, warranted a diagnosis of infectious mononucleosis but in which the Paul-Bunnell test yielded consistently negative results. Paul (1941) reported the test positive in 90% of 50 cases, but he mentioned a report by Erf, who found the test positive in only 40% of a series of cases. In the outbreak investigated by Halcrow *et al.* (1943) 68% of the patients had titres of 1 in 64 or more. However, in many such reports no mention is made of differential absorptions, and had differential absorption of the antibodies with guinea-pig kidney and ox-blood cells been done it is possible that the number of patients with significantly raised titres might have been even less.

Serology

Attempts have been made to explain the negative serology of otherwise characteristic cases of infectious mono-

nucleosis. Tidy (1952) stressed the significance of the time factor in the development of the antibodies, as did Kaufman (1944), who mentioned one patient who was seronegative on the tenth and eighteenth days, and who became seropositive five months later without any intervening illness. Hoagland (1952), however, found the test positive by the twenty-first day in all but 3 of his 56 cases. The possible effect of chemotherapy in preventing the development of antibodies was discussed by Fuller (1941), Tidy (1941), Paul (1941), and the *Lancet* (1941). The severity of the disease seems to be unrelated to antibody production, as patients may remain seronegative after a severe illness (Barber, 1941). Himsworth (1941) suggested that antibody development might be related to the absolute number of monocytes, while Warren (1941) thought that the percentage of abnormal lymphocytes might be the determining factor. Davidsohn (1937), Fuller (1941), and Whitby and Britton (1950) favoured the opinion that the seropositive and the seronegative cases were caused by different, though closely related, viruses. It is evident that the significance of a negative Paul-Bunnell test in an otherwise typical case varies with different authors. Hoagland (1952) insists on a positive test before calling the disease infectious mononucleosis, whereas others will accept the diagnosis so long as the clinical and haematological pictures are suggestive—in spite of a negative serology.

The characteristic blood picture of infectious mononucleosis has been fully described by Tidy (1934) and Bernstein (1940), and consists of an absolute and relative lymphocytosis accompanied by the appearance of numerous abnormal lymphocytes. Not infrequently this classical picture may be absent. Early in the disease a polymorphonuclear increase may occur, or the initial picture may be one of leucopenia. In some instances a lymphocytosis does not appear at any stage of the illness. The presence of abnormal lymphocytes is a constant feature of the disease, and in those cases without a lymphocytosis it may be the only suggestive finding. Reyersbach and Lenert (1941) reported a symptomless, seronegative outbreak of infectious mononucleosis in a children's convalescent home which has often been quoted as supporting evidence for the existence of a subclinical form of infectious mononucleosis (*British Medical Journal*, 1947). The complete absence of abnormal lymphocytes in all of these cases is against such a diagnosis, and suggests that the authors were, in fact, observing an outbreak of acute infectious lymphocytosis (Moyer and Fisher, 1950). Although the presence of abnormal lymphocytes is a characteristic finding in infectious mononucleosis, it is not pathognomonic. Similar cells have been described in association with many conditions, including mild upper respiratory infections (Stuart *et al.*, 1936; Warren, 1941), tonsillitis (Wilson and Cunningham, 1929), allergic conditions (Randolph and Gibson, 1944), brucellosis (Wise, 1943), measles (Benjamin and Ward, 1932), infective hepatitis (Thewlis and Middleton, 1925; Havens and Marck, 1946; Horstmann *et al.*, 1947), and rubella (Whitby and Britton, 1950).

The situation would appear to be that, although the blood picture is not pathognomonic of infectious mononucleosis, the characteristic changes associated with an upper respiratory infection, tonsillitis, or abdominal pain, together with generalized lymphadenopathy and often splenomegaly, frequently complete a syndrome for which the

diagnosis of infectious mononucleosis seems to be warranted and is often made. In a variable percentage of such cases this diagnosis is confirmed by the Paul-Bunnell test.

Present Investigation

The present paper describes an investigation of 27 cases in which the diagnosis of infectious mononucleosis was made on clinical and haematological evidence, but in all cases the Paul-Bunnell test was consistently negative. The nature of these infections is discussed and their features are compared and contrasted with those of infectious mononucleosis.

All of our patients were seen at the medical centre of an Army camp. Apart from one case, that of a boy aged 6, the ages ranged from 17 to 30. This investigation was initiated by the observation that cases of minor upper respiratory infections, sore throats, abdominal pains, or rashes were noticed to have a moderate generalized lymphadenopathy and blood changes suggestive of infectious mononucleosis. The cases were drawn from about 500 military personnel in the camp. It was decided that patients having lymphadenopathy in association with their illness should be further investigated haematologically and serologically. Many patients who would have qualified for further laboratory examination (because lymphadenopathy was present) were subsequently excluded because of the limited time available to carry out the investigations together with routine duties. Our cases occurred during September to November, 1952, after which they became less frequent and eventually uncommon. In view of the short period over which a large number of cases were observed, had a similar basic clinical picture, and gradually became less frequent, we concluded that we were dealing with a localized epidemic of the disease. In three instances—a medical orderly, one of the authors, and his wife—there was direct evidence that the cases were related by history of personal contact. Twenty-seven patients were examined and submitted for full haematological and serological investigations.

Clinical Features

Rhinitis.—Twenty-four patients complained of "stuffiness of the nose" and had copious nasal discharge. This was one of the presenting symptoms in 10 cases, the remaining 14 having had a marked rhinitis during the week preceding their reporting sick.

Sore Throat.—Six patients had an initial complaint of sore throat. Two of these had tonsillar and pharyngeal injection without exudate, two had follicular tonsillitis, and two had an ulcerative tonsillitis resembling Vincent's angina, although *Sp. vincentii* was isolated from only one of those ulcerative cases. Eight other patients had mild sore throat.

Headache.—This was not a prominent symptom, and occurred in only eight patients.

Cough.—Five patients had a cough, and in two of these the signs of mild bronchitis were noted.

Abdominal Pain.—In four patients this was the initial complaint. In one case pain in the left hypochondrium was accounted for by the presence of a tender palpable spleen. In another patient suprapubic pain and frequency of micturition suggested a cystitis, but this was ruled out by subsequent urinary examination. The pain was epigastric in the remaining two patients, and in all instances abdominal pain subsided within 24 hours.

Bowel Upsets.—Two patients complained of diarrhoea, and a further case had marked constipation. Gastro-intestinal upsets, nausea, and anorexia were not features of our cases.

Lymphadenopathy.—The presence of enlarged glands was, by selection, a constant feature of all cases. The cervical glands were most commonly involved and adenitis was almost invariably restricted to the posterior triangles of the neck. As has been observed previously, the left posterior triangle

Halcrow *et al.*, 1943). Twenty-four patients had enlarged glands in the left posterior triangle of the neck, and the right posterior triangle was involved in only 13 cases. In four cases the enlarged cervical glands were tender. Initially the glands were characteristically small and firm. They tended to become larger and softer during the first week, increasing to the size of a marble. Enlargement of the axillary glands was noted in 15 patients, and inguinal glandular enlargement occurred in 21 patients, in two of whom the glands were tender.

Splenomegaly.—The spleen became palpable in nine cases, and in three of these was tender. In five patients splenomegaly was noted at the first attendance. In three cases the spleen became palpable during the next few days. In the remaining case the spleen first became palpable during a recurrence of the disease six weeks after his first attendance. In four of these cases the period over which splenomegaly was noted to persist was 1 day, 5 days, 6 days, and 10 weeks respectively.

Pyrexia.—Fever was not a constant feature of our cases, as was the experience of Halcrow *et al.* (1943). Seventeen patients were pyrexial at some stage of their illness, with temperatures varying between 99 and 102° F. (37.2 and 38.9° C.). In 16 cases the pyrexia subsided after two to four days. The remaining patient, a young boy of 6, had a prolonged low-grade pyrexia for 38 days.

Rash.—In three cases a rash was the presenting feature and two others developed a rash during their illness. The rash was urticarial in two cases and rubelliform in three. The eruptions all subsided within two days.

Herpes Labialis.—Three patients developed a mild herpes labialis.

Meningismus.—In one patient, a boy aged 6, an initial diagnosis of meningitis was made in view of the findings of neck rigidity and bilateral Kernig's signs, which subsided within 24 hours.

Case Reports

The following case-histories illustrate the variety of the clinical pictures we encountered in this series.

Case 9.—A recruit aged 18 complained of a head cold, present for one week. He was apyrexial, and had marked nasal congestion, and numerous enlarged lymph nodes were palpable in the left posterior triangle of his neck. One week later he was well, but the glandular enlargement persisted. Three weeks later he complained of a recurrence of his cold, and had a mild herpes labialis. The cervical lymphadenopathy had increased and glands were palpable in the right posterior triangle, axillae, and groins. He remained apyrexial. During the next 14 days his symptoms cleared and his glandular enlargement subsided.

Case 10.—A warrant officer aged 30 complained of nasal congestion and a painful neck. He was apyrexial and there were several small tender glands in the left posterior triangle of his neck. His spleen was firm and easily palpable. His inguinal glands became enlarged four days later. Six weeks after his first attendance the enlarged cervical nodes had almost resolved, but the spleen was palpable on deep inspiration.

Cases 5 and 13.—These were admitted with diagnoses of follicular tonsillitis. Both had a typical follicular tonsillar exudate. Their temperatures on admission were 100.8 and 99.4° F. (38.8 and 37.4° C.) respectively. Case 5 had enlargement of the lymph nodes in the right posterior triangle of his neck, in the left axillae, and in both groins. A rubelliform rash of bathing-trunk distribution was present, lasting three days. Case 13 had glandular enlargement in the left posterior triangle of his neck, axillae, and groins, and, in addition, both tonsillar glands were enlarged and tender. Case 5 became apyrexial after two days with penicillin therapy, and in Case 13 sulphonamides were effective in the same time.

Case 3.—A recruit aged 17 complained of suprapubic pain and frequency of micturition. His temperature was

multiple small cervical glands in the left posterior triangle. After two days some larger glands were palpable in his left axilla. A mid-stream specimen of urine, obtained on admission, was sterile. He became apyrexial on the third day of his illness.

Case 11.—An N.C.O. aged 19 presented with tender inguinal adenitis. He was apyrexial. The glands subsided within a week. Two weeks later he developed herpes labialis, nasal congestion, and sore throat. Forty days after his first attendance he returned with pain in the right side of his neck. The cervical glands of both posterior triangles were much enlarged, and in addition moderate axillary and inguinal lymphadenopathy was noted. His spleen became palpable two days later. Fifty-seven days after his first attendance he was admitted with a recurrence of his coryzal symptoms and rubelliform rash of bathing-trunk distribution. He had generalized lymphadenopathy and his spleen was again palpable. His temperature was 99° F. (37.2° C.). His rash, splenomegaly, and fever subsided within three days, when he was fit to return to duty.

Case 1.—A soldier's son aged 6 became suddenly ill and complained of headache. His temperature was 101.8° F. (38.8° C.), and the only other abnormal findings were some slight neck stiffness and bilateral Kernig's sign. His younger brother had been in hospital two weeks previously with a lymphocytic meningitis which, in view of the prevailing outbreak of poliomyelitis, had been labelled as non-paralytic poliomyelitis. On the following day our case was much brighter and his signs of meningismus had disappeared. Although he remained asymptomatic a low-grade pyrexia (99 to 99.4° F.—37.2 to 37.4° C.) persisted. On the seventh day of his illness small beadlike glands appeared in both posterior triangles of his neck, with larger nodes in his axillae and groins. He was then seen at regular intervals, when his pyrexia was noted. An x-ray film of his chest, and the Mantoux reaction, urine examination, and Paul-Bunnell test, yielded no positive results. He remained apyrexial until the 38th day, and his lymphadenopathy persisted. He made a good recovery and has had no recurrence to date.

Serology

The number of serological tests and the period covered by them (as calculated from the first day of the illness) are shown in Table I.

TABLE I.—Showing the Number of Paul-Bunnell Tests Done in Each Case, the Period Covered, and the Highest Titre Obtained

Case No.	No. of Tests Done	Period Covered by Tests (Days)	Highest Titre Obtained
1	3	29	Negative
2	2	26	"
3	2	25	"
4	2	24	"
5	3	27	"
6	3	23	1 in 16
7	4	56	1 in 32
8	2	16	Negative
9	2	29	1 in 16
10	4	46	1 in 8
11	2	56	Negative
12	1	10	"
13	1	21	"
14	2	13	"
15	0	0	1 in 16
16	2	33	Negative
17	2	21	"
18	1	13	"
19	2	28	1 in 4
20	1	24	Negative
21	1	23	"
22	1	26	1 in 4
23	2	38	Negative
24	1	28	1 in 4
25	1	16	Negative
26	1	16	"
27	1	16	"

In Cases 7, 10, and 16 a titre of 1 in 16 was obtained, and Dr. A. G. Messer suggested that absorption tests should be carried out after initially increasing the titres by altering the concentration of the sheep-cell suspension from 1% to 0.2% and substituting centrifugation for incubation. With this altered technique a titre of 1 in 128 was obtained in

each case and this was reduced by guinea-pig kidney to less than 1 in 4, showing that the antibodies were not of the type associated with infectious mononucleosis.

Although in most cases the Paul-Bunnell tests were repeated, they yielded consistently negative results. In all cases the tests were carried out when the lymphadenopathy was at its height and when one would expect the test to be positive (Tidy, 1952).

Haematology

The blood changes are analysed in Table II. Although the lymphocyte count exceeded 50% of the total white-cell count in only 10 cases, all of our patients had a maxi-

TABLE II.—Analysis of Blood Changes

Max. White-cell Count	No. of Cases	Max. % of Lymphocytes	No. of Cases
11,000—	9	30—39	8
16,000—	10	40—49	9
20,000+	8	50—59	8
		60—69	2
Max. Absolute Lymphocytes		Max. % Abnormal Lymphocytes	
4,000—	8	10—19	12
5,000—	2	20—39	8
6,000—	9	40+	7
8,000—	6		
10,000+	2		

mum total lymphocyte count of over 4,000 per c.mm. These results are comparable with those recorded in other epidemics of infectious mononucleosis.

The morphology of the abnormal lymphocytes has been well described by Downey and McKinlay (1923). The lymphocytes which we classed as abnormal had the following features: (1) Their size varied from that of a small lymphocyte to that of a monocyte; the majority were large. (2) The cytoplasm was basophilic and in most cases showed vacuolation, which often gave the cells a foamy appearance. (3) The nuclei were frequently lobulated or had other morphological abnormalities; increased staining of the nuclear chromatin was often seen. The abnormal cells which we encountered belong to Downey's classes I and II.

Discussion

While many features of our cases resemble those of infectious mononucleosis, the differences are worthy of consideration.

Evans and Robinton (1950) commented on the apparent scarcity of reports of epidemics of infectious mononucleosis. They attempted to determine the degree of infectivity of the disease by examining the 63 close contacts of five seropositive cases of the disease at a girls' college. Only one of the contacts showed any abnormal lymphocytes and none had antibodies in diagnostic titre. It is of great interest that, although 21 of the contacts had recently suffered from such conditions as sore throat, upper respiratory infection, primary atypical pneumonia, and mumps, none showed the presence of abnormal lymphocytes. Evans and Robinton concluded that these results and the inability to transmit the disease experimentally (Evans, 1947, 1950) showed that infectious mononucleosis was essentially a sporadic and not an epidemic disease.

Hoagland (1952), from a study of 56 seropositive cases, concluded that infectious mononucleosis had a restricted clinical picture and that the concept of the disease as one of protean manifestations arose from the inclusion of seronegative cases, which he did not regard as true examples of infectious mononucleosis. He surveyed the clinical picture as described in other reports where all the cases were seropositive. Thus acute abdominal pain was not a symptom of any of his cases, nor was meningitis noted. Read and Helwig (1945) recorded only three examples of meningitis out of 300 seropositive cases. None of Hoagland's patients had a rash, and Milne (1945) encountered a rash in only 3.6% of a seropositive group of patients.

It may be doubted whether it is possible in practice to classify patients in the older age groups, even under broad diagnostic headings, for it is the exception rather than the rule for elderly patients to suffer from one disease alone. There are, without doubt, patients who present a clinical picture indicative of a combination of "functional" disorder and organic dementia. Affective disturbance is often the leading symptom in cerebral arteriosclerotic dementia, and less frequently in senile dementia, and this association may not be purely due to chance as is sometimes suggested. On the other hand, the occurrence in aged patients of uncomplicated functional psychiatric illnesses in contradistinction to organic psychoses has been clearly recognized since the days of classical descriptive psychiatry, and it is not surprising that, using case records alone, it was possible to differentiate between psychoses showing predominantly either organic or functional features (Post, 1951). Similarly, Roth and Morrissey (1952) were able to point out that senile dementia and depressive psychosis occurring during the senium are two quite separate conditions.

It is contended that for practical purposes most elderly patients with psychiatric disorders can be allocated to one of the three groups given above, and that, as a result of an out-patient consultation, one of the following recommendations can be made: (1) admission to hospital for active psychiatric treatment or attendance for out-patient psychiatric treatment, or (2) home care under supervision of a general practitioner without special psychiatric treatment or admission to chronic wards of mental hospitals primarily for nursing care.

In this study the term "active psychiatric treatment" is not reserved only for those patients who received physical treatment, but also includes those for whom a planned course of psychiatric therapy designed to ameliorate the clinical condition was recommended. It has been thought desirable to include in the same treatment group both home care under supervision of the general practitioner and admission to chronic wards in mental hospitals primarily for nursing care, because these recommendations depended not only on the patient's clinical condition and its severity but also on other factors such as suitability of home accommodation, economic status, and the existence of relatives willing to undertake care of the patient. In effect, treatment recommendations have been classified into two main categories: active and other. If on follow-up these recommendations proved to have been suitable in a significantly high proportion of cases, one might be led to conclude that the diagnostic and prognostic classifications on which they were largely based were also, on the whole, correct and useful.

Method of Investigation

Since 1949 most of the patients over 60 referred to the Maudsley Hospital for consultation have been examined by one of us (F.P.), who has also been responsible for recommending their treatment. Patients thus referred do not form a representative sample of old people with psychiatric illnesses, as acutely disturbed patients are rarely seen in an out-patient clinic, and for this reason examples of acute toxic confusional psychosis were not encountered. Many patients were quite fit to attend the hospital, but had been a problem to their doctors for some time; the behaviour of most did not make the need for any particular type of care or treatment imperative. This study is based on 192 patients over 60 personally examined during 1949 and 1950. Table I shows their age and sex distribution.

TABLE I.—Age and Sex of Patients Included in Survey

Age	Males	Females	Total
60-64 years	27	54	81

70-74	10	20	30
75-79	3	12	15
80 years and over	1	1	2
Total	62	130	192

$\chi^2=0.9$; d.f.=3; $P=0.80$ when $\chi^2=1.005$.

The assessment of a patient took between 45 and 75 minutes, and usually began by obtaining information from the accompanying friend. In the examination of the patient, behaviour, mood, and thought content were noted, and a brief assessment was made of the degree of intellectual preservation, with special reference to orientation, past and recent memory, and retention. A physical examination focusing attention on neurological and cardiovascular abnormalities completed the examination. Where possible the patient's own account of the development of symptoms was obtained. The opportunity was taken for a discussion of the patient's troubles, so that even in those cases in which no positive treatment was offered the interview was useful. The co-operation received from the patients and relatives in the follow-up seems to indicate that they regarded the interview as worth while.

In allocating patients to one of the three diagnostic categories whose usefulness is under investigation, evidence

coming from the life history and development of symptoms was given prime consideration. The history of the illness and its relationship to the previous adjustment of the patient were particularly helpful diagnostic pointers. Evidence of gradual decline of the ability to deal with everyday tasks and of impairment of memory was a good indication of dementia, which was almost always confirmed on examination of the patient. On the other hand, it was held that apparent intellectual impairment evinced during the stress of examination was less reliable than the description of intellectual decline given by the informant accompanying the patient. Special inquiry was usually needed to elicit a history of fainting turns, transitory pareses, or speech disturbances; and this, even in the absence of neurological signs or patchy intellectual defects, was regarded as indicative of cerebral arteriosclerosis. In doubtful cases the occurrence of perseveration and failure in manipulating and recalling recent personal and general events were thought to provide more convincing evidence for dementia than the repetition of numbers, addresses, or test stories.

On the whole, it was found that most cases of organic dementia were sent for consultation at a time when the condition had become well established, and the diagnosis only rarely presented a real problem. By contrast, the onset in affective illnesses was as a rule much more recent, and presented a clear-cut and rapidly evolving change from the patient's previous level of adjustment. The most valuable pointers in the subject's life history were previous affective reactions or dysthymic tendencies, in the sense either of lifelong mood swings or of moroseness often associated with so-called obsessional character traits. Difficulties encountered with patients of this type of make-up when exhibiting both affective and organic mental symptoms have already been mentioned.

The differentiation of mild affective states occurring in persons with long-standing neurotic difficulties from the group of chronic psychotic, neurotic, or character disorders was problematical in a number of instances; but on the whole this last group stood out clearly in terms of biographies rather than of clinical pictures defined on examination. To what extent the "caricaturing" in old age of previously unsatisfactory and unstable personalities, as seen in this group, may mark the beginning of a dementing illness did not have to be considered during this investigation, which was concerned only with the usefulness of our three diagnostic categories for short-term prognosis and choice of treatment. Only four patients were excluded from classification: a woman with an arrested G.P.I.; a woman with a hemiplegia without psychological symptoms; a woman with a doubtful conversion hysteria, denying previous neurosis; and a man with an advanced cerebral tumour.

Unless the patient had been kept under observation, a letter was sent after the lapse of at least one year to the relative who had accompanied the patient or, if he had originally come alone, to the patient himself asking for information in general terms. In the rare instances in which this letter remained unanswered, the family doctor or the hospital to which the patient had been recommended was approached, and in this way failure to elicit information occurred in only 14 of 192 cases. Though in a number of instances the patients were followed over longer periods, for the purposes of this study their status has been recorded as between 12 and 18 months after the first consultation. A postal follow-up was regarded as reliable enough to discover whether the patient was still alive, at home, or in hospital. No analysis has been made of the descriptive statements concerning the subject's mental state; these qualitative accounts are briefly considered later.

Assessment of Results

Among the patients examined there was a marked preponderance of affective disorders. There was only one hypomanic man in this group, which otherwise ranged from severely agitated, deluded, and perplexed patients to mildly anxious and dejected people, and which also included

patients with some paranoid symptoms. Recent development of the disorder, either for the first time or, more often, in repetition of similar attacks throughout life or late maturity, was common to all in this group. Most patients had illnesses of moderate severity, retaining "insight" and a wish for help, and it is not surprising that this group should preponderate at an out-patient clinic. There were 46 patients with organic psychoses of old age. Finally, 33 others were regarded as long-standing cases of psychoses (mainly paranoid schizophrenia), neurosis—for example, chronic obsessional states and various types of hysteria—and character disorders—for example, paranoid personalities.

Recommendation of long-term institutional care had to be made in only 11 cases, including nine with advanced senile dementia. Seventy-five patients were referred back to their doctors with advice for future management. Some of them were seen on two or three occasions, and assistance was given by the psychiatric social worker in many instances. Active psychiatric treatment was recommended in 102 cases. In-patient treatment was advised for 95 of these, and most patients were admitted on a voluntary basis to the Bethlem Royal Hospital or to the regional mental hospital; there were only six refusals. Regular out-patient attendance for social and psychological treatment was advised in only seven cases. This unsatisfactory state of affairs was partly owing to the fact that at the time the geriatric service of this hospital was still in the process of gradual development. At present, much larger numbers of patients are given out-patient supervision, but, even so, in a considerable proportion admission to hospital has to be recommended ultimately, possibly because there is reluctance among general practitioners to send old people to a psychiatrist unless they feel admission should be considered. Mildly deteriorated, anxious, depressed, and lonely old persons who made up 11.2% of the random sample of the aged population examined in Sheldon's (1948) field study are only rarely seen in the psychiatric out-patient clinic.

In determining the utility of this diagnostic classification two main issues arise: (1) Does the diagnostic classification help to decide the appropriate treatment? (2) Are the results of treatment in accordance with the clinician's expectations? It must be stressed here with regard to the first question that we do not expect a diagnostic classification to fix automatically the appropriate treatment. It can do no more than help the clinician in his decision. There are some patients who are not easy to classify into the three categories used here because they show features of more than one diagnostic category. These patients have been arbitrarily assigned to one or other category and may require different treatment from that given to others in the same diagnostic group.

If it is not possible in elderly patients to differentiate clearly between diverse diagnoses, and if their treatment recommendations are based on other criteria, we should expect to find equivalent proportions of patients receiving the various treatments in each of our diagnostic groups. Table II shows the treatment recommendations by psychiatric diagnosis.

TABLE II.—Treatment Recommendations by Psychiatric Diagnosis

Disorder	Active Psychiatric Treatment	Other Treatment	Total
Recent affective	85	24	109
Long-standing	7	26	33
Organic	10	36	46
Total	102	86	188

$\chi^2=56$; $P<0.0001$.

tric diagnosis. There are obvious differences with respect to treatment between diagnostic groups and these are too large to be due to chance ($\chi^2=56$, $P<0.0001$). It may be argued that age might have been a determining factor in recommending treatment. Table III shows recommendations by age; the proportions of patients receiving active

TABLE III.—Treatment Recommendations by Age

Age	Active Psychiatric Treatment	Other Treatment	Total
60-64 years	42	37	79
65-69	33	30	63
70 years and over	27	19	46
Total	102	86	188

$\chi^2=0.9$; $P=0.3$.

treatment in each of the age groups are similar ($\chi^2=0.9$, $P=0.30$). There seems reason to believe, therefore, that the diagnostic classification did determine on broad lines the type of treatment recommended. Thus for affective disorders of recent onset we find that the predominant recommendation is active treatment; for each of the other diagnostic categories the most frequent recommendation is reference back to general practitioner or institutional care. As stated earlier, in each diagnostic group there were some patients who showed atypical features. If the grouping of the cases by diagnosis gives positive guidance on treatment recommendation to the clinician we should expect to find that the typical case in each diagnostic group receives the typical treatment—for example, active treatment for affectives—and, *mutatis mutandis*, atypical cases receive atypical treatment. Table IV shows for each group the treatment recommendations for the typical and atypical cases. The differences are significant (in each case P is less than 0.02) and thus support this contention.

TABLE IV.—Treatment Recommendations by Psychiatric Diagnosis

Treatment Recommendation	Psychiatric Disorder					
	Acute Affective		Long-standing Psychotic, Neurotic, or Personality		Organic	
	Typ.	Atyp.	Typ.	Atyp.	Typ.	Atyp.
Active psychiatric treatment	76	9	2	5	2	8
Other treatment	15	9	22	4	31	5
χ^2 using Yates's correction. Probability (P)	9.836 0.01 > P > 0.001		5.544 0.02 > P > 0.01		12.92 0.001 > P > 0.0001	

To test the validity of the advice given at consultations, and, indirectly, the usefulness of the diagnostic categories on which it was based, each case was scored either as *recommendation successful* when the outcome after one year was in accordance with expectation, or *recommendation unsuccessful* when this was not so. All patients whose follow-up has been unsuccessful were classed as failures, as were all who had been recommended for active treatment but who had remained in hospital continuously throughout the follow-up period. Admissions to hospital or institution in all cases in which supervision by the general practitioner had been advised were scored as failures. Deaths were scored as indicating faulty disposal when they were unexpected in the sense of being intimately associated with the psychiatric illness whose nature or severity had not been correctly assessed—for example, suicide in a patient returned home, or death from cerebral thrombosis in a person diagnosed as suffering from a recurrent depressive psychosis. Cases of affective illness which responded to active treatment but had to be readmitted during the follow-up period were counted as successful predictions in view of the well-recognized tendency of affective illnesses to recur.

The next problem is to see whether the patient's response to treatment was in accordance with the clinician's expectations. If classification by diagnosis aids the clinician to make an appropriate treatment recommendation, then we should expect to find that, on the whole, typical cases responded in accordance with expectation and that the outcome of atypical cases was more difficult to predict. In all, there were 148 cases which were so clear-cut as to be

easily classifiable into the three diagnostic groups used. Of these the clinician was able to predict correctly in 83%. The remaining 40 cases, which although assigned to one of the three groups showed symptoms of one or two of the other categories, had an accurate prediction rate of only 52.5%. This difference is highly significant ($\chi^2=16.5$, $P<0.0001$).

The outcome (Table V) was successfully predicted in 83% of the affective disorders, and it was found easier to predict the outcome of typical rather than atypical cases, for the success rates (proportion of successes to all cases) were 88% and 55% for typical and atypical cases respectively; this difference is highly significant, as the likelihood of obtaining

TABLE V.—Result of Predictions by Psychiatric Diagnosis

Result of Prediction	Psychiatric Diagnosis					
	Acute Affective		Long-standing Psychotic, Neurotic, or Personality		Organic	
	Typ.	Atyp.	Typ.	Atyp.	Typ.	Atyp.
Successful	80	10	18	5	25	6
Failed	11	8	6	4	8	7
χ^2 using Yates's correction. Probability (P)	7.987 0.01 > P > 0.001		1 P > 0.30		2.6 P > 0.10	

so large a difference by chance is less than 1 in 100. In the long-standing disorders the overall success rate was 70%, with 75% in the typical and 55% in the atypical cases. For all organic psychoses the success rate was 67%, with rates of 76% and 46% for typical and atypical cases respectively. These differences are not large enough to be considered due to other than to chance. If we compare the success rates for typical cases only in each of the three diagnostic groups—that is, 88% for affectives, 75% for the long-standing, and 67% for the organic—the differences are not significantly large. The outcome of recommendations in 69 out of 76 (91%) typical affectives receiving active treatment, and in 17 out of 22 (77%) typical long-standing cases, and in 24 out of 31 (77%) typical organic cases receiving other treatment were successfully predicted. On the other hand, in only five out of nine (55%) of atypical affectives receiving active treatment were successful predictions achieved. The difference between results in typical and atypical affectives is statistically significant (χ^2 , using Yates's correction, =5.5; $P=0.02$). Thus it would seem that when a diagnosis of typical affective disorder is made the outcome of treatment can be predicted with good likelihood of success. The numbers of atypical cases in the other two diagnostic groups are very small, but similar results are obtained—that is, in atypical long-standing cases receiving other treatment only one out of four successes was obtained, and one success out of five atypical organic cases receiving other treatment was achieved.

Additional support for the claim that most patients were assessed correctly at the out-patient consultation is provided by a comparison of the death rates. During the follow-up period 12 of the 30 senile demented and 3 of the 16 cerebral arteriosclerotics had died—that is, 1 in 3 of the patients classified as afflicted with one of the old age organic psychoses, or 1 in 2½ if the two patients who could not be traced are presumed dead. By contrast, only 2 of the 33 people with long-standing personality disorders had died (1 in 17, or on the unjustified assumption that all 5 whose follow-up had failed were dead, 1 in 4½). Finally, of the 109 patients with affective disorders only 7 were known to have died—1 in 15; or, if all 7 failed follow-up cases are assumed to have died, 1 in 8. As the age distributions for the three diagnostic groups are different the mortality rates should be age-standardized. This is hardly meaningful for the small numbers involved, but in each age group the mortality rates are higher for the organic disorders than for the other two groups (Table VI).

TABLE VI.—Deaths by Age Group and Psychiatric Diagnosis

Diagnosis	60-64 Years	65-69 Years	70+ Years	Total
Affective disorders: No. of patients	46	42	21	109
" " deaths	3 (6.5%)	4 (9.5%)	0	7 (6.4%)
Long-standing neurotic, psychotic, and personality disorders: No. of patients	20	8	5	33
" " deaths	0	1 (12.5%)	1 (20%)	2 (6.1%)
Organic disorders: No. of patients	13	13	20	46
" " deaths	1 (7.7%)	4 (30.8%)	10 (50%)	15 (32.6%)

Our follow-up method is not reliable enough to allow qualitative assessment of the patients' state of health, but a brief examination of adequate statements given in 144 surviving cases demonstrates for each diagnostic category a pattern in accordance with expectation. Of the surviving organic patients only 3 were reported to be much improved (this includes 2 arteriosclerotics), 12 were unchanged, and 13 had become more severely demented. Twenty of the people with long-standing disorders were unchanged, only 3 had grown worse, and 3 were claimed to have improved in mental health. The mental health of the patients with affective disorders had definitely deteriorated in only 6; 52 were described as free from symptoms, and 32 either had not recovered at all or had shown frequent recurrences without a downward trend having become apparent.

Conclusions

An evaluation of our follow-up results would be incomplete without recording some of the errors of clinical judgment which were brought to light. One patient committed suicide and another one attempted it while awaiting admission as voluntary patients, and a suicidal attempt by a patient diagnosed as suffering from a mild depressive reaction in a setting of arteriosclerotic dementia and recommended for continued home care must also be recorded. A chronic drug addict died of accidental poisoning and ought to have been placed under supervision. Less serious mistakes, though more humiliating for the prognostician, were (1) the man diagnosed as suffering from a mild hypochondriacal depression who died four days later of a cerebral haemorrhage (post-mortem report); (2) the woman assessed as a paranoid senile dement who was described as much benefited by a prefrontal leucotomy, though still in hospital. Further errors have become evident in cases followed for more than 18 months, but long-term prognosis was not attempted in this investigation, as we know too little about the natural history of the psychiatric illnesses of old age, and in any case will never be able to predict the occurrence of external stresses which may influence their course and outcome.

While not making light of these errors of judgment, it is claimed that as a rule the correctness of the original assessment was confirmed by the subsequent course of the disorder. Patients who were classified as suffering from affective reactions or phasic mood-disorders, and who were thought likely to benefit from active psychiatric treatment, responded in the great majority of cases with recovery or at least temporary remission of symptoms. Patients categorized under the heading of long-standing personality disorders did not deteriorate into more seriously disturbed states because specialist treatment was withheld, nor did they improve very much in the few instances in which hospital admission was advised. In the organic groups some success can be claimed in picking out patients likely to respond to active hospital treatment—for example, on account of affective components—and in deciding the question whether institutional care was necessary or could be postponed without inflicting undue hardships on the patients or their families.

The results of this study seem to support the claim made initially that, even at a single out-patient consultation, clinical assessment of aged patients in terms of transitional

reactions, or long-standing personality disorders, or dementing illnesses is possible. It is useful in allowing us to concentrate our limited facilities for active treatment on the patients most likely to benefit. But classifying our patients with a view to "disposal" does not mean that we subscribe to a watertight system of disease entities, or assume that affective illness precludes insidious organic dementia. The fact that active treatment was advised in 17 patients belonging to groups thought to be therapeutically unrewarding indicates that we have not been using our three types rigidly, but merely as points of orientation. To an increasing extent we are attempting to treat elderly patients as out-patients whenever possible. Apart from the obvious advantages, this furnishes us in doubtful cases with a period of observation during which to assess the relative importance in the individual patient of irreversible dementia, lifelong or long-standing personality disorder, or of affective, and thus mostly reversible, reaction.

Summary

Of 192 patients over 60 attending consecutively for psychiatric consultation at an out-patient clinic, 188 were allocated to one of three clinical groups: (a) organic psychoses of old age; (b) long-standing neurotic, psychotic, or character disorders; and (c) affective illnesses of recent onset. Corresponding recommendations for their treatment were made.

The status of the patients 12-18 months later demonstrated that these categories had been useful pointers towards making prognostic assessments and recommendations for treatment.

The assumption was supported that affective illnesses in aged patients show a favourable immediate response to active treatment.

PREMATURE DELIVERY IN HAEMOLYTIC DISEASE OF THE NEWBORN

BY

H. B. WATSON, M.B., F.R.F.P.S., M.R.C.O.G.
Obstetrician and Gynaecologist, Solihull Hospital

V. MARY CROSSE, O.B.E., M.D., D.P.H.
Paediatrician, Solihull Hospital

AND

W. L. F. HATCHUEL, M.B., M.R.C.P. D.C.H.
Paediatric Registrar, Solihull Hospital

Premature delivery of the baby with haemolytic disease of the newborn has been widely condemned (Allen, Diamond, and Vaughan, 1950; Mollison and Walker, 1952; Bourne and Williams, 1953) because the premature baby with haemolytic disease is less likely to survive and more likely to develop kernicterus than is the full-term baby. However, in our experience, individual cases do arise in which there are definite clinical indications for premature delivery of the baby. This is exemplified in the following case.

Case Report

A married woman aged 33 attended Solihull Hospital in August, 1951, and gave the following obstetric history. Her first pregnancy, in 1939, ended in a stillbirth at 28 weeks

gestation; her second pregnancy, in 1941, ended in an abortion at 24 weeks; her third pregnancy, in 1943, ended in a stillbirth at 38 weeks gestation (at this time she had a blood transfusion, but the full details are not available, and, of course, this was before the days of routine rhesus grouping); her fourth pregnancy, in 1945, ended in a stillbirth (spina bifida) at 36 weeks; and her fifth pregnancy, in 1950, ended in a stillbirth at 36 weeks; there was an associated mild toxæmia, and antirhesus antibodies were found early in this pregnancy. Her last menstrual period was April 3, 1951. She was blood group A Rh-negative (cde/cde), and blocking antirhesus antibodies were present in the serum. The husband belonged to blood group O Rh-positive; the most likely genotype being CDE/cDE.

The pregnancy continued normally, and serological examination showed virtually no change in the antibody titre. At the thirty-third week of pregnancy she described a reduction in the frequency and strength of the foetal movements. She stated: "The baby moves as if it is tired." When questioned further she said that the other babies had behaved similarly prior to the intrauterine death of the foetus. It was therefore thought that unless the baby was delivered within a short time it would die *in utero* like its predecessors, and that nothing more would have been achieved than in the previous pregnancies. The spur to action was the symptom of diminishing foetal movements.

Accordingly, on November 27, lower segment caesarean section was performed, and a living male child weighing 4 lb. 6 oz. (2 kg.) was delivered. It was noticeably pale at birth, and the findings on examination of the cord blood were: Group O Rh-positive; genotype cDE/cde; haemoglobin, 4.8 g.%; direct Coombs test positive.

A replacement transfusion was given three hours after birth and 430 ml. was exchanged (100 ml. per lb.—220 ml. per kg.). Next day the jaundice had deepened, but an attempt at a second replacement transfusion failed. At this stage the haemoglobin was 18.2 g.%. During the following month it was necessary to give three small "topping-up" blood transfusions. At 21 months the baby was normal in every respect.

In September, 1952, the mother returned to the antenatal clinic when 12 weeks pregnant. Serological examination confirmed the presence of blocking antirhesus antibodies of approximately the same titre as in the previous pregnancy, and it remained so throughout this pregnancy. At the thirty-fourth week of this pregnancy the foetal movements again diminished, and the patient was immediately admitted to hospital and caesarean section again performed. A living male child weighing 3 lb. 10 oz. (1.6 kg.) was delivered. The spleen was just palpable and the liver edge was 2 cm. below the costal margin. There was slight oedema of the legs, and jaundice developed within one hour of birth. The findings on examination of the cord blood were: Group O Rh-positive; genotype cDE/cde; haemoglobin, 6.5 g.%; direct Coombs test positive. A replacement transfusion of 600 ml. (166 ml. per lb.—365 ml. per kg.) was given four hours after delivery. Jaundice became more severe on the following day and lasted 24 days. "Topping-up" blood transfusions were given on the eighteenth and the sixtieth days. At seven months the baby was completely normal.

Discussion

It is obvious from the mother's history that she belongs to the group of women who in each pregnancy have infants severely affected by haemolytic disease of the newborn, and it seems that if a mother's first affected infant is stillborn or hydropic, subsequent infants delivered at term are unlikely to be viable (Davies, Gerrard, and Waterhouse, 1953). Our patient had had five successive stillbirths or abortions, and the outlook for further pregnancies seemed even more hopeless. We considered that the only chance of having a viable infant was by premature delivery. The serological findings, the diminishing foetal movements, and the condition of these two babies at birth indicated that premature delivery was a life-saving procedure. The indication for premature delivery

was diminishing foetal movements, and caesarean section was thought to be the ideal method for this patient. Mollison and Walker concluded that premature delivery was contraindicated from the consideration of the mortality rates in a series of cases, "the choice of treatment being determined by random numbers" (Mollison, Mourant, and Race, 1952). We feel that each case should be treated individually according to its clinical merits.

In view of this case, it would seem that there is still a place for premature delivery of the infant in cases of haemolytic disease of the newborn. The indication for such treatment would be a patient with a history of two or more stillbirths, whose husband is homozygous, Rh-positive. We suggest that diminution of foetal movements is a symptom of importance, that it requires the case to be treated as an emergency, and that premature delivery should be carried out in a hospital equipped both for replacement transfusion and for the care of premature babies. It also demands the daily supervision of the patient in the last weeks of pregnancy, especially in cases that show by the pattern of their history that they are liable to produce severely affected infants. Mollison and Walker showed that "the total death rate in the 'induced' group is higher than in the group allowed to go to spontaneous delivery." However, in our experience premature delivery can produce a live birth instead of a stillbirth; and, even though the baby is premature, kernicterus can usually be prevented by one or more adequate replacement transfusions. In the group of severely affected cases of haemolytic disease of the newborn there is the opportunity of rearing a normal living child by premature delivery, and to achieve this the complete co-operation of the obstetrician and paediatrician is essential.

Summary

A case of rhesus iso-immunization of severe type is described.

After several stillbirths, two living babies were delivered prematurely by caesarean section.

The symptom of diminution of foetal movements in two severely affected babies is described.

This symptom is an indication for premature delivery of the foetus in order to prevent another stillbirth and in the order to give a possibility of survival.

With the close co-operation of the obstetrician and paediatrician this can be achieved.

We acknowledge the help given by Dr. W. Weiner, of the Birmingham Regional Blood Transfusion Service, and the medical and nursing staffs of Solihull and Sorrento Hospitals, who so willingly assisted in the care of this patient and her babies.

Last July the Standing Conference of Societies Registered for Adoption held a conference at Roehampton, a report of which is now available. Papers were read and discussed on co-operation between adoption societies and local authorities, co-operation in case work, the point of view of the natural mother, heredity as it concerns adoption, and difficult placement. Discussion centred on legislation that is required to prevent the private placing of children for adoption (even by the children's own mothers), the complex factors entering into any estimate of heredity, the placing of older and handicapped children, and a plea for greater confidence in placing children in good adoptive homes even though their social background is poor. The report is obtainable from the honorary secretary, Gort Lodge, Petersham, Surrey, price 5s.

INCARCERATED AND STRANGULATED INGUINAL HERNIA IN THE FIRST YEAR OF LIFE

REPORT ON 45 CASES

BY

JOHN RENDLE-SHORT, M.B., M.R.C.P., D.C.H.

Late Senior Paediatric Registrar, Department of Child Health, Welsh National School of Medicine

AND

CYRIL HAVARD, F.R.C.S.

Surgical Registrar, United Cardiff Hospitals

The incidence of strangulated hernia in the first year of life is variously reported by different authors, perhaps owing to the lack of uniformity in the definition of "strangulation." It is usually considered that an incarcerated hernia is an irreducible hernia in which there is obstruction to the passage of intestinal contents, and that a strangulated hernia is an irreducible hernia in which there is interference with the blood supply of the bowel, irrespective of whether or not the gut is viable. If, therefore, in any series, only those cases are recorded in which the gut is strangulated, the incidence is obviously lower than if incarcerated hernias are also included. But, clinically, incarceration can prove as dangerous as strangulation, and, in fact, in three out of five fatal cases in the present series no strangulation was present.

Incidence

The incidence of strangulation in inguinal hernia in infancy varies from the statement by Stammers (1951) that "in a long experience of children's surgery I have never seen a strangulated irreducible inguinal hernia" to those of Potts *et al.* (1950), who say that 19% of their series were incarcerated. Thorndike and Ferguson (1938), in a series of 1,740 herniorrhaphies in children, found "strangulation" in 106, of which 45 occurred in the first year of life—"true strangulation," however, was present in only five cases.

According to Potts *et al.* 70% of all congenital inguinal hernias occur on the right side. Strangulated inguinal hernia is also much more common on the right side, Thorndike and Ferguson reporting an incidence of 80% in children up to 12 years of age.

The sex incidence is even more striking. Uncomplicated inguinal hernia is nine times more common in male than in female infants (Herzfeld, 1938), while strangulation was reported by Thorndike and Ferguson to occur in 25 males to every one female. When strangulation does occur in the female, the Fallopian tube and ovary are often found in the sac.

The age incidence of strangulation is remarkably constant, the greatest number of cases up to the age of 12 years being found in the first year of life, and most of these occur in the first three months; about 50% of Thorndike and Ferguson's 45 cases were under 3 months of age.

Presentation of Cases

The present series comprises 45 infants under 1 year of age: 43 were treated in the United Cardiff Hospitals during the past six years, one was seen at St. David's Hospital, Cardiff, and one at the East Glamorgan Hospital, Church Village. Fifteen of the children were seen personally by one or other of us.

The sex ratio was similar to previous series; only once did the condition occur in a girl; in this case the hernial

sac contained the right ovary. In all but three cases the offending hernia was on the right side, although in four cases a left inguinal hernia which could easily be reduced was present. In one of the left-sided cases a right-sided hernia was also found, but this was reduced by taxis. The age incidence is given in Table I.

Age in Months	No. of Cases	Age in Months	No. of Cases
0-1	11	6-7	6
1-2	12	7-8	2
2-3	4	8-9	1
3-4	3	9-10	0
4-5	1	10-11	1
5-6	3	11-12	1

In the accompanying graph the age incidence is arranged so as to be comparable with the figures given by Thorndike and Ferguson. The cases in our series may be divided into two groups.

Showing age incidence of the 45 cases of the present series (O—O—O) compared with the 45 cases of Thorndike and Ferguson (X—X—X).

Group 1

This group consisted of infants who presented with signs and symptoms of intestinal obstruction—vomiting, abdominal pain and distension, and constipation or sometimes the passage of blood-stained mucus. There were 29 children in this group. Most of them were under 2½ months old, and the hernia had sometimes been present for only a few hours before the onset of the obstructive symptoms.

Indeed, in about one-third of the cases the symptoms started before the hernia appeared. This often led to difficulty and delay in diagnosis. Table II shows the various diagnoses with which the children in Group 1 were sent into hospital.

TABLE II.—Diagnoses on Admission to Hospital of Children in Group 1

Diagnosis	No. of Cases
Strangulated or irreducible hernia	22
Diarrhoea and vomiting	2
Vomiting, ? cause	2
Intestinal obstruction	2
Pyloric stenosis	1
	29

It is possible that the hernia was sometimes missed because it was not searched for. Babies tend to have a roll of fat in the groins, and an inguinal hernia is quite small and easily overlooked, as the following case illustrates.

Case 6.—A 14-day-old baby, birth weight 6½ lb. (3.1 kg.), was admitted to hospital with a diagnosis of gastro-enteritis. He had been well until two days before admission, when he started to vomit his feeds and have screaming attacks in which he drew up his legs. The vomit soon became blood-stained. He was constipated at first, but just before admission passed two pink liquid stools. On examination (J. R.-S.), he was seen to be a moribund dehydrated baby, vomiting foul yellow fluid. His abdomen was very distended, but no hernia was noticed. When seen by a surgeon (Mr. Foster) about half an hour later, a right inguinal hernia was observed which reduced quite easily. Despite this the child died within a few hours. At necropsy the peritoneal cavity contained 2-3 oz. (57-85 ml.) of sero-sanguineous fluid. A Meckel diverticulum ½ in. (1.3 cm.) long was present which was normal, but the adjoining gut was covered with petechial haemorrhages and had probably been contained in the hernial sac.

All the five deaths (18% of Group 1) in this series occurred in Group 1. Brief details of these are given.

Case 11.—A premature twin boy, birth weight 3 lb. 1 oz. (1.6 kg.), was admitted when 10 weeks old with a history of three days' vomiting, constipation, and abdominal distension. He had had bilateral inguinal hernia for three weeks. The child was so ill that a blind ileostomy was performed, but seven days later he suddenly died. At necropsy the bowel was found to be loosely obstructed in a right inguinal hernia.

Case 16.—A 4-months-old boy was admitted with a history of vomiting, constipation, and a lump in the right groin for two days. The child was very ill, and at operation the gut in the hernial sac was found to be gangrenous, and was resected. The child died a month later from an abscess at the site of the gut resection.

Case 17.—A 2-weeks-old boy, birth weight 5½ lb. (2.5 kg.), was admitted with a history of two days' vomiting and constipation. A small right inguinal hernia was noticed; this was reduced, but as the child's condition did not improve a laparotomy was performed. This revealed an annual constriction at the terminal ileum, caused by the hernia, but no obstruction was then present. The child died four days later. Necropsy revealed a generalized peritonitis.

Case 27.—A 5-weeks-old boy was admitted with a history of vomiting for three days. His stools had been a mixture of blood and mucus and his abdomen was distended. Apparently no hernia was noticed, but at laparotomy a loop of gut was found to be entering the right hernial orifice. It was thought that the baby also had a volvulus. He died eight days later, and at necropsy gangrenous areas of small gut were found and a volvulus was still present.

In this series successful gut resection was performed only once, and this was on a child in Group 1.

Group 2

Group 2 consisted of 16 children with an irreducible hernia, without obstruction or with only minimal symptoms of obstruction. The babies were all over 2 months old, and the hernia had in almost every instance been noticed previously. There were no deaths in this group.

Discussion

To facilitate comparison the total number of patients with intussusception under 1 year of age operated on in the United Cardiff Hospitals during the comparable six-years period was computed. These amounted to 67, of whom only five were under 3 months of age. Apart, therefore, from congenital abnormalities of the intestine, which are usually manifested within the first week of life, strangulated hernia is the commonest cause of intestinal obstruction under 3 months. Pyloric stenosis should not be confused with it, as the onset is less abrupt, abdominal distension is confined to the upper abdomen, and a pyloric tumour is always palpable. The only other cause of intestinal obstruction in this age group is acute infantile Hirschsprung's disease—again a condition which is almost confined to boys. This rare disease can present as intestinal obstruction, with vomiting, constipation, and gross abdominal distension. After rectal examination there is often a dramatic improvement with the passage of quantities of wind, the abdomen deflating visibly. The diagnosis may be confirmed by a barium enema.

If a hernia is not easily reducible the child should be given chloral, the foot of the cot elevated, and a cold pack placed on the hernia. It is probably justifiable to persevere with these measures for three hours. At the end of this time, or as soon as a severely ill baby has been resuscitated, operative reduction of the hernia should be performed.

Summary

Forty-five cases of incarcerated inguinal hernia under 1 year of age have been studied; of these 44 were in boys, and 42 were on the right side.

The cases have been divided into two groups: Group 1, presenting with symptoms of intestinal obstruction, comprised mainly the younger babies, in whom often

no hernia had been noticed before. There were 29 babies in this group and 18% of these died.

Group 2 consisted mainly of older babies in whom an easily reducible hernia had been observed previously, but in whom the hernia had suddenly become irreducible; obstructive symptoms were minimal. There were 16 babies in this group and no deaths.

It has been shown that, in the age group 1 week to 3 months, strangulated inguinal hernia is the commonest, almost the only, cause of intestinal obstruction.

Owing to the ease with which an inguinal hernia can be missed in a baby, it is essential that the inguinal region should be carefully examined in every infant presenting with symptoms of acute intestinal obstruction.

We wish to express our thanks to the surgeons of the United Cardiff Hospitals for permission to use the notes of cases under their care, and to Professor A. G. Watkins for his criticism and advice.

CHANGES IN DENTAL HYPOPLASIA AND CARIES AMONG THE CHILDREN OF FINNISH LAPPS, 1939-50

BY

R. V. HOLMES JONES, B.A.

AND

M. J. MYNOTT, B.A.

(From St. Thomas's Hospital Medical School)

In 1939 a small survey of Finnish Lapps was made in order to discover the state of dental health among children living a semi-nomadic existence far from civilization (H. Mellanby, 1940). Since that time Europe had been at war for six years and for seven more has enjoyed a precarious peace. It was thought that these disturbed living conditions might be reflected among other ways in alterations in the structure of the children's teeth and their susceptibility to decay. For this reason the present survey was undertaken during the summer of 1950.

Most of the children examined belonged, as before, to the Inari Lapps, but a few families of nomadic Fell Lapps were also inspected. Since the ceding to Russia in 1944 of the Petsamo area in the far north of Finland, the Skoltje Lapps have ceased to exist as a separate entity. Some have become Russian subjects, while others are scattered throughout the rest of Finnish Lapland. The Fell Lapps inhabit the Enontekio and Kilpisjärvi districts, sandwiched between Sweden and Norway (see Map). In this area a walk was made from Hetta northwards to the Norwegian border in the company of the local postman, three "summer villages" being visited. A few more children were seen in schools at Karasuendo, on the Finno-Swedish border, the total number of Fell Lapps inspected being ten. Ninety-two Inari Lapps were seen in Vuotso and in Lapp huts scattered along the length of the Utsjoki river and the Finnish bank of the Teno river from Utsjoki to Karagasniemi.

Methods

Only the deciduous teeth of pure Lapp children between the ages of 2 and 14 years were examined, a distinction being made between pure Lapps and half-castes. Some of these half-castes were Finno-Lapps (whose numbers are steadily increasing as the Lapp population becomes less isolated), but

FINNISH LAPLAND, 1950

the majority were German-Lapps, a permanent reminder of the German occupation between 1941 and 1944.

Each mouth was inspected with an illuminated mirror and a standard probe. The structure of the teeth was estimated by the method described by M. Mellanby (1927a, 1927b, 1934), the grades of M-hypoplasia being judged by rubbing a sharp pointed probe over the labial surface of the teeth. The extent of caries in each tooth was also judged by the same method as that used by Mellanby (1934), the Dental Disease Committee (1936), and Mellanby and Mellanby (1948), being estimated as caries 0, 1, 2, or 3 according to the size of the cavity. To obtain average hypoplasia and caries figures the total hypoplasia and caries figures for each group were added up separately and divided by the number of teeth examined for structure and caries. This gave the average hypoplasia figure (A.H.F.) and average caries figure (A.C.F.). A measurement of the extent of healing caries was not attempted.

Results

The results are compared throughout with those obtained in the 1939 investigation by Dr. Helen Mellanby.

Structure of Inari Lapp Children's Teeth.—When the structure of the deciduous teeth of these Inari Lapp children is compared with that found in 1939 (Table I), there is seen to be a slight increase in the A.H.F. The considerable deterioration in structure of the complex teeth (molars) since 1939 has been incompletely counterbalanced by the improvement found in the incisors and canines. However, further analysis of the results into various age groups, as set out in Table II, shows that this general picture is erroneously simple. While the A.H.F. of the 2-5-years age group was slightly below the 1939 total average of 1.09, that of the 6-9-year-olds was higher. There were too few children

TABLE I.—Structure of Teeth of Inari Lapp Children Aged 2-14 Years

Molars	1.63	1.81	1.67
All teeth	0.97	1.39	1.13

between 10 and 14 years with teeth whose hypoplasia could be assessed to obtain representative figures for this age group.

Caries in Inari Lapp Children's Teeth.—The incidence and extent of caries in the different age groups of Inari Lapps are set out in Table III. Of the 92 children studied, only 6

TABLE III.—Incidence and Extent of Caries in Deciduous Teeth of Inari Lapp Children

Age Group	No. of Teeth Examined		% Carious		A.C.F.	
	1939	1950	1939	1950	1939	1950
2-5 years	208	843	24.0	22.9	0.39	0.36
6-9 "	313	452	68.3	42.8	1.57	0.85
10-14 "	(57)	(66)	(43.9)	(57.6)	(0.92)	(1.07)
Total	578	1,361	50.0	30.9	1.15	0.55

were caries-free. Nevertheless, this is an increase on the number reported by H. Mellanby—namely, 3 out of 70. When the total number of teeth is considered comparison shows that the incidence and extent of caries have sharply decreased over the intervening years. This change has occurred almost entirely in the 6-9-years age group.

Relationship Between Structure and Caries.—Table IV shows that teeth with good structure—namely, those with no surface hypoplasia—are less liable to be attacked successfully by the carious process than those showing M-hypoplasia. This relationship has been demonstrated in all previous surveys using M-hypoplasia standards (notably M. Mellanby, 1923, 1934; Mellanby and Coumoulos, 1946; Mellanby and Mellanby, 1948, 1950, 1951; King, 1940). Furthermore, from a comparison with the 1939 figures it will be seen that the percentage of hypoplastic teeth which are carious is significantly lower in 1950 than in 1939.

Teeth of Fell Lapp Children from Enontekio.—Although only 10 children in the Enontekio area were inspected (owing to the great difficulty in reaching the nomadic families) and eight of these were between the ages of 8 and 11 years, the difference between the teeth seen in this group and those of the settled Lapps was so pronounced that the figures seem worth mentioning: 81% of the deciduous teeth were decayed, as compared with 46% in the same age group (8-11 years) of the Inari Lapps.

TABLE IV.—Percentage of Caries in Normal and Hypoplastic Deciduous Teeth of Inari Lapp Children

	Teeth with No Hypoplasia		Teeth with 1-3 Hypoplasia*	
	No.	% Carious	No.	% Carious
Simple, 1939	79	7.6	170	24.7
" 1950	335	3.3	393	11.5
Complex, 1939	40	52.5	203	70.9
" 1950	37	(43.2)	582	53.9
Total, 1939	119	22.7	373	49.9
" 1950	372	7.3	975	36.4

* Teeth with gross hypoplasia have been excluded from this and other tables dealing with structure.

Discussion

The chief finding of this survey is the decrease of caries incidence amongst the 6-9-year-old Inari Lapps, although the structure of their teeth, as judged by surface hypoplasia, is worse than just before the war. As diet is believed to be largely responsible for determining the structure of the teeth (Mellanby, 1934; Mellanby and Coumoulos, 1947), and also to influence the rate and extent of dental decay, the changes of food habits among these Lapps during and after the war have been investigated.

Dr. H. Mellanby (1940) found that the staple foods among the Inari Lapps in 1939 were reindeer meat, dried fish, potatoes, rye bread, and margarine. The universal drink was coffee liberally sweetened with sugar. Two noteworthy points are that almost all the salmon was at that time sold to the tourist hotels and that very little fresh fruit was eaten.

Although the Russo-Finnish war of 1939 did not appreciably alter the food habits of the Inari Lapps, throughout the second war (1941-4) and the German occupation, in the final stages of which 200,000 well-paid German troops were present in Finnish Lapland, much more "European food" was imported. Moreover, during this period the Lapps enjoyed an economic boom, working for the Germans and supplying them with meat and fish. So during the years 1941-4 the Lapps lived on a diet containing more cereals, sugar, and potatoes than in 1939 but much less meat and fish. In view of this it seems probable that the calcifying power of their diet at this time was low. However, in 1944, as one condition of the Finnish peace treaty with the Russians, the Germans were driven from North Finland. As the Germans retreated they employed a scorched-earth policy. In order to escape some of the consequences of this action the Inari and Utsjoki Lapps were evacuated to Kalajoki in central Finland, while many of the Enontekio Lapps moved over into Sweden. In the Kalajoki community the Lapps existed on a subsistence diet, and diseases such as typhoid were rampant, whereas in Sweden and Enontekio Lapps were well housed and fed. When they returned to their own country in mid-1945 almost all the buildings had been burnt or blown up (we saw only one house left standing since 1939) and living conditions were extremely crude for the next two or three years. During this time the Lapps lived largely on fish and meat, and food supplied by various philanthropic organizations.

Since 1948 the diet has gradually been reverting to the 1939 pattern. The main differences to-day are that less fish is sold to tourists, and that the Lapps seem more conscious of the value of eating fresh fruit. In addition, expectant mothers through Finnish Lapland are now visited by the district nurses and considerable prenatal care is exercised.

Although representative figures were not obtained, the teeth of the 10-14-year-old children might be expected to show a similar structure to those inspected in 1939, these teeth having been formed between 1936 and 1940. The period of formation of those aged 6-9 years coincided with the German occupation of Lapland, and it seems possible to account for the defective structure of the teeth of the children in this age group as being due to the particularly low calcifying power of the diet at this time. The children aged 2-5 years have recovered and slightly improved upon the pre-war structure, as would be consistent with a diet of higher calcifying power.

When considering factors which might be expected to influence decay it will be realized that the teeth of the oldest group have had a chequered existence since eruption. The effects of these factors have been so balanced that the caries figures are now the same as in 1939. Teeth in the youngest group, with slightly better structure, show slightly less decay than in that year. But the striking change is that the A.C.F. of children aged 6-9 is only just over half its 1939 counterpart in spite of the teeth having a worse structure. In broad terms, therefore, the post-eruptive influences since 1945 must have been less damaging than in the previous years. This can be explained either by an increased tooth resistance due to a higher post-eruptive dietary calcium intake or by a decrease in the factors favouring decay. However, if the calcifying power of the diet during this time is reflected in the tooth structure of the children under 5, the dietary calcium since 1945 has been substantially the same as before the war. Therefore it seems that the teeth of the 6-9-year-olds are less carious, not because they are more resistant, but because there are fewer external influences favouring decay. Although more meat and fish was eaten during those years the one factor in the diet which is known to have decreased is sugar. A tentative conclusion on this evidence must be that a low-sugar diet decreases the chance of caries.

With regard to the caries figures of the Enontekio and Inari Lapps it is significant that in 1945 the former moved over to Sweden, where they fed well by European standards (with plenty of sugar and vitamin-fortified margarine), while in their homes after their return they were able to trade with smugglers travelling between Norway, Finland, and Sweden who largely carry spirits, sugar, and margarine. So in addition to their vitamins A and D intake (contributed mainly by the margarine and fresh fish) being as high as, or possibly higher than, that of the Inari Lapps, their sugar consumption also was much higher. Now since the state of their teeth is so much worse than that of the Inari Lapps, they must have been subjected to factors favouring decay to a much greater extent than the Inari Lapps' teeth. In this case a high-sugar diet might be incriminated.

Summary and Conclusion

The changes found in both Fell and settled Lapps fall in line with other wartime studies and the conclusion of Toverud (1951) that "the knowledge gained through the greatest dietary experiment forced upon us strengthens the value of more natural foods and less of easily fermentable carbohydrates in the prophylaxis against dental caries."

The teeth of 92 settled and 11 nomadic Lapp children were inspected for caries and surface hypoplasia.

The state of the teeth is compared with that existing in 1939.

An attempt is made to correlate the changes found in the teeth with the alterations in diet during the intervening period.

We would like to thank Lady Mellanby for her guidance and instructions before undertaking this survey; and to express our gratitude to Dr. H. Mellanby for her help, advice, and encouragement.

CHILDREN'S NURSING UNIT

BY

JOS. A. GILLET, M.B., Ch.B., D.P.H.

Medical Officer of Health, County Borough of Rotherham

Following on a high infant death rate in Rotherham during the winter of 1948 and early 1949, considered to be largely due to cross-infection in hospital, the health committee in March, 1949, approved a scheme for the establishment of a children's nursing unit as part of the home nursing service. It was to be at the disposal of the family doctor as a first line of defence so that a child could be nursed at home in its own environment, except when conditions were such as to make this impossible, or when special treatment necessitated removal to hospital. It was also appreciated that the value of the education of the mother in practical preventive methods and treatment during illness, with the necessary equipment, even in what might appear at first sight to be hopeless domestic conditions, would ultimately be of benefit to the community and that such action would help to reduce the pressure on hospital accommodation.

Preparations for the Scheme

Authority was given to obtain special nursing equipment, including infants' clothing, treasure cots, the necessary gowns, masks, storage cupboard, and nursing bags. Some of this equipment was given to the service, the treasure cots being presented by the Rotherham District Nursing Benevolent Association; and the children's nightgowns, coats, vests, etc., were either knitted locally or received in gift parcels from New Zealand, the remainder being purchased.

One of the Queen's Nursing Sisters on the home nursing staff undertook a postgraduate course covering children's diseases, and she was made responsible (under the direction of the home nursing superintendent) for this special service. Later on in the year, a second nurse received similar training. During 1952 both nurses undertook further hospital duty as refresher courses.

The doctors practising in the town were informed of the facilities available and the unit began to function in June, 1949. Cases are notified direct to the superintendent, usually by telephone by the general practitioners, and the special home nurse visits the home to assess whether the case is suitable and what equipment is needed. The equipment is kept in the nurses' home and special containers are packed and sterilized ready for use in infectious cases.

During the winter months cases are so numerous that the two special nurses are unable to deal with them all, and each home nurse attends the overflow cases on her district, giving a specially detailed report on all cases after each visit. Additional assistance is also given to the unit by the Queen's candidates as part of their training. The frequency of visiting depends on the child's condition; often it is necessary to pay three or four visits daily. The home nurse is in frequent consultation with the general practitioner, who is informed immediately if the child does not appear to be responding to treatment. The parents are encouraged to contact the nurses' home if they are unduly worried about their child's condition, and a nurse (usually the superintendent) pays a visit immediately. Night calls have been very few, and it is felt that the assurance of a visit from the nurse at any time removes a good deal of the parents' anxiety.

Equipment

Details of the equipment now used by the unit are as follows: 4 treasure cots; 1 dozen sheets; 2 pillows; 3 enamel pails; 6 wash basins; 6 enamel trays, 6 by 4 in.

(15 by 10 cm.); 6 "stay bright" measures, 1 pint; 6 receivers and 6 gallipots; thermometers; rubber gloves; masks; gowns; nightgowns and vests, 1 dozen of each (to be loaned out); 1 dozen towels (to be loaned out); nightgowns and vests to be given away (these are gifts from the Women's Voluntary Organizations in Australia and New Zealand). All new garments are made specially for us.

The special tins for use in infectious cases, such as measles, scarlet fever, ophthalmia neonatorum, and pemphigus, contain all the necessary equipment for nursing the child, so that the nurse's bag need not be taken into the sick-room. The tins contain: gown, mask, gloves, envelopes, message papers and chart, syringe and needles, thermometer and lotion, boric crystals, surgical spirit, powder, "dettol," undine, and pipette. Relatives usually send to the nurses' home for the cot (which folds up and is easily carried), sheets, and pail. In infectious cases the special tin is either taken by the nurse or called for by a relative of the patient.

When the child is convalescent the nurse ceases to attend and all the articles on loan are returned to the nurses' home, with the exception of clothing for small infants, which the parents are allowed to keep, much of it having been received as gifts from New Zealand and from interested local people. All returned articles and equipment which have been into the child's home, whether used or not, are soaked in 5% solution of dettol for 24 hours and then removed and boiled. The cot canvas, sheets, and towels, after being hung outside to dry, are sent to the laundry in the usual way.

Details of Work Done

This children's nursing unit, which has now been in operation for over three and a half years, has proved to be very popular with the general practitioners in the area, and is widely used by them. Table I gives details of the patients

TABLE I

	1949	1950	1951	1952
Cases nursed	435	621	508	713
Visits paid	4,151	5,870	4,150	5,837

under the age of 15 years who have been treated, and of visits paid by this unit from its beginning in 1949 up to December 31, 1952.

Details of the work of the children's unit during 1952, when 713 cases were nursed, are given in Table II.

TABLE II

	Under 1 year	1-5 years	6-15 years	Total
Brought forward at Jan. 1, 1952	1	8	1	10
New cases, 1952	225	284	194	703

Visits paid	2,038	2,268	1,531	5,837

Table III gives details of the "infectious" cases nursed during 1952 and their disposal.

A comparison of the infant deaths occurring in 1948 with those of 1952 is given in Table IV. When considering these figures it must be pointed out that the establishment of a premature baby unit some two years ago has effected some reduction in the number of deaths from prematurity, but there has also been a most striking reduction in the number

TABLE III

TABLE IV

	1948	1952 (provisional)
Total infant deaths	114	43
Infant mortality rate	70	32
Deaths from prematurity	27	12
Deaths from enteritis	31	—

of infant deaths since the establishment of the children's nursing unit. It is worthy of note that the overall incidence of enteritis in Rotherham also fell during the same period, possibly due to the nursing of cases at home instead of in hospital.

Apart from figures, the experience gained has shown that it has been well worth while to undertake this special children's work, some of its advantages being: (1) the child remaining at home in familiar surroundings is less liable to fret; (2) the danger of cross-infection is lessened; (3) the mother is encouraged to help in the nursing of the child, and the health teaching to parents and relatives done in these cases is considerable; (4) the call on hospital beds for sick children has been reduced.

Sixty delegates attended the seminar on foot health organized recently by the Central Council for Health Education at St. John House, Collingham Gardens, London. The seminar was for medical officers of health. The first lecture was given by Mr. T. T. Stamm, F.R.C.S., on "Development and Function of the Foot." Mr. Stamm followed this lecture with another the following day on "Foot Examination and Foot Defects." In the afternoons parties of delegates toured two factories to see shoes made by machine mass-production and hand methods. Lectures and demonstrations on foot health education methods and media were given by Dr. W. Emrys Davies. The discussion panel took as its subject "Foot Defects—Where Does the Cause Lie?" Members of the Panel were Dr. E. K. Macdonald, Medical Officer of Health for Leicester; Dr. Doris Craigmile, Assistant Medical Officer of Health, Ealing; Mr. Edward Rayne, Director of H. & M. Rayne, Ltd. (shoe manufacturers); Mr. J. Korn, Principal of the Cordwainers Technical College, London; and Mrs. Alice Buxton, Liaison Officer to the Foot Health Educational Bureau of the Central Council for Health Education. One group queried whether any available footwear was suitably shaped or priced for the growing child, economy and high prices being a recognized cause of shoes being worn too long until they are outgrown. Lieutenant-Colonel J. M. Milne, Adviser in Physical Medicine, R.A.M.C., reported that 80% of the Army intake showing foot defects were handed over to the physical training instructor, and that 60% of defects were postural or connected with the feet. Foot infections, he said, were not a major problem.

AN OUTBREAK OF FOOD-POISONING
DUE TO *CL. WELCHII*

BY

A. BECK, M.D., L.R.C.P.&S.Ed.

AND

W. C. TURNER, M.D., D.P.H., D.I.H.
Deputy Medical Officer of Health, Royal Borough of
Kensington

It has been shown that heat-resistant *Cl. welchii* may be the cause of food-poisoning (Oesterling, 1952; Hobbs *et al.*, 1953). The clinical picture of this condition is described by these authors as that of a pure lower-bowel affection—that is, diarrhoea and griping—without the vomiting and general symptoms, such as pyrexia and headaches, seen in food-poisoning due to staphylococci and salmonellae. The usual medium of infection is a meat dish which has been prepared the day before being consumed and has been kept under conditions favourable to the multiplication of bacteria. The relatively mild and short course of this illness and the fact that it is caused by an anaerobe which will escape detection in the usual tests for intestinal pathogens probably explain why this type of food-poisoning has attracted little attention before.

Description of Outbreak

We recently had an opportunity of investigating such an outbreak in a general hospital in which 44 persons were affected—39 patients and 5 staff. The number of persons at risk was approximately 360. The cases were distributed among seven wards of the 450-bed hospital. The persons affected fell ill about 8–16 hours after consumption of some roast pork served for lunch. The pork had been cooked the day before and was allowed to cool for about three to four hours in the open before being stored in the refrigerator. The next morning it was sliced in the kitchen, and freshly prepared hot gravy was added before it was distributed in closed hot trolleys to the wards.

The same night a number of patients fell ill with diarrhoea and acute abdominal pain; the stools were watery and only occasionally some mucus was present; one person had blood in the stool. There was no vomiting, but some patients complained of slight nausea; no pyrexia was noted. Most of the patients recovered by the following midday or evening.

Bacteriological Investigations

Stool samples of all persons affected and of the kitchen staff were cultured. In addition a remnant of the suspected roast pork and 12 random samples of raw pork from the kitchen refrigerator were examined; the latter were taken from joints which were derived from five different sides; the side from which the remnant of roast pork came could not be identified. None of the gravy was left. The faeces, in addition to being subjected to the routine examination for intestinal pathogens, were inoculated into bottles of meat broth; these were steamed for one hour, incubated overnight, and then subcultured on to anaerobic blood-agar plates. In positive cases an almost pure growth of *Cl. welchii* was obtained. The colonies had the characteristic appearance of this organism except for the initial absence of haemolysis, which, however, developed after a few days' standing. They gave a positive Nagler reaction which was suppressed by *Cl. welchii* type A antitoxin.

Smears prepared from the remnant of roast pork and the samples of raw pork revealed numerous Gram-negative and Gram-positive bacilli, some of the latter containing sub-terminal spores. Portions weighing about 1 g. were removed from the inside and outside of the pork and after being minced were suspended in 10 ml. of meat broth. The suspensions were plated direct on to aerobic and anaerobic blood-agar plates and then incubated overnight. Next day the meat-broth cultures were heated for five minutes at 80° C. and then subcultured on to anaerobic blood-agar plates.

Results

The stool specimens were somewhat slow in coming in, so that on the first day only 14 samples were examined; 10 of these were found to contain *Cl. welchii*. Specimens from 26 other patients were examined during the following two weeks and of these only eight were positive. None of the kitchen staff was found to carry this organism.

A small number of *Cl. welchii* colonies were found in the direct anaerobic culture from inside the roast pork. They were heavily outgrown by coliforms and some anthracoid bacilli; there were also some coagulase-positive staphylococci present. A better growth of *Cl. welchii* was obtained after overnight enrichment of the roast pork in meat broth.

The strains isolated from the faeces and pork were submitted to Dr. Hobbs, who kindly typed them. She reports that 6 out of 17 faeces strains and the two cultures isolated from the remnant of the roast pork served belong to her provisional type 1. The remaining 11 faeces strains do not fall into any of her types 1–10. Two strains isolated from the 12 random samples of raw pork belonged to type 6 and 10, and one strain was not typable. Dr. Hobbs suggests that this outbreak might have been due to a mixed infection with at least two types which she occasionally has observed (Hobbs *et al.*, 1953: outbreaks 6, 13, and 14 in Table 2).

Discussion

The high incidence of heat-resistant *Cl. welchii* found in faeces, particularly in the early specimens, and the recovery of organisms of the same serological type from the faeces and roast pork leave little doubt about the aetiological significance of this bacterium in the present outbreak. The proportion of positive findings would probably have been higher still if more specimens had been examined earlier. On the other hand, the recovery of heat-resistant *Cl. welchii* in 8 out of 26 patients up to 14 days after the symptoms had subsided serves to demonstrate that some bacteriological evidence of the nature of the outbreak can be obtained even one to two weeks after the acute illness. Owing to difficulties in obtaining repeat specimens no precise information is available on the duration of the excretion of this organism. Five out of 10 patients were, however, found to be carrying it three weeks after the onset of disease, and two gave a positive repeat culture after five and six weeks respectively.

It is not possible to state with certainty at which stage of preparation the meat became infected, and, unfortunately, owing to the method of marketing, the pork could not be traced beyond the slaughterhouse. The pork consumed on the day of the outbreak was derived from three and a half sides which formed part of a consignment of five sides kept in the hospital cold store. The origin of the remnants of the raw and roast pork could not be traced, as all the meat had been jointed the day before the outbreak. The finding of serological types in the raw meat different from that found in the roast meat probably indicates that the latter was derived from a different side. The recovery of *Cl. welchii* in 3 out of 12 samples of raw pork is in agreement with the high incidence (20%) reported by Hobbs and her co-laborators. The absence of *Cl. welchii* carriers among the kitchen staff exonerates them from having contaminated the meat. It is therefore likely that the pork was already infected in the raw state with *Cl. welchii* and that the spores, which, owing to their great heat-resistance (Hobbs *et al.*, 1953) survived heating in the centre of the joint, germinated under the favourable temperature conditions during the

prolonged cooling. There was further opportunity for bacterial multiplication on the following day, when the sliced pork was warmed with hot gravy.

The disproportion between the high number of persons apparently at risk and the number of people affected may be due to chances of distribution of contaminated and non-contaminated joints, or to variations of individual susceptibility as observed by McClung (1945).

The evidence presented emphasizes the danger of consumption of meat dishes prepared the previous day. Ideally, meat should be eaten on the day it is cooked. When this is not practicable provision should be made for rapid cooling after cooking, adequate refrigeration, and speedy serving of the meat after removal from the refrigerator.

Summary

An outbreak of food-poisoning due to heat-resistant *Cl. welchii* is described.

The organism was recovered from roast pork which had been consumed and from the faeces of 18 out of 40 persons affected.

Cultures isolated from the roast pork and from 6 out of 17 stools were of identical serological type. Other evidence, however, suggested that the outbreak was due to a mixed infection with at least two serological types.

The risk involved in the serving of meat dishes prepared the day before their consumption is emphasized.

We are indebted to Dr. Betty Hobbs for carrying out the typing of the cultures isolated from this outbreak. Our thanks are also due to Dr. M. W. Hutchings for help in following up these cases and to Mrs. E. Arnold for valuable technical assistance.

Medical Memoranda

Multiple Mongolism in a Family

Mongolism as a rule occurs only sporadically in family pedigrees, and it was formerly believed that there was never more than one mongol born in a family. This theory usually holds good, as Warner (1949) could collect from the world literature only 42 families in which two siblings were affected, excluding instances when twins were involved.

The birth of three mongoloids in one generation of a family is rarer still, and we have failed to find a previous instance in British literature. The first description of such an occurrence was that of Herrman (1917). Reports by van der Scheer (1919), Fantham (1925), Malkin (1928), Bixby (1940), and Benda (1947) followed. Recently the following came to our notice.

FAMILY HISTORY

The father, a farm cowman, was born in 1905, and the mother, formerly a domestic servant, was born in 1909. They married in 1925, and are known to belong to the dull group of a rural population, the maternal family being of poorer stock than that of the father. There is no consanguinity or history of mental disease in the ascendants. Both parents are virtually feeble-minded and are unable to remember the year of their marriage, the dates of birth of their children, or the years in which three children died. They could recall the sequence of the children's birth only with mutual prompting and with the assistance of one of their daughters. The mother has had five miscarriages,

but is uncertain when two of them occurred. Known miscarriages took place in 1939, 1942, and 1946.

The birth order of the children is as follows: girl, D, 1926; girl, B, 1930; girl, K, 1931; girl, E, 1932; boy, H, 1934; girl, M, 1937; girl, F, 1941; girl, P, 1943; boy, R, 1945; girl, C, 1948. Of these, the girl, P, died at the age of 14 months from tuberculous peritonitis and the boy, R, at 6 months from pneumonia. Apparently no unusual symptoms were experienced during any of the pregnancies.

H is now employed as a cowman, K and B as factory hands in semi-skilled work, and F attends school, having an intelligence quotient of 101. D, who was admitted to a certified institution in 1933, is a mongol imbecile with an intelligence quotient below 30. M was admitted to the same institution in 1941, and is likewise a mongol imbecile, with an intelligence quotient of 30. E was recognized as a typical mongol by the family practitioner shortly after birth and died aged 4½ months, the cause of death being certified as mongolism and bronchitis.

COMMENT

Such families have aroused interest from two aspects. Firstly, it was hoped that their study might lead to an eventual elucidation of the condition, and, secondly, they should be borne in mind when the mother of a mongol seeks advice about whether future pregnancies may result in the birth of further mongol children.

This case well illustrates the contention that hereditary factors indicative of germinal inferiority are evident in the majority of instances of multiple mongolism. It further supports the thesis that in such cases there is an increased tendency to miscarriages; indeed, some of these may be abortions of mongols. It is suggested that if advice is sought by the mother of a mongol child and the family background and medical examination of both parents prove satisfactory, then the "mother can be encouraged to have more children without risk" (Benda, 1947).

Our thanks are due to Dr. T. W. E. Royden, the family practitioner, for his help in the study of this family.

Chlorcyclizine Hydrochloride Poisoning in an Infant

Toxic effects with antihistamine drugs are common in adults, but are seldom severe enough to require hospital treatment. Children have frequently been the subject of acute accidental poisoning by these drugs, probably because of the attractive presentation of the pills, and the effects have often been extremely serious. A number of fatal cases have been described. The main clinical feature of them all has been convulsions. The increased liability to fits in epileptics taking diphenhydramine hydrochloride ("benadryl") and tripeleminamine hydrochloride ("pyribenzamine") was shown in E.E.G. studies by Churchill and Gammon (1949). In large doses the antihistamines appear generally to act as central convulsants.

Rives *et al.* (1949), in their fatal case due to methapyrilene hydrochloride, reported the occurrence of cerebral oedema with petechial haemorrhages, which might account for this clinical picture. Their case also showed an acute nephrosis. Tobias (1949) reported the first fatal case in this country. It showed similar clinical features to the present case, but the patient died in three hours. There was no necropsy report. In two cases the necropsy findings were confined

to lung congestion, acute emphysema, and early bronchopneumonia (*British Medical Journal*, 1951). The latter three cases were all due to mepyramine maleate ("anthisan") poisoning, as were the cases reported by Miller and Pedley (1950) and by Prain (1950), in which the findings were essentially the same, with the addition of cerebral congestion. The mepyramine cases all showed a massive catarrhal discharge from the upper respiratory tract. This does not seem to have been seen with other antihistamines.

Davis and Hunt (1949) reported a fatal case due to diphenhydramine poisoning in a child aged 2 years. The clinical picture was again similar, except that respiratory depression occurred and was the eventual cause of death. The necropsy findings were generalized congestion of the lungs, brain, and other organs, with some petechial haemorrhages into the thymus and myocardium.

Various lines of treatment have been suggested, one of them being the use of histamine itself (*Lancet*, 1950). The value of this would seem doubtful, since direct antagonism between the substances in question has never been demonstrated, although it is possible that free antihistamine might be rendered harmless in this way. Gaddum (1948) suggests that antihistamines may act by blocking the histamine receptors, and this is also the view held by White (1950), who states: "Antihistamines do not antagonize histamine by combining with it chemically or by inducing opposite pharmacological responses, as does adrenaline . . . they block histamine receptors in the tissues. It therefore seems doubtful whether histamine can be effective. . . . In some people, notably asthmatics, even though saturated with an antihistamine, it is possible that injections of histamine would produce severe reactions."

The use of various histamine-releasing drugs has also been advocated, but such a view can gain little support from the generally accepted theory of antihistamine action as briefly stated above. Geiringer (1952) states that morphine might well be of value on account of its histamine-releasing property. The danger of morphine in children on account of their peculiar sensitivity to its respiratory depressant action is well known, and would make one extremely reluctant to use it.

Both atropine and adrenaline hasten death from mepyramine poisoning in experimental animals. Overdosage with histamine also hastens death, although small doses appear to be beneficial; the ratio of histamine to antihistamine required for this beneficial effect varies greatly from species to species (Geiringer, 1952). The amount likely to be of value in man is at present unknown. It would therefore seem unjustifiable to administer histamine in cases of antihistamine poisoning, at least on present knowledge.

The following case would seem to be the first serious toxic effect reported due to chlorcyclizine hydrochloride ("histanin"). The treatment adopted was similar to that used in the case reported by Snyderman (1949), who described poisoning by methapyrilene hydrochloride ("thylene hydrochloride") in a child of 16 months. There was a convulsive stage lasting four hours, controlled by soluble phenobarbitone and chloral. The child had completely recovered after 24 hours. A short period of cardio-respiratory depression was successfully overcome with rectal caffeine.

CASE REPORT

At noon on January 14, 1952, a boy aged 16 months took 18 tablets of chlorcyclizine hydrochloride (50 mg. each, total 900 mg.) which had been prescribed for his mother for nausea of pregnancy. He was almost at once discovered to have done so. At 12.45 p.m. he began to look vacant and was taken to the doctor's surgery, where he vomited. He was sent to the casualty department, where he arrived at 2 p.m. He was then having incessant generalized convulsions and was cyanosed.

His stomach was washed out with sodium bicarbonate solution, and intramuscular paraldehyde, 0.25 ml., was given every ten minutes. At 3 p.m. soluble phenobarbitone, 1 gr. (65 mg.) every 20 minutes, was substituted for the paraldehyde, and atropine, 1/200 gr. (0.32 mg.), was given, as his

secretions were becoming excessive. His condition had improved sufficiently at 4.30 p.m. for him to be transferred to the children's ward. On arrival there at 5.15 p.m. he was slightly cyanosed. There were continuous generalized convulsive movements. Respiration was rapid (55 a minute) but full.

Treatment was continued on similar lines, with both paraldehyde, 1 ml. intramuscularly every 30 minutes, and sodium phenobarbitone, 1 gr. intramuscularly hourly. Prophylactic penicillin, 100,000 units six-hourly, was given. Convulsions ceased at 8.30 p.m. and did not recur. Anticonvulsants were discontinued.

The next day he remained extremely sleepy. His eyes were open and he appeared to watch events without much interest. His blood picture showed: Hb, 110%; white cells 22,000 (polymorphs 58%, eosinophils 2%, lymphocytes 32%, monocytes 8%); red cells appeared normal. His progress over the next three days was slow: the level of consciousness gradually improved, but he appeared very ataxic. There were no localizing signs in the central nervous system. On January 18 he remained still drowsy and his actions were rather automatic. Dexamphetamine sulphate, 2.5 mg. twice daily, was started. This resulted in some speeding up in the process of recovery. On January 23 the patient was sitting up, but very unsteadily. There was no nystagmus. His expression was vacant at times; his intelligence did not appear to be great. Blood picture showed: Hb, 82%; red cells, 4,500,000; C.I., 0.9; white cells, 7,000 (polymorphs 52%, eosinophils 1%, lymphocytes 43%, monocytes 4%).

On January 26 dexamphetamine sulphate was omitted and he was discharged from hospital. He was due to be seen at the out-patient clinic on February 14, but was unable to attend, as he had pulled a pot full of nearly boiling tea over himself a week before and had suffered severe scalds. When seen on February 21 he was perfectly fit and appeared normal in all respects, having completely lost his vacant expression. A further blood picture showed: Hb, 75%; white cells, 22,000 (polymorphs 41%, eosinophils 4%, lymphocytes 51%, monocytes 4%). The raised white blood count was of doubtful significance in view of his recent burns, but no abnormal cells were seen.

There was no albuminuria or other evidence of renal damage at any time.

COMMENT

This was a severe case of poisoning by an antihistamine drug, the main features of which were the prolonged convulsive stage of nearly seven hours, unassociated with any respiratory depression, and the slow recovery, with lethargy and ataxia.

When the child was first seen the most pressing problem seemed to be to stop the convulsions, for it was felt that their continuance would inevitably lead to cerebral damage. Treatment was therefore confined to anticonvulsant drugs.

The child made an uninterrupted recovery despite the use of several drugs which have an adverse effect in experimental animals, and it seems doubtful whether laboratory tests in these animals are applicable to man.

I wish to thank Dr. S. D. V. Weller for permission to publish this report on his patient; Dr. W. E. Budd for assistance in the treatment; and Dr. D. Finlay, of Burroughs Wellcome and Co., for supplying much valuable information.

Reviews

THE NAVY AT WAR

The Royal Naval Medical Service. Volume 1: Administration. By Surgeon Commander J. L. S. Coulter, D.S.C., R.N. History of the Second World War, United Kingdom Medical Series, Editor-in-Chief Sir Arthur S. MacNalty, K.C.B., M.A., M.D., F.R.C.P., F.R.C.S. Prefatory Note by Editor-in-Chief. (Pp. 512; 13 plates. 50s.) London: Her Majesty's Stationery Office. 1954.

The Medical Department of the Royal Navy are to be congratulated on the appearance of this history of the administration of the Royal Naval Medical Services in the second world war. Every medical officer who served with the Senior Service will be pleased to read this book, for it has much to interest him, and when we remember the very small and quite inadequate volume which appeared after the first world war our gratification is accentuated. Although several medical officers have served on the editorial committee for varying periods and have acted as the editor of the *History* from time to time, the person who has really been responsible for this volume is the official editor, Surgeon Commander Coulter, and all who know him realize what a great job he has done.

The Navy in wartime is quite a different thing from that in peace, and in the ships themselves there is often a 60% increase of the normal complement of personnel. When this fact alone is considered, together with the possibility of the ship serving in any of the seven seas, sometimes in tropical climates and sometimes in arctic, this makes the life of a ship's medical officer a busy one. With every new war there are bound to be new weapons for fighting the ship, and new conditions and new problems arise for the medical officer. The administration of a self-contained unit such as a battleship is quite a different problem from that of a unit ashore. The black-out conditions and the rigid requirements of damage-control organization in wartime have to be seen to be appreciated.

The second world war necessitated a vast expansion of the Naval Medical Service both in personnel and in hospitals. The Royal Naval blood transfusion service in Camden Town came into being in 1942 and with it the blood transfusion units which were to do such excellent service as the war progressed. Some of the large Naval hospitals at home suffered extensively from enemy bombing, and auxiliary hospitals had to be equipped and staffed. All this was carried out while various research problems were being pursued, such as underwater blast, immersion foot, and the prevention of burns. The Naval medical establishments abroad increased as the war progressed and patients were evacuated by air from many of these. This volume enumerates all these establishments and hospitals and gives the number of patients treated in each and the capital expenditure involved. We look forward to seeing the second volume, to be devoted to campaigns, for we know Surgeon Commander Coulter will give us another very interesting book.

CECIL WAKELEY.

A BIOLOGIST'S PHILOSOPHY

The Mind and the Eye: A Study of the Biologist's Standpoint. By Agnes Arber, M.A., D.Sc., F.R.S., F.L.S. (Pp. 146. 16s.) Cambridge: The University Press. 1954.

Dr. Arber is an eminent botanist and historian of botany, already well known to students of medical history for her volume on herbals. Her experience as a research worker extends over fifty years, and for the past twenty she has been reading widely in philosophy ancient and modern. This experience and reading are here synthesized in language clear and simple but weighty with thought and close reasoning. The result may be aptly termed a testament of biology. It is a work of high excellence that will delight all research workers, and not merely biologists.

The author begins by outlining the research worker's evolution from tiro to philosopher. His first job in life is to find a clearly defined problem, or a field in which such a problem may emerge. The second stage is to find the requisite facts by observation or experiment, and the third is to interpret the facts. The fourth stage is the testing of the conclusions, and the fifth is the publication of the results. The sixth stage is a broadening of interest that leads the worker to consider his results in the wider context of thought in general—in other words to philosophize—a stage most likely to be reached late in life, when the urge to contemplate surpasses the desire to garner.

In the first half of the book the author discusses the five pre-philosophic stages, and includes a fascinating chapter on the art of scientific writing, preserving Gauss's splendid dictum: "I have had my results for a long time; but I do not yet know how I am to arrive at them." The second half of the book is a discussion on the relations between biology and philosophy, and will stretch the pia mater of anyone unfamiliar with Plato and Aristotle, Dante and Descartes. The topics dealt with include biology and truth, the fundamental assumptions of biology, biological antitheses, and antitheses and dialectic. The general theme is that many paired concepts, such as form and function, body and mind, and mechanism and teleology, are artifacts and therefore imperfect representations of a higher unity, the final aim of biology being the fusion of metaphysical and scientific thinking. If this book were mediaeval its author would have been concisely designated (and justly renowned as) *Agnes Conciliatrix*.

RAYMOND WHITEHEAD.

CIRCULATORY DYNAMICS

Circulatory Dynamics: Physiologic Studies. By Professor Carl J. Wiggers, M.D., Sc.D., F.A.C.P. Modern Medical Monographs No. 4. (Pp. 107; 44 figures. \$4.) New York: Grune and Stratton. 1952.

The young cardiologist of to-day is more or less forced to make use of techniques for which he may have had little basic training. To him especially this short monograph by a famous physiologist should prove invaluable. It incorporates the essence of many of the author's contributions to the field of circulatory dynamics over the past forty years, his own original interpretations being re-evaluated in the light of subsequent work. The basic laws of haemodynamics are stated and carefully explained in simple language and with helpful illustrations. The classical contributions of Bowditch (1871), Howell and Donaldson (1884), Frank (1895), Henderson (1906), and Starling (1914) are described in sufficient detail, followed by a short summary of the author's own data. In the last chapter he discusses the heart's adaptations to abnormal conditions in various diseases—which he regards as "experiments performed by nature on animals and human beings."

It was a very great pleasure to read this delightful monograph, which is a perfect model of its kind. The author's name is its best recommendation, but had it been written by an unknown worker no praise could have been too high for it.

PAUL WOOD.

TOXAEMIA OF PREGNANCY

Toxaemias of Pregnancy. By John Sophian, M.D., F.R.C.S., M.R.C.P., M.R.C.O.G. Foreword by F. J. Browne. (Pp. 230; 37 figures. 25s.) London: Butterworth & Co. Ltd. 1953.

Those who take an interest in recent work and views on the cause and nature of pre-eclampsia and eclampsia will be aware of the hard work and enthusiasm which Mr. Sophian has brought to bear on these problems during the last ten years. He has long been a staunch advocate of the Trueta renal shunt as the mechanism underlying the manifestations of these diseases, and, with Professor K. J. Franklin, has demonstrated by animal experiment a utero-renal reflex which might bring the shunt into operation. In this monograph he presents a clear and full statement of his views, supported partly by personal observations but mainly by a

review of the literature. The latter is extensive and intensive, although it sometimes savours of selection and interpretation to suit a particular theory. For strong conviction and an urge to spread a gospel are rarely compatible with complete impartiality.

The clinical aspects of toxæmia of late pregnancy and allied states such as hypertension and renal cortical necrosis are discussed in the light of biochemical and pathological changes in the affected organs, the whole being introduced by accounts of the embryology, anatomy, and physiology of the kidney. These are detailed and will be best appreciated and evaluated by those who are experts in the particular fields. An unfortunate slip which the clinician will notice is the statement that the "Bull, Joekes, and Lowe diet" for anuria has a high protein content.

The author discusses other modern theories of the cause of toxæmia of pregnancy, though most attention is naturally given to his own concept. Not everyone will agree that this offers the complete answer to the problem, but the book is none the less valuable in that it cannot fail to be both a source of reference and a stimulus to thought and discussion among all workers in the diseases with which it is concerned, and thus indirectly, as well as directly, further the search for the cause and logical treatment of what still remains one of the greatest hazards of childbearing.

MODERN TREATMENT

Modern Treatment Yearbook 1954: A Yearbook of Diagnosis and Treatment for the General Practitioner. Edited by Sir Cecil Wakeley, Bt., K.B.E., C.B., LL.D., M.Ch., D.Sc., F.R.C.S., F.R.S.E., F.R.S.A., F.A.C.S., F.R.A.C.S. Published for the Medical Press. (Pp. 352; 69 illustrations. 21s.) London: Baillière, Tindall and Cox. 1954.

This is an attractive and reasonably produced volume in a series that has been appearing yearly with slight variations of title and format for the last twenty years. The volumes were originally entitled "Modern Treatment in General Practice," but the convention that it is only the general practitioner who finds it difficult to keep up to date has now happily been abandoned. The present volume contains 35 articles on a variety of topics which range from common scalp infections to injuries of the semilunar cartilages, from congenital clefts of the lip to carcinoma of the cervix.

A high proportion of the writers belong to the younger generation, and the articles are crisp and informative. The book performs well what it sets out to do, which is to describe in simple terms some practical forms of treatment where there have been advances in recent years. Nevertheless, it is noteworthy that two out of every three contributors are surgeons and there are only two articles which do not deal with gross physical disease—one on enuresis and one on the aftercare of the mental patient. This last article mentions that there are approximately 200,000 patients receiving mental hospital care in the United Kingdom, other than mental defectives, and that between one-third and one-quarter of all absence from work in factory workers may be due to neurotic illness. We must hope that in years to come Sir Cecil Wakeley may be able to find young and vigorous authors who can divert our attention to these important fields.

L. J. WITTS.

TEXTBOOK OF PHARMACOLOGY

Pharmacology. By J. H. Gaddum, Sc.D., F.R.S., M.R.C.S., L.R.C.P. Fourth edition. (Pp. 562; 89 illustrations. 35s.) London: Geoffrey Cumberlege. 1953.

The arrival of the fourth edition of this textbook may not attract much attention except from those directly concerned with teaching or learning the subject, and if this should be so it is a pity. The book is primarily written for medical students, but it is of real value for all who are teaching clinical medicine. Indeed, it is difficult to think of another book of a similar convenient size which so well summarizes the advances in basic knowledge of importance for the clinical teacher.

Professor Gaddum's sentences are short, and this gives great precision to his statements. His exposition is none the less graceful, and the certainty of touch with which he picks out the essential points makes the book admirable for reading by the fire, a page or two at a time, to re-cement our basic knowledge and to promote our reflection. One may doubt, indeed, whether some medical students will sufficiently appreciate and enjoy a book where information is so closely packed.

Much attention is given to quantitative studies, and the chapter on general pharmacology, with its discussion of the calculation of error and explanation of frequency distribution from the fate of the marbles which were given by a rich man to his friends, forms an excellent introduction to statistical methods. A fair amount of attention is paid to the chemical structure of related substances, though this is done unobtrusively. The difficulty of showing convincing similarities is at once apparent when the formulae for the antihistamines or for the atropine-like substances are considered.

The serious problem of nomenclature remains as far from solution as ever. There is now a list of international non-proprietary names (I.N.N.), which Professor Gaddum, as in duty bound, has followed. Thus he describes the new remedy of the thiouracil group as thiamazole. However, a recent paper in this *Journal* described it as methimazole, which is the approved name of the B.P. Commission, and this paper informed the reader that the substance was sold as "tapazole." It is also known as "mercazole"!

The book is one of the Oxford Medical Publications, and is printed and illustrated beautifully. It is unfortunate, however, that this new edition has been so slow in appearing, for the third edition was exhausted some time ago.

J. H. BURN.

INDUSTRIAL MEDICINE AND HYGIENE

Outlines of Industrial Medicine, Legislation, and Hygiene. By James Burnet, M.A., LL.B.(Lond.), M.D., F.R.C.P.Ed. Second edition. (Pp. 122. 10s. 6d.) Bristol: John Wright and Sons. 1953.

Dr. Burnet, in his preface to the second edition of this book, anticipates the criticism most likely to be levelled—the inevitable compression of so many subjects into so small a space. He remarks that it is meant only to serve as an introduction to their study for students of industrial medicine. In some respects the book achieves this object; the section on industrial legislation especially will be found useful to anybody who may later have to acquire a detailed knowledge of the complications of the Factories Acts and the National Insurance (Industrial Injuries) Act. The whole section on industrial diseases, however, especially "Poisons," is so severely curtailed that many essential facts are omitted, while some of the information given is misleading and inaccurate. Dinitrophenol, for example, is said to owe its industrial prominence to its use as an explosive, with no mention of its principal modern use as an insecticide, and in the list of toxic symptoms caused by it one of the most characteristic, extreme loss of weight, is not mentioned. The statement that tetrachlorethane may be used for "doping" aeroplanes was correct up to 1918 but is certainly not so now, and few authorities would regard bleeding from the gums as an early sign of benzene poisoning.

Preventive measures are described at the end of each account of an industrial poison so vaguely as to be almost valueless. Under "Amyl Acetate," for example, the statement that "these consist in limiting the amount of exposure and in reducing the concentration of this liquid" means little or nothing. While it is quite impossible in a book of this size to give anything like a full account of the many subjects touched upon, it is a pity that space should be devoted to non-essentials instead of to some of the more important aspects which have been treated very sketchily.

ETHEL BROWNING.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 20 1954

EHRlich AND VON BEHRING CENTENARIES

The strange coincidence of the births of Paul Ehrlich and Emil von Behring on successive days in 1854 afforded a unique opportunity for a twofold centenary celebration. This took place on March 13 to 16 at Frankfurt-on-Main—the scene of their collaboration during the 'nineties in the study of diphtheria antitoxin. Delegates representing universities and medical schools and organizations all over the world attended the celebration, which began with a tour of the Paul Ehrlich Institute on March 13 and a reception by the Frankfurt municipality. At a ceremony on the following day the Paul Ehrlich Prize for 1954 was presented to Professor E. B. Chain, scientific director of the International Research Centre for Chemical Microbiology at Rome. On March 15 a visit was paid to Marburg, where the rector of the Philipps University presented three von Behring Prizes—for 1948 to Professor Hans Schmidt, of Marburg, for 1952 to Sir Macfarlane Burnet, of Melbourne, and for 1954 to Professor M. Heidelberger, of New York. Finally on March 16 a scientific session—arranged jointly by the Paul Ehrlich Institute, the Philipps University, and the Johann Wolfgang Goethe University at Frankfurt—was held under the presidency of Dr. Th. Madsen and Sir Henry Dale, and papers were read on a variety of subjects by distinguished contributors from several countries. Earlier in the proceedings Sir Henry Dale, on behalf of the Medical Research Council in London, had handed over to the Paul Ehrlich Institute a number of historical documents relating to Ehrlich and his work.

This issue of the *Journal* contains papers on Ehrlich by three authors who all worked with him—Sir Henry Dale, Professor Carl Browning, and Miss Martha Marquardt—and one paper on von Behring by Sir Arthur MacNalty. The chief claim of von Behring to everlasting fame is as the discoverer of antitoxin. That the diphtheria bacillus produces an exotoxin was proved by Roux and Yersin in 1888. Two years later von Behring and Kitasato proved the

presence of a protective and transferable antibody in the blood of animals immunized with killed cultures of diphtheria and tetanus bacilli, and gave the name of antitoxin to it. It was in the application of this discovery to therapeutics, particularly of diphtheria, that his collaboration with Ehrlich took place. Von Behring must also be credited with having laid the foundations of active immunization against diphtheria: it was he who actually introduced the use of toxin-antitoxin mixtures for this purpose, although these were to be entirely supplanted not many years later by preparations of toxoid. Among his other achievements none ranks with these: in some of his beliefs about tuberculosis he was frankly mistaken, and his methods of immunization against this disease were of doubtful value.

No one will dispute that Ehrlich was the greater of the two men: he was indeed one of the very greatest that medical science has ever produced. As will be evident from these accounts of him—and particularly from the intimate and purely personal account of Martha Marquardt, his biographer, and his secretary from 1902 until his death at the age of only 61 in 1915—he was a man of a quite different type from von Behring: the qualities accounting for that difference were evidently among those which most inspired affection among his associates. Of his long record of achievements Sir Henry Dale's paper gives a most illuminating account, which deserves to be read by all those not fully familiar with its subject. The astonishing feature of this career is its separation into three parts, each devoted to a subject quite distinct from the other, and any one of which would have sufficed for lasting fame. The main outcome of the first of these periods, during which he was concerned largely with reactions between dyes and components of living cells, may be said to be nothing less than the foundation of the modern science of haematology. Ehrlich not only perfected methods of staining blood cells, but described them and traced their development with a thoroughness to which the still frequent use of his name in connexion with the cytology of the blood and marrow is a fitting tribute. Out of this work came the idea of using aniline dyes as drugs. This was to be developed only in the third stage of his career.

What intervened here was von Behring's discovery of antitoxin, and the task of applying this in therapeutics. It was Ehrlich who was responsible for the production of diphtheria antitoxin of sufficient potency for clinical use by a prolonged course of immunization. But out of these efforts grew much more; indeed, in three separate directions these studies provided a basis for all later work in this field.

Three forms of toxin were identified, including toxoid, which was later to provide the means of active immunization. Methods were devised for measuring the specific activity of an antitoxic serum, and the use of a reference standard for the first time was the model for all subsequent methods of biological standardization. Finally, as an outcome of studies of immunity, the scope of which extended far beyond the single problem of diphtheria, Ehrlich developed the famous side-chain theory. However our views of this may have been modified by subsequent observations, the pictorial conception of interlocking parts on the surface of molecules has become a commonplace in the literature of immunology.

In the third phase of his career, which developed out of the first, Ehrlich was almost solely responsible for creating a new therapeutic method which was to revolutionize the whole of medicine. He had invented the word "chemotherapy" years earlier in connexion with a by no means unsuccessful attempt to treat malaria with methylene blue: this experiment, conducted in 1891, was, as Sir Henry Dale points out, a landmark of the highest significance, since it was the first attempt ever made to treat an infection by means of a synthetic substance acting directly on the micro-organism causing it. The principle that dyes, with their high affinity for constituents of the microbic cell, should have a selective action on them underlies much of Ehrlich's subsequent work and that of his successors at Frankfurt. Eventually, indeed, it led to the discovery of the sulphonamides, although almost by accident, since in fact the dye moiety of the "prontosil" molecule was soon proved to be therapeutically inert. Although the discovery of prontosil was not announced until twenty years after Ehrlich's death, it can properly be regarded as an outcome of his work. Of his own direct achievements—the demonstration of the action of trypan red in trypanosomiasis and the discovery of salvarsan—the former was only a stage on the way to the subsequent discovery of "germanin," but the second was of the highest immediate practical significance, and placed chemotherapy with synthetic drugs for the first time on an assured footing. Had Ehrlich not lived, it is quite possible that chemotherapy, except with quinine and emetine, would still be unheard of at the present day, for without the encouragement given by the results obtained with their forerunners even the antibiotics might have remained mere microbiological curiosities, their therapeutic powers unsuspected. Bulloch's¹ uncompromising verdict on Ehrlich, "The greatest scientific worker in medicine in the last fifty years," is not likely to be disputed.

HAEMOLYTIC DISEASE OF THE NEWBORN

In 1952 haemolytic disease of the newborn caused the deaths of 435 infants in England and Wales:¹ this is in addition to the 30% of affected babies who are stillborn with hydrops foetalis.² Apart from this mortality and the crippling effects of kernicterus among those who survive this complication, the possibility of the condition is an anxiety to the parents in the one in eight of all pregnancies where a rhesus-negative mother lacks a factor, usually D, present in the father and foetus. In these pregnancies there is a risk of maternal immunization from a foetal source and of the subsequent passage of antibodies across the placenta, with the destruction of the infant's red blood cells. It is still not clear why only 5% of rhesus-negative mothers become sensitized by pregnancy, but the danger of previous blood transfusion with rhesus-incompatible blood is now well known: Levine³ found that the mother had received a transfusion in 180 out of 220 affected first pregnancies, and that this doubled the stillbirth rate in this group. In spite of the increasing complexity of blood groups, over 90% of haemolytic disease of the newborn is still found to be due to sensitization to the Rh-positive D antigen. The great majority of the remaining cases are due to foetal-maternal ABO incompatibility, while other blood antigens—such as c, E, and Kell—are rarely to blame.

There is still no method of true prophylaxis against immunization to the Rh factor. Unsuccessful efforts in the past at inhibiting antibody formation by administration of vaccines,⁴ ethylene disulfonate,⁵ and haptens⁶ have their modern counterpart in the administration of A.C.T.H. and cortisone, which have been given both antenatally to the mother and after birth to the affected baby. that treatment with cortisone and A.C.T.H. is disappointing as a routine measure, preventing neither haemolysis nor kernicterus. It remains to be seen whether there is a place for their carefully controlled use in severely affected pregnancies in an effort to reduce sensitization and promote the birth of a liveborn infant suitable for exchange transfusion. Efforts to ensure a live baby by early induction of labour in affected pregnancies have been shown by Mollison and Walker⁹ to carry a disproportionate risk of kernicterus in the prematurely born infant. The case for premature delivery in certain circumstances is argued elsewhere in this issue by Drs. H. B. Watson, V. Mary Crosse, and W. L. F. Hatchuel; and the combination of early induction and exchange transfusion has recently been advocated by Davies and her colleagues¹⁰ in cases where there has been a previous hydrops foetalis and the father is homozygous. In a group of eleven such pregnancies they obtained a live-born infant in every case after induction at 30-36 weeks. Further, these authors believe that the birth of stillborn or hydropic babies may be predicted from the pattern of past disease in the previously affected sibling: after the birth of an infant with hydrops foetalis 80% of the next affected babies were also born hydropic, while after a live-born infant the subsequent affected baby was born alive in 83% of cases. This observation is at variance with the commonly held opinion that there is a steady deterioration with each successive pregnancy, but, if it is confirmed, it may be of great use in prognosis and in the planning of treatment in individual families.

Routine examination for antibodies in saline and albumen or detection of sensitization by the indirect Coombs test is now used more for planning of hospital delivery and treatment than as a guide to prognosis in the infant. Though high incomplete antibody titres, and particularly a rapid rise or fall, are generally of serious significance, sometimes mothers of gravely affected infants show low titres, while in a recent Birmingham series¹¹ titres of 1:512 or more indicated either a rhesus-negative or a hydropic baby.

Treatment of the affected infant aims at the prevention of anaemia and kernicterus: replacement transfusion of at least 90% of the infant's blood by fresh Rh-negative compatible donor blood meets this purpose in all moderately or severely affected infants with a positive Coombs test. The necessary quantity of blood can be calculated from the nomogram of Veall and Mollison¹²: this aims at leaving a packed cell volume of 50%, and a further transfusion should not be necessary. Ideas differ about the exact indi-

cations for exchange transfusion, but most authorities agree that it should be given whenever there has been a previous pregnancy ending in hydrops or kernicterus, when the baby weighs under 5½ lb. (2.5 kg.), or when the cord haemoglobin level is below 15.5 g.% in full-term babies. As the risk of kernicterus has been shown to bear a close relationship to the serum bilirubin level in the first few days after birth,^{13 14} all untreated babies must be watched carefully for the onset of jaundice and should be treated by exchange transfusion if the serum bilirubin rises above 20 mg. per 100 ml. or if any early signs appear of brain damage from kernicterus. Criteria for re-exchange transfusion are similar. Working on these principles, Hsia¹⁵ has reported no case of kernicterus after 250 successive exchange transfusions, thus virtually eliminating this complication. However, lesser degrees of kernicterus may possibly occur in deeply jaundiced babies without the usual signs of brain damage: Gerver and Day¹⁶ found that the intelligence quotient in a group of children who had been deeply jaundiced at birth and who had not had an exchange transfusion was 16.8 points lower than that of their older siblings who had escaped haemolytic disease; whereas in a group of children only slightly jaundiced at birth there was no depression of the intelligence quotient.

The mechanism of damage to the basal ganglia in kernicterus remains obscure, but the nature of the pigment has been investigated extensively. Claireaux¹⁷ and Waters and his colleagues¹⁸ have both isolated bilirubin from kernicteric brains, while Kuster and Krings¹⁹ induced kernicterus experimentally in kittens by intravascular injection of bilirubin. Vogel²⁰ believes that bilirubin after crossing the blood-brain barrier is converted into mesobilirubin within an already damaged brain cell. The variety of bilirubin responsible in these cases would appear to be the indirect-reacting type, present in excess in haemolytic disease of the newborn. It is uncertain whether the pigment has a direct toxic effect on cells of the basal ganglia made more susceptible by prematurity or liver immaturity, or whether it merely stains nerve cells already damaged by anoxia, anaemia, or antigen-antibody reaction.

Haemolytic disease due to ABO incompatibility can also be an important cause of jaundice in the first 36 hours of life. There is a risk of ABO incompatibility in one-third of all pregnancies, and up to half of the affected infants are firstborn. Although ABO sensitization has been found to follow administration of antitoxins containing horse serum,²¹ vaccines, pooled plasma, and even group O neutralized blood, not one of the eleven cases

recently described by Crawford, Cutbush, and Mollison²² gave such a history. Since soluble ABO substances are actively secreted by the infant's tissues and cross the placental barrier freely, high maternal anti-A or anti-B titres often occur in heterospecific pregnancies with normal infants. In the absence of a previously affected infant, antenatal diagnosis is thus very difficult. After birth, a combination of early jaundice, negative or weakly positive direct Coombs test, and, usually, moderate anaemia with spherocytosis and increased fragility in the infant's blood suggests "icterus praecox." This is confirmed by the presence of a high anti-A titre in the mother's serum which can haemolyse the infant's cells *in vitro*.²² Although stillbirth is rare in such cases, kernicterus may occur; therefore exchange transfusion is advisable if the infant becomes jaundiced in the first 24 hours or the bilirubin rises above 15 mg. per 100 ml. in that time.

CHANGE OF SEX

During recent years the medical profession has shown an increasing awareness of the plight of those unfortunate individuals whose genitalia do not correspond precisely to the normal for either sex, and has attempted by more accurate diagnosis at birth to avoid a later change of established sex. Very few of these cases are true hermaphrodites—that is, possessors of both ovarian and testicular tissue; most are pseudohermaphrodites. In the ordinary terminology male pseudohermaphrodites have testicles together with external genitalia of partly or wholly feminine character; they are often pronounced at birth to be girls and brought up as such until increasing masculine physique or behaviour leads to the suspicion of error. In female pseudohermaphrodites virilization of the external genitalia in an individual having ovaries, uterus, and Fallopian tubes commonly results from adrenal cortical hyperplasia beginning during foetal life. The subject of intersexuality as a whole is a complex one, and apt to provoke much unprofitable speculation, but its practical aspects are of importance to all those who treat infants and children. A brief summary has been given by Williams¹ in this *Journal*. A full diagnosis cannot always be made on simple clinical examination, even by the most experienced observer, and later embarrassments may be avoided by careful investigations undertaken during the first weeks of life. A change of the accepted sex may be advisable in some male pseudohermaphrodites who have been regarded as girls and, especially since the introduction of cortisone, in some female pseudohermaphrodites brought up as boys. Such changes

should be accomplished as early as possible in the child's life, and the diagnosis should be established beyond doubt by exploration and gonadal biopsy. In each individual case the surgeon must feel confident that the chances of ultimate gain outweigh the immediate risks of psychological injury, and the whole-hearted co-operation of the parents is indispensable.

Some of the "changes of sex" which have been reported in adults fall into an altogether different category. The change has been effected in transvestists—individuals who are both anatomically and physiologically normal males or females, but who suffer from a psychological aberration which leads them to adopt the clothes and habits of the opposite sex, to which they feel they should properly belong. The classical example of transvestism is provided by the case of the Chevalier d'Eon, who, although remarkable for his gallantry in battle, was accustomed to frequent the court of Louis XV in the garments and finery of the women of that time. There is no doubt that a streak of exhibitionism was a feature of his and subsequent cases of transvestism. The phenomenon is most often encountered in males during the third and fourth decades of life, and, although the attitude may be permanent, some transvestists have been content in their later years to return to the ordinary conventions. In modern times all the resources of plastic surgery and of endocrinology have been used, or perhaps sometimes misused, in assisting transvestists to acquire, in irrevocable fashion, the superficial aspects of the opposing sex, and the publicity which has accompanied such transformations has brought to light an unexpected prevalence of the desire for change of sex. All surgeons whose interest in the subject is known have received pathetic letters from these unhappy people, and Hamburger² has recently analysed a series of no fewer than 465 demands for his assistance after the details of one of his cases were published in the lay press. While afflicted individuals deserve the utmost sympathy, many medical men will endorse the view expressed in a recent report³ that a sublimation rather than a direct satisfaction must be found for abnormal sexual urges; and it is hoped that workers in this field will give as much consideration to the social and legal implications as to the individual and technical aspects of the problem.

TETRACYCLINE

The introductory paper by Dr. Maxwell Finland¹ of Boston at the Symposium on Antibiotics² held in Washington last October included some observations on tetracycline, the newly discovered substance of which chlortetracycline (aureomycin) and oxytetracycline (terramycin) are both minor modifications. A fuller account by Finland and his colleagues³ of a study of this new drug has now appeared, and is fully characteristic of the combined thoroughness and celerity of these workers in appraising any new development in antibiotic therapy. Their laboratory studies confirm the greater stability of tetracycline, and the almost exact

parallelism of its inhibitory activity with those of the two other drugs against various species of bacteria: the only differences, and these were of small degree, were that oxytetracycline was most active against *Ps. pyocyanea*, chlortetracycline against staphylococci and certain streptococci, and tetracycline against *Bact. coli*, *Shig. sonnei*, and *Proteus vulgaris*. Cross-resistance between the three was complete. Single doses of tetracycline were given intravenously and both single and repeated doses orally to volunteers, and serial blood assays were carried out. Although the results show a fairly wide scatter which seems to be inevitable in tests of this kind, it is evident from them that fully adequate blood levels are not only regularly attained but sustained for many hours after each dose. The drug was excreted in the urine in high concentrations, but the few observations on cerebrospinal fluid levels were less promising, only two out of seven subjects having a detectable level, one-eighth and one-thirty-second of that in the blood.

Tetracycline was used for the treatment of 118 patients, in most of them for infections of the air passages or urinary tract, the former including pneumonia, "chronic bronchopulmonary infections with acute exacerbations," and acute pharyngitis, and the latter being divided into "acute" and "acute exacerbation of chronic"—an important distinction, since the latter are much less susceptible to any treatment. Although the results are stated in brief detail, they are summed up simply as equivalent to those obtainable with either of the other tetracyclines, and more attention is given to side-effects. It has appeared from the first that the only substantial advantage of tetracycline is its lesser liability to cause gastro-intestinal disturbances, and this the present observations bear out. These disturbances include not only nausea and other subjective effects, vomiting, and simple diarrhoea, but a severe enteritis apparently produced by the multiplication of antibiotic-resistant staphylococci: this condition has even been fatal in the experience not only of Finland and his colleagues and others in the United States but of various authors in Europe. Finland, Grigsby, and Haight⁴ have recently reported a study of the relationship between dosage and the drug used to the frequency of this complication; they found that this could be approximately halved by a moderate reduction in dose, and that the overall frequency of diarrhoea in patients given oxytetracycline was 19%, whereas with chlortetracycline it was 10%. Among the former patients staphylococci were regularly found in the faeces, whereas chlortetracycline diarrhoea was often not staphylococcal. In the present series of 118 patients given tetracycline, 5 had diarrhoea, which was "mild and brief except in one patient, in whom it lasted for two days"; only 2 had staphylococci in their faeces. It thus seems that this drug may well be preferred to its forerunners as better tolerated and less liable to cause a dangerous form of superinfection, particularly in patients requiring prolonged treatment.

"HOSPITALISM"

In 1869 there appeared in the *Edinburgh Medical Journal* a series of articles by Sir James Young Simpson on hospitalism (as he called it) and its effects, in which he described "the hygienic evils which the system of huge and colossal hospital edifices has hitherto been made to involve."¹ In the course of his discussion he referred to the suggestion made by him some 20 years earlier² that these "crowded palaces" should be replaced by villages or cottages with one or at most two patients in each room and which, if made of iron instead of brick or stone, could be taken down and rebuilt every few years—"a matter apparently of much moment in hospital hygiene." Many changes have taken place since that time, but one of the most difficult decisions the general practitioner may be called upon to make is when to send a sick child to hospital and when to let it be nursed at home. He has to balance, for example, the distress caused by separation against the lack of facilities for proper care in the home, and hitherto the absence of skilled and readily available nurses has often tipped the balance in favour of the hospital. For this reason alone the account of the Rotherham experiment described by Dr. J. A. Gillet on page 684 deserves study by other local health authorities. In 1949 the health committee of that county borough approved a scheme for the establishment of a children's home nursing unit which made it easier for a sick child to be nursed at home and remain under the care of the family doctor.

The wise step was taken of suggesting to general practitioners that they should telephone directly to the home nursing superintendent for assistance: special equipment was kept in the nurses' home, and the service was designed to deal with infectious as well as non-infectious cases. Parents were encouraged to inquire at the nurses' home if worried about the child's condition, and night calls are said to have been very few, probably for the reason that the parents knew that help was available immediately if required. By 1952 a total of 713 children under the age of 15 years, three-quarters of whom were under the age of 5, had been nursed without a death, and only 27 children had to be removed to hospital. Dr. Gillet, in his account of the scheme, includes among its advantages the familiarity of home surroundings, the lessened danger of cross-infection, the encouragement of the mother to help in the nursing of the child, and the reduced call on hospital beds. He might have added two other points. First, that this service demonstrates effectively the part which can be played by a local health authority in aiding the general practitioner and relieving the hospital, and secondly that if the mother is permitted to take a central place in the care of the sick child the sense of family responsibility as a whole is greatly strengthened.

A memorial service to the late Dr. N. Gerald Horner, editor of the *British Medical Journal* from 1928 to 1946, will be held at St. Pancras Church on Friday, March 26, at 12 noon.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

TESTS OF THYROID FUNCTION

BY

RUSSELL FRASER, M.D., F.R.C.P.

Reader in Medicine, Postgraduate Medical School of London; Physician, Hammersmith Hospital

At times the diagnosis of disordered thyroid function is obvious on the first examination, but often the clinical signs do no more than suggest such a diagnosis, and it is then that further tests are needed. Several tests of thyroid function are available for the clinician, a fact which itself indicates that none is both easy and universally valid alone. However, if the best test is chosen for the problem which the patient presents, the laboratory can usually supply a useful measurement. But misleading inferences may be drawn unless the test is chosen in the light of the patient's clinical condition, and its results interpreted in the light of both the patient's history of recent drugs and his or her general clinical condition.

Not all hospitals can have facilities for all the tests; radio-iodine tests, in particular, require costly apparatus. In the larger centres where the latter is available, radio-iodine offers the simplest initial test for most patients; but careful use of the other tests can usually circumvent the need for this test. Where all tests are available one may summarize their uses as follows. With nervous patients the basal metabolic rate (B.M.R.) is apt to be high and the radio-iodine test is therefore preferable for assessing thyroid function. With patients who have had, within the six previous months, some thyroid operation or treatment or antithyroid or iodine-containing drugs, radio-iodine tests are difficult to interpret and are best avoided. Otherwise radio-iodine is the best test for recognizing or excluding thyrotoxicosis, and the B.M.R. combined with plasma cholesterol the best test for recognizing or excluding myxoedema.

Basal Metabolic Rate Test

This test measures the main effect of the thyroid hormone. It is most commonly done on in-patients; but with suitably equipped laboratories the out-patient can be tested, after being instructed on the day before. The patient attends fasting on the morning of the test, and has the measurement made after half an hour's rest on a bed or couch in a suitably screened and quiet alcove of the laboratory or ward. The usefulness of the test depends on the technician's ability to get the patient calm and restful both before and during the test. To achieve this it is usually necessary to have a routine involving two or more measurements on successive mornings, the first test being preceded by a trial run to accustom the patient to the procedure. The two main readings should agree within 10% of each other and the patient should have been calm, otherwise it is likely that the reading has not been "basal." The test consists in recording the patient's oxygen consumption during a period of six or more minutes. This is usually done with a spirometer connected by two wide-bore tubes to a mouthpiece, into and from which the patient breathes with a nose-clip applied; soda lime is in the apparatus to remove the carbon dioxide, and a drum records the change in spirometer level and so the oxygen consumption.

The result is calculated with the aid of tables; first the oxygen consumption is converted to its equivalent in heat production per unit of surface area (calories per square metre per hour), and then by reference to age and sex tables this is usually converted to "percentage normal."

Till recently the standards commonly used were from American surveys (Dubois, Benedict, or Boothby) based on the tests made on the first visit to the laboratory—that is, with little special effort to make the patient basal. Recently Robertson has published an English series of standards based on duplicate tests agreeing within 5%. With equivalently careful technique the latter standards should be used; their values are about 10% lower than the American standards. With careful technique the normal range is $\pm 10\%$, but in most laboratories it is $\pm 15\%$. The laboratory should therefore state on its report the normal limits for its technique and standards.

There are two main limitations to the usefulness of the B.M.R. test—the difficulty of ascertaining whether the patient really was basal during the test, and the possibility of non-thyroid causes of raised or lowered B.M.R.; the former is the more serious. The "basal" state means as nearly as possible at complete muscular, mental, and digestive rest (12 hours after food covers the last requirement); with nervous patients, in whom the problem commonly arises, this is difficult and sometimes impossible to achieve, and the nearness of the achievement is always hard to assess; inadequacies here can only raise the result. The important non-thyroid factors which may also cause a truly raised B.M.R. are fever, increased respiratory effort (notably that of circulatory failure, in which the rate may be raised up to +25%), phaeochromocytoma, leukaemia, and polycythaemia. The non-thyroid causes of a lowered B.M.R. are usually readily recognized—starvation, severe oedema, and Addison's disease. Obesity also alters the B.M.R., mainly by affecting the standards; if the standard is derived from the actual weight a lowering down to -25% is usual, while it will be nearly equivalently raised if the previously normal weight is used. With seriously abnormal general nutrition it is usually unsafe to infer the level of thyroid function from the B.M.R., except when it is raised in a wasted patient showing no evidence of another primary disease.

Clearly it is difficult definitely to diagnose hyperthyroidism on the basis of a raised B.M.R., but such a suspicion can usually be eliminated by finding a normal result, and a lowered value confirms a suspicion of myxoedema. Thus the B.M.R. is a good screening test for confirming myxoedema or for eliminating the suspicion of thyrotoxicosis when other tests are impracticable; however, if the rate is raised one must be sure that it was basal before accepting it. With nervous patients when this is in doubt it is helpful to estimate a "somnolent B.M.R."—that is, an estimate after an intravenous sedative given to induce sleep—there can then be no doubt that the patient was basal, and if the value is still raised or still normal it can be accepted.

Radio-iodine Tests

These tests assess thyroid-cell activity by measuring the speed of iodine metabolism. During the past ten years radio-iodine tests have become an important addition to the tests of thyroid function. Fortunately their limitations are largely covered by previously available tests, and radio-iodine tests are reliable and particularly useful where the other tests tend to be unsatisfactory.

There are various methods by which radio-iodine may be used to measure the speed of movement of iodine atoms through the body, and so the thyroid cellular activity; all these methods differ only in lesser detail—the important advantages and disadvantages of this type of test apply to

them all. The great advantage of this type of test is its independence of the nervous condition of the patient, and its great disadvantage is its liability to modification by previous drugs. The radiation given to the patient does not exceed that given the patient in such standard x-ray diagnostic investigations as a barium meal. The procedure for the patient is equally simple: after drinking what appears to be water or receiving an intravenous injection, he usually attends for two measurements comparable to having an x-ray examination (see Fig. 1), for a blood sample, or collects some urine samples (see Fig. 2).

The principle of the test is to "label" the body's extracellular fluid (E.C.F.) iodide pool by an intravenous or oral "tracer" dose of radioactive iodide—that is, a dose so small in weight that it is an insignificant addition—whose radioactivity, however, permits its subsequent measurement in various sites such as the thyroid region of the neck, the

Fig. 1.—Apparatus used for measuring radioactivity in the neck. (1) Counter at standard distance from neck. (2) Ratemeter activated by counter which records on both dial (3) and paper (4). The "standard" (1/10 of the dose to be given intravenously) (5) is being counted in front of the patient's neck: later the counter will record over the neck alone.

thigh, or in blood or urine samples at chosen times. This test is really measuring the speed of the movement of iodine atoms through their cycle in the body (Fig. 3); usually by measuring the speed of thyroid uptake (the rate at step B in Fig. 3) or sometimes by measuring the speed of thyroid uptake plus secretory discharge (step B + step C). A simple but clinically adequate theory of the functional basis is as follows. The administered radioactive iodide rapidly comes into equilibrium with the circulating iodide of the E.C.F., whence it is extracted at constant rates (expressed as percentage of the pool per hour) only into the urine and thyroid; after mixing with the thyroid's store the latter is discharged from the thyroid at a rate (percentage of store discharged per hour) depending jointly on the size of the thyroid store and on thyroid secretory activity. As radio-iodine tests involve no measurement of the absolute amount of natural iodide in the body they can give no measure of the absolute amounts of iodine involved; but useful inferences can be derived merely from the rates of these percentage transfers. Two or more measurements are usually taken from which can be calculated these rates of percentage transfer, or, in the simpler

tests, a single measurement may be made of the concentration reached in one site by a standard time, which will give a less specific index of these rates.

There are three main procedures by which radio-iodine is used clinically to assess thyroid function: (a) Measurement of the uptake in the neck (this is the most sensitive), the thyroid clearance (rate at step B), or, as a fairly adequate test, the total thyroid concentration reached at 24 or 48 hours; if the last is used, it is assumed that renal function is approximately normal. (b) Equivalent measurements of the urinary excretion—that is, to obtain either a rate index or a total excretion in a standard time, each of which gives a reflection of thyroid uptake. From three samples of the 48-hour excretion can be derived the "T" index, a rate index of thyroid uptake independent of renal function. (c) Measurements of the appearance of hormonal or protein-bound radio-iodine in the plasma; a sample at 48 hours suffices for this test. Provided a type of test giving a rate is used, the two former are equally sensitive with patients who can collect urine accurately; for recognizing hyperthyroidism the third test is equally sensitive, but it involves too small amounts of radio-iodine for use in the recognition of myxoedema. Thus the tests are approximately equivalent, and are subsequently considered together.

All clinically confirmable, untreated thyrotoxicosis is readily recognized, the average uptake being about 10 times the normal (cf. a B.M.R. of 1,000%). Some other hyperplastic glands, apparently non-toxic goitres, may give similarly raised uptakes; but little harm would come if these were treated as toxic glands, which they may become later.

FIG. 3.—The body's iodine cycle. Radio-iodine tests measure the speed of this cycle, usually by measuring at step B, C, or F.

Slightly increased uptake by this test is therefore probably best treated as a normal value. However, any patient who has taken an antithyroid drug such as thiouracil for some months, or has had a recent thyroidectomy, will also show a high thyroid uptake owing to iodine depletion. And conversely any patient who has had iodine in any form will show a lowered uptake—thus thyrotoxicosis may be masked for this test. This inapplicability after iodine, antithyroid drugs, or other thyroid treatment is the main limitation of tests with radioactive iodine; but the B.M.R. test is valid in these circumstances. The test can also be used for the recognition of thyroid deficiency, but here it is not as sensitive; while all patients with absent thyroid function will be recognized, a proportion of those with partial failure will not give abnormal results. Again the results may be invalidated by previous drugs. The test cannot therefore be used to exclude myxoedema, though it may help to confirm its presence; but the B.M.R. test can be safely used to recognize myxoedema not discernible by this test.

Serum or Plasma Protein-bound Iodine

This test measures the level of circulating thyroid hormone, but is technically difficult because of the small amounts involved—the normal range being 4 to 8 µg. per 100 ml. plasma—that is, about 1/1,000 of the range of most

FIG. 4.—Multi-centred epiphyses at left femoral head in a girl of 5 with hypothyroidism.

plasma estimations. As the test can usually only be accurate to about ± 1 µg. per 100 ml. doubtful results may be found in doubtful cases; and it is also lowered in diseases with low plasma proteins. For these reasons, though theoretically possibly the best test of thyroid function, it is best regarded as a research tool rather than one for routine clinical work.

Other Tests

Plasma Cholesterol.—This is a useful test by which to supplement the B.M.R. estimation for the recognition of hypothyroidism. In this condition it is usually, but not always, raised (over 250 mg. per 100 ml. plasma), though of course it may also be raised from other causes—for example, in obstructive jaundice and in diabetes mellitus. In doubtful cases confirmation of the thyroid deficiency may be obtained by re-estimation of this value after two to four weeks of thyroid, 1 gr. (65 mg.) per day, when a fall of over 30% of the previous value should be expected in myxoedema, but not when plasma cholesterol is raised for other reasons. This test is of no value for the recognition of raised thyroid function.

Urinary Creatine Excretion or Plasma Creatine.—Most but not all thyrotoxic patients will show increased excretion of urinary creatine (over 200 mg. per 24 hours) or an increased plasma creatine level (over 0.6 mg. per 100 ml. plasma); but so also will patients with some other conditions involving muscular wasting. A creatine-tolerance test, based on either of these measurements, is also used but it has the same limitations.

Electrocardiographic Evidence.—Complete or nearly complete myxoedema leads to non-specific changes in the

electrocardiogram, flattening of T waves, and a general lowering of voltage. These changes can help to confirm the diagnosis, particularly if they are reversed after two to three weeks' thyroid therapy.

Radiography of Bone in Children.—Before growth is completed, x-ray pictures will always show the growth-retarding effect of thyroid deficiency, three to five or more years' retardation in bone age tending to confirm this diagnosis. In the very young a specific x-ray finding may be used to confirm the diagnosis of myxoedema—epiphyseal dysgenesis and stippled epiphyses; epiphyses formed during the deficiency will show multiple instead of single centres (Fig. 4).

Reports of Societies

ANALYTICAL PSYCHOLOGY

The Section of Psychiatry of the Royal Society of Medicine, met on March 9, with the president of the section, Dr. E. B. Strauss, in the chair, for a discussion on "The Theory and Practice of Analytical Psychology."

The Collective Unconscious

After referring to Frankfurt University's decision to confer the degree of Dr. nat. Phil. on Dr. Strauss, Dr. E. A. BENNET began by emphasizing the tentative nature of certain important formulations in Analytical Psychology. The hypothesis of the collective unconscious, for example, although a distinctive feature of Professor Jung's contribution to psychiatric thought, was not propounded as a dogma but as an attempt to explain the existence of impersonal elements in the mind. The symbolism found in schizophrenic thought processes had suggested to Jung that the basic structure of the human psyche was as little personalistic as the body.

Dr. Bennet, tracing the origin of this hypothesis, said that it first occurred to Jung in 1909. In that year Freud and Jung were visiting the United States to give a series of lectures. During the voyage and while in America they analysed each other. Jung, at this time, had a notable dream, containing material of an archaic character, and this he produced in the analytical sessions with Freud. Their mutual efforts, however, failed to bring meaning to the dream. Freud's interpretation, indeed, seemed not to do justice to the dream. In the dream, Jung was in an ancient house and, wondering what was downstairs, he descended to a cellar and thence to a second cellar. Gazing through a square hole in the floor of the second cellar he saw skulls and prehistoric remains. Further reflection led Jung to see in the dream a picture of the developmental stages of the human mind: the rooms, the cellars, and prehistoric remains being the cultural periods through which mankind has passed—the germ of the Collective Unconscious.

Freud, although he never accepted Jung's developed work on the impersonal collective unconscious, was well aware of non-personal psychic elements—material, he observed, which could not originate from the dreamer's adult life or from his forgotten childhood. Yet the concept of the collective unconscious played no part in the theory or the practice of psycho-analysis.

Biological motives or instincts, Jung maintained, were accepted by all, and yet the assumption that there are instincts was about as daring as the hypothesis of the collective unconscious. The Jungian archetypes, or pre-existent forms in the psyche, were close analogues of the instincts and might indeed be thought of as the unconscious images of the instincts themselves. The evidence in support of the theory of the collective unconscious came in part from the study

of dreams and symbolism. One method used to link the conscious ego with this impersonal, objective region of the mind was the procedure of "active imagination." Spontaneous drawing and painting were used in this work and had proved of much value in therapy.

Cybernetics and the Psyche

Dr. ANTHONY STORR said that Jung regarded all psychological theories as being largely subjective confessions, not as creeds which must be believed. We were a long way as yet from building up a universally valid psychology.

One of Jung's basic ideas was that the psyche was a self-regulating system, with a reciprocal relationship between conscious and unconscious. The physiologists propounded a similar point of view in cybernetics, which was based on the idea that the body was also a self-regulating system with homeostatic mechanisms which kept the internal environment on a middle course between various pairs of opposites such as hot and cold, acid and alkaline, etc. A neurosis could be regarded as an attempt on the part of the psyche itself to remedy a disturbance in equilibrium.

The unconscious had a compensatory function in relation to consciousness, and this could be detected by the study of dreams. Examples were given of dreams which illustrated this compensatory function. The first example was of a woman whose maternal instinct was repressed and who had a dream of a child being run over: this revealed her unconscious desire to have children. The second example showed the unconscious reaction to a too great dependence on the mother: the patient had a dream in which the mother appeared as intensely hostile and threatened to crush her.

One had to consider the goal towards which the psyche was aiming in trying to understand unconscious material. Jung believed that there was a possibility of reconciling the opposing elements in the psyche, and that this was the goal towards which all psychological activity was ultimately directed. The reconciliation between conscious and unconscious was known as the Self in Analytical Psychology and represented a fusion of opposites. The exponents of cybernetics regarded the body as goal-seeking in much the same way, the goal in that case being the maintenance of homeostasis.

The Analysis

Dr. F. O'DONNELL FINIGAN described the procedure in analysis in some detail. Analysis was a joint endeavour, whereby a human situation and a technique became complementary to a mentally creative process. Early on the analyst made the patient feel that he was valued for himself and that the extent of his difficulties and the degree of his achievements were recognized. A series of interviews took place, each of 50 minutes, two or three times a week for several months or longer; a couch was rarely used.

Dreams were spontaneous expressions of the human psyche, expressing both conscious and unconscious attitudes of the individual, and their interpretation was an essential part of analysis. A dream series could be more readily understood than an isolated dream, and later dreams might intimate the need for amplification or re-interpretation of earlier dreams. To the patient was commended the value of writing down each dream on waking, the ideas he associated with it, the current circumstances of his life, the place and date of the dream.

Transference, the ascription by the patient of aspects of his own unconscious mind to the analyst, was usual though not invariable, and it had to be recognized at once, but only be interpreted where necessary. The art came in recognizing the right moment and the right way, in saying neither too much nor too little. Counter-transference, the analyst being affected by the patient in spite of himself, had similarly to be watched for and understood, and even on occasions to be interpreted to the patient. The analyst had to be ever vigilant and aware of what was happening in analysis, and of his own limitations.

LOCAL MEDICAL SOCIETIES

Devon and Exeter Medico-chirurgical Society

The fenestration operation for otosclerosis was the subject of an address by Mr. Philip Scott to the Society on February 18. Otosclerosis, he said, was a common disease afflicting perhaps 1 in 250 of the population. It was seen more often in females than males, and there was a family history of the disease in perhaps half the cases. The disease usually became apparent in early adult life or young middle-age, but might occur from the age of 10 upwards. Pregnancy appeared to accelerate the condition.

Loss of appreciation of high frequency notes or loss of bone conduction contraindicated operation, and usually it was unwise to operate on those over 50. Otherwise, in selected cases and experienced hands, fenestration could be expected to give very considerable improvement in 70% of cases, and some improvement in almost all. Successful fenestration gave the patient hearing as good as that provided by the best types of hearing-aid. Initial failures which had brought the operation into some disrepute had been caused by gradual closure of the fenestrae over a period of months and unsuccessful attempts to disarticulate the stapes.

Manchester Medical Society

Speaking at a meeting of the Section of Medicine on February 24 on dyspnoea, Professor Ronald V. Christie said that from simultaneous records of the tidal air and intrathoracic pressure it could be shown that in health, whether at rest or on exercise, we breathe at the rate and depth which is most economical in terms of respiratory work. The rapid, shallow breathing associated with heart failure and pneumonia was just another illustration of this rule; this change in rhythm should therefore be considered as a beneficial compensatory phenomenon which occurs when the lungs become more rigid.

Nova et Vetera

SOME MORE RARE BOOKS

The name of John Banester, the Elizabethan surgeon who was recently the subject of a note in these columns (February 6, p. 329), appears again in a book to be sold on March 24 from the library of the Earl of Derby. It is the first edition of the (posthumous) *Workes of that famous Chyrurgian, Mr. John Banester*, London, 1633. The second of the three volumes is entitled *An Antidotarie Chyrurgicall: or Storehouse of all sorts of medicines*, and the third *A Storehouse of Physicall and Philosophicall Secrets*. Other old medical books in the same sale include Philip Barrough's *Method of Physick*, 1639; Thos. Bonham's *The Chyrurgions Closet: or, an Antidotarie Chyrurgicall, furnished with varietie and choyce of Apophlegms, Balmes, Baths, Caps, Cataplasmes, Caustiks . . . Diets, and Wound Drinks, Defensatives, Dentifrices, Electuaries, . . . now drawne into method and forme by Edward Poeton of Perworth, London, 1630*. Jacques Guillemeau is represented by *Child-birth, or the Happy Delivery of Women*, London, 1635, of which the *Short Title Catalogue* lists only one copy, that in the British Museum. William Harvey's *Anatomical Exercitation concerning the Generation of Living Creatures*, London, 1653, is a translation into English of the *De Generatione Animalium* published in 1651. Another unusual textbook, with engraved portrait of Queen Elizabeth I, is *The Closet of Physical Secrets with certain approved medicines . . . and supplied with the Child-bearers Cabinet*, London, 1652. It calls itself a "Treatise concerning the Plague and the Pox." The remaining medical books in the sale are of less interest.

Correspondence

Rh Antibodies and Domiciliary Midwifery

SIR.—As Dr. M. Chalk says in his concluding remarks (*Journal*, February 20, p. 457), it is a very great thing to have given the mother peace of mind and happiness. It is a greater thing to have given her the conditions in which she is most likely to have a successful outcome to her pregnancy and labour, and the greatest thing of all is to give her both peace of mind and a happy outcome. The decision whether she is to be confined at home or in hospital should have this combined end in view, and this decision can only be made by the practitioner, who knows all the facts.

No laboratory worker, reporting on a sample, will presume to "instruct" the clinician who sent the sample for investigation, because only the clinician is in a position to correlate all the information on which the decision should be based. But the clinician would not be obtaining the best result from the laboratory investigation which he requested unless the laboratory worker, as well as baldly reporting the result, were to offer his suggestions in regard to the interpretation of the result, and the various lines of action arising out of it. To deny this is to reduce the laboratory worker to the status of a medical auxiliary, and to deprive oneself of the benefit of the accumulated experience of one's laboratory colleagues.

Both Dr. Chalk and Dr. C. W. Walker (*Journal*, March 6, p. 580) agree that a patient with rhesus antibodies should be delivered under conditions providing for (a) a clinical examination of the infant at birth, (b) facilities for an immediate Coombs test and Hb estimation, and (c) facilities for an immediate exchange transfusion if indicated. If these conditions can be fulfilled at the patient's home, there is no need to override her wish to be delivered there. If they cannot, it is for the practitioner to decide, as in other obstetrical abnormalities, whether he can advise her to take the risks to the infant arising from their absence.

If there is some ground for criticism of the psychological approach to the patient at certain hospitals, as seems to be suggested by Dr. C. W. Walker's last paragraph, the remedy would seem to lie in a representation to the hospital clinicians concerned, rather than to deprive the patient of facilities which she needs.—I am, etc.,

Cambridge.

C. B. V. WALKER.

SIR.—In view of the interest in this subject aroused by Dr. M. Chalk's letter (*Journal*, February 20, p. 457) and the subsequent correspondence, I feel that the experience of one hospital's obstetric and paediatric departments may be worth reporting. The obstetric department handles 600–700 deliveries per year, and a total of 34 mothers with rhesus antibodies have been delivered here during the last five years. Of these, 27 (79%) gave birth to living rhesus positive babies showing a positive Coombs test on the cord blood. All these received either exchange transfusion or simple transfusion through the umbilical vein, and some received subsequent transfusion when a fall of haemoglobin made it necessary. The remaining seven cases (21%) comprised one (3%) with an Rh-positive child having a negative Coombs test, three (9%) with Rh-negative children, and three (9%) foetal deaths, including a case of hydrops foetalis, a macerated stillbirth, and a therapeutic termination of pregnancy.

A follow-up on the 27 affected living children shows that there have been five deaths, a mortality of 19%, one of these occurring during replacement transfusion of a child found subsequently to have a cardiac abnormality which probably contributed to its death. The remaining four deaths were from kernicterus, and all of these had received only one or more simple transfusions, usually because an attempt at exchange transfusion had failed. I may add that none of these deaths due to failure of exchange transfusion occurred during the past two years. Among the 18 babies surviving exchange transfusion there were no deaths. Three babies

have so far shown signs of permanent brain damage, and of these one had a simple transfusion only, one had a partial exchange transfusion, and the third had an exchange transfusion and a subsequent simple transfusion.

Although this series covers a comparatively small number of cases, it bears out strongly the advantages of immediate exchange transfusion through the umbilical vein as recommended in the M.R.C. memorandum No. 27 on "The Rh Blood Groups and Their Clinical Effects." Our figures suggest that a mother with Rh antibodies in her serum has about an 80% chance of producing an affected living child, and that immediate exchange transfusion will give such children the best chance of survival. The fate of these children may be compared with that of three affected babies born of mothers who for one reason or another did not have antibody titrations performed during pregnancy. Two of them received no treatment because the condition was not recognized until the second or third day of life, and the third received an exchange transfusion which was not started until nine hours after delivery. All these babies died with kernicterus. While it is true that a certain proportion of babies will survive with no treatment or with a small transfusion about the tenth day, these do not constitute the majority, as Dr. Chalk suggests in his letter. Rapidly developing jaundice, which occurred in about 70% of our cases, with a progressive anaemia is the rule rather than the exception, and the risk of death from kernicterus in the untreated or inadequately treated case is considerable.

While it is of course true that the patient, advised by her own doctor, must decide whether the confinement is to be conducted at home or in hospital, I feel that it is only right that the above figures should be taken into account in coming to such a decision. Even where 24-hour laboratory facilities are available to the practitioner, and immediate admission of the affected child can be arranged, valuable time will be lost which may make all the difference between recovery and death. Exchange transfusion as soon after delivery as the performance of the necessary laboratory tests will allow seems to give the babies the best chance of survival, and this usually means delivery in hospital.—I am, etc.,

Maldenhead.

F. E. T. SCOTT.

The Lucid "I"

SIR.—Conciseness and the avoidance of ambiguity are held to be the principal requirements of any literary style to be employed in scientific writing. "I" is both concise and precise, but is studiously avoided by single authors except in written versions of work first presented orally. I should be interested to learn from you, Sir, or from any of your readers, what contributions to lucidity are considered to be made by the avoidance of the first person. Much of the matter recorded in a paper is the intimate concern of the author. He often makes the observations he records; he forms the impressions he describes; he draws his own conclusions, adds his comments, and makes his suggestions. Now most authors are only too anxious to put their names on contributions. Why this seemingly bashful avoidance of "I" in the text? If an author feels free to write "Brown's results," surely Brown himself, discussing these same results, can write "my results."

The disadvantages of avoiding "I" on principle are numerous. The use of the passive voice sometimes introduces literary difficulties which are solved either by making literary blunders or by resorting to clumsy circumlocutions. One of the worst results of using "it" and the passive is the confusion that is liable to arise as soon as the work of another author is referred to. Having mentioned "Brown, 1953," a writer who follows up with, "It is concluded that . . ." is in danger of attributing his own conclusion to Brown, who might have none of it. If an author is stating his own conclusion, why doesn't he make that clear by using "I" as fearlessly as he uses "Brown"? Having heard the views of some of my colleagues on this matter, I am inclined to believe that the prejudice against "I" is rooted in a pretence of objectivity where no such ideal is in

fact achieved, or in the vague notion that scientists should appear to be impersonal even when they are not being objective. A single author who writes phrases like "it is felt that" or "it is recommended that" is attempting to give a veneer of universality to feelings and activities peculiar to himself. I should class such phrases with "It broke," used by careless housemaids to explain a disaster.

Multiple authors appear not to be as anxious to avoid "we" as the single author is to avoid "I." This seems to me to indicate that the avoidance of "I" is founded upon those very personal and emotional factors which the objectors claim to be trying to avoid. If two can say "we," nothing but squeamishness can prevent one from saying "I." It is true that many of the technical operations reported by an author may have been carried out by assistants and that the passive best serves in their description. On the other hand, conclusions, impressions, intentions, expectations, suggestions, and especially feelings, expressed by the author, if they be his, should be properly described as his own. If accuracy really is desired let us have "I," "me," and "my" wherever necessary.

Even scientists are subject to phenomenalism; and every observation, since it involves perception, is partly subjective. Disagreements, failures to confirm, and reinterpretations are so common in science that the subject deserves to be mentioned whenever this is a significant ingredient. Either let us hear a sound case for the avoidance of "I" or let us revert to the forthright style of Boyle or Leeuwenhoek.—I am, etc.,

London, S.W.1.

HAROLD B. HEWITT.

Intra-arterial Transfusion

SIR.—The letter of Mr. W. G. Mills (*Journal*, February 13, p. 393) inquiring about cases of intra-arterial transfusion in obstetric patients prompts me to record a case which I encountered in August last year in which the technique appeared to be life-saving.

A fit woman, aged 24 with two children, was at term and the foetus was lying transversely. No apparent cause could be found for this and the lie was easily corrected to a longitudinal one. It was felt that when her labour began gentle external version should be done to correct the lie. Her labour began early in the morning, and the house-surgeon gently performed external version. The patient complained of some abdominal discomfort and shortly after this she suddenly collapsed. On my arrival the registrar had begun an intravenous transfusion with blood and the third pint was being given. The patient's condition when I first saw her was such that at first I had difficulty in deciding whether she was alive or not. There was no palpable pulse, respiratory movements were just perceptible, the patient was deeply unconscious, and the blood pressure was unrecordable. Rapid abdominal examination convinced me that the uterus had ruptured. I hastily exposed the radial artery at the wrist, but its calibre was so small that I was quite unable to put a cannula into it. The possibility of intra-aortic transfusion was not considered, as the necessary needle was not readily available and it would have, in my opinion, harmed the patient to move her on to her side at this stage. Two pints (1.1 l.) of blood were transfused under pressure using a sphygmomanometer bag into the brachial artery within a matter of about six minutes. Towards the end of the second pint the patient's pulse once more was palpable and respiration became more regular. She was still unconscious. While transfusing the third pint she was moved to the theatre, and her condition was such that I was able to open her abdomen with the expert aid of my anaesthetist, Dr. I. Gow. The uterus had ruptured from the fundus to the lower uterine segment in the mid-line along the posterior wall. There were about five pints (2.8 l.) of free blood in the peritoneal cavity and the foetus had escaped from the uterus.

I performed a rapid subtotal hysterectomy, and during this time a further two pints (1.1 l.) of blood were given intra-arterially under pressure. An hour later the patient was conscious and her condition was much improved. The skin temperature of the hand was a little low for about 36 hours and then reverted to normal. The puerperium was uneventful and the patient was discharged on the fourteenth post-operative day. She has remained well since.

In retrospect I am convinced that intra-arterial transfusion was life-saving here, and in similar circumstances where

profound shock was persisting or becoming worse in spite of adequate intravenous transfusion I would be prepared to do the same thing again, although I feel that if the radial artery can be entered at the wrist this is a safer procedure than using the brachial artery.—I am, etc.,

Manchester, 20.

R. W. BURSLEM.

Methylpentynol

SIR.—With reference to Dr. A. G. Boag's disappointment in methylpentynol as an alternative to the barbiturates (*Journal*, February 13, p. 393), a few impressions from general practice might not go astray. When this substance first appeared it was hailed and acclaimed as the answer to "the barbiturate problem," even attracting the attentions of the lay press. Unfortunately it now seems difficult, if not impossible, to wean on to methylpentynol those patients who have been taking barbiturates for anything but a short time; such patients take as much as four capsules—that is, 1 g.—in place of half a grain (32 mg.) of phenobarbitone, with little or no effect, save a possible stomach-ache. Patients with bona-fide anxiety states derive little help from methylpentynol, as do those whose sleep is prevented by pain or the malaise of serious illness. Yet methylpentynol is almost invariably successful where sleep is disturbed by the activity of a mind which never ceases to churn over the problems of everyday life. Two capsules, in such cases, taken in bed, and preferably with a warm drink to minimize the possibility of gastric irritation, usually result in a patient peacefully asleep within half an hour. Those who are helped in this manner rarely feel undue drowsiness; they just fall asleep, usually having felt more contented for a short while, with a lightening of anxiety which never amounts to euphoria. It seems that methylpentynol permits sleep by counteracting mild emotional tension, rather than by inducing sleep after the fashion of the barbiturates.

Methylpentynol in elixir form should be valuable in paediatrics, where its indications are similar to those of chloral hydrate; as with the latter compound, it is of little avail as an anticonvulsant. It seems justifiable to suggest that methylpentynol is neither superior nor inferior to the barbiturates; their indications differ, and methylpentynol will earn its place in therapeutics as did the barbiturates. Poor results will be forthcoming if it is anticipated that methylpentynol will do the heavy work of the barbiturates; on the other hand, barbiturates are frequently employed when methylpentynol would do a better job, with less depression and less risk.—I am, etc.,

London, N.11.

NEVILLE DAVIS.

Anaesthetic Explosions

SIR.—Some suspicion has been directed recently to the reservoir bag, on being disconnected from a Boyle's anaesthetic machine, causing explosion of cyclopropane and oxygen. The following seems to me to be the explanation.

The inside of the bag becomes dry owing to fresh gases continually entering it. Friction of rubber and talc of adjoining surfaces by continuous movement causes an electrostatic charge to develop. On sudden deflation on disconnecting, the bag collapses to a flattened shape by infolding of the opposite sides. The area on which the charge is spread is suddenly halved, and the voltage of it thereby suddenly doubled, according to well-known laws. Sparking potential is reached near the neck, which is bathed in inflammable vapours issuing from the collapsing bag.

The obvious solution is to keep the inside of the bag damp by passing the gases over water in the trichlorethylene or ether bottle.—I am, etc.,

Birkdale.

N. S. WALLS.

SIR.—When we were taught our anaesthetics 25 years ago we were told that it was unwise to use chloroform, because if a death occurred whilst this was being used the coroner would request a full explanation as to why this agent had been selected. Explosions in operating theatres occur too

frequently—sometimes with loss of life. If cyclopropane and ether were removed from all theatres we could have few explosions in this country. Whilst in no way suggesting that these anaesthetics should be abolished, I do suggest that ether bottles should be removed from machines and from the theatres when not wanted for the case being anaesthetized. A bakelite screw cap will cover the bottle, leaving it ready for use when required. These caps can be found in most hospital pharmacies. I am sure that little inconvenience would be caused if cyclopropane cylinders were similarly removed. This would make impossible the accidental turning of the handle which has happened to most of us. The simpler suggestion of removing the handle is not so effective, as others have a habit of replacing it. These steps, which can be taken without cost, are more practical than many of the very expensive alterations which are now advocated.

As many anaesthetists no longer give ether to adults it is possible to eliminate the risk of explosions in at least 50% of our cases. In any hospital where these precautions were instituted a real appreciation of the explosion risk would soon become widespread and as a result still greater care would be taken when explosive mixtures were used. I am sure that all concerned will give these points their serious consideration.—I am, etc.,

Portsmouth.

H. B. C. SANDIFORD.

Anaesthesia in Out-patient Departments

SIR,—The suggestion in your leading article on anaesthesia in out-patient departments (*Journal*, February 27, p. 505) that the "out-patient department sees little of trained anaesthetists" is not quite accurate. You have not taken into account the attendance of consultant anaesthetists at dental out-patient sessions. In the London area alone there are well over 100 sessions each week where anaesthetics are given by consultant anaesthetists. Many anaesthetists at teaching hospitals make a point of attending out-patient sessions, as they rightly consider that this is by far the best place to teach simple anaesthetic techniques to students. It is comparatively useless for a student to watch the anaesthetic for, say, a gastrectomy. He will not learn anything which will subsequently be of use to him in general practice, and his presence is a distraction to the anaesthetist. How different it is in the dental out-patient department, where the signs and symptoms of anaesthesia may be repeated 20 or 30 times at each session. One way of avoiding accidental death in minor anaesthetic procedures is to use local analgesia instead of general anaesthesia. In the out-patient department of University College Hospital 94% of all minor surgery is done under local analgesia. This of course further reduces the opportunities of students in learning simple general anaesthesia, but it is safer for the patient when the anaesthetist is unskilled.

With regard to trichlorethylene ("trilene"), Professor Webster was quite right in stressing the importance of premedication.¹ Sudden deaths from trilene anaesthesia where premedication had not been given have already been reported in this *Journal* by more than one observer.² This is without doubt the reason why, in the interest of maternal safety, the Central Midwives Board still withholds permission for midwives to use it when they are not under medical supervision.—I am, etc.,

London, W.1.

Erythromycin

SIR,—With dismay I read your leading article (*Journal*, January 30, p. 261) saying that yet another antibiotic had been released freely on prescription. I am a general practitioner trying, when I have time to remember, to maintain and raise my clinical standards. I have been taught, and from my own experience believe, that penicillin is the best

antibiotic for all staphylococcal, streptococcal, and pneumococcal infections, and in my opinion it works best when injected. Penicillin is cheap, it costs no dollars, and it is without toxicity. If I have a patient with some condition that does not respond to penicillin, then to me this is an indication for a second opinion or for laboratory testing of sensitivities. It is not an indication to embark upon a new expensive antibiotic.

Since erythromycin covers the same range of organisms as penicillin, it would seem that one can treat one's patients either by mouth with erythromycin or by injection with penicillin. After a time the doctor who uses the needle will be unpopular.

It is argued that erythromycin will be of use, since it will deal with organisms resistant to penicillin, but, since this can only be determined through a hospital laboratory, it will never concern a general practitioner. Furthermore, inadequate doses of any antibiotic may lead to resistant strains. A course of penicillin injections prescribed and given means that much penicillin in the body, but a box of erythromycin tablets may be anywhere. I urge that erythromycin be kept for hospital use only.—I am, etc.,

Gorleston-on-Sea.

H. A. EVANS.

A Cosmetic Amputation

SIR,—I have followed the correspondence on this subject with considerable interest, and am now emboldened to raise a few points that have not been elucidated by your contributors. The first: what is a cosmetic amputation? I imagine it to be an amputation that is less likely to offend the aesthetic sense of the beholder than another. This, of course, is a subject on which I hesitate to express an opinion, because I may myself be deficient in artistic sense since I still prefer Michelangelo to Henry Moore. It has apparently been assumed by all the correspondents that the hand in which the head of the metacarpal bone has been removed together with the finger leaves a better cosmetic result than a hand in which the same finger has been amputated at the metacarpo-phalangeal joint.

Now I venture very humbly to question this as a fact. In my view the hand that has had a carefully planned operation for removal of the head of the metacarpal, with the scar invisible, becomes a grotesque object. There is something abnormal about it. It is now malformed rather than deformed, and it demands a second look: is it a congenital abnormality, or what is this strange thing? Only by careful scrutiny can the casual observer see that the man has suffered an injury. Contrast this with the impression made upon the observer of the man who has had a finger amputated at the knuckle-joint. It is accepted for what it is, the result of injury, and it does not demand a second thought. Human nature has been injured to injury from the birth of time. But there has always been horror at the thought of congenital malformation.

A second point: in planning his operation the surgeon must take into consideration that the hand on which he operates is the complement of the other hand, and that, in fact, almost one-third of its function is to act in opposition to and in collaboration with the other. The third point is the balance of the hand—a book could be written on this subject. Suffice it for me at the moment to draw attention to the fact that the middle finger acts practically along the middle line of the palm, and its action must be distributed evenly over the metacarpal heads. The fourth point is the function of the flat hand, as opposed to the hand used in one of the various grips. The flat hand is used in very many types of occupations from paper making and press operating to charring. Any interference in this function by disturbance of the metacarpal arch may be a serious handicap. The fifth point concerns painful nerve endings. These, of course, should not occur after any operation. But, if they do occur, they cause far more disability if they are placed up in the palm of the hand than over the end of the metacarpal head.

In a final paragraph, Sir, may I venture to sum up many years' personal experience in the treatment of industrial injuries in this way: I do not know of any case justifying the amputation of the head of the fifth metacarpal bone. I do realize that on very rare occasions the hand is improved in function for a particular industry after amputation of

the head of the second metacarpal bone. One such case may be the working jeweller who has to handle light forceps in the affected hand.

Finally, I have not seen a case of a patient with an amputation through the metacarpo-phalangeal joint who has asked to have the head of the bone removed, except for pain.—I am, etc.,

London, W.1.

HUGH GRIFFITHS.

The Cerebrospinal Fluid in Diagnosis

SIR,—May I comment on one or two points arising from Dr. J. N. Cumings's article "The Cerebrospinal Fluid in Diagnosis" (*Journal*, February 20, p. 449)? In discussing the sugar content of the C.S.F. in meningitis of tuberculous and viral origin, he states that in "virus meningitis" the sugar is normal or only very slightly reduced, while in tuberculous meningitis it is decreased to 20–35 mg./100 ml. Although this is undoubtedly true in the majority of cases, there are exceptions in which errors of diagnosis and treatment will result if these figures are accepted as diagnostic criteria.

In the period 1950–2 I was able to study a number of patients suffering from meningitis of both types who were admitted to the Whittington Hospital under the care of Dr. Michael Ashby. In three cases of "benign lymphocytic meningitis" the C.S.F. sugar was reduced to the levels quoted above as being typical of tuberculous meningitis. The actual ranges found in the different patients were 30–45 mg. and 28–42 mg. and 33–37 mg./100 ml. The first two patients had positive complement fixation tests for the mouse lymphocytic choriomeningitis virus, while the third had a virus meningitis of unknown origin. A woman of 55 who was eventually found to be suffering from meningo-vascular syphilis had before treatment C.S.F. sugars varying from 17 to 27 mg./100 ml.

A recent paper¹ has reported low C.S.F. sugars in about 10% of cases of meningitis due to lymphocytic choriomeningitis virus, and less often in mumps meningitis and meningitis caused by the and less often in mumps meningitis and meningitis caused by the virus of herpes simplex. Conversely, although it is usual for the C.S.F. sugar to be reduced substantially in tuberculous meningitis, this is not an invariable finding. In some early cases the sugar is within normal limits, and this finding should not be allowed to prejudice the clinician against a diagnosis of tuberculous meningitis. I have also seen a case in which, while there was no difficulty in finding the tubercle bacillus in the C.S.F., in the fortnight before death the sugar was normal (46–72 mg./100 ml.). This patient was having the usual systemic and intrathecal streptomycin during this time.

Apart from the demonstration of the tubercle bacillus in the C.S.F., there is no single aspect of the findings in the fluid which can, of itself, be regarded as diagnostic of tuberculous meningitis. As Dr. Cumings states, it is only when the clinical pathologist is willing to spend considerable time in examining films for acid-fast bacilli that treatment can be started in the certain knowledge that the meningitis is tuberculous. The finding of a low C.S.F. sugar in a patient with a lymphocytic meningitis should not automatically result in the patient starting the long ordeal of streptomycin therapy with all its dangers and discomforts for the patient.

Finally, Dr. Cumings states that a "paretic curve in the absence of a positive Wassermann reaction only occurs in disseminated sclerosis, inclusion-body encephalitis, and a few cases of encephalitis lethargica." Two patients with virus meningitis were seen who had strongly paretic Lange curves for short periods at the height of their illnesses. A male of 32 developed lymphocytic meningitis 17 days after an attack of chickenpox, but his serum showed a rising titre in the complement fixation test for lymphocytic choriomeningitis. His Lange was strongly paretic on the 8th and 10th days of the meningeal illness, but had returned to normal on the 15th day. A male of 28 with lymphocytic meningitis had a paretic Lange on the 14th day of his illness, and the Lange had returned to normal on the 19th day. Complement-fixation tests for the virus of lymphocytic choriomeningitis were negative. In both these cases the C.S.F. contained large numbers of lymphocytes (500–2,000), raised protein (200–650 mg./100 ml.), and sugars of about 35 mg./100 ml. In both patients the W.R. in blood and C.S.F. was consistently negative. In another patient, in whom the complement-fixation test for lymphocytic choriomeningitis was negative on the 8th day and mildly positive on the 31st day, the Lange was normal on the 9th day.

Thus it appears that the Lange colloidal gold curve may be of the paretic type for short periods in the acute phase

of some forms of virus meningitis. A paretic Lange with no serological evidence of syphilis has also been reported in some cases of subacute cerebellar degeneration 'on association with carcinoma of the breast,' ovary, and bronchus.²—I am, etc.,

Abbreviations

SIR,—Early in my professional training I was taught that it was most provincial to use local names, colloquialisms, and abbreviations in technical papers and presentations. Even the development of an alphabet Government under the late Mr. F. D. Roosevelt did not change this basic idea as far as I know.

In reading British publications of all kinds I am constantly plagued by abbreviations. A typical example is in the very well done report on immunization against diphtheria given by Butler, Barr, and Glenn in the February 27 issue of the *Journal* (p. 476). I still would like to know what A.P.T., P.T.A.P., F.P.T., and Lf are, even though I can hazard a good guess at some of them. To me, at least, a much better way to write is illustrated in the same issue in an article by Bayliss and Steinbeck (p. 486) in which they say, "In certain diseases corticotrophin (A.C.T.H.) . . ." Henceforth, A.C.T.H. could be used without any doubt of its meaning.—I am, etc.,

U.S.A.F. Hospital,
Arrington, Herts.

CHARLES H. MORHOUSE.

Child Life and Health

SIR,—Members of the public health service will be greatly cheered by Professor Charles McNeil's Fleming Memorial Lecture (*Journal*, March 6, p. 533) in which he expresses the opinion that success in the promotion of health in childhood in the future rests with the child welfare services.

Your leading article in the same issue (p. 569) accepts this view provided that the importance of the family doctor in such services is fully recognized. The foundations of child life and child care are in the home rather than in the hospital, and you therefore rightly express the opinion that "the need is for an increasingly close link between the general practitioner and the children's services provided by the local health authorities." By a happy coincidence, one valuable means of furthering this aim appears in the *Supplement* of the same issue of the *Journal* (p. 61) in the form of the B.M.A. statement encouraging co-operation between general practitioners and health visitors. I should like to suggest that therein lies a real opportunity for further success in the sphere of child health.—I am, etc.,

Oxford.

J. F. WARIN.

Advice on Weight-lifting

SIR,—I have occasion to see a fairly large number of men who have attended hospital, and in many cases have been operated on, for back injuries due to lifting. They have returned to work, often with corsets, and usually advised to avoid heavy lifting. In no single instance has any one of them been shown how to lift properly and avoid further injury. Might it not be a good thing, not only that factories, but also hospitals, should give advice on this matter?

The Home Office Industrial Museum, Horseferry Road, S.W.1, has a special display and posters illustrating the right and wrong way to lift.—I am, etc.,

Farnham Royal.

M. E. M. HERFORD.

Toxicity of Pyrimethamine

SIR,—I write to report two further cases of overdose with pyrimethamine, as I feel all such episodes with new drugs should be given as wide publicity as possible.

In view of Dr. R. Y. Taylor's report (*Journal*, August 1, 1953, p. 285) of a fatal case, all parents to whom these

tablets are issued are warned to keep them well out of the reach of small children. Despite this, two small girls aged 18 months and 3 years obtained possession of the household supply and are estimated to have disposed of 25 tablets, each of 25 mg., by 8 a.m. on January 30, 1954. When seen at 9 a.m. they had already begun to vomit and were encouraged to continue vomiting with doses of salt and water and of tinct. ipecac. Apart from pallor and an expression of apprehension, probably caused by the mother's scolding, they appeared to be free of other symptoms. The elder child had a convulsion at 11 a.m. Five minutes later she had fully recovered and was co-operative. Vomiting at intervals continued until 1 p.m., when she fell asleep, and on waking at 4 p.m. she was normal in every respect. Apart from vomiting, the younger child showed no ill effects, though she is believed to have had much the smaller share of the missing tablets.—I am, etc.,

Swaziland.

W. G. DAVIDSON.

Overdosage of Teething Powders

SIR,—In your issue of December 12, 1953, p. 1330, you publish the account of an inquest on a child whose death was attributed to mercury in teething powders, and append a note to the effect that one large firm of manufacturers had informed you that they had discontinued mercury as an ingredient. This morning I have seen in hospital a child of 15 months with a very extensive and vivid eruption which I diagnosed as a drug-rash from phenolphthalein (in all probability) before I even asked about teething or other powders. The child had, in fact, had several powders made by the firm in question. The percentage incidence of idiosyncrasy towards this drug must be low, because laxatives containing it are taken in enormous numbers, but actual cases of phenolphthalein eruption are by no means rare, and they can be very severe. It may be doubted if it is much of an improvement on mercury for administration to young children. *Incidents in Scyllam cupiens vitare Charybdim.*—I am, etc.,

Glasgow, C.S.

J. FERGUSON SMITH.

Incidence of Cancer of the Cervix

SIR,—Having for some time believed that the usual textbook statements about the relative frequency of carcinoma of the cervix and of the body of the uterus bear little relation to fact, I was pleased to note the paper by Dr. J. W. Mager and Professor W. Kearney (*Journal*, February 20, p. 434) giving their rather unusual findings. This stimulated me to analyse the records of the Department of Pathology of the Women's Hospital, Liverpool, for the two years 1952-3, and I found that during that period 1,817 endometrial curettings, 757 uteri (the vast majority total hysterectomy specimens), and 679 cervixes (including biopsies and those removed in the course of repair operations) were examined. In this material 92 cases of carcinoma of the body were discovered, 4 of which were epidermoid in type, and 88 cases of carcinoma of the cervix, 2 being adenocarcinomas. Thus it can be seen that the incidence of each type was virtually equal.

Consulting the Registrar-General's returns for England and Wales for 1951 and 1952, it was found that during this period 5,132 women died from carcinoma of the cervix, 2,422 from carcinoma of the body, 68 from other forms of carcinoma of the uterus, including chorion epithelioma, and 461 from "carcinoma of the uterus," site unspecified. This 2:1 ratio in favour of carcinoma of the cervix as a cause of death does not necessarily mean that it is twice as frequent as carcinoma of the body, as the former affects, in general, younger women and is less amenable to treatment. I feel there is quite enough evidence for us to modify textbook figures of relative frequency to read that carcinoma of the cervix is at the most twice as common as carcinoma of the body, and would be interested to hear the opinion of others on this matter.—I am, etc.,

Liverpool, 8.

ROBERT P. TOWERS.

Doctors' Handwriting

SIR,—Mr. Geoffrey Keynes (*Journal*, February 20, p. 458) raises the question whether prizes for good handwriting might be awarded in the medical schools. Perhaps my own experience may be worth contributing to the discussion.

I joined the Society for Italic Handwriting and read all the books, and the first question was whether I should go back to the beginning and learn italic or whether I should set to work and rebuild my own hand. In either case it would be quite futile to work hard for half an hour or so every day at a new hand and then spend the rest of the day writing my old one; and it was obvious that I could never get through my work if I had to write everything all day very carefully and very slowly. The only solution was to learn to type; then if I typed all my letters I ought to be able to manage my prescriptions and certificates in a new hand. So I set to work with a typewriter, but I soon discovered that learning to type would take all the time I could spare for many months. It was very hard work, but it was surprisingly interesting, partly because it was so very like learning to play golf. I then wrote to one of the italic handwriting authorities and I was told that that also took a lot of learning. And that is not the end of it; it seems to be pretty certain that in the case of an adult both accomplishments have to be kept up by daily work or the skill is soon lost. And even daily work is not quite enough, the adult beginner will always have to write his italic or use his machine with a good deal of care. If that is so, it seems extremely doubtful whether any general practitioner could find time and energy to become good at both. If the choice is between learning a new hand and learning to type I think the doctor is bound to choose the latter: typewriting is always easier to read than any handwriting; a good typist can type very much quicker than anybody can write; and it is a great advantage to be able to make two or three carbon copies.—I am, etc.,

Wetherby, Yorkshire.

R. L. KITCHING.

Diabetes Insipidus Associated with Pulmonary Disease

SIR,—I have recently seen a case very similar to that described by Dr. R. B. Raffle in his article (*Journal*, February 20, p. 436), which was likewise referred to me through the mass radiography department, for which I am grateful to Dr. E. E. Mawson.

This woman, 52 years of age, was complaining of some dyspnoea on exertion which made her rather easily exhausted. She had never wheezed, nor had she had any cough or sputum; at times, especially in the cold, she experienced some paroxysmal chest pain. On careful questioning, she decided that her breathlessness had not greatly increased since 15 years previously when she first reported it to her doctor. After an x-ray at that time she was sent to a sanatorium, where she was told, after five months' observation, that no active tuberculosis could be found. In the following year she developed diabetes insipidus. Recent examination showed her to be in good general condition, slightly overweight at 10½ stone (66.7 kg.). Clinically her heart, lungs, skeleton, and skin seemed normal. There was no lymphadenopathy or enlargement of the spleen. X-ray of her chest showed widespread miliary mottling with slight reticulation, and the appearance was identical with the sanatorium film taken 15 years before. X-ray of her pituitary fossa was normal, and her blood cholesterol 255 mg. per 100 ml.

I considered that the diagnosis lay between xanthomatosis and sarcoidosis. As the patient was disinclined to come into hospital for any attempt at confirmatory measures such as liver biopsy, I tested the tuberculin neutralizing powers of the serum. In five patients giving an average diameter of 8 mm. reaction with 1 in 10,000 old tuberculin intradermally, this patient's serum produced complete inhibition of the reaction. This finding would seem to point very strongly, although not certainly, to a diagnosis of sarcoidosis, and I feel that this test merits a further clinical trial in attempting to establish such a diagnosis when no biopsy is practicable.—I am, etc.,

Bristol.

The Nephrotic Syndrome

SIR,—In his article on "The Nephrotic Syndrome" (*Journal*, December 26, 1953, p. 1389) Professor J. R. Squire claims to have devised a new method of calculating the "true" clearance and the reabsorbed amount of protein by the nephrotic kidney. I think his material is very valuable, but his way of presenting it not too illuminating. I do not see why it should be necessary to mix albumin and total protein clearance together in order to calculate the filtered clearance of albumin. This can be achieved very simply by plotting UV_{AIB} (excreted amount of albumin) against P_{AIB} (plasma concentration of albumin) or against $P_{AIB} \times$ glomerular filtration rate, if the "relative" clearance is to be determined. Assuming that the experimental data

are on a straight line, the reabsorbed amount of albumin may be calculated by extrapolation, the filtered clearance being given by the slope of the tracing. The same operation may be done on every protein fraction, even on total proteins. According to the theory the experimental straight line will intercept the vertical axis at the origin if the substance is only filtered, above if it is filtered and excreted, and below if it is filtered and reabsorbed. But of course this kind of speculation should be accepted only with great reserve, as long as the shape of the experimental curve cannot be determined accurately near the intercept on the axis.—I am, etc.,

Berne.

Controlled Use of Nasal Decongestants

SIR,—It is desirable, apparently, to remind colleagues engaged in family practice that the use of nasal decongestant medication, whether inhaled, by spray, or by drops, should be suitably controlled. I have seen four patients in the last 10 weeks whose nasal symptoms disappeared when the use of a decongestant was discontinued. The latest patient stated that she had been using "fenox" at the rate of a bottle per day, for about nine weeks. She was advised to stop the instillations at once. She spent an extremely miserable 24 hours thereafter, and was barely able to be restrained from using the drops. After this, the recovery was rapid and complete.

In my experience, the use of decongestant drops in acute rhinitis is of doubtful value, as the mucosal congestion and consequent hypersecretion of mucus are the result of the action of the body's defence forces, and should not be retarded. In my view, decongestants are of value only if there is interference with sinus drainage, or if Eustachian congestion is present. Certainly decongestants should not be used in nasal allergy, as this so often proves to be a long-term condition, and it is in such cases that the disadvantages of their use tend to manifest themselves.

The foregoing has long been common knowledge among rhinologists, but it is perhaps less widely appreciated among general practitioners. It is in their hands, to some extent, to warn patients against long-continued use of these drugs. In addition, although many of the manufacturers of these drugs warn patients as to the frequency of use advised, they do

not always warn them as to the duration over which use may be continued. These cautions should certainly be emphasized.

According to Martindale,¹ the drug mainly used is naphazoline hydrochloride or nitrate.—I am, etc.,

Glasgow.

College of General Practitioners

SIR,—At the inception of the College most of us who joined did no more than give it a good start in life with a little cash and a lot of good will. A few have carried the burden of work that really made the venture live, and I have been amazed at their efforts in so short a time. It ill becomes any of us to raise an imagined grievance to the status of an issue of "general interest to actual or prospective members" (Dr. D. G. Berry, *Journal*, February 27, p. 520). If "general lethargy" there has been, who is guilty? Not the College Council.—I am, etc.,

Gateshead.

K. T. BROWN.

The Basis of Sensation

SIR,—Referring to Dr. E. D. Adrian's Banting Memorial Lecture (*Journal*, February 6, p. 287) requesting new light in the physiology of sensation, I should like to submit the following suggestion. The anatomical structure of the central nervous system seems to indicate one definite difference between the centrifugal and centripetal pathways—that is, the number of links being much more numerous in the afferent leads—besides the more complicated stratification of most of their intermediaries like retina, corpora geniculata, etc., and cortical representations with their densely packed small cells, especially if compared with the efferent, much simpler organized system. As a preliminary explanation one might accept the supposition that motor stimuli arise intrinsically and do not need a lot of translation on their journey to the peripheral neurons. On the other hand, sensation is started by extrinsic, heterogeneous stimuli which require quite a bit of being "taken in."

What I should like to know is whether there is such a difference marked in the electrical currents as produced by the two kinds of pathways, or are there other means of differentiating them histologically and/or physiologically? I am, etc.,

Cardiff.

R. BAUER.

Treatment of Subacute Bacterial Endocarditis in a Patient Sensitive to Penicillin

SIR,—In a recent article (*Journal*, February 27, p. 500) Drs. H. W. Balme and A. E. Dormer emphasized the need for using an effective bactericidal, as opposed to a bacteriostatic, antibiotic as early as possible in subacute bacterial endocarditis. This restricts the number of available antibiotics, and if it happens that the patient is already sensitive to the one of choice a difficult problem arises. Drs. Balme and Dormer have described a method of overcoming this sensitivity, and as we have recently applied the same method with success to a similar case we believe that it deserves to be more widely known.

The patient was a business man of 58 who was admitted to hospital in June, 1953, under the care of Dr. A. L. Jacobs. He had had an obscure febrile illness for some weeks; at first negative results were obtained from all the usual investigations, but it soon became clear that he was suffering from subacute bacterial endocarditis as he developed an early aortic diastolic murmur and the blood cultures became positive at the same time. The organism grown was a *Staphylococcus viridans* which was sensitive to the usual antibiotics, including aureomycin. It is important to note, however, that aureomycin had no effect on the fever and that, although the organism was sensitive to aureomycin *in vitro*, positive cultures were obtained while the patient was having maximum doses of this drug. It was evident that penicillin was the agent of choice in this case, but unfortunately the patient was known to be sensitive to it; he informed us that he had been given penicillin in 1952, when he was treated for

dermatitis, and he reacted with oedema of the face. As we felt it imperative to give penicillin he had an injection of the sodium salt, and he promptly reacted with an erythematous rash of the limbs and oedema of the face and eyelids. We therefore gave him full doses of mepyrmine maleate by mouth in the hope of suppressing his sensitivity and followed this with 50,000 units of penicillin, but a similar reaction occurred associated with some dyspnoea. Dr. Dormer now kindly suggested to us the method of Maslansky and Sanger¹; treatment was accordingly begun again with crystalline penicillin 100,000 units and mepyrmine maleate solution 50 mg. mixed in the same syringe and injected intramuscularly. This was given twice a day and subsequently six-hourly. The penicillin was then slowly increased to two mega units and the mepyrmine maleate was reduced and, after a fortnight, finally discontinued. Evidently the patient had become desensitized. No untoward reaction either local or general occurred at any time. The effect on the bacterial endocarditis was immediate; fever ceased after the second day of treatment and did not return and the patient slowly became well enough to leave hospital. The ultimate result was disappointing, as cardiac failure eventually supervened and the patient died in January of this year. This was not altogether unexpected in view of the aortic incompetence, and necropsy showed a large perforation of the right posterior cusp of the aortic valve, leaving no more than a rim of this cusp intact. There were some vegetations on the free edges of the other two cusps, attributed to a terminal recurrence of this infection of which there was evidence shortly before death. On his final admission large doses of penicillin were given without reaction.

Glaxo Laboratories Ltd. kindly examined for us mixtures of penicillin and mepyrmine maleate solutions and found that they were compatible, and that there was no loss of potency of either drug in 24 hours at room temperature. The penicillin was found to dissolve satisfactorily directly in the mepyrmine maleate solution, but it took slightly longer than in water. It appears that this method of overcoming penicillin sensitivity may be of value in similar infections in which penicillin is the antibiotic of choice; it is noteworthy that the patient preferred the mixed injection to penicillin alone, as he found that there was less local pain.

We wish to express our thanks to Dr. A. L. Jacobs for his assistance with this case, and to Dr. Dormer for his helpful suggestion.—We are, etc.,

K. C. ROBINSON.

Abdominal Testicles and Fertility

SIR,—In "Any Questions?" (February 13, p. 409) under the heading of "Abdominal Testicles and Fertility" you state: "The view which is becoming generally accepted now is that treatment for undescended testicles should begin at an early age, perhaps at 3 to 5 years."

Denis Browne¹ divides this condition into two groups: (1) the retractile testicle, which represents 80% of all undescended testicles, and (2) congenital deformities—ectopic testicles. Group 1, which can be brought into the upper scrotum by bimanual palpation, will descend normally before puberty without treatment. Group 2 is unaffected by hormone treatment and requires operation. The age recommended for operation is 9 years.² At Great Ormond Street and at the Boston Children's Hospital the endocrine treatment of undescended testicle is never used.—I am, etc.,

Neomycin in Pyogenic Skin Diseases

SIR,—In recounting his experiences with neomycin and terramycin in the treatment of skin infections, Dr. G. A. Grant Peterkin (*Journal*, February 27, p. 522) makes a valuable comparison of the efficiency of these antibiotics. From his, and other accounts, terramycin (oxytetracycline) at least equals the undoubted effectiveness of aureomycin (chlorotetracycline) as might be expected from their closely

similar formulae. There is, however, a more sinister resemblance, in that Gram-positive cocci resistant to one are invariably resistant to the other. At the present time new antibiotics are discovered almost before one has learnt the names of their predecessors, to be used and discarded when they have lost their effectiveness as though the supply is inexhaustible. In my recent series of cases of pyoderma (*Journal*, February 6, p. 314) 51% of *Staph. pyogenes* isolated were resistant to penicillin, 20% resistant to chloramphenicol, and 2% resistant to aureomycin. During the past year 7% of strains isolated from skin out-patients have shown resistance to aureomycin and terramycin. Aureomycin and terramycin remain the most potent weapons we have against penicillin-resistant staphylococcal infections.

In France up to 23% of staphylococci resistant to all antibiotics are recorded,¹ while in America up to 61% of staphylococci resistant to aureomycin and terramycin have been found in hospital infections.² It seems unlikely that erythromycin will prove of more lasting value in combating staphylococcal infections. The ease with which bacterial resistance to it can be acquired *in vitro* has been demonstrated by Dr. D. Hobson (*Journal*, January 30, p. 236), evidence which is supported by the production of a carrier rate of resistant strains of staphylococci which reached 75% five months after adoption of erythromycin for general use in an American hospital.³ Fears are already being voiced in America⁴ that ointments which contain erythromycin may rapidly increase the incidence of resistant strains of bacteria. In a recent authoritative account of the principles of treatment in pyogenic skin infections Pillsbury and Kligman⁵ advocate the avoidance of topical application of compounds which might be required later for the treatment of some serious internal affection, and state that for this reason they do not use terramycin or aureomycin locally. They find bacitracin and neomycin reasonably safe and having a wide enough spectrum of antibacterial effect to yield extremely satisfactory results with the added advantage that they are unsuitable for internal use.

To suggest that aureomycin and terramycin should never be used locally is unrealistic, since they yield such excellent results when all else fails in sycosis barbae and other deep staphylococcal infections. If used judiciously we should succeed in preserving their usefulness. If they are used as a routine for all cases of pyoderma, what now acts as a tempest among bacteria may become no more than a mouse's sneeze.—I am, etc.,

Sheffield.

Dangers of Induced Hypotension

SIR,—A recent article in your *Journal* (February 6, p. 324) deprecated the use of hypotension in surgery and published figures showing a mortality of one in 500. Every new drug, every new treatment, immediately produces the fervent protagonist and the equally fervent antagonist, and time and experience must be allowed to effect their mellowing influence on both. Is it not possible that the figures of one in 500 may have been arrived at by the over-enthusiastic use of these drugs?

My own personal experience (250 cases) is too small to be reliable, but so far I have had excellent results. Patients submitted to sub-mucous resection of the nasal septum are incomparably more comfortable if the nose is not packed. Such operations as external ethmoidectomy, and dacryocysto-rhinostomy are indeed made much less difficult, and this also applies to thyroidectomy and radical mastectomy. Surely here is a weapon in the armamentarium of the anaesthetist which should not be lightly discarded.—I am, etc.,

Folkestone.

HARRY F. GRIFFITHS.

Obituary

H. A. BRITTAIN, O.B.E., M.Ch., F.R.C.S.

The sudden and unexpected death on March 4 of Mr. H. A. Brittain, senior orthopaedic surgeon to the Norfolk and Norwich Hospital, has deprived orthopaedic surgery of one of its most able surgeons and original thinkers. He was 50 years of age.

Herbert Alfred Brittain was the son of the late Mr. J. W. Brittain, of Dublin. He was educated at Sedbergh School and Trinity College, Dublin, where he graduated M.B., B.Ch. in 1926, and five years later he obtained both the M.Ch. and the F.R.C.S. After holding the post of house-surgeon at Bristol Royal Infirmary, he became senior house-surgeon at Leicester Royal Infirmary and later at the Royal National Orthopaedic Hospital. In 1932 he was appointed assistant general surgeon to the Norfolk and Norwich Hospital, and in 1935 he became the first orthopaedic surgeon to that hospital. In addition to being a brilliant surgeon with a distinguished academic career, he had an original turn of mind, and as early as 1935 introduced a method of insertion of a triffin nail for the fixation of fractures of the neck of the femur, an account of which was published in this *Journal* in 1938. This method has stood the test of time, as it is still practised extensively to-day. At about the same time he started developing new methods of arthrodesis, especially of the hip-joint, and eventually perfected a method of ischio-femoral arthrodesis, which is particularly applicable in cases of tuberculous disease of the hip and which is generally known as the "Brittain operation" not only in this country but all over the world, for it has become the standard operation for dealing with this crippling disease both in children and in adults. The operation is fully described in his book *Architectural Principles in Arthrodesis*, and was the subject of his Hunterian Professorship of the Royal College of Surgeons in 1940.

Mr. Brittain was a Fellow of the British Orthopaedic Association, serving on the executive committee, and was also a member of the International Orthopaedic Association, having many friends among his colleagues both in this country and abroad, particularly in America and Portugal. In fact he was known to a wide circle of orthopaedic surgeons in almost every country in the world where this type of surgery is practised. During the last war he served in the R.A.M.C., attaining the rank of lieutenant-colonel, and was awarded the O.B.E. for his services.

Brittain, known to his friends as "Tommy," had exceptional vigour, both mentally and physically. His professional activities and the writing of many contributions to orthopaedic literature would have been sufficient to exhaust most men, but in addition, while he was in Norwich, he became a keen hunting man, and in 1946 had the misfortune to sustain a fracture-dislocation of his cervical spine as a result of an accident while taking part in a point-to-point race. He not only survived this and the major operation which followed, but actually returned to the hunting field again, a demonstration of his enthusiasm, bravery, and determination. It was this spirit—not to be overcome by any obstacle—that was dominant in his work and in his play. In 1952 he was seriously ill with thrombosis for many months, but again managed to recover from this and actually returned to his work and his hunting once more.

His name will live for many years on account of his outstanding work as an orthopaedic surgeon. He leaves a widow, formerly Miss Sonia Barclay, and two daughters, to whom our deepest sympathy is extended.—G. K. M.

Mr. R. C. HOWARD writes: I would like to pay tribute to my late chief, Mr. H. A. Brittain, with whom I was closely associated as a registrar and later as a junior colleague. I owe my present position to him, and seldom has a young surgeon had a more stimulating and happy discipleship. Wherever he went he left his mark—here was a man who could not be ignored. Loved and almost worshipped by countless patients, he must have become used to adulation, and yet, strangely enough, humility was one of his virtues. But it was the right sort of humility—private not public. He was a gifted conversationalist and writer of the English language, with an incisive mind; and he loathed pedantry and plagiarism. Loving life with a youthful zest, he always made it exciting for others: dullness and boredom were alien to him. The orthopaedic department here in Norwich has lost its first and probably its greatest orthopaedic surgeon, but his memory will live on in the basic principles of orthopaedic surgery that he taught so thoroughly, and in the enthusiasm for the truth which he has bestowed on all those who came under his influence.

A. M. CLARK, M.C., Ch.M., F.R.F.P.S.

Mr. Alfred M. Clark, who was on the surgical staff of the Glasgow Royal Infirmary, died on February 13, after a very brief illness, at the age of 60.

Alfred Mackenzie Clark was educated at Glasgow Academy and Glasgow University, where he graduated M.B., Ch.B. in 1915. He then entered the R.A.M.C. and served continuously on the Western Front in the first world war until demobilization. In 1918 he was awarded the Military Cross for services in the field. After the war he studied law at Balliol College, Oxford, and was called to the Bar by the Inner Temple in 1921. However, his real interests lay in surgery, and after holding resident surgical appointments at the Radcliffe Infirmary and the post of assistant demonstrator in anatomy in Oxford University he returned to Glasgow and joined the staff of the Royal Infirmary in 1922. In 1929 he became a Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow, and five years later received the higher degree of Ch.M., with high commendation, from Glasgow University. During this period he was specially interested in the problems of surgical shock and the treatment of burns, and he wrote several papers on these subjects.

In 1938 Mr. Clark was appointed surgeon in charge of wards at Glasgow Royal Infirmary and honorary lecturer on clinical surgery in the University. In addition to his general surgical commitments, he assumed control and direction of the wards for the treatment of burns. In collaboration with Professor J. P. Todd, of the Royal Technical College, Glasgow, he was one of those primarily responsible for the research work which culminated in 1944 in the Medical Research Council's publication, *Studies of Burns and Scalds*. From the outbreak of war in 1939 he added to his already onerous duties that of visiting surgeon to Law Junction Hospital. This appointment he relinquished in 1945. In the same year, but most regretfully and reluctantly, the pressure of general surgical work made him give up the direction of the burns unit. Thereafter he devoted much time and energy to the surgery of the thyroid gland, a branch of surgery to which he brought singular skill and judgment.

N. G. HORNER, M.A., M.D., F.R.C.P., F.R.C.S.

Dr. O. C. CARTER, chairman of the Journal Committee of the British Medical Association, writes: There is little to add to the worthy tribute which the *Journal* paid last week to the memory of a former editor, except perhaps a postscript from the present chairman of the Journal Committee, who served on that committee in the days when Horner was editor. The first impression one would have was his extreme courtesy and kindness to all who came into contact with him; at the same time it was so transparent that he was an outstanding medical man of letters and only accepted the very best both from himself and from those who worked around him. Furthermore, Horner was of an exceedingly retiring and shy disposition, and yet anybody who went to him for advice and help always came away feeling that they had seen someone who had taken an interest in their problem and wished to give them all the help that was possible.

Although Horner was quiet and reserved, he had a great sense of humour and a very ready wit, and his writing showed the elegance and style which was so characteristic of the man. During his editorship the reputation and status of the *British Medical Journal* grew, and, although during the last few years that he held his high office he suffered a great deal from ill-health, he carried on for longer than most men with his affliction would have done; and when the time came for him to go, it was with a very sad heart. His death has deprived the profession of one of their colleagues who was pre-eminent in the world of medical journalism, and the Association has lost a member who was one of its officials of outstanding eminence and unfailing loyalty. We salute his memory.

We are indebted to H.C., an old contributor, who writes: May one who served under Gerald Horner during the whole of his editorship, and of his assistant editorship before that, add a word of sincere tribute to a man of unusual quality? I vividly remember my first interview with him, on November 9, 1917, shortly after he joined the staff of the *Journal*. He was instructing me about a special piece of work, and some of his ideas of the journalistic craft which he expressed then I have never forgotten; but, such was his modest and diffident manner, he hardly glanced at me during the whole of the briefing, but kept his eyes on the Lord Mayor's procession which was passing under his window looking down on the Strand.

Horner was often contrasted with his great predecessor, Sir Dawson Williams, but the contrast was less marked than was supposed. It was a contrast of manner rather than of substance. Dawson Williams was feared by those who did not know him, and inspired extraordinary devotion among those who did. Horner was feared by no one, though he could be caustic, but to those who broke through the circle of his shyness he showed affection which was returned. The editorial office in Dawson Williams's time resembled the deck of a battleship, with a good deal of shouting of orders and running about; in Horner's time it was more like an Atlantic liner, with captain, crew, and passengers never raising their voices.

The skill of an editor is largely in his excisions. When my own "copy" was cut by Dawson Williams I had to acknowledge that he had removed what was platitudinous and repetitive, but I mourned the ragged edge. What was left did not "read." This divinity did not shape our ends, he rough-hewed them how he would. Horner's method was much more precise. His knife was as briskly at work, but it was more fastidious, and the cut ends were not left gaping.

I cherish a long letter from Dr. Horner, dated May 29, 1942, and rescued from the blitz. In it he lamented the restrictions of paper control, which had cut down the editorial pages of the *Journal* to 32 a week. But he did not

stress the mortification this must have meant to himself. Instead he spoke with regret of the diminution of work which it must entail for an old contributor, and the letter contained such compliments and pleasant words as are too personal to quote. But it was significant of the man who was labouring under the great strain of editorship of an important journal in those days, and towards whom even then the shadows of a long illness were approaching. He was a man who did not disdain to praise, and yet his praise was always so discerning that it left one with the curious feeling that one had still to deserve it.

Mr. JOHN KEITH HAMILTON BENSON died in Warrington on January 12 at the early age of 35. A student at Manchester Dental School, he had a brilliant career, graduating B.D.S. in 1940 with first-class honours. He was in quick succession house-surgeon, demonstrator, assistant clinical lecturer, and then lecturer in dental surgery at Manchester. His main interest was oral surgery, and for a time he was in charge of the oral surgery clinic there. In 1948 he was graded as a consultant, and to equip himself better he then took the unusual course of resigning his appointment and becoming again a student—this time of medicine. He graduated M.B., Ch.B. in 1952, having obtained the F.D.S. R.C.S. in 1949. Last year he was appointed lecturer in dental surgery at Queen's University, Belfast, and he held a consultant appointment at the Royal Victoria Hospital. Almost immediately afterwards he became the victim of a malignant growth, and after a long illness, borne with great bravery and without complaint, he died at his home in Warrington. Better known, perhaps, to his former colleagues in Lancashire, he had a rapidly extending circle of friends in Northern Ireland. His brilliance in both clinical and academic fields was matched by his technical skill, and all were combined with an unassuming friendliness that was masked by a natural reserve. His death is a great loss, and to his parents and brother we offer our heartfelt sympathy.—P. J. S.

Dr. H. L. MILLES, consultant physician to Worcester Royal Infirmary, died on January 18, after a short illness, at the age of 55. Herbert Leslie Milles, who was born on June 27, 1898, was educated at King's School, Worcester. Anxious to serve in the first world war, he left school as soon as he could and enlisted as a regular officer, being posted to the 1st battalion of the Buffs. He served with distinction, and won the Military Cross in March, 1919. Leaving the Army soon afterwards, he went up to Christ's College, Cambridge, to read medicine. After taking an arts degree in 1923 he entered King's College Hospital Medical School to receive his clinical training, and while at King's he was a member of the senior lawn tennis team which won the inter-hospitals tennis cup in 1924 for the first time. He qualified M.R.C.S., L.R.C.P. in 1926, proceeded to the M.A. in the following year, and was elected M.R.C.P. in 1931. After holding the post of resident accoucheur at King's College Hospital he was appointed Sambrooke medical registrar there, a post he held until 1932. Prior to that he had worked for a time at the Edinburgh Royal Infirmary as senior house physician. Thus he had wide hospital experience before finally settling in practice at Droitwich Spa, where he became consultant physician to Highfield Hospital for Rheumatic Diseases and St. John's Hospital for Rheumatic Diseases. He was also honorary physician to Worcester Royal Infirmary. During the last war he was deputy medical superintendent and physician in charge of the medical division of Barnsley Hall E.M.S. Hospital. A few years ago he published in the *Journal* one of the first reports in this country of poisoning by one of the organic phosphorus insecticides, and he had also written papers on the subject in which he was specially interested, rheumatology.

We are indebted to Mr. F. R. KITTERMASTER, headmaster of the King's School, Worcester, for the following appreciation: Herbert Milles was a brilliant and devoted doctor, but what made him universally beloved was not so much his

Medico-Legal

CRIPPLED GIRL AWARDED £5,000

A 6-year-old girl, who, it was stated, will be a cripple for life, was awarded a total of £5,000 damages at Notts Assizes on March 10 against a children's hospital matron and a hospital management committee. It was claimed that a plaster cast was put on her left leg too tightly and that the leg would remain shrivelled.

The child, Christine Margaret Bayliss, of Mansfield, Notts, sued, through her father, Mrs. Bertha Blagg, aged 57, matron of the Gringley-on-the-Hill Children's Hospital, and the Nottingham No. 5 Hospital Management Committee, alleging negligence. The allegations were denied.

Opening the case for the girl, Mr. Fearnley-Whittingstall said that the result of wrapping the leg in a plaster spica which was too tight, or was left on too long, was "a most appalling necrosis of the tissues, deformity of the left foot, paralysis of the muscles controlling toes, foot, and ankle, and the grossest possible disfigurement." The child's illness began in November, 1949, and the only cure was to immobilize the hip. In June, 1950, she was taken to the hospital and was first put on a frame to keep the hip still. In January, 1952, she was put into her plaster case by the matron.

Normally she was a bright and happy child, but when her father called to see her on January 5, she had "completely and absolutely changed." He saw her again next day and said that "the baby had changed into an adult overnight." Mr. Fearnley-Whittingstall said that when Mr. Bayliss suggested to the matron that the plaster was too tight, she said: "This is not the first plaster I have put on." He was completely snubbed. On January 16, the plaster was removed, and Mr. Bayliss received a letter which stated that Christine was now all right, and that the doctor had said that the hip was almost recovered and would not require being put into plaster again. It was not until June 27 that the father was told for the first time that his daughter was going to be a cripple for life.

Mr. Frank W. Holdsworth, orthopaedic surgeon at two Sheffield hospitals, said that the only reasonable explanation for the condition of the leg was that under the plaster there was a small sore which became infected. Most of the calf muscle was destroyed. He thought the change in the child's appearance and manner would be a warning of this, and it would be reasonable to think something was wrong and the plaster should be removed.

Parent's Right to Know

Opening the case for the defendants, Mr. R. C. Vaughan said that the charge brought against the matron was a grave one. She had been matron for 18 years and in the nursing profession all her working life.

Mr. Vaughan was questioned by the judge on the long delay in telling the parents of their child's deterioration. "I would like to know if this is the system under our State medical service. The parent has a right to know—this isn't Russia."

Mr. Vaughan: Nurses and doctors will shut up like clams, and you'll never get any information out of the hospital as to what is wrong with yourself, far less your child.

Judge: If it were a child of mine, I would change my doctor.

Mr. Vaughan: One can't get facts from hospitals. They are grossly impertinent when you ask.

Giving evidence, the matron said that after putting on a plaster they were able to tell if it was too tight by seeing whether the child could still wiggle its toes. She did not agree there was an obvious change in Christine; her demeanour was the same, only a little subdued. The matron said that on January 14 she examined the foot and it was normal. It was not until the next day when the toes turned blue that she gave orders for the plaster cast to be removed. On January 29 when the leg became discoloured and turned a greenish-blue they realized they had "a bad leg."

achievements and successes as a doctor, but the way he lived his life—his achievements and triumphs as a person. He began his career as a regular soldier, and, though he soon turned his talents to medicine, he had two great qualities essential to a soldier—courage (to which not only his Military Cross but his whole life bore witness) and abundant physical energy. Up to five years ago he took great delight in all kinds of bodily exercise; and in such things as games, dancing, and skiing he found great pleasure and refreshment, as well as an outlet for his physical energy. Then came the first of his heart attacks, and he found himself cut off in a moment from many of the things that had given him most delight. Without a word of complaint he turned his energy and enthusiasm to other things, and began to develop his interest in books, music, and painting—a wide range of quite different activities, that filled with interest every moment of his busy life. And what was still more remarkable, he retained his interest and enthusiasm for what others were doing in the things he could no longer do himself. What an effort this cost him we do not know, but it is certain that this acceptance and conquest of his limitations caused him to grow in spiritual stature. Then, as the years went by, and he had more serious illnesses, he knew that his time here was not likely to be very long; but, still cheerful and uncomplaining, with no grudge against the cruelty of circumstance, he devoted himself unsparingly to his work and to his many other interests, particularly painting, with never-failing excitement and enthusiasm.

No doubt the love he inspired was due in part to his unfailing enthusiasm, which welled up, continually renewed, from some inexhaustible source. It made no difference whether it was his medical work, his painting and other interests, or the interests and doings of his friends. There was just as much delighted and delightful enthusiasm for the interests of others as there was for his own, and his frequent "By Jove!" and "I say" were not just habits of speech; they were the hallmarks of the infectious interest and enthusiasm that he showed for every side of life. In the sense that Rupert Brooke used the phrase, he was a great lover, and he left the world much richer in love than when he came to it.

By the death of Dr. J. E. JEFFREY on February 21 at the age of 64, Dunbartonshire has lost one of the best type of family doctors. Born at Aytoun, Berwickshire, where his grandfather and father had practised, on August 19, 1889, John Edward Jeffrey was educated at Duns Academy. After leaving school he spent a few years in business before he turned to medicine, beginning his medical studies at Glasgow University early in 1914. In the following year he volunteered for service with the chemical section of the Royal Engineers and served in France for nearly four years, latterly being attached to the R.A.M.C. He was awarded the D.C.M. for gallantry in rescue work. Returning to his studies in 1919, he graduated M.B., Ch.B., with commendation, in 1922. After holding a resident post at Stobhill Hospital, Glasgow, he spent a year at Hartwood Mental Hospital, Shotts, Lanarkshire, but the inherited desire for the work of a general practice asserted itself, and in 1924 he took over a small practice in Dalmeir and Clydebank. So devoted was he to his work that he soon built up a large and successful practice and joined in partnership with Dr. L. Crombie. A man of high principles, he was always methodical and painstaking in his work, and while he did not suffer fools gladly, freely gave of his best to help those in need. For many years he was the efficient honorary secretary of the Clydebank Burgh Panel Committee. In middle age he married Miss Margaret M. Craig, then matron of the Western Infirmary, Glasgow, and this was a most happy union. For nearly a year he had been in failing health, but he carried on his work almost to the end and bore with fortitude what he knew was an incurable malady. At the cremation service many colleagues and friends attended to pay their tribute to his memory, and their sympathy goes out to his widow, his mother, and his sisters.—L. C. and W. G.

Dr. William Thomson, the medical officer attending Gringley Hospital, said that he visited the hospital twice a week, sometimes more. He saw the plaster put on Christine's leg, and examined it. It was then satisfactory, and on other visits during the next two weeks he did not see anything unsatisfactory in her condition. On January 16, when the plaster was removed, there was swelling in the calf and foot. The skin had an unhealthy look and there was a grey pallor in the calf. He thought there had been some pressure on that area. The leg began to improve after the plaster was removed, but at the end of January it became discoloured and the tissues of the calf started breaking down. He began to be more worried about the outcome, and Mr. Sydney A. S. Malkin, the orthopaedic surgeon, saw the child on February 24. Looking back on it, he would have preferred to have called in Mr. Malkin sooner to share the responsibility.

Circulatory Defect

Mr. Malkin, the surgeon, told the court that it was a circulatory defect which caused the wasting of the child's calf muscles. His considered opinion was that there had been a spasm of the blood vessels in the calf, perhaps caused by the cold weather. Describing Mrs. Blagg as an extremely good matron, Mr. Malkin said that he would be proud to have a plaster as good as this to his name. Of Dr. Thomson's treatment Mr. Malkin said: "On the whole I think he did extremely well."

Mr. Vaughan: Do you feel you could have been of any help in saving this child's eventual leg condition if you had been called in earlier?—I don't think I could have done anything at all.

Mr. Malkin said that Dr. Thomson was one of the two best students, among 400 in his year, when he qualified at Glasgow. The Judge: I know dog doesn't eat dog, but were you shattered when you were shown this leg on February 24?—I certainly was.

Would you have liked to have seen it sooner?—I should.

Mr. Malkin said that in 30 years' experience he had never known another case in which such a deterioration had taken place without his being called in, or one in which so much deterioration had taken place in so short a time.

In his final address for the defence Mr. Vaughan said the position had been crystallized by his Lordship in unmistakable terms that there was a deliberate attempt by the hospital to conceal and misrepresent to the family the condition of the child.

The judge said that he was quite satisfied the plaster was put on with care and skill—it was the subsequent events that were in issue.

Mr. Vaughan said that there was nothing whatever on the plaster cast which could have caused a pressure spot. The matron and nurses had sworn that the skin on the leg was unbroken when the plaster was taken off. That left only the theory that there was some disease which caused the leg to swell, filling up the original space between the leg and the plaster, and causing constriction.

The judge said he thought that Dr. Thomson was on the horns of a dilemma, and it was a question of up to what point the doctor considered that the child's trouble was trivial. He did not expect doctors to be prophets, but they should be able to assess the possibilities.

The judge criticized the hospital authorities for their secrecy towards the child's parents.

Mr. Vaughan: While these people have the power it must remain so.

Judge: Maybe they will not always have the power.

Mr. Vaughan: I think it has lasted too long and become too settled.

The judge said, "When we had assisted voluntary hospitals, if I was brought in from the street a dying pauper, any treatment I received—no doubt of the best that science could provide—was an act of charity. Now we have gone over to the State system and it is a matter of right for which every citizen has paid. The hospital authorities are just as much his paid servant as anybody else. If anybody has got a different idea they had better think again."

The judge said that the matron had given four explanations for her reticence: (1) she did not realize how bad the child was; (2) she did not have an opportunity of telling

the parents; (3) she thought the parents had already been told; (4) she thought they would worry if they knew. Commenting on the written reports of Dr. Thomson's hospital treatment of Christine, the judge said: "While the appalling deterioration was taking place—and it was nothing short of appalling—there was no note anywhere of it."

Judgment

In his judgment, given on March 13, Mr. Justice Stable referred to tributes paid to the matron and the doctors and said it was well that in addition to this particular case they should recall the hundreds of happy, useful men and women who were walking about to-day, and whose health was largely attributable to the devoted service of these two persons. The particular failure in this case did not detract at all from the countless successes, or from the indefatigable work by the matron which resulted in these successes.

He was satisfied that there was a high degree of negligence over a protracted period of time. The matron did not observe for herself or heed the warnings she received of the marked deterioration in this child's condition practically from the moment the plaster was put on. Was Dr. Thomson led into a sense of optimistic security by the over-optimism of the matron, or was he really blind to the rapid deterioration of the child's condition? Although he despaired of finding out what was going on in the doctor's mind, the judge said he thought the attitude of the matron was easier to explain. She was so confident of her skill that, when she discovered she had been wrong, although in the back of her mind she knew exactly what the truth was, and what potentialities there were in this child's condition, she shut her own mind to the truth and deliberately refused to believe what she knew to be true. Of late they had seen a number of actions brought by dissatisfied patients or parents against hospitals, surgeons, and doctors. Now that the national health had become a matter of national concern he thought that, if a policy of covering up a bad mistake was pursued, the result must be a diminution in public confidence and an increase in the number of claims of that sort.

SEX AND THE LAW

[FROM OUR MEDICO-LEGAL CORRESPONDENT]

Very early in the law student's career his consideration of the sovereignty of Parliament in England is illuminated by the aphorism of De Lolme: "It is a fundamental principle with English lawyers that Parliament can do everything but make a woman a man, and a man a woman." This reflects the fact that one of the fundamental assumptions of any legal system has been that man is man and woman is woman, and that metaphorically never the twain shall meet.

From time to time the advance of medical science drives a coach and four through the fundamental assumptions which lawyers may perhaps be forgiven for having cherished, and raises novel problems which are not easily solved. For example, until the recent spread of artificial insemination it was regarded by lawyers as self-evident that if there was a child of a marriage that marriage must have been consummated, since without coitus children would not be born. It has now been held that a child born as a result of artificial insemination with the husband as donor remains legitimate even though its parents' marriage is subsequently annulled on the ground that it was never consummated.

Even more tortuous legal complications might arise from a change of sex. English law does not cater specially for someone who in the ordinary sense is neither a man nor a woman, although with predominantly male or female characteristics, nor does it for someone who from being what is ordinarily called a man becomes what is ordinarily called a woman. There seems to be no legal attempt anywhere to define what a man or what a woman is, and, though medical men may express good common-sense views of what the legal determining factor in intersex cases should be,¹ until the question arises directly for determination in

¹ See for instance Armstrong, C. N., *Proc. roy. Soc. Med.* 1953, 46, 301.

the courts or is determined by Parliament it is not possible to forecast the law's answer. If present knowledge of hormone control of sexual characteristics turns the problem into one which the community can no longer treat in its law as non-existent, then it will be for Parliament to disprove De Lolme's limitation on its sovereignty and define what is to turn a man into a woman.

Medical Notes in Parliament

Visits by Full-time Consultants

Dr. BARNET STROSS asked the Minister of Health on March 11 if he would permit consultants who were engaged on a full-time salaried basis to make domiciliary visits when requested, and to receive payment on the scale applicable to consultants working part-time. Mr. IAIN MACLEOD replied that under the arrangements agreed in 1949 additional payment must not be made for domiciliary consultations by whole-time officers. Any alteration of this provision would be a matter for the Medical Whitley Council.

Dr. STROSS said that men working full-time in consultant service had no perquisites and no allowances, and on the average their income was somewhat less than the income not only of part-time men but of general practitioners. Would the Minister do something to see that their status was recognized? Mr. MACLEOD said he recognized the justice of a good deal of what Dr. Stross had said, if not necessarily agreeing with it all. Part of the complications arose out of the 1949 agreement, and part by the operation of the ordinary income-tax laws relating to whole-time appointments. It was precisely matters of this kind that would come before the Whitley Council.

Mr. ANEURIN BEVAN hoped that the Minister would not solve the problem by converting all the full-time salaried staff to part-time. Mr. MACLEOD replied that there were varied trends and different views in the different regions about this. Dr. STROSS pointed out that people like himself recognized the excellent work done by the full-time men, but the last thing they wanted was to reduce the status of the part-time people. Mr. MACLEOD said he recognized that, but they should not pretend that the standard of conduct or anything else was higher or lower among part-time or full-time men. They were all members of the same profession.

Waiting-time for Hospital Out-patients

Mr. GEORGE JEGER asked the Minister of Health on March 11 if he would issue instructions to remedy out-patients at hospitals being kept waiting unduly long by consultants arriving late for appointments. Mr. IAIN MACLEOD said that he was aware there were complaints from time to time, and he was always prepared to look into any allegation of serious mismanagement; but generally he regarded these matters as primarily for hospital authorities themselves to manage.

Mr. JEGER pointed out that hospital authorities might be loth to take action because they would not want to have any bad feeling between themselves and the consultants, although they grumbled privately. Appointments systems were no use if the consultants did not keep to them. Mr. MACLEOD said that he was looking into the matter to see if they could collect any useful information which might be sent to the hospitals in the form of circulars.

Mr. KENNETH ROBINSON said that patients were summoned a quarter of an hour before the first could be seen, and always arrived a quarter of an hour before they were summoned. Mr. MACLEOD added that there were a number of other complications, one of which was that some places were so pleasant and attractive and the canteen so delightful that many patients arrived early and treated the place as a club. Mr. J. RANKIN added the opinion that the root of the trouble was that the consultant was also in private practice.

Hospital Capital Expenditure

The MINISTER OF HEALTH announced on March 11, in reply to a question by Dr. R. F. B. BENNETT, that it was no longer necessary for him to require that capital expenditure on projected hospital works from non-Exchequer funds should count against capital allocations made to hospital boards. It would still be necessary for him to scrutinize proposals to incur such expenditure by reference to any Exchequer maintenance expenditure that might be involved, the effect on the development of the hospital concerned, and the needs of the hospital service.

Replying to Mr. ANEURIN BEVAN, the MINISTER stated that there was no intention of raiding the capital of the Hospital Endowment Fund. There were three sources from which the hospitals had money: the endowments of teaching hospitals; the comparatively small amount issued annually as income from the Hospital Endowment Fund to non-teaching hospitals; and the gifts they might have accumulated since the Act came into force, under the provisions made by Mr. Bevan, including such possibility, for example, as the use of funds made available by the King Edward's Hospital Fund, or anything like that. The moneys for the sort of expenditure he referred to would be those coming in either the first or third categories. They had been used from time to time, but it had always been insisted, as a matter of Government policy, that any money so used for capital investment should count against the total allocated to the Ministry of Health and sub-allocated to the regions. It was that provision that had been removed.

Factors in Air Pollution

The City of London (Various Powers) Bill afforded the House of Commons another occasion for discussing smoke pollution on March 10. It was referred to a select committee after second reading, and a general debate took place on two proposed instructions (both afterwards withdrawn) to the committee: Dr. BARNET STROSS wanted the committee to insert a provision that the Common Council should publish an analysis of the atmosphere annually for at least 10 years, beginning with 1954; and Sir HERBERT WILLIAMS wanted the committee to delete Clause 4, which empowers the City Corporation to establish a smokeless zone.

These proposed instructions were simply the machinery by which each of them sought to secure a debate on atmospheric pollution. Sir Herbert Williams asserted that scientific knowledge was inadequate, and his purpose was to advocate extended research. A major tragedy such as that of December, 1952, occurred only occasionally, but a lot of people died all the year round, in small numbers, from the same cause.

Dr. BARNET STROSS said that in Iceland the capital and the surrounding area was free of smoke, and the incidence of cancer of the skin there was exceedingly low; there had only been four cases in the five years 1944-9.

Mr. WALTER ELLIOT said that what was really wanted was greater application of existing laws against pollution of the atmosphere. It was no use simply saying, "Let us take action."

Mr. SOMERVILLE HASTINGS thought that merely to develop smokeless zones would not mean much, because there was as much sulphur oxides given off from coke or smokeless fuel, and nearly twice as much from oil, as from coal. Smokeless zones might even do harm, because in fog it was cold as much as "smog" that was dangerous.

Mr. ERNEST MARPLES, Parliamentary Secretary to the Ministry of Housing and Local Government, expressed Government support of the Bill and the project of a smokeless zone in the City. He said that the Government was determined to do all in its power to conquer the evil of air pollution. That was no lukewarm intention; the Government was enthusiastic about it. But the diagnosis must be thorough and accurate before action was taken, and the action must then be undertaken with determination and imagination.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending February 27 (No. 8) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Vital Statistics

Paratyphoid in Cardiff

We are indebted to Dr. W. P. PHILLIPS, deputy M.O.H. of Cardiff, for the following information: On March 5 the Public Health Department was notified by the City Isolation Hospital that four cases of paratyphoid B infection had been admitted the day before. Four additional cases, admitted for other conditions over the three previous days, were probably also infected. Up to March 12 93 patients have been admitted.

Within two hours field inquiries gave the probable source of infection and the food which was the common factor. Doughnuts, buns, and slices containing artificial cream have been constantly recurring in the history of almost every case. The probable date of infection was February 18 20. The bakery was visited immediately and samples of artificial creams and finished confectionery were taken for bacteriological investigation. Results have so far been negative. Forty members of the staff had blood taken for agglutination tests. Specimens of urine and faeces were obtained from all. Two members of the staff, who two years ago were known to have had positive stools, but later had repeated negatives, were stopped from work as an immediate precaution. They have since proved negative. Eight others on the staff showed some agglutination, but of no diagnostic significance. They were stopped from work and one of them has since been found to be excreting paratyphoid B in the faeces. All of the others are clear so far.

There have been no unusual clinical features, except that in six patients there was a history of abdominal pain and vomiting 24 hours after eating the suspected food. These symptoms cleared up in a few hours and the typical illness developed four or five days later.

Infectious Diseases

The largest fluctuations in the trends of infectious diseases in England and Wales during the week ending February 27 were increases of 240 for scarlet fever, from 1,223 to 1,463, 156 for dysentery, from 754 to 910, and 155 for measles, from 1,944 to 2,099, and a decrease of 63 for acute pneumonia, from 932 to 869.

A small rise in the number of notifications of scarlet fever was reported from every region of the country. The largest local increases were 38 in Essex, from 107 to 145, and 30 in Lancashire, from 157 to 187. The largest increases in the incidence of measles were 48 in Somersetshire, from 62 to 110, and 43 in Kent, from 51 to 94. 11 cases of diphtheria were notified, being 8 fewer than in the preceding week. 2,098 cases of whooping-cough, 1 less than in the preceding week, were notified. The largest fluctuations in the number of notifications of whooping-cough were rises of 41 in Kent, from 73 to 114, and 32 in Southampton county, from 78 to 110, and falls of 27 in Derbyshire, from 62 to 35, and 25 in Yorkshire West Riding, from 179 to 154.

24 cases of acute poliomyelitis were notified; these were 2 more for paralytic and 3 more for non-paralytic cases than in the preceding week. The largest returns were London 3 (Lewisham 2), Warwickshire 3 (Birmingham C.B. 3), and Essex 3 (Clacton 2).

A rise in the incidence of dysentery was reported from most outbreaks; the only large exception was a fall in Kent from 59 to 12. The largest increase was in Lancashire, from 180 to 235. The largest centres of infection during the week were Lancashire 235 (Bolton C.B. 53, Eccles M.B. 53, Preston C.B. 38, Ormskirk U.D. 18, Wigan C.B. 11, Liverpool C.B. 10), London 116 (Islington 42, Chelsea 14, Hackney 11, St. Pancras 10), Yorkshire West Riding 116 (Leeds C.B. 29, Bradford C.B. 19, Halifax C.B. 16, Royston U.D. 16), Staffordshire 70 (Cannock U.D. 58), Essex 69 (Walthamstow M.B. 38), Middlesex 49 (Enfield U.D. 14, Hendon M.B. 11), Norfolk 42 (Norwich C.B. 40), Warwick-

shire 33 (Birmingham C.B. 27), Durham 31 (Sedgefield R.D. 17), Surrey 20, and Gloucestershire 19 (Bristol C.B. 19). The notifications of dysentery in Scotland rose to 222. The largest returns were Glasgow 103, Dundee 30, Lanark county 25, and Edinburgh 24.

Week Ending March 6

The notifications of infectious diseases in England and Wales during the week included pneumonia 709, scarlet fever 1,379, whooping-cough 2,034, diphtheria 34, measles 2,449, dysentery 1,007, acute poliomyelitis 18, paratyphoid fever 15, and typhoid fever 1.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus -----. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

Salmonellae in Duck Eggs

The need to cook duck eggs very thoroughly is emphasized once again by two articles published recently (*Monthly Bull. Minist. Hlth (Lond.)*, February, 1954). The first is a report from the Salmonella Subcommittee of the Public Health Laboratory Service. During the years 1950-2 over 13,000 duck eggs were examined in England, and it is estimated that the salmonella-infection rate of individual eggs was about 0.15%. The second article, by Dr. C. R. Murdock, from the Northern Ireland Hospital Authority, Central Laboratory, is concerned with large batches of eggs examined in Northern Ireland in 1951-3. Salmonellae were isolated from 48.2% of the batches of duck eggs, and they were also isolated from 2.1% of batches of hen eggs. These percentages must depend in part on the size of the batches, which varied between about 4,000 and 20,000 eggs.

Medical News

Sims Commonwealth Travelling Professors.—At a meeting of the Council of the Royal College of Surgeons on March 11 Professor R. I. Harris and Dr. Donald Hunter were appointed Sims Commonwealth Travelling Professors for 1955. Professor Harris, who until recently was assistant professor of surgery at Toronto University and specializes in orthopaedics, has been asked to visit Great Britain, Australia, and New Zealand. Dr. Hunter, director of the Department for Research in Industrial Medicine at the London Hospital, has agreed to visit Canada and Rhodesia.

Medical Society of London Dinner.—The Medical Society of London on March 9 at Claridges Hotel carried out the instructions of its founder, Dr. J. C. Lettsom, that it should hold an anniversary dinner meeting on or about March 8. The chair was taken by the president, Mr. E. W. Riches. The guest of honour was Colonel the Hon. J. J. Astor, and among the guests present were Sir Cecil Wakeley, P.R.C.S., Mr. A. A. Gemmell, P.R.C.O.G., Sir Heneage Ogilvie, President of the Hunterian Society, and Dr. R. Cove-Smith, President of the London Harveian Society. Colonel Astor proposed the toast of the Society. Saying that health came high on the list of priorities, he remarked that it involved an incredible amount of work for an incredible number of people, not to mention that 2,000 journals and periodicals were necessary to disseminate the output of medical knowledge. He answered in the negative his own question, "Is any institution of greater national importance than the teaching hospital?" with authority and conviction as chairman of the Middlesex Hospital. Mr. Riches, replying, referred to the growth of the Society, founded in 1773 for "the advancement of the science of medicine and surgery exclusively." There were now 589 fellows—considerably more than the strength of 30 physicians, 30 surgeons, and 30 apprentices that the founder laid down. Mr. Riches thought that not the least of the Society's achievements was the unity and friendship which it created among medical men. He paid tribute to the officers, Dr. Hope Gosse, Dr. Cuthbert Dukes, Sir James Walton, and Dr. Johnston Abraham, and the work of the Hon. Secretaries, Mr. Nils Eckhoff and Dr.

W. R. M. Drew. The toast of the visitors, proposed by Sir Harold Boldero, was acknowledged by Dr. R. Cove-Smith. Some 200 fellows and guests were present.

Royal Commission on Mental Laws.—The Royal Commission on the Law Relating to Mental Illness and Mental Deficiency (see *Journal*, January 23, p. 221, and February 13, p. 417) is now ready to receive evidence on subjects within its terms of reference, which are:

"To inquire, as regards England and Wales, into the existing law and administrative machinery governing the certification, detention, care (other than hospital care or treatment under the National Health Service Acts, 1946-52), absence on trial or licence, discharge and supervision of persons who are or are alleged to be suffering from mental illness or mental defect other than Broadmoor patients; to consider as regards England and Wales the extent to which it is now or should be made statutorily possible for such persons to be treated, as voluntary patients, without certification; and to make recommendations."

Any persons wishing to submit evidence should send a memorandum of evidence in writing to the secretary of the Royal Commission at 23, Savile Row, London, W.1.

Ciba Foundation.—The Ciba Foundation continues to fulfil admirably its function as an international centre where medical and chemical research workers can meet for informal discussion. Its home in Porton Square, London, gave hospitality to over 500 guests last year. There were five symposia during the year and 28 discussion meetings. The outstanding features of the symposia are that speakers are carefully selected so as to bring together active workers from several countries, current research is freely discussed, and the proceedings are published with little editing as quickly as possible. The subjects of last year's symposia were: "Preservation and Transplantation of Normal Tissues," "The Peripheral Circulation in Man," "The Kidney," "Hypertension: Humoral and Neurogenic Factors," and "Leukaemia Research." Another useful function of the Foundation is the running, with the Institut National d'Hygiène in France, of the Anglo-French Exchange Bursary for recently qualified medical men. In 1953 six British doctors went to France and five French doctors came here.

Germ Warfare Exercise.—In Bahaman waters this year at least 20 miles away from the nearest land and clear of normal shipping routes there will be trials of British defences against biological warfare. There have already been trials off the coast of Scotland to obtain technical data for this year's exercise. This announcement comes from the Ministry of Supply, which maintains the research station at Porton, Wiltshire, where work of this nature is done. Biological warfare could be waged directly against man himself or against his food supplies. For the former virulent micro-organisms (or their toxins) might be used, but presumably these would have to be resistant to chemotherapy and antibiotics and the victim population non-immune. Crops could be attacked by insects or fungi as well as by bacteria and viruses. In either case there would remain the problem of delivering enough active material to the target.

Canadian Journal of Microbiology.—In August the National Research Council of Canada will start publication of the *Canadian Journal of Microbiology*. The journal will appear bimonthly under the editorship of Dr. R. G. E. Murray, Department of Bacteriology, University of Western Ontario. It will publish papers describing original research in all phases of microbiology, regardless of country of origin, and in either English or French. Review papers will not be accepted. The subscription rate will be \$3 a year.

Faculty of Anaesthetists.—The following have been elected by postal ballot to the Board of the Faculty of Anaesthetists of the Royal College of Surgeons: Dr. Frankis T. Evans (London), Dr. William W. Mushin (Cardiff), and Dr. H. J. V. Morton (Hillingdon).

Chair of Bacteriology at Aberdeen.—Dr. Alexander Macdonald, reader in bacteriology at Liverpool University, has been appointed professor of bacteriology at Aberdeen

University. He will succeed Professor John Cruickshank, who has held the chair since 1926. Dr. Macdonald, who is 43, graduated in medicine at Aberdeen in 1937. He takes up his new appointment in the autumn.

Sir John H. Parsons, F.R.S., the ophthalmologist, who is now in his 86th year, has had conferred on him the honorary membership of the Illuminating Engineering Society. Sir John is the oldest living founder member of the society and a past president of it.

Mr. Geoffrey Keynes is to receive from Edinburgh University the honorary degree of Doctor of Laws at the graduation ceremonial on July 8, for his distinguished work as a bibliographer and editor.

Professor A. C. Frazer, professor of pharmacology at Birmingham University, has been appointed honorary consultant in metabolic diseases to the Army.

Dr. Honor Vivian Smith has been elected to the May Readership in Medicine at Oxford for a period of seven years from October 1, 1954.

Mr. E. S. Perkins, Wernher Research Fellow at the Institute of Ophthalmology, has been appointed to the London University Readership in Ophthalmology tenable at the institute.

COMING EVENTS

The Physical Society.—The 38th annual exhibition will be held at Imperial College, South Kensington, London, S.W.7, from April 8 to 13.

Conference of the British Occupational Hygiene Society.—The conference will be held at the London School of Hygiene and Tropical Medicine on April 6. The theme will be the problems arising in industry from the use of materials which present a danger to the health of workers. Further details may be obtained from the honorary secretary, Mr. P. C. G. Isaac, Public Health Engineering Laboratory, King's College, Newcastle-upon-Tyne, 1.

European Association against Poliomyelitis.—A symposium on the hospitalization of poliomyelitis cases during the acute phase will be held at the Clinique Médicale des Enfants, 149, rue de Sèvres, Paris, on April 8 and 9. The general assembly of the association will take place on April 10 at the Institut Pasteur. Further information may be obtained from the Secrétaire-général, Association Européenne contre la Poliomyélite, 130, rue de Linthout, Bruxelles.

Tour of Israel.—The Medical Association of Israel is organizing a 25-day tour of Israel for European physicians and their families, both Jewish and Gentile. The tour will take place in June or July this year, and will include visits to Jerusalem, Tel-Aviv, and Haifa. Travel will be by plane and the inclusive cost about £200. In addition to expeditions to places of historical and contemporary interest, the Israel Medical Association is arranging a medical programme. Further information may be obtained from Dr. Eustace Chessier, 92, Harley Street, London, W.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Friday, March 19

ABERNETHIAN SOCIETY, St. Bartholomew's Hospital.—4.30 p.m., Professor W. Melville Arnott: Aetiology of Cardiovascular Disease.
MIDDLESEX COUNTY MEDICAL SOCIETY.—At Hillingdon Hospital, 3 p.m., clinical meeting. 4.45 p.m., Dr. J. H. Bullen: Medical Curiosities Arriving at London Airport; Dr. H. V. L. Finlay: Urinary Infection in Childhood.

Monday, March 22

INSTITUTE OF NEUROLOGY.—5 p.m., Professor D. Denny-Brown (U.S.A.): Positive and Negative Factors in the Cortical Contribution to Movement.

Tuesday, March 23

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. R. E. Billingham: Experimental Handling of Skin.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor D. M. M'Phersey: Treatment of Obliterative Vascular Disease.
WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., Mr. G. C. Knight: Investigation of Cerebral Tumour.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Dangers of Fowl Pest to Man

Q.—What is the nature of fowl pest prophylactic? Is the eating of a chicken which has fowl pest or has recently been inoculated against the disease likely to cause illness in man?

A.—The two conditions which come under the general term of fowl pest are fowl plague and Newcastle disease. The latter is endemic in this country at the present time. It is, however, a notifiable disease under the Diseases of Animals Acts, is controlled by a slaughter policy, and it is hoped that eventually it will be completely eradicated. The immunization of birds by live virus obtained from the developing egg and by formalinized virus with and without adjuvants has been investigated in America and elsewhere with varying degrees of success. Vaccination is, however, unlikely to be used in this country unless other measures for the control of the disease are unsuccessful, since it is held that its adoption would inevitably lead to the perpetuation of fowl pest as an endemic disease.

There are no authenticated reports of a generalized disease in man. But it has been demonstrated that the virus will set up an acute bilateral conjunctivitis which lasts from three to seven days and may be accompanied by slight systemic disturbance. In one case a veterinary surgeon engaged in poultry diagnostic work developed a Newcastle disease infection of the eye two days after handling chickens in the active stage of the disease. There is no evidence that the virus can infect man through the ingestion of an infected carcass: moreover, the virus is easily destroyed by moderate heat.

Sepsis among Butchers

Q.—My butcher tells me that the superficial pricks and abrasions suffered by his men when handling frozen Argentine meat invariably suppurate and healing is prolonged—a condition which does not occur when dealing with home-killed meat. Can you explain this, and advise how to prevent it?

A.—This experience is not confirmed by the chief meat inspector of a large metropolitan market. Only the bacterial content can explain this effect; there are no chemical or other changes in frozen meat which could account for it. Meat is a good culture medium, and in so far as it becomes contaminated and is held at a temperature permitting the growth of potentially pathogenic bacteria it may come to harbour increasing numbers of them. This rule applies both to frozen and to home-killed meat, and the latter unless very fresh (possibly the butcher mentioned has his own slaughter-house and thus deals in exceptionally fresh meat) can contain as many bacteria as the former.

Presumably the question does not refer to specific infections which can be acquired from meat, such as erysipeloid due to *Erysipelothrix rhusiopathiae*. This is a very intractable condition unless treated with penicillin. For ordinary non-specific sepsis no precautions or treatment can be suggested other than those dictated by common sense—protection of the hands so far as possible against injury, the antiseptic treatment of cuts, etc., and thorough washing after work. If the problem is serious the use of a germicidal soap with a persistent action, such as one containing hexachlorophene, might be worth while. It is as well to mention that a person with staphylococcal skin sepsis should not be permitted to handle meat: staphylococcal food-poisoning can be caused in this way.

Wednesday, March 24

●BRITAIN-CHINA FRIENDSHIP ASSOCIATION: CULTURAL AND SCIENTIFIC COMMITTEE.—At 45, Russell Square, W.C., 7.30 p.m., Dr. H. Joules: Social Medicine in China.
EUGENICS SOCIETY.—At Burlington House, Piccadilly, W., 5.30 p.m., Dr. J. M. Tanner: Physique and Choice of Career.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Viral Diseases of the Skin.
INSTITUTE OF UROLOGY.—4.30 for 5 p.m., Mr. A. C. Morson: Non-tuberculous Infection of the Renal Tract.
●LONDON MARRIAGE GUIDANCE COUNCIL.—At Royal College of Nursing, 7 p.m., Dr. Ethel Dukes: Effect of Early Environment on Marriage.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. T. Rowland Hill: Diseases of the Nervous System in Relation to the Public Health (illustrated).
SOCIETY OF APOTHECARIES OF LONDON.—5 p.m., Seventh Joseph Strickland Goodall Memorial Lecture by Dr. Paul Wood: An Appreciation of Mitral Valve Disease.
WEST LONDON HOSPITAL MEDICAL SCHOOL.—At Medical Society of London, 5 p.m., Seventh Simpson Smith Memorial Lecture by Professor C. G. Rob.

Thursday, March 25

●INSTITUTE OF CARDIOLOGY.—9.30 a.m., Sir John Parkinson: Radioscopy of the Heart.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. J. A. Dudgeon: Viral Diseases of the Skin.
INSTITUTE OF NEUROLOGY.—5 p.m., Professor D. Denny-Brown (U.S.A.): Visuo-Motor Mechanisms in the Cerebral Cortex.
LIVERPOOL MEDICAL INSTITUTION.—7.30 p.m., annual meeting of members. 8.15 p.m., Sir Henry Cohen: The Collagen Diseases and their Response to Cortisone and A.C.T.H.
LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Royal Free Hospital School of Medicine, 8.30 p.m., annual general meeting, followed by a Brains Trust: "What is the Future for Medical Women?"
LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—At Dorchester Hotel, 6.45 p.m. to 1 a.m., annual dinner dance.
ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Professor Ian Aird: Medical and Other Trends in the Union of South Africa (with lantern slides).
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor J. B. Kinmonth: Lymphangiography in Clinical Surgery and particularly in the Treatment of Lymphoedema.
●WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—At South Kensington Hotel, 7.30 for 7.45 p.m., Dinner meeting: Sir Hugh Griffiths: The Doctor in the Witness Box.

Friday, March 26

●INSTITUTE OF ALMONERS.—At B.M.A. House, 6 p.m., annual general meeting. Professor A. Leslie Banks: Clients and Patients.
INSTITUTE OF DERMATOLOGY.—5.30 p.m., clinical demonstration by Dr. B. F. Russell: Epidermal Tumours—Naevoid, Benign, and Malignant.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY.—3.30 p.m., Professor F. C. Ormerod: Foreign Bodies in the Food and Air Passages.
INSTITUTE OF NEUROLOGY.—5 p.m., Professor G. H. Monrad-Krohn (Oslo): Emotional Innervation with special regard to Facial Hyperemia.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.—7.30 p.m., papers by Dr. F. Lancoley, Dr. J. G. Feinberg, and Dr. M. G. McEntegart: Laboratory Aspects of Trichomonas Vaginalis. A discussion will follow.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Urology Lecture by Professor Raymond Darget (Bordeaux): Treatment of Malignant Diseases of the Bladder.
ROYAL SANITARY INSTITUTE.—At Library Lecture Hall, School Street, Darwen, Mr. E. P. McGlynn: Housing; Dr. R. C. Webster: Old Age.

Saturday and Sunday, March 27 and 28

ST. STEPHEN'S HOSPITAL, Chelsea, S.W.—Saturday and Sunday, March 27 and 28, 10 a.m. each day, concentrated week-end course on the Rheumatic Diseases.

APPOINTMENTS

EAST ANGLIAN REGIONAL HOSPITAL BOARD.—A. E. Gibbs, M.B., B.Chir., Senior Medical Officer (Assistant Physician in Geriatrics), St. Leonard's and Walnutree Hospitals, Sudbury; P. J. Dwyer, M.B., B.S., M.R.C.O.G., Registrar in Obstetrics and Gynaecology, East Suffolk and Ipswich Area.
COWELL, T. R., Wymn, M.B., Ch.B., House-physician, Clatterbridge General Hospital, Bebington, Wirral, Cheshire.
WESTON, JOSEPH W., M.R.C.S., L.R.C.P., D.T.M.&H., Senior Hospital Medical Officer, Royal Infirmary, Halifax (Leeds Regional Hospital Board).

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Caldwell.—On February 28, 1954, at Aberdeen, to Margaret, wife of Dr. T. S. Caldwell, Kinlairs, Aberlour, Banff, a son.
Duncan.—On February 14, 1954, to Marjorie, wife of Dr. E. H. Duncan, 69, Norbury Court Road, London, S.W., a second daughter—Julia Mary.
Ecob.—On February 24, 1954, at Southampton General Hospital, to Ann (formerly Griffiths), M.B., Ch.B., wife of Colin Ecob, M.B., Ch.B., a daughter—Elizabeth Ruth.
James.—On February 23, 1954, at the Woolwich Memorial Hospital, London, S.E., to Joyce (formerly Johnson), wife of Dr. C. W. L. James, a brother for David and Rosemary—Brian.
Owen.—On March 3, 1954, at St. David's Hospital, Bangor, to Dr. Gwen Ellis Owen (formerly Hughes), wife of Arthur W. Owen, of Caernarvon, a son.

DEATHS

Ord.—On February 25, 1954, at his home, Bell Close, Marlborough, Wilts, Reginald Whistler Ord, M.R.C.S., L.R.C.P., formerly of Dover, Kent, aged 86.
Pearse.—On February 20, 1954, at Colwyn Bay, Denbighshire, Herbert Henry Pearse, M.R.C.S., L.R.C.P., Surgeon Captain, R.N., retired, aged 86.
Pearson.—On February 24, 1954, at St. Mary's Hospital, Eastbourne, Sussex, Allan Campbell Pearson, M.C., M.B., B.Ch., D.P.H., late of London, S.W., aged 79.
Smith.—On February 23, 1954, at Moseley Bank, Cheshire, Henry Elkington Smith, M.D., aged 81.
Williamson.—On January 8, 1954, at Dumfries, Joseph Bannister Williamson, M.B., Ch.B., Captain, R.A.M.C., retired.

Detergents

Q.—What are detergents and what is their general composition? Have they any harmful effect on plants if applied to the leaves?

A.—The term detergent is often used as synonymous with wetting agent; its true meaning is a cleansing agent. All wetting agents are not good detergents. If the term is used in its broad sense there are three main classes of wetting agents. Nearly all have long carbon chains, and these fatty groups may be negatively or positively charged or the substance may be uncharged. Amongst the former are soaps and the sulphonated fatty alcohols or petroleum sulphonics acids. A well-known example of one with a large positively charged group is cetrimide, which is mainly trimethylcetylammonium bromide. The two groups of charged wetting agents are incompatible and mutually precipitate one another. There is now a large group of uncharged wetting agents such as "Tweens" (polyoxyalkylene derivatives of fatty esters of sorbitan) and the "Tritons" (polymers of derivatives of polyoxyethylene phenols). Wetting agents are very widely used as vehicles for insecticides and other chemicals applied to growing crops. Any phytotoxic effects that have occurred are not usually attributed to the wetting agents contained in the preparations.

Blood Picture in Children

Q.—In what way does the normal blood picture of children differ from that of adults? Is there any difference between the sexes? Please give figures for children aged 3, 6, 9, and 12.

A.—The normal blood picture of children, as distinct from infants, is very little different from that of the adult with regard to the haemoglobin level and the red cell and total leucocyte counts. The differential leucocyte count, however, shows a higher proportion of lymphocytes, the normal adult differential count not being attained until about the 6-9th year. Sex differences in childhood are negligible. The haemopoietic system of the child is more sensitive to extraneous influences than that of the adult. For example, in acute infections, where an adult will respond with a moderate leucocytosis the child may react with a very high count and show a number of myelocytes in the peripheral blood. Sometimes a lymphocytosis may follow a pyogenic infection. Fluctuations in the leucocyte count are often rapid. The following are average normal blood findings at different ages:

Age (Years)	Hb (g per 100 ml.)	Red Cells (in Millions)	White Cells (per c.mm.)	Poly-morphs (per c.mm.)	Lymphocytes (per c.mm.)
3	12.4	4.5	10,000	4,500	5,000
6	13.6	4.7	8,000	4,500	3,000
9	13.5	4.8	6,000	3,500	2,000
12	14.0	5.0	6,000	3,500	1,800

Keeping Qualities of Ether and Chloroform

Q.—For how long will ether and chloroform remain safe and reliable to use for anaesthesia when kept in glass-stoppered bottles away from the light?

A.—It is generally recommended that ether in bottles should not be used after having been kept in store for longer than a period of about 12 months. In copper-lined tins, the period is a little longer. There is still considerable doubt, however, about the possible harmful effects, so far as clinical anaesthesia is concerned, of using ether which has been stored for longer periods. In one important paper on the subject,¹ comparison between the clinical effects of samples of pure and "impure" ether on over 2,000

patients failed to show any significant difference in the course of the anaesthesia or in the frequency of complications.

Similarly for chloroform, one year should be regarded as the safe upper limit for storage.

Multiple Sebaceous Cysts

Q.—Would you please suggest treatment for multiple sebaceous cysts? The man in question has widespread sebaceous cysts over the face and body.

A.—Multiple sebaceous cysts, usually a familial, naevoid affection, may be removed surgically. An alternative treatment is by diathermy needle. The needle point of the active electrode is passed into the cavity through the follicular orifice and a current passed until there is blanching of the skin round the needle up to 3 mm. diameter. A crust forms which in the course of a week can be removed, often bringing the sac away with it. The treatment is described by Robbins and Pensky.¹

NOTES AND COMMENTS

Hazards of Fluoroscopy.—Dr. W. H. TATTERSALL (Bournemouth) writes: I am surprised that you should suggest that a diagnostic chest fluoroscopy session might be continued for as long as three hours ("Any Questions?" February 27, p. 532). In my experience, after about an hour of such work the concentrated mental effort, and the considerable physical exertion involved in moving the patient about behind the screen, call for a rest. Fatigue and the risk of error may increase insidiously after that time; I cannot recollect continuing such a session beyond an hour and a half. For such work the operator must be dark-adapted. Although 65-70 kV at 3 mA may be adequate for the examination of many individuals, it is better to use up to 80 kV and 5 mA so as to examine the patient quickly and confidently, rather than to protract the examination because of hesitation to use a brighter beam. It is then possible to scan the whole chest thoroughly from all possible angles in 60 seconds or so. Allowing another minute for patients to change places, and to record one's findings, it is feasible to examine about 30 persons an hour. Certainly if a fluoroscope is adequately protected and properly used there is no risk to health, but anyone doing this sort of work regularly should make sure that such conditions do exist. It is not difficult to arrange for a physicist to estimate the scattered irradiation with ionization chambers, while the National Physical Laboratory supply test film for the quantitative measurement of an operator's exposure to cumulative irradiation. It seems prudent to avoid approaching the maximum safe dose if one is specializing in this kind of work.

OUR EXPERT writes: The figures I gave are those in current use at hospital and are more than adequate for anybody properly adapted. They are, in fact, those used for barium meal examination. The risk of scatter at the higher kV and mA is, of course, greater. Two or three hours are the usual screening sessions in x-ray departments, provided the sessions and the rota of patients are well organized.

"Any Questions?" Book.—The second book of selected "Any Questions?" is available, price 7s. 6d. (postage 6d.). Copies may be obtained either direct from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1, or from booksellers.

RESULTS OF METHONIUM TREATMENT OF HYPERTENSIVE PATIENTS*

BASED ON 250 CASES TREATED FOR PERIODS UP TO 3½ YEARS, INCLUDING 28 WITH MALIGNANT HYPERTENSION

BY

F. H. SMIRK, M.D., F.R.C.P., F.R.A.C.P.

Professor of Medicine, University of Otago, Dunedin, New Zealand

Except in malignant hypertension, the outlook of the individual hypertensive patient treated only by rest, sedation, and the amelioration of complications is difficult to assess unless the prognosis has evidently deteriorated because of substantial cardiac failure or renal impairment.

Individual prognosis is hazardous, especially in milder cases, but the expectation of survival among large groups of hypertensive patients has been well worked out in terms of their presenting clinical features. Among such groups of patients the expectation of survival is related to the extent of hypertensive changes in the retina, the presence or absence of heart failure, cardiac asthma, breathlessness, substantial electrocardiographic changes and, in a general way, with the height of the blood pressure, especially the diastolic pressure. The age at which the patient begins to show such abnormal manifestations, and the sex, have a strong bearing on outlook. While different views are expressed, a scrutiny of the manner in which authors have gathered their clinical material, and of the age and sex of the patients, reveals that the divergencies are less than would appear at first sight. Differences in case selection, not always of an obvious kind, influence comparisons of the results of medical and surgical treatment.

In many publications on groups of patients submitted to sympathectomy, those who have impaired renal function, who have had heart failure or a previous stroke, or who are 60 years or more may be rejected. The selection may be such that the patients who are operated on have in any case a better outlook than the generality of cases, or a worse one if patients with malignant hypertension constitute a large proportion of the sympathectomy cases. It is important, therefore, to divide up hypertensive cases into a sufficient number of age groups and clinical categories, as these differ greatly in their outlook. Perhaps the clearest demonstration of the importance of subdividing the classes of hypertensives comes from Keith, Wagener, and Barker (1939), who showed the re-

*Communicated in part at a meeting of the British Medical Association (New Zealand Branch) in February, 1953, and in part as Wm. McIlraith Guest Professor, Royal Prince Alfred Hospital, Sydney, October, 1953.

lationship between retinal changes and outlook in a series of hypertensive patients collected at the Mayo Clinic. Their series comprised 146 cases of malignant hypertension (grade IV), 37 of grade III, 26 of grade II, and only 10 of grade I. Possibly the preponderance of severe cases is related to the fact that patients are sent from a distance to the Mayo Clinic. My experience has been that cases referred from a distance are on average more severe.

The object of the present paper is to give an account of our experience with methonium treatment of hypertensive cases, mostly of substantial severity, over a period of three years and seven months. Over 250 patients have been treated. The effects of treatment upon the clinical manifestations secondary to hypertension have been of the same kind irrespective of the cause of high blood pressure. Later results confirm and to some degree improve on those published earlier (Restall and Smirk, 1950; Smirk and Alstad, 1951). This paper mainly concerns problems which could not be dealt with adequately at an earlier stage. Results in malignant hypertension (excluding nephritis) and in patients with hypertensive heart failure or cardiac asthma are given in detail. In the mortality studies on malignant hypertension we have reported on 28 patients, including all who died and all living patients on treatment for five months or more. In mortality studies on patients in grades III, II, and I, almost all the 142 patients have been on treatment for periods between one and three and a half years. For comparison there is a series of 71 untreated patients investigated by the same methods. These control cases were mainly patients who presented themselves for investigation and possible treatment on or after November, 1949, and were judged suitable for methonium treatment. They were not treated, either because of shortage of supplies or because they decided against treatment. On the whole these cases were somewhat milder than those treated.

It has become clear that there is a significant improvement in the life expectation of malignant hypertension cases. Other groups also show an improvement, but further observation will be needed before definite conclusions can be drawn.

Reports of clinical improvement with effective methonium treatment have been published by Rosenheim (1952), McMichael (1952), and Morrison (1953). There is general agreement concerning the character of clinical improvement when it occurs.

Method

The technique of treatment and the methods of determining the adequacy of control over blood-pressure levels have remained the same in principle but have improved in detail in the course of the past three and a half years. The methods used have been described elsewhere (Smirk, 1950, 1952b, 1952c; Smirk and Alstad, 1951; Kilpatrick and Smirk, 1952). The method at present advocated has been described recently (Smirk, 1953a, 1953b). Greater detail is available in the latter paper.

1. Mortality Experience in Treated and Untreated Patients

Survival Times of Patients with Malignant Hypertension

All cases classified here as malignant hypertension have shown a clear-cut papilloedema, with some other retinal manifestations, such as circumpapillary oedema, hard and soft exudates, retinal haemorrhages, etc. In case of doubt the binocular ophthalmoscope was employed. No case diagnosed as malignant hypertension has been excluded from the series, but cases of nephritis are not included even though the fundal changes are of the grade IV type. Our malignant hypertension patients comprise 28 who have been on continuous treatment with methonium salts; four others who were on treatment for a time and then stopped; and 11 patients who were untreated, these having been seen mostly in the years before methonium treatment started. The results are set out in Tables I and II.

M.S. = Months of survival. * Sympathectomy.

TABLE II.—Average Periods of Survival

	Group A				Group B				Group C			
	Died		Survived		Died		Survived		Died		Survived	
	No.	M.S.	No.	M.S.	No.	M.S.	No.	M.S.	No.	M.S.	No.	M.S.
Treated with methonium	1	6	12	24	0		8	18.9	6	10.3	1	39
Controls (local)	1	6	2	28	6	1.87	0		2	1.25	0	
Controls (Keith <i>et al.</i> 1949)	5	13.3	4	26	8	1.8	2	9	4	1.3	0	

M.S. = Months of survival.

Of the treated patients seven died after periods of treatment lasting 10, 15, 31, 6, 2, 4, and 1 months. The clinical state and reaction to treatment of the patients who died are set out below:

Case E8 was admitted in a moribund condition. Case 227 was close to uraemia with repeated vomiting and high total N.P.N. He improved for a time, but died in three months from uraemia. Cases 76, 52, and 49 were admitted in advanced congestive failure with severe cardiac asthma. They improved for a time: Cases 76 and 52, up to the time of their deaths by cerebral haemorrhage, were active, able to climb stairs, and looked after their own homes. Case 49 recovered from heart failure and was able to climb stairs, but developed bilateral pneumonia, from which she died. She had poor renal concentrating capacity, and the underlying condition was partly responsible for a fatal outcome. Case 206 had extreme dryness of the mouth and loss of appetite under effective methonium treatment which had cleared his papilloedema. During attempts to modify and improve the regime he got out of control and developed acute pulmonary oedema, from which he died. Case 337 had advanced renal changes and died from intercurrent infection. Of the patients who were not treated, 9 out of the 11 were dead in six months; two are alive, one at 24 months and one at 32 months, the latter having had a sympathectomy. The four additional patients who had a period of treatment and then stopped treatment had 3, 3, 17, and 7 months under methonium treatment and showed the usual degrees of clinical improvement while on treatment; they survived periods of 3, 15, 1, and 2 months without treatment before death occurred.

Of the 21 surviving patients, 15 are leading productive lives: 11 men are at work, and 4 women are doing housework. Two male patients are expected to return to work within a few weeks (Tables III and IV).

One female patient who managed her house and garden for 28 months became completely incapacitated by a hemiplegia during the last nine months.

Mortality Figures in Patients Who Could Have Been Considered for Surgical Treatment

A high proportion of our patients with malignant hypertension presented in a condition in which sympathectomy could not have been contemplated (group A on the classification of Keith, Woolf, and Gilchrist, 1949). There were others with disabilities which would not have altogether prevented sympathectomy—such as a previous major cerebral accident (two cases), an older age group than is ordinarily accepted (two cases), or a degree of cardiac failure or cardiac asthma (four cases) which, though it does not prevent sympathectomy in less serious cases, is associated with a worse prognosis in malignant hypertension (group B on the classification of Keith *et al.*, 1949). Seven patients presented with advanced cardiac or renal changes (group C).

When, however, we consider the results of adequate methonium treatment in patients who do not have any of the above-mentioned objections to sympathectomy, we find that up to the present only one patient out of a total of 13 has died. This patient lived for six months. The surviving patients in group A have lived for an average of 24 months. In a group of patients selected in a similar way by Keith *et al.* (1949) and treated by rest and sedation, five died at

13.3 months and four survived for an average of 26 months. We had eight patients who came to us before methonium treatment was available and also three patients with malignant hypertension who refused treatment or came when supplies were insufficient. Of these 11 patients, nine died at an average of 1.8 months, and two, including a sympathectomy case, have survived for an average of 28 months after the first diagnosis of malignant hypertension was made.

Comparison of the Groups with the Series of Keith *et al.* (1939)

Our control series of untreated malignant hypertension cases is only 11 in number, but our experience has corresponded with that of Keith *et al.* (1939) in a much greater series. In the present series of untreated patients 18% were alive at 18 months; in the methonium-treated group 75% were alive at 18 months.

Comparing similar groups of patients with malignant hypertension, methonium treatment has been associated with extension of the survival period.

Survival Times of Patients with Essential Hypertension (Grades III, II, and I)

The grades of hypertension referred to above are those of Keith *et al.* (1939). Grade I cases show minimal or no retinal changes; grade II show distinct hypertensive changes in the retinal arteries, such as nipping of the arteriovenous crossings or waist-like narrowings of arteries, but no other changes; grade III show haemorrhages, hard or soft retinal exudates, retinal oedema, or some combination of these but without papilloedema. In certain cases retinal oedema encroaches on the disk edge and blurs its outline, but does not lead to actual elevation of the disk: such cases have been classified as grade III, the doubtful cases being examined for papilloedema by the binocular ophthalmoscope. Thirty-four patients and 15 controls were classified grade III; 89 treated patients and 38 controls were grade II; 20 treated patients and 7 controls were grade I. A total of 142 were treated (the great majority for 12 to 42 months). The 60 controls were collected over the same period of time.

The deaths are set out in Tables V and VI. With both treated and control patients it is evident that the mortality experience with grade III is less favourable than with grade II, and grade II less than grade I, in which latter there were no deaths in either the treated or the control series. The results of treatment in grade II may be approaching statistical significance, but the results in grade III as set out in Table V do not seem so promising. The number of patients in this group and the duration of experience are insufficient to justify any conclusion. It should be mentioned, however, that seven of the grade III cases were of much greater severity than any of the control series, and four of the deaths occurred in this group. Were these seven patients not counted, so making the treated and control

series more comparable, the difference in mortality would still not be great—33% deaths among controls and 22% among treated patients.

When grades II and III are considered together the mortality difference shows that more experience is needed before a definite pronouncement can be made. The obvious betterment in health and the statistical significance of the results in malignant hypertension give grounds for hope that the figures may be improved by the use of more effective methods of obtaining control over blood-pressure levels—as, for example, by the use of M. & B. 2050A orally or in a solution of polyvinylpyrrolidone for subcutaneous injection (Smirk, 1952a, 1953a, 1953b).

2. Changes in the Physical State of Patients with Malignant and other Forms of Hypertension

Effect of Control of Blood-pressure Level on Retina in Malignant Hypertension

Papilloedema cleared in 21 out of 23 patients who were on effective treatment for five months or more; the two who have not cleared at five and six months are much improved and look like doing so. Eight other patients showed improvement, but papilloedema was still perceptible at the last observation made. These include patients who did not maintain treatment (two cases) or went off treatment (two cases) or died within six months (three cases with renal insufficiency). The remaining patient has been on treatment about three months. In most instances disappearance of papilloedema takes three to four months, sometimes six months, of intensive treatment; and a reduction of blood pressure to normal or near normal levels at the trough of the fall is necessary. With the better control obtained latterly, it has been our experience that papilloedema can be dispersed in almost all instances and that failure to do so after four months' treatment is usually an indication that the blood-pressure reduction is insufficient in degree and duration. A clear reduction in the amount of papilloedema should be evident in three to four weeks, with reappearance of a physiological cup or of a part of the disk edge. The last residues of oedema take longest to disperse. It often happens that one disk is entirely clear of papilloedema and the other has lagged behind in improvement.

Within the first month of effective treatment soft exudates should have disappeared, there should be no fresh haemorrhages, and as a rule old haemorrhages have been dispersed. Hard exudate at this stage usually stands out shiny and with sharp edges. With effective treatment the hard exudate begins to soften at the edges and loses some of its shiny clear-cut delineation, looking more like soft exudate in some instances. Substantial dispersal of hard exudate is unlikely under six months and some may remain after 12 months, but it will be absorbed in most patients who have been under effective treatment for 12 to 18 months. In a few instances the edge of the disk will remain a little fuzzy as the result of post-papilloedema changes.

Examinations of such patients with the binocular ophthalmoscope have been made in most cases by Dr. Rowland Wilson in order to be sure that this was not residual papilloedema. New blood vessels round the edge and sometimes on the disk are a common residual finding after the papilloedema. In some instances the disk is pale, suggesting a minor grade of optic atrophy even though vision is good. The generalized vasospasm of so many patients with malignant hypertension tends to disappear and the general calibre of the arteries returns almost to a normal level. Such arterial changes as nipping of the arteriovenous crossings and waist-like narrowings in the course of arteries remain behind, but I am unable at this stage to comment on the question of whether any recession in such changes occurs or not.

At an early stage of our work a few patients with malignant hypertension were treated by continuous subcutaneous administration of hexamethonium bromide over a period of approximately 12 days, using an electrically operated power-driven syringe (Smirk, 1951). By this means the blood

pressure was kept only a little above the normal level day and night. Papilloedema then seemed to clear much more rapidly than with intermittent blood-pressure falls from thrice-daily injections of aqueous hexamethonium bromide. Preparations have been devised which are absorbed more slowly owing to admixture with polyvinylpyrrolidone or dextran. The most satisfactory of these is the longer-acting methonium compound M. & B. 2050A dissolved in 20% aqueous polyvinylpyrrolidone, ephedrine hydrochloride being added to 1 in 200 concentration in order to prolong absorption by local vasoconstriction. With two, or at times three, injections daily of this preparation it has been possible to obtain a much better control than with three injections daily of aqueous hexamethonium bromide. In most instances oral administration of M. & B. 2050A is equally satisfactory. Under these conditions, apparently related to the better control over blood-pressure levels, dispersal of papilloedema and of other retinal manifestations seems to be accelerated.

Effect of Control of Blood-pressure Level on Retina in Patients with Grade III Changes

The appearance in these patients is similar to that in malignant hypertension except that there is no elevation of the optic disk. The disappearance of retinal haemorrhages, soft exudate, retinal oedema, and finally of hard exudate takes place in much the same way as in malignant hypertension.

Effect of Control of Blood-pressure Level in Heart Failure, Cardiac Asthma, and Simple Breathlessness

Hypertensive congestive heart failure or cardiac asthma was relieved by methonium therapy without the use of digitalis, mersalyl, or salt-free diet in 20 of the 36 cases. In most instances patients returned to the degree of activity appropriate to their time of life. Of the remaining 16 cases, seven required digitalis or mersalyl initially; but later, when methonium therapy was well-established, digitalis and mersalyl were withdrawn without recurrence of failure. In one patient who went into heart failure while on digitalis the failure was controlled by blood-pressure reduction; digitalis was omitted, but it was not possible to manage without a salt-free diet. In five other patients who went into failure while on digitalis (ages 51, 71, 70, 60, and 80) the breathlessness was considerably lessened, but remained an important disability and the digitalis could not be withdrawn. In three patients there was deterioration. In one we had been unable to establish an effective regime because of side-effects; in another case necropsy revealed that an extensive left ventricular infarction had maintained heart failure; in another uraemia and left heart failure were associated.

Of 27 patients under 60 years, six did not work, 11 men returned to gainful employment (one died later from a stroke), and 10 women were engaged in housework (two died later from a stroke).

With a few exceptions it has been possible to remove cardiac asthma and congestive heart failure and to render breathlessness unimportant without recourse to digitalis, mersalyl, or salt-free diet, except that a regime of "no added salt except in cooking" is sometimes advised. In a few instances where digitalis was in use before the patient came into hospital the dose was maintained at the level on which the manifestations of congestive failure had developed.

Attacks of cardiac asthma can be cut short by the administration of an appropriate dose of hexamethonium bromide or one of the other effective methonium salts, the patient being propped up in the sitting posture. If by fractional administration the blood pressure is reduced to as near normal as the patient will tolerate, a great degree of relief from breathlessness is commonly encountered as the blood pressure falls, even in cases of severe cardiac asthma. Fractional administration is advised because, were the dose given an excessive one, the normal counter-measure of

lowering the patient to the horizontal position in order to re-elevate the blood pressure could scarcely be applied if there was considerable orthopnoea.

It is a considerable advantage to heart-failure patients if the use of digitalis, mersalyl, or salt-free diets can be avoided because in most cases heart failure due to hypertension can be relieved without these measures. Recurrence of breathlessness provides a very useful warning that the degree of control over blood-pressure levels is insufficient. Sometimes, however, it is not possible to dispense with additional measures at the outset. It is better then to supple-

ment methonium treatment by occasional injections of mersalyl, since when these are omitted it will soon be discovered whether the regime has allowed a sufficient recovery of the cardiac muscle. In about one in four cases, and especially in the elderly, a digitalis regime may be required as well as blood-pressure control.

Effect of Control of Blood-pressure Level on the Electrocardiogram

Reference was made in an earlier publication (Smirk and Alstad, 1951) to improvement in the electrocardiogram

Before

After

FIG. 1.—Case 204, male aged 45. The x-ray film prior to treatment was taken August 28, 1951, and corresponded with mild congestive heart failure and attacks of cardiac asthma. These cleared on methonium treatment without other measures. The patient returned to work. Second film was taken May 4, 1953.

Before

After

FIG. 2.—Case 14, male aged 46. Before treatment there was mild breathlessness but no congestive failure or cardiac asthma. The first x-ray film was taken on January 27, 1950. Breathlessness cleared on methonium treatment. The second film was taken on June 12, 1953.

following effective blood-pressure reduction. These changes did not take place at once in response to the lower blood pressure, but were progressive over a period of up to a year or more. The results in our series of cases have been analysed since by Doyle (1953), and his report on hypertensive patients in general applies equally to malignant hypertension cases. With effective blood-pressure reduction of sufficient duration, the voltage of the R and S waves is decreased; the depressed ST segments in leads reflecting left ventricular potentials ordinarily return to the isoelectric level; inverted T waves in the left ventricular leads either become less inverted or become positive; raised ST segments and over-average T waves in leads reflecting right ventricular potentials and the cavity side of the left ventricular potentials show a return of the ST segment towards the isoelectric level and a decrease in the height of the T waves. A useful working rule is that if electrocardiographic defects show no improvement within a few months there is need for a more substantial control over blood-pressure levels. At a later stage any relapse of electrocardiographic signs has the same significance. Necropsy evidence has shown that, at least in some instances, gross muscular hypertrophy remains even though the electrocardiogram has returned almost to normal.

Effect of Control of Blood-pressure Level on Heart Size

It has been reported already that an unequivocal decrease in heart size is encountered not only in patients who have had congestive heart failure but in a small proportion of

FIG. 3.—The figure surveys the changes in transverse heart diameter following methonium treatment. The number of patients with increase of diameter is shown by hatched columns; the number of patients showing decrease is denoted by black columns.

patients who have not had heart failure. Taking patients who have not had heart failure, there appears to be a general trend towards decrease in heart size as judged by measurement of the cardiac silhouette, though most of the individual changes in heart size lie within the possible range of variation for repeated x-ray pictures on the same individual. Fig. 1 shows an example of the effect on heart size of hexamethonium bromide in a patient with congestive heart failure; Fig. 2 an example of decrease in heart size in a patient who had no heart failure. Fig. 3 shows the changes of heart size in 76 patients after periods of several months to three years on treatment. It will be seen that when the change is outside the usual limits of variation it is more usually in the direction of decrease.

Effect of Control of Blood-pressure Level on Headache and Giddiness

The effect on headache and giddiness was referred to in earlier papers (Restall and Smirk, 1950; Smirk and Alstad, 1951), where it was indicated that failure to relieve headache and giddiness with an adequate regime was most exceptional. In preliminary discussions with patients the prospect of such relief may be mentioned as highly probable if they are prepared to take an amount of trouble comparable to that of a diabetic patient on insulin. In order to obtain such results the regime must be adjusted in terms of the reaction of the individual patient to the hypotensive agent. Thus, three adequate injections daily of hexamethonium bromide subcutaneously with adoption of

the sitting posture throughout the night (body inclined at 45 degrees from the horizontal) commonly relieves headache. Some patients, however, still have morning headaches on this regime. The administration of an extra dose of hexamethonium bromide before retiring or the administration of an appropriate number—say 1 to 4—tablets of hexamethonium bitartrate with a little food to prolong the absorption will often, when combined with the sitting posture, prevent the development of headache the next morning. The administration of hexamethonium bromide in 20% polyvinylpyrrolidone proved more effective than the simple aqueous solution.

Latterly a further advantage has been obtained by the use of M. & B. 2050A in polyvinylpyrrolidone with 1 in 200 ephedrine hydrochloride incorporated in the mixture in order to delay further the absorption from subcutaneous tissues. A suitable injection at night commonly prevents morning headache. Alternatively or additionally an appropriate dose of M. & B. 2050A by mouth, usually taken with a little food so as to delay the absorption further, will relieve morning headache. From what has been said it should be clear that, in order to obtain relief from headache in almost all cases, a number of clinical trials have to be made and individual regimes devised to suit particular patients.

Discussion

Our results represent, at the most, the experience of three and a half years, and with the majority of patients a shorter time; but, even so, if our data be accepted there has been a fundamental change in the immediate outlook as regards survival of malignant hypertension patients as well as amelioration of symptoms and signs as reported previously (Restall and Smirk, 1950; Smirk and Alstad, 1951). This is achieved by methods which unfortunately need scrupulous long-term control and great expenditure of time, and which in general are not, but sometimes are, hard on the patient because of side effects.

The object of treatment is to reduce the blood pressure to near normal levels for as much as possible of the 24-hour day. A few patients have been treated by hexamethonium bitartrate by mouth, others by three daily injections of appropriate doses of aqueous hexamethonium bromide. Later the hexamethonium bromide was dissolved in 20% or 25% polyvinylpyrrolidone in order to prolong the period of absorption, and in some instances a further prolongation was effected by the addition of 1 in 200 ephedrine hydrochloride to the injection mixture. In the last fifteen months several patients have been treated by a new methonium compound, M. & B. 2050A (Smirk, 1952a, 1953a, 1953b; Wien and Mason, 1953; Maxwell and Campbell, 1953). This substance, dissolved in 20% polyvinylpyrrolidone, particularly when 1 in 200 ephedrine hydrochloride is added to prolong absorption by local vasoconstriction, acts more effectively than some 12 other methonium compounds which we have tested. The substance has the advantage that it may be administered also by mouth in most cases, with effective reduction of blood pressure. The detail of the method of controlling the dose of a methonium compound has been simplified (Smirk, 1953a, 1953b), but the method of control here advocated does not differ in principle from the more cumbersome methods used at an earlier stage in the treatment of this series of patients. Without control over the blood-pressure level of sufficient degree and duration the results of methonium therapy are most disappointing.

Common errors include: neglect of day and night control of posture; control of dosage in terms of occasional casual blood pressures; neglect of drug toleration; use of oral hexamethonium in cases in which this is ineffective; in injection treatment the use of syringes graduated in 0.2 ml. instead of 0.01 ml.; and the absence of effective instruction to patients with a written account of their regime.

In our patients, blood pressures are measured by technicians throughout six or seven hours of the day at approximately half-hourly intervals for five or six days of the week

and for three weeks. During this period each dose is adjusted in terms of response to previous doses—a kind of biological assay. The patient thereby gains a considerable insight into the principles underlying treatment. After the initial three weeks the patient attends the hypertensive clinic—weekly at first and later at longer intervals. Occasional all-day tests are made, but most of the control at this stage is in terms of hypotensive symptoms. Casual blood pressures are taken, but they are of very little use in the control of dosage. Quite high blood pressures may be encountered in out-patients whose blood pressure, with methonium, is satisfactory under home conditions.

Summary

On three and a half year's experience it appears already that the prognosis of malignant hypertension is much improved by effective control over the blood-pressure level by the administration of methonium salts.

The result of treating all of 28 malignant hypertensive patients, including seven with substantial renal insufficiency or advanced heart failure, is that 21 are living and seven dead. The average survival time of those who died is 9.7 months and of those who are still alive 22.8 months. A considerable majority of the survivors are leading productive lives, the men working at their previous occupations and the women doing housework.

In hypertensive patients with retinal grades II and III, taken together, the mortality figures are better in 122 treated cases (16.4%) than in 53 controls (28.2%), but no claim of statistical significance is made.

Objective improvements include: (a) the disappearance in most cases of such changes as papilloedema, retinal oedema, soft exudates, haemorrhages, and, after long treatment, of star-shaped macular figures; (b) the return to work of most patients under 60 presenting with malignant hypertension, cardiac asthma, or congestive heart failure, including in most instances the elimination of the use of digitalis, mersalyl, or substantial salt restriction; and (c) the electrocardiographic improvement and tendency to decrease of heart size. The consistency with which these results have been reproduced during three and a half years leads me to state that less satisfactory degrees of improvement are usually due to inadequacy of the regime used.

In a minority of patients the doses of methonium salts which relieve hypertensive manifestations lead to much discomfort from side-effects. Methods of alleviation which have helped some cases are suggested.

Acknowledgment is made to Miss M. Poppelwell for secretarial assistance, to the Otago Hospital Board for helpful co-operation, and to May & Baker Ltd. for supplies of hexamethonium bromide and of M. & B. 2050A. Expenses have been defrayed in part by the Medical Research Council of New Zealand.

ORAL CORTISONE TREATMENT OF HYPOPITUITARISM

BY

H. L. SHEEHAN, M.D., D.Sc., F.R.C.P.,
F.R.C.O.G.

Professor of Pathology, University of Liverpool

AND

V. K. SUMMERS, M.D., M.R.C.P.

Consultant Physician, Walton Hospital, Liverpool

In early trials of the therapeutic value of cortisone in hypopituitarism, the hormone was given in large dosage (75 to 100 mg. daily) for periods of about one to three weeks. The results were encouraging, but in some ways not satisfactory (Summers and Sheehan, 1951). Other workers using this dosage observed no beneficial effects (Robertson and Kirkpatrick, 1951; Brown and Greenblatt, 1952). Since then, a much lower dosage of cortisone has been tried for the continued treatment of these patients. Originally the cortisone was given either by injection or by implantation of pellets, but more recently oral therapy has been found just as efficient and far more convenient. Reports of single cases treated for long periods with doses of 12.5 to 25 mg. daily have been published by Thorn *et al.* (1950, 1951), Clark *et al.* (1951), Levy (1952), Perkins and Rynearson (1952), Roberts *et al.* (1952), McCullagh and Schaffenburg (1953), Tardy (1953), Dontigny (1953), Mathisen (1953), and Fourman and Horler (1954). More recently, a series of three cases treated in this way have been recorded by Hart (1953), and two cases by McCullagh *et al.* (1954). All these workers have reported good results from prolonged therapy at low dosage.

A few investigations have been made of the therapeutic value of cortisone in the treatment or prophylaxis of hypopituitary coma (Allott and Simmons, 1951; Sheehan and Summers, 1952; Paniagua *et al.*, 1952; Caughey *et al.*, 1952; Hijmans, 1952; Heyde, 1953). In addition there have been several reported studies of the effects of cortisone administered for very short periods for diagnostic tests or physiological studies, but these are not of direct relevance to the subject under consideration here.

Treatment of Present Cases

The following account concerns four patients with severe hypopituitarism who have been given small doses of cortisone orally over periods of about two years. Three of these were typical examples of severe hypopituitarism due to post-partum necrosis; the fourth was a man with hypopituitarism of unknown aetiology, probably due to some form of atrophy and scarring of the pituitary.

The patients were studied for a preliminary observation period of two to three weeks without treatment, and for a further control period of five weeks, during which 3 gr. (0.2 g.) of thyroid siccum was given daily. No significant effect was noted from the administration of thyroid. (This point merits a short interpolation. The warnings given in almost all textbooks about the dangers of thyroid therapy in patients with hypopituitarism appear to be overstated. Most of these patients tolerate ordinary dosage of thyroid without any recognizable ill effect. From a study of the occasional cases reported in the literature where the administration of thyroid was followed rapidly by coma, it seems probable that the patients were already on the point of developing coma in any event. Nevertheless, when

thyroid treatment is given, reasonable care should be taken. If the dosage is raised too much because of the lack of response, gastro-intestinal upsets and loss of weight can be produced; these two effects are serious in any patient suffering from hypopituitarism.)

After these periods of preliminary study, cortisone was given orally as "cortone" without any other treatment. The initial dosage was 12.5 mg. daily for one to two weeks, followed by 25 mg. daily for two to four weeks. In one patient it was increased to 37.5 mg. for two weeks and to 50 mg. for one week. Subsequently the amount was gradually reduced in all cases to 12.5 mg. daily as a maintenance dose. When the dosage was raised to 25 mg. one of the patients began to complain of insomnia. Another patient slept satisfactorily with this amount but had insomnia when the dose was increased to 37.5 mg. daily; she recovered when it was reduced to 25 mg. again. In all subsequent treatment the dosage was maintained at a level low enough to allow normal sleep.

Clinical Effects of Treatment

In all four cases there was a marked improvement in the general condition within three or four days. The patients became mentally alert and took a normal interest in their surroundings. They had an obvious sensation of well-being, became physically energetic, and were no longer sensitive to cold. Thus they were able to resume all their ordinary activities in the home and outside. The improvement was maintained satisfactorily on a daily dose of 12.5 mg.

The initial period of treatment with 25 mg. produced in all cases a normal capillary flush of the cheeks, a return of axillary secretion, and the occurrence of sweating on exercise. This improvement, once established, was maintained by 12.5 mg. daily. No changes developed in the face or elsewhere suggestive of a Cushing syndrome, even after two years' treatment. An experimental increase of the dosage to 50 mg. daily in one patient caused excessive perspiration.

Two of the female patients had no change in body hair, but the third female patient developed a small amount of pubic hair and some thickening of the head hair after six months' treatment. The male patient, in the course of six months' treatment, developed a slight amount of pubic hair and a slight return of hair on the legs; his beard became stronger, so that he needed to shave daily instead of once or twice a week.

The amenorrhoea was not affected in any way. No exact details are available about the libido of the female patients, but there was a return of a normal degree of pudor. Striking changes were, however, observed in the male patient, who for the previous five years had been completely without libido and had had no erections or other evidence of sexual activity. During the first three weeks of treatment with 12.5 mg. and 25 mg. of cortisone daily there was no obvious change. When he was given 37.5 mg. daily he began to have erections two or three times a week. After discharge from hospital on a maintenance dose of 25 mg. daily he continued to have frequent erections and had coitus two or three times a month, although no emissions occurred.

In two patients the blood pressure remained unchanged, the levels before treatment having been 130/80 and 140/90. In the third patient there was a slight rise, from 125/75 before to 140/75 during treatment. The fourth patient developed an irregularly increasing hypertension. The blood pressure was 130/80 previously and rose slowly during the first year of treatment to levels fluctuating between 150/90 and 180/130; subsequently it gradually returned to its original level.

Two of the patients had a definite increase in weight during several months' treatment; one rose from 104 to 135 lb. (47.2 to 61.2 kg.), and the other from 107 to 130 lb. (48.5 to 59 kg.). The third patient had a slight weight gain, rising from 92 to 96 lb. (41.7 to 43.5 kg.). The fourth patient lost weight during the thyroid treatment, falling from

162 to 151 lb. (73.5 to 68.5 kg.); on cortisone treatment she gradually regained this lost weight, and remained at 160 to 165 lb. (72.6 to 74.8 kg.).

Biochemical Changes

With these small and slowly increasing doses of cortisone there was none of the gross polyuria which follows immediately after parenteral treatment with high dosage. Nevertheless the urine volume slowly increased. Three of the patients had the following mean urine outputs before treatment and while on maintenance dosage respectively: (a) 1,120 and 1,680 ml., (b) 1,150 and 1,730 ml., and (c) 1,100 and 1,900 ml.

Kepler water diuresis tests were made on two of the patients. One whose maximum diuresis on the morning of the test had been 30 ml. an hour before treatment had a maximum of 140 ml. after treatment. The other had a previous maximum hourly excretion of 100 ml.; this increased during treatment to 165 ml. an hour.

It is well known that there is a great increase of nitrogen excretion in the urine when large doses of cortisone are given. This did not occur in the present series with low dosage. In one case the daily output of urea was unaffected by the treatment; in another there was a slight fall in the output of urea and creatinine, possibly in relation to nitrogen storage in the muscles.

There was always an increased output of 17-ketosteroids in the urine. Before treatment the output in the four patients had ranged between 0.2 and 1 mg. a day. On the maintenance doses of 12.5 to 25 mg. daily the urinary excretion of 17-ketosteroids ranged between 2.1 and 2.8 mg. a day. The increased output of 17-ketosteroids expressed in mg. daily corresponds to about 6% of the daily dosage of cortisone.

No significant changes were observed in the serum chemistry. The serum sodium remained at about the low range usual in these patients (280 to 300 mg. per 100 ml.) and the serum potassium fluctuated between 17 and 20 mg. per 100 ml. The serum cholesterol showed the usual wide fluctuations between 105 and 355 mg. per 100 ml., without any recognizable effect of treatment. The blood urea was rather high (commonly about 35 to 65 mg. per 100 ml.), but again there was no constant change related to the administration of cortisone.

There was no very significant alteration in the sensitivity to insulin, but the patients commonly showed some improvement in their response to hypoglycaemia. Several insulin-tolerance tests (using 0.03 unit per kg.) were performed in three of the patients; the mean blood sugars, expressed in mg. per 100 ml., were as follows:

Patient	Minutes:	0	20	40	60	120
A	Before treatment	72	52	37	40	42
	During "	77	49	49	54	66
B	Before treatment	95	67	50	63	65
	During "	96	61	63	73	74
C	Before treatment	102	57	66	73	88
	During "	86	63	64	68	81

The basal metabolic rate was studied in detail in only one patient. It had been -20% before treatment and continued in the range of -20% to -30% during cortisone treatment.

There was a definite though variable improvement in the anaemia. One patient with R.B.C. 4,100,000 and Hb 80% improved gradually to R.B.C. 4,700,000 and Hb 93%. The second patient, with R.B.C. 3,400,000 and Hb 70%, rose to an average of R.B.C. 4,200,000 and Hb 82%. The third patient with R.B.C. 4,000,000 and Hb 72%, rose to R.B.C. 5,000,000 and Hb 100%.

Effect of Cessation of Treatment

In three of the patients the cortisone therapy was stopped for a period of three months after about nine months' treatment. This produced a gradual but progressive deterioration in the

clinical state, so that at the end of a month they were almost back to the same condition as before treatment. They complained of marked asthenia, lack of perspiration, sensitivity to cold, and low urine output. The female patient who had had some return of pubic hair and thickening of head hair during treatment showed considerable regression of this hair growth after cessation of the cortisone. The male patient noticed that he required to shave very much less often, and his libido and erections had disappeared entirely within about two months. Two of the patients began to complain of rheumatic pains in the knees and ankles about two months after stopping treatment, though there were no recognizable physical changes in the joints.

After the three months without cortisone these three patients were put back on the maintenance dosage of 12.5 mg. daily, as it was clearly necessary for their continued health. Their condition improved rapidly, and within about a week they were as well as they had been when under cortisone therapy previously. All the patients have continued in remarkably good health for the past year on this maintenance dosage, and there is nothing to suggest any loss of effect of the cortisone after two years of treatment. It is important to note that none of the patients have, up to the present, developed hypopituitary coma or any of the symptoms which accompany its incipient stages. This may possibly be related to the improved responsiveness to hypoglycaemia.

Effects of Large Dosage

As was recorded in our previous paper, though large dosage of cortisone produced a striking improvement in the physical condition, psychological disturbances changed the patient's attitude so much that prolonged treatment with large dosage was impossible. Similar observations have been made in three further cases given large doses during the past two years. Two of these patients were typical severe cases of post-partum hypopituitarism; the third patient, also female, suffered from hypopituitarism of uncertain aetiology. These patients were given cortisone orally in a dosage of 50 to 100 mg. a day for one to three weeks. There was usually an improvement in the physical condition for two or three days, but then various psychological disturbances occurred. One of these patients had previously been mentally normal, though dulled by the pituitary deficiency. When she was given large doses of cortisone she developed insomnia and had mild delusions. The second patient had always had a psychotic personality. During the control period she suffered from a variety of delusions, though she had lucid intervals lasting a few days. While on treatment she became definitely worse mentally and was very negativistic. The third case is of particular interest.

A woman aged 58 had had typical severe post-partum hypopituitarism since the age of 33. She had been receiving 100 mg. of testosterone weekly for two years before the present admission. During the last few months she had gradually developed, in addition to her hypopituitarism, what appeared clinically to be a true myxoedema (not what is sometimes called pituitary myxoedema), with coarse scaly skin, gross oedema of the orbits and lips, a croaking voice, and a rapidly progressive loss of head hair. Psychologically she varied between torpor and vulgar abusiveness; her behaviour became what is commonly described as "nasty drunk." She was given 100 mg. of cortisone daily for two weeks. This had no recognizable effect on the physical signs of myxoedema, and her mental condition deteriorated further. She was then given 3 gr. (0.2 mg.) of thyroid siccum daily. Within a week the appearances of myxoedema were much diminished and her mental state was improving. At the end of three weeks she had returned to her condition of six months before; she appeared clinically to be an ordinary case of hypopituitarism and was a peaceful and placid woman again. Continued treatment with this dosage of thyroid and testosterone kept her in reasonable health for several months. After this, cortisone (12.5 mg. daily) was then added to the other treatment. This rapidly produced the characteristic improvement in the general condition.

After about three or four days she developed a transient diuresis, and within the next two weeks she became able to do all her housework and go out shopping.

Conclusions

Several aspects of the syndrome of hypopituitarism could reasonably be considered as manifestations of the secondary thyroid hypofunction. These include the mental slowness and lack of interest, the physical sloth, the extreme sensitivity to cold, and the absence of sweating; symptoms which are characteristic of myxoedema. It is therefore very interesting that these particular aspects are influenced by cortisone, which is an adrenal hormone, but not by thyroid.

Until ten years ago a variety of treatments were used in hypopituitarism, but, apart from the effect of pregnancy, the results were not impressive. When testosterone was first introduced its value was obvious, and the patients and their relatives usually insisted that the treatment should be continued. Cortisone in small dosage produces even greater enthusiasm, and all the patients treated so far have invariably returned for a further supply of tablets well before their last supply is exhausted.

Testosterone produces in patients with hypopituitarism a sensation of well-being and improves the physical strength and mental activity. It causes a regrowth of pubic and axillary hair and some return of libido. Cortisone has similar but greater effects on the physical and mental activity, though it does not usually restore body hair. We have therefore tried the effect of giving both substances together, but have not observed any definite additive effect apart from that on the body hair. If after a course of this combined therapy the testosterone is stopped and the cortisone is continued alone, the patient's general condition remains as good as before. On the other hand, a patient who has had cortisone and testosterone together is not nearly so well if an attempt is made to continue treatment with testosterone but without cortisone.

It is a common practice to prescribe a combination of many kinds of treatment for hypopituitarism: thyroid, oestrogens, deoxycortone, sodium chloride, and various vitamins. There are theoretical reasons for administering all of these substances, but detailed studies are required to ascertain what effect is actually produced when each of them is administered singly for a period to patients who are being kept on maintenance treatment with cortisone. The only definite observation we have made is that in certain cases the puffiness of the eyes is reduced by a combination of thyroid and cortisone, but not by either given separately.

From our limited experience up to date it seems that cortisone therapy is the most useful method of long-term treatment of patients with hypopituitarism. A dosage of 12.5 mg. orally each day appears to be adequate for maintenance. A dosage of 25 mg. is equally satisfactory, but it does not produce a proportionate improvement in the signs or symptoms. Larger dosage, such as 50 to 100 mg. a day, is very apt to produce transient mental disturbances; this is in marked contrast to the tolerance of large dosage which is shown by patients with rheumatoid arthritis.

The cortisone used in this work was provided from a generous gift made jointly to the Medical Research Council and the Nuffield Foundation by Merck and Co., Inc.

ANALYSIS OF 1,400 CASES OF ACUTE INJURY TO THE HEAD*

BY

G. F. ROWBOTHAM, B.Sc., F.R.C.S.

Regional Consultant in Neurological Surgery

I. N. MACIVER, M.B., F.R.C.S.Ed.

JUNE DICKSON, M.B., B.S.

AND

MARJORIE E. BOUSFIELD

(From the Regional Centre of Neurological Surgery, Newcastle-upon-Tyne)

Between the years 1941 and 1951 2,000 cases of acute injury to the head were admitted to the General Hospital, Newcastle-upon-Tyne, and were treated in the department of neurological surgery. Of these, 1,544 were aged 13 and over (1,281 male, 263 female), and 456 were children up to the age of 12. The death rate in this consecutive series of cases was 10.5%.

In this paper a detailed analysis is given of 1,000 of the adults and 400 of the children; these cases were those of the above series who were admitted to hospital between the years 1945 and 1951. The adults were nursed in the department of neurological surgery; most of the children were nursed in the department of paediatrics.

The primary objects of this study were: (1) to determine the sources and causes of acute head injuries that occur in a provincial city and area engaged in the heavy industries of shipbuilding and mining; (2) to set on record a statistical statement of the severity and the nature of the injuries sustained; (3) to analyse the cause of death and to appraise methods of surgical treatment; (4) to inquire into the long-term results with the object of discovering whether and how morbidity can be minimized; and (5) to bring to the notice of the surgical world once again the magnitude and importance of this branch of medicine.

An analysis of 1,000 adult cases is given (Table I). It will be seen that 444 of them, or nearly half the total, were due to road accidents, and just over 19% of these accidents were fatal. Table II shows the great preponderance of these injuries in the productive period of life, underlining once more the serious social and economic aspect of injuries which for the most part should not happen.

Table III shows, what would be expected, a graver prognosis for patients admitted in a state of semicomma and coma.

*The preparation of this work was assisted by a Research Grant from No. 1 Regional Hospital Board.

Consciousness to confusion	724	27
Semicoma	101	27
Coma	175	121
Total	1,000	175

In 940 of the cases the injury was closed, with possible internal compounding; among these there were 151 deaths. Sixty patients had an open injury of the vault, and 24 of them died. There were 221 associated injuries in the 1,000 cases, as follows: abdominal 3 (2 deaths); thoracic 19 (6 deaths); limbs 114 (16 deaths); spine 11 (no deaths); facio-maxillary 74 (9 deaths). Major operations had to be performed in 209 cases (74 deaths) and minor operations in 166 (16 deaths). The duration of stay in hospital averaged 12.9 days. The disposal of those who survived is shown in Table IV.

TABLE IV.—Disposal of 825 Patients

Home	756
Rehabilitation centre	18
Convalescent	12
Military or naval depot	12
Transfer to other centres (thoracic, facio-maxillary, psychiatric)	6
Miscellaneous	21

To complete the analysis of the cases we give (Tables V and VI) some figures relating to the 400 cases of injury to the head in children (up to the age of 12). Of these, 147 were due to road accidents; there were 20 deaths (13.6%). As many as 149 of the 400 children sustained injury as a result of falling from a height: 5 (3.3%) of these died.

Table VII gives details of the level of consciousness on admission. In the great majority of the cases (368) the injury was closed, with possible internal compounding; 26 (7.1%) of these children died. In 32 cases there was an open injury of the vault, with 8 (25%) deaths. Among the 400 cases there were 38 associated injuries, as follows: thoracic, 3 (no deaths); limbs, 20 (2 deaths); facio-maxillary, 14 (no deaths); pelvis, 1 (1 death). A major operation was necessary in 70 cases (6 deaths)

and a minor operation in 27 cases (no deaths)—that is, out of the total 400. The average duration of stay in hospital was 9.3 days. Of the 366 survivors, 351 were discharged home, 7 to a convalescent centre, and 8 to other hospitals.

Cause of Death in Adult Cases

The cause of death in the 175 fatal adult cases is briefly reviewed below.

Group 1. Admitted in Coma

Of the 175 patients admitted in a state of coma, 121 died (69.1%). A high death rate from head injuries sufficiently severe to render a man comatose is, of course, to be expected, particularly as it is in this group that severe associated injuries are encountered. In 80 cases examined at necropsy cerebral contusions and lacerations, and surface and intracerebral haemorrhages, were found in all varieties of combination, degree, and extent. In every case the macroscopical injuries of the brain tissue were judged to be severe enough either to account for or to contribute substantially to the cause of death. In many there were extensive macroscopical injuries to non-vital areas only; in these, however, the physics of injury were such that vital centres (brain stem, thalamus, and hypothalamus) must, to some extent, have been damaged. In those cases in which there was no vital evidence of macroscopical or microscopical damage to the vital centres it was impossible to judge whether presumed submicroscopical damage could have accounted for death.

In all cases in which there was no gross demonstrable damage to the vital centres there was always gross damage to the non-vital areas; in other words, no patient died of uncomplicated concussion. This does not mean, of course, that a patient could not, in fact, die from injuries to the vital centres of submicroscopical dimensions: this problem is still far from final solution.

In no instance did we come to the conclusion that life could have been saved either by surgical decompression or by the turning of a bone flap, since massive oedema of the brain never occurred without septic encephalitis, and since, in those cases in which there was a local blood clot, there was a contusional or lacerational damage in other parts of the brain. From the surgical point of view we came to the conclusion that the only procedure that might have been of value was drainage of the cerebrospinal fluid, either by lumbar puncture or through a trephine hole in the vault of the skull.

Group 2. Cases Admitted in Semicoma

Of the 101 patients found on admission to be in a state of semi-coma, 27 died (26.7%).

At post-mortem examination 10 were judged to have died as the result of irreversible physical injuries to the brain tissues similar in severity and nature to those found in the coma group.

In a further 10 cases there were obvious contusional injuries in non-vital areas, but these were judged not to be irreversible. We came to the conclusion that in these cases a substantial contribution to the cause of death was the effect of injuries elsewhere in the body. This subgroup particularly calls attention to the importance of the integration of the treatment of a patient as a whole and of the close observation of the minutiae of nursing. When a patient, for example, is in a state of shock it is obviously wrong to inflict further shock by, say, reducing a fracture or submitting him to any other operative procedure before it is absolutely necessary. Also, any kind of asphyxia due to a faulty airway will aggravate the cerebral state, as will overheating or the incorrect administration of fluids.

In the remaining seven cases in which there were no injuries elsewhere in the body to contribute to the cause of death, the extent and degree of the damage to the brain was such that we felt that better-designed surgical therapy might have saved lives; this applied particularly in those cases in which there was a large unilateral acute subdural haemorrhage. We are now coming to the conclusion that when, for some clinical evaluation, open operation is deemed necessary acute subdural haemorrhages can be treated most adequately by the turning of a large osteoplastic flap with wide opening of the dura mater.

In actual practice the difficulty, of course, is to correlate the clinical picture with the pathological happenings. Our objective here is to show that in borderline cases of life and death pathological phenomena amenable to surgical treatment do, in fact, occur in a small percentage of cases. Therefore, skilled and painstaking clinical examinations may occasionally meet with gratifying reward.

Group 3. Cases Admitted in a State of Confusion or Full Consciousness

Of the 724 patients who were either conscious or in a state of confusion, 27 died (3.7%). The causes of death can be classified as follows:

(1) *Injuries to the brain unassociated with extradural haemorrhage.*—There were 19 cases of this type: five patients died from pyogenic infection resulting from massive compound frontal injuries; three died following operations for severe compound frontal injuries (sepsis did not develop); four died from massive intracerebral haemorrhages such as occur from natural processes—although classified as having died from the head injuries, they probably died from apoplexy; six died from lacerations of the brain associated with either subdural or subarachnoid haemorrhages (three of these were over the age of 70); and one died of cerebral thrombosis.

(2) *Mild concussion with severe injuries elsewhere in the body.*—In these three cases severe associated injuries were the obvious cause of death.

(3) *Extradural haemorrhages complicated by injury elsewhere in the brain.*—In the three cases in this group there were (a) a unilateral extradural haemorrhage, associated

with a subdural haemorrhage on the same side, and cerebral oedema; (b) small bilateral extradural haemorrhages, associated with a laceration of the brain and bilateral subdural haemorrhages; and (c) an extradural haemorrhage, associated with a large intracerebral haemorrhage.

(4) *Uncomplicated extradural haemorrhages.*—The following were the findings in the two cases recorded: (a) a large extradural haemorrhage due to laceration of the lateral sinus (the onset of compression in this case was so rapid that operation was not possible); (b) a large extradural clot developed after operation for the lifting of a simple depressed fracture—the result, probably, of faulty surgical technique.

From the above description it will be seen that a patient can lapse into unconsciousness from a wide variety of causes after a latent interval following a head injury. Nevertheless, in clinical practice it is dangerous not to diagnose every case of latent unconsciousness as being due to compression of the brain by a surface haemorrhage that can be relieved by surgery. In all cases in which there had been a history of a latent interval, whether the patient was admitted unconscious or conscious, the presence or absence of an extradural clot was always determined either in life or at necropsy.

Extradural haemorrhages occasionally occur associated with severe intrinsic injuries in which there has been no latent interval. More rarely, bleeding from a torn dural sinus may be so rapid that the latent interval is virtually non-existent.

Mechanical Forces Causing Brain Injury

By the nature, degree, and distribution of the lesions found at necropsy in many of the brains, it was judged that the head at the time of accident had been subjected to a series of forces, each acting differently. For example, a patient's brain may be injured when he is flung from his seat, when his head strikes a resistant object, or, again, when it is jerked violently backwards in a rebound. From the distribution of the major lesions it was obvious that the hemispheres, rather than the brain stem and cerebellum, take the brunt of the injury. It was also clear that the hemispheres of the brain not only move in relation to each other but they both frequently move across the brain stem to injure it. Subdural and subarachnoid bleeding is caused not only by the tearing of veins that drain from the surface into dural sinuses but also as the result of laceration and contusion. Severe lacerations are almost certainly caused by the impact of the brain on the cutting edges of bone or of dural partitions. A ruptured vessel on the surface can bleed inwards to cause an intracerebral haemorrhage. No special structure remains immune from injury. Linear as well as rotational forces are nearly always active. Whatever the acting force, it is distortion that ultimately produces the pathological lesion. From the post-mortem findings it is impossible precisely to reconstruct the physics of the injury.

Analysis of Operations

The details of the 209 major operations and 166 minor operations carried out in the 1,000 cases are as follows:

Major Operations	
Compound fractures of the vault	44
Compound fractures of the base (internal comminuted)	3
Closed depressed fractures of the vault	41
Extradural haemorrhages:	
With latent interval	27
Without	5
Acute subdural haematoma	69
Decompressions	2
Enucleation of eye	4
Major lacerations of the scalp	14

Minor operations for minor lacerations of the scalp were done in 139 cases, and for burr-holes for inspection or drainage in 29.

In addition many lumbar punctures were carried out for drainage and diagnostic purposes.

Extradural Haemorrhages

Among the 1,000 adult cases investigated there were 28 cases of extradural haemorrhage with compression of the brain in which there was a latent interval. Operations were carried out in 27 and one patient died before operation could be performed. Of the 27 patients who were operated on, 17 survived and 10 died. The main details are given in Table VIII.

TABLE VIII.—Massive Extradural Haemorrhages with Latent Period

Sex	Age	Cause	Site	Source

M.M.A.—Middle meningeal artery. * Operation was not performed in this case.

Of the 10 patients who died following operation, it was found at necropsy that in five cases there were other injuries in the brain, such as lacerations, and subdural and intracerebral haemorrhages.

In the four cases in which complications were not found in the brain, each patient had been in a state of deep unconsciousness on admission, and death in every instance was due to brain-stem compression resulting from too-long-delayed operation. Death in the tenth case was due to a post-operative extradural clot after elevation of a simple depressed fracture—the result, probably, of faulty surgical technique.

Based on our experience, our guides for operative procedure are as follows: (1) Whenever possible the operation is carried out under local analgesia, care being taken to procure a free airway and full oxygenization. (2) The clot is widely uncovered, if necessary by a bone flap; we now rarely use the classical subtemporal exposure by the muscle-split method. (3) (a) After gentle evacuation of the clot and sealing of the bleeding vessels, care being taken at all stages not to inflict further pressure on the already embarrassed brain, the operation is halted until signs of recovering consciousness are obvious. When this stage is reached the wound can be closed in the usual way. (b) If, half an hour after the removal of the blood clot, there is no sign of returning consciousness the dura mater is widely opened. (c) If there is still no sign of return of consciousness half an hour after the decompression has been provided, then the temporal lobe of the brain is lifted and the edge of the tentorium severed to relieve possible tentorial herniation.

Crushing Injuries of the Head

For the head to be crushed between two external objects without first being put into violent motion must, by the circumstances of accident, be exceedingly rare. After having applied the strictest criteria we found that only nine cases fulfilled the requirements of a true crushing injury.

If a head be crushed heavily enough it will disintegrate and death will be more or less instantaneous. In our short series, in the eight patients who lived we could recognize three degrees of injury: (1) severe compound fracture with laceration of the brain; (2) compression of the brain and fracture of the skull without compounding; and (3) fracture of the skull without brain compression.

The crushing type of injury is particularly apt to inflict irreparable damage on special structures and the cranial nerves.

The following were sequels of the above eight cases: unilateral deafness in three, labyrinthine injury in one, unilateral blindness in two, unilateral anosmia in one, and squints in three.

One of the examples of crush injury to the head was that of a young miner whose head became trapped between two tubs. He tried unsuccessfully to free himself; the tubs moved towards each other and the man heard a loud cracking sound as his skull fractured. He then felt himself going unconscious and remembered no more until he woke up in hospital 36 hours later to find that an operation had been carried out. On admission he was deeply unconscious. X-ray examination of the skull showed that a piece of bone as large as the palm of a hand had been pushed inwards towards the brain. The bone was elevated and the patient made a complete recovery, there being no retrograde amnesia. The particular interest in this case is that forces of compression produced a state of unconsciousness indistinguishable from that caused by change in speed of movement.

Cerebral Injury During Pregnancy

In two instances women were injured when pregnant and in neither case did the injury cause abortion.

One woman aged 20 was two months pregnant when she sustained a compound wound of the frontal bones with laceration of the brain tissue. She also sustained a comminuted fracture of the upper jaw and lacerations about the face. After extensive cerebral, facial, and dental surgical treatment she made a satisfactory recovery. Her child was born at the normal time, was healthy in every way, and remains so at the age of 4 years. Another observation of interest is that the patient's mother has noticed that her daughter has been much more optimistic and even-tempered since the accident, the change no doubt being due to the leucotomizing effect of the injury on the frontal lobes of the brain. Temperamental changes following head injury are almost invariably in the adverse direction.

The second case was that of a woman aged 28 who was eight months pregnant when she was injured. She survived for three and a half days only, but at no time during this period were there any signs of abortion, the foetal pulse being plainly heard until the mother's circulation began to fail on the third day.

Associated Injuries

In cases of head injury associated injuries to the face, body, and limbs are common. Dislocation of the cervical spine with cord contusion is a well-known complication, as are injuries to the pleura and lungs.

We are, however, particularly anxious to call attention to the facio-maxillary problem which occurs in head injuries and to the necessity for co-operation between the neurological and the facio-maxillary surgeon.

Apart from severe lacerations about the face and scalp that necessitated special plastic repair, 17 complicated frac-

tures of the jaw were treated by our colleague Mr. Godfrey Hutchinson, in his dental department.

When a fracture of the jaw is associated with a state of concussion the decision of when to operate is one which requires considerable surgical experience and judgment. As regards concussion it is wiser to delay facio-maxillary treatment until the patient is well on the way to recovery. On the other hand, if repair of a fractured jaw is delayed too long a satisfactory end-result is jeopardized. It has been our experience that when a mouth injury does not immediately interfere with breathing, treatment of a fracture of the jaw can be postponed until the third day, provided systemic antibiotic treatment is started immediately.

Microscopical Examination of the Brain Stem*

Of the brains obtained whole at post-mortem examination and hardened in 10% formalin, the brain stems of 50 have been cut in their longitudinal axis and examined microscopically.

In five cases there was evidence of gross contusions, the microscopical details of which were similar to those found in the hemispheres. In themselves, these contusions were judged to be severe enough to account for death; in other words, the vital centres had been irrevocably damaged. From the sections it was obvious that post-traumatic hemiplegia must, on occasion, be due to brain-stem damage, the crus cerebri in one case having been torn. Brain-stem and basal ganglia damage may occasionally result from the tearing effects of haemorrhages that start at the surface.

Injuries undetectable by naked eye were easily demonstrable in 10 cases by magnification and showed as typical contusions. Indeed, it is becoming increasingly obvious that in many of the cases that end in death the brain stem has been injured in a physical way. Whether these lesser contusions could in themselves have accounted for death it has not yet been possible to judge; they must, however, have substantially contributed to it.

By definition, presumed injuries of submicroscopical dimensions cannot, of course, be seen through the microscope, but this does not mean that they do not in fact exist; newer methods might demonstrate them. Damage to neurones can be direct or indirect through injury to their supplying blood vessels. No uniform pattern of change in angio-architecture can be determined in the brain stem.

Follow-up Reports

An inquiry was made into the long-term results of 250 consecutive adults who were injured during the years 1949 and 1950. The survey was carried out by means of a questionnaire, and 236 replies were received.

Of these, 169 patients reported that they had returned to normal work and 57 to light work, but 38 of these were eventually able to resume their original work, giving a total of 207 who finally were able to return to normal employment. Nineteen have remained on light work up to the time of writing. Ten have so far not returned to any form of work. Of the 226 patients resuming work of any kind only 10 have been unable to work regularly.

Seventy-eight patients were free from symptoms on leaving hospital; the symptoms of the remaining 158 were headache, dizziness, loss of smell and taste, and tinnitus. Four patients reported attacks of black-outs.

Changes in personality were reported in 49 cases, severe changes such as mental delusions occurring in only three, the remainder being lack of concentration, bad temper, depression, nervousness, and loss of memory.

The average length of time after discharge from hospital before starting work and the type of work undertaken are given in Table IX.

*This is a preliminary statement on work being carried out in the Research Laboratory of the Department of Surgery, University of Durham.

A similar inquiry was made into the long-term results of 100 children who had received injuries to the head during the years 1949 and 1950; this group was also consecutive.

TABLE IX

Type of Work	Average Period After Discharge Before Resuming Work
Return to normal work	10½ weeks
Return to light work and then normal work resumed	27 "
Remaining on light work up to date	32 "
Worked irregularly	16 "

The survey was carried out by means of a questionnaire to the parents; 82 replies were received.

Of these children, 51 were of school age when injured, 30 were below that age, and one child was already mentally retarded and unable to attend school.

Forty-three children were able to return to school in their pre-accident class and were able to compete with their age groups. In eight cases the educational standard was affected, the children either being returned to their original class but not moved up with their age group in the normal way or, immediately on return to school, being found to be below standard and placed in a lower class. In these eight cases it is judged that an intellectual injury of some degree has occurred which is likely to influence adversely the scholastic career of these children for the rest of their lives.

Fifty-two children were free from symptoms. Thirty complained of headache and/or dizziness. Fits were reported in four cases.

Changes in temperament were noticed in 27 instances, the main symptoms being nervousness, lack of concentration, faulty memory, bad temper, and bed-wetting, the parents stating in each instance that these manifestations had not been present before the injury.

Discussion

From the figures announced by the Ministry of Transport 5,250 people died during 1951 as the result of injuries received on the roads. So far as can be estimated, at least 60% succumbed as a direct result of injury to the head, and for every death four or five people receive non-fatal injuries.

This subject is important, not only because of the magnitude of these figures but because healthy people, not those already incapacitated by disease, lose their lives or are maimed. Indeed, the economic loss to the nation because of injuries to the head is enormous. Our figures, however, show that road carnage constitutes only 44% of the total number maimed or killed, the remainder being due to accidents in industry, in the mines, in the home, etc.

To meet the increasing needs of cerebral trauma, not only are further facilities for treatment and rehabilitation necessary but postgraduate schools at university level must soon be established for the instruction of those whose responsibility it will be to care for the head injured away from special centres. Whether such centres should be named "head injury" or "traumatic" is of little importance. A seven-day, 24-hour service is necessary, including facilities for radiology and for all other ancillary investigations. Here again we should like to call attention to the necessity for the closest co-operation between the neurological and the facio-maxillary surgeons in the treatment of head injuries.

The imperfect liaison between the hospital and the general practitioner has been, and still remains, a weak link in the problem of head injury. We believe that much advantage would accrue from visits by the general practitioners to patients in hospital during the acute stages of the injury, and this important postgraduate association should be fostered. Also, much waste of man-power could be avoided if, when the time comes for consideration of a patient's

return to work, a conference between the general practitioner and the specialist were held in the patient's home surroundings when every aspect of the case could be reviewed. In this way unnecessary hardships could be eliminated and extremes of judgment tempered.

Finally, our post-mortem studies have shown that in a considerable percentage of deaths the injuries received are of such magnitude that they must be irreversible from the moment of infliction. Therefore, again we should like to stress the importance of prevention in the solution of this problem, which should be constantly in the minds of the medical profession, the ruling bodies, and the general public. The chance of serious injury about the head to the individual remains far too high.

Summary

Between 1941 and 1951 2,000 cases of acute injury to the head were admitted to the General Hospital, Newcastle-upon-Tyne. The results of an analysis of 1,400 of these (1,000 adults and 400 children) are given. In the 1,000 adult cases there were 175 deaths, 87 of them due to road accidents; 38 of the deaths resulted from accidents in industry. Of the 175 patients admitted in a state of coma, 121 died. There were 28 cases of extradural haemorrhage with compression of the brain in which there was a latent interval of consciousness: one patient died before operation was possible; of the 27 operated on 17 survived and 10 died.

Of the 400 cases in childhood (up to the age of 12 years) 147 were due to road accidents and 149 to falling from a height: 34 of the children died, 20 of them having been admitted in a state of coma.

CLINICAL AND EXPERIMENTAL STUDY OF SEGMENTAL PAIN FROM THE SHOULDER

BY

N. W. NISBET, F.R.C.S.Ed.

Associate Professor of Orthopaedic Surgery, Dunedin Hospital, New Zealand

The pain from diseases of the shoulder such as supraspinatus tendinitis or capsulitis is always referred. Although radiation to the arm and hand has been recorded, the distribution of this referred pain has received scant attention in studies of this common group of diseases from orthopaedic sources, nor indeed has it often been mentioned. The importance of its recognition lies in the differentiation from other causes of referred pain into the upper limb, so that unnecessary mistakes in diagnosis can be avoided. Further, clinical and experimental studies of this sort may shed light on the problem of referred pain and on the segmental supply to the shoulder-joint and related structures.

The pain is diffuse and deep, and can be reproduced by experimental noxious stimuli in several ways: one is by injections of 6% saline into the deep structures around the joint. If carried out accurately this method correlates the structure of origin and the segmental reference arising therefrom. It also closely simulates the pain found in clinical cases. Kellgren (1949), in

an extensive review of this subject, advises that each investigator should become his own guinea-pig, because by this painful experience much can be learned, not the least being the difficulty of finding suitable expressions to describe it. In a series of such experiments carried out on myself, the deep pain had a "metallic" quality, but as this is clearly an ambiguous description, meaning nothing to anyone except to me, the simple term deep pain is adhered to. As its name implies, the pain is felt deep in and not on the skin, because it is due to noxious stimuli acting on the spinal segments. This causes a false localization of the pain through unknown phenomena occurring in the central nervous system. It has a maximum intensity proximally and fades peripherally. Patients have described it as "running down the bone and out through the fingers."

Kellgren (1938) showed that experimentally produced pain from interspinous ligaments was always a diffuse segmental pain if the stimulus was strong enough. This also holds for the short tendons and muscles of the shoulder, even though these structures are not centrally placed, as are the interspinous ligaments. I found that irritation of the supraspinatus tendon or muscle belly produced deep pain on the outer aspect of the arm, and sometimes in the forearm and thumb. After the initial injection, which always produced the diffuse segmental pain immediately, the pain could be reproduced hours later by moving the shoulder. On injection of the supraspinatus muscle belly a spot was found

that produced a continuous band of reference along the length of the limb (Fig. 1). Local tenderness was also noticed. The segmental pattern of this false localization is discussed later.

Present Investigation

The clinical cases and the segmental pain they displayed are here described. During this study a special clinic was opened, so that the questioning and examination of the patients and the charting of the referred pain could be carried out leisurely, which, as every orthopaedic surgeon knows, cannot be done during the hubbub of a routine orthopaedic clinic. In 8 out of 26 patients with supraspinatus tendinitis the pain was referred to the outer aspect of the arm and lower part of the deltoid muscle in an area that reached to just above the elbow (Fig. 2). It was occasionally referred as two narrow bands, on the antero- and postero-lateral aspects of the arm (Fig. 3).

FIG. 1.—The spinal segmental distribution in several injections of 6% saline into the supraspinatus muscle and tendon. Oblique hatching indicates muscle; transverse hatching and stippling indicate tendon. The arrows show points of injection.

In 18 cases the pain radiated down the entire length of the antero-lateral aspect of the upper limb, terminating at the base of the thumb (Fig. 4). The thumb, forefinger, or middle finger was included either singly or together in many cases, with a distinct predominance in the radial fingers.

In 15 patients with spasm of the short rotator muscles associated with tendinitis or injury, and in whom the shoulder was partially stiff, the pain was widely referred to

FIG. 2.—The average distribution of pain in eight cases of supraspinatus tendinitis. The dark area indicates maximum intensity. This corresponds to the fifth cervical segment. Figs. 3a and 3b. —A variation in the reference of the pain in supraspinatus tendinitis, as antero- and postero-lateral bands.

the area of the deltoid muscle and outer aspect of the arm to terminate above the elbow (Fig. 5).

In 35 cases of "frozen" shoulder the pain radiated from the epaulette region into the arm, in many spiralling across the dorsal aspect of the forearm to reach the dorsum of the hand (Fig. 6). Occasionally the pain was referred along the antero-lateral aspect of the forearm to reach the palm (Fig. 7). One or all of the fingers were often included, and there was a distinct tendency for predominance in the middle, ring, and little fingers. In a few the pain was referred to the side of the neck and cheek or to the inner side of the arm and chest wall (Fig. 8). In six cases the pain was referred diffusely to the whole arm, but with accentuation in certain segments (Fig. 9). As was to be expected, a quantitative increase of the diffusion of the deep pain occurred in the more extensive lesions, and this will be discussed elsewhere.

Discussion

In other words, despite the diffuseness and difficulty of description and location of this pain, a distinct segmental pattern was displayed.

Head (1893, 1900) and Foerster (1933) depicted the fifth and sixth cervical dermatomes as occupying the antero-lateral aspects of the upper limb, extending to the base of the thumb. If it is assumed that the supraspinatus muscle and tendon are supplied by the fifth and sixth cervical segments through the supraclavicular nerve, then in disease of these and related structures it is probable that the referred pain will appear to be blended and shared in varying degree between them. This is because of the close association of the two spinal segments in the formation of their nerve supply. In any case, the pain may not involve the whole segment of reference (Hilton, 1950). This is borne out by experimentally produced deep pain in the instance of this tendon. Anatomical variations, such as pre- and post-fixation of the brachial plexus and the segmental preponder-

FIG. 4.—The distribution of pain in 18 cases of supraspinatus tendinitis. The fifth and sixth cervical segments are probably involved. The numerals indicate a preponderance of pain in the digits on the radial side of the hand.

ance in the formation of peripheral nerves, must have a considerable influence on the distribution and fluctuation of referred pain in the upper limb, and probably accounts for the surprisingly high or low segmental reference in some cases of shoulder disease. Kellgren (1939) has shown the significance of anatomical variations in the instance of the

FIG. 5

lumbar spinal roots. The segmental impression of deep pain from the supraspinatus tendon and related structures corresponds to the dermatome chart of Last (1949) and closely approximates to the segmental distributions of Kellgren (1938) in many injection experiments.

The fifth and sixth cervical segments are usually said to supply the shoulder-joint itself (*Gray's Anatomy*, 1949). In "frozen" shoulder, however, as has been shown, the segmental reference may extend from the fifth to the eighth cervical segments, and sometimes more. The occasional higher or lower reference may be tentatively explained by the anatomical variations mentioned above, or there may be a central spread in the spinal cord, on the basis of the wide intersegmental synapses in the tract of Lissauer, as postu-

lated by Earle (1952). This distribution closely follows the dermatome chart of Last (1949) and the spinal segmental patterns of Kellgren (1938) formed by experimentally produced pain from the interspinous ligaments. It does not conform to the "strip" pattern, so popular nowadays, to be found in papers by Keegan and Garrett (1948), Young, (1949) and Walshe (1952), nor indeed to the map in Lewis's (1942) book, in which the dermatome of the eighth cervical segment occupies territory on the inner side of the arm. It is to be clearly understood that the pain is not actually in the anatomical entity known as a "dermatome," which is an area of skin, but, all the same, diffuse and deep as it is, the central misinterpretation of its distribution is that given above.

These latter conceptions ignore the axial lines. This applies particularly to the dermatome of the eighth cervical segment, which is usually the lower border of the segmental reference. Since all, or mainly the ulnar, fingers were included in referred pain from "frozen" shoulder it does seem that the eighth cervical segment was usually the lowest to be stimulated (Fig. 6). Thus when the capsule of the shoulder-joint was widely irritated and was the source of the noxious stimuli, the pain was falsely located in the territory between and cephalic to the axial lines. Further, Last (1949) and Hilton (1950) suggest that the segmental and the nerve supply of the muscles are the same as those of the joint they move, so, according to this reasoning and from the evidence deduced above, the segmental supply to the shoulder must span the fifth to the eighth cervical segments at least, without allowing for any anatomical variations. This is supported by the charts depicted in *Gray's Anatomy* (1949), but awaits definite anatomical proof.

The explanation of diffuse pain in the "whole" arm is bound up with the mystery of referred pain, and it is not my intention to become involved in this paper in a discussion of the various hypotheses on this abstruse subject, or to discuss the peripheral or central mechanism that may be involved. Those interested will find recent conceptions in Sinclair, Weddell, and Feindel (1948), and Hardy, Wolff, and Goodell (1952). But it is extremely unlikely, as is so often suggested by writers on physical medicine, that the entire brachial plexus becomes "sensitive" in acute lesions of the shoulder, to account for the widespread reference of the pain. It is much more likely to have a neuro-anatomical basis from phenomena occurring within the central nervous system.

Summary

Pain from lesions of the shoulder is usually a referred deep pain. Experimentally produced referred pain from the shoulder closely simulates that found in disease.

The referred pain from various lesions of the shoulder, although diffuse, displays a distinct segmental distribution.

It is suggested that this furnishes evidence to support the opinion that the fifth to the eighth cervical segments supply the shoulder.

FURTHER OBSERVATIONS ON THE METABOLIC STIMULATING EFFECT OF SALICYLATE

BY

J. B. COCHRAN, M.B., B.Sc., F.R.F.P.S., M.R.C.P.
(From the Clinical Chemotherapeutic Research Unit of the
Medical Research Council in the Gardiner Institute of
Medicine, University of Glasgow)

It has been shown (Cochran, 1952) that salicylate causes a pronounced and progressive increase in oxygen consumption when given in full therapeutic dosage to normal and subacute rheumatic subjects. It was suggested that this effect of salicylate might be of fundamental importance in the therapeutic action of the drug. The present paper is a continuation of this work and concerns two further aspects. Firstly, it is seemed possible that salicylate might behave in an anomalous fashion in the acutely ill febrile patient, and therefore the effect of the drug on oxygen consumption in the treatment of acute rheumatic fever has been studied. Secondly, it is well known that salicylate (*ortho*-hydroxybenzoate) is effective in the cure of acute rheumatic manifestations, while its isomers (*para*- and *meta*-hydroxybenzoate) are inactive. The effect of these isomers on oxygen consumption has been studied.

Method

Oxygen consumption was measured, using a closed-circuit type spirometer, and the values obtained were corrected

FIG. 1

FIG. 2

FIG. 3

FIG. 1.—Effect of aspirin on oxygen consumption and body temperature in a patient with acute rheumatic fever. Although the temperature has fallen by 4.8° F. (2.7° C.) the level of oxygen consumption has increased and slowly falls when aspirin is gradually withdrawn. FIG. 2.—Results obtained in a second patient with rheumatic fever. The temperature has fallen by 4° F. (2.2° C.), but the metabolic rate remains at an elevated level until an abrupt fall occurs when aspirin is suddenly withdrawn. FIG. 3.—Results obtained in a third patient with acute rheumatic fever. An abrupt fall in temperature is accompanied by a progressive rise in oxygen consumption, which falls only when aspirin treatment is stopped.

for temperature and barometric pressure. The rheumatic fever patients had three consecutive five-minute tracings taken each morning at a constant time and the results were averaged. This routine was continued throughout the course of treatment. When it was desired to test the effect of a single dose of a drug each subject acted as his own control and was in the fasting state. After two or three consecutive tracings a single dose of the test drug was given by mouth and serial estimations of oxygen consumption were made at roughly 20-minute intervals for two to three hours.

Results

Observations were made on three patients admitted with acute rheumatic fever who received aspirin in full therapeutic doses of approximately 2 g. four-hourly. In each case the expected clinical improvement with relief of arthritis and fall in temperature occurred within 24 to 48 hours of starting treatment. In Figs. 1 to 3 the daily levels of oxygen consumption are plotted with the oral temperature obtained just prior to the oxygen measurement. In Fig. 1 it is seen that although the temperature has fallen by 4.8° F. (2.7° C.) the level of oxygen consumption has actually increased. When aspirin is gradually withdrawn the metabolic rate slowly falls. In Fig. 2 the temperature has fallen by 4° F. (2.2° C.), but the metabolic rate remains at an elevated level until an abrupt fall occurs when aspirin is suddenly withdrawn. In Fig. 3 there is a similar pattern of changes. The abrupt fall in temperature is accompanied by a progressive rise in oxygen consumption, which again falls only when aspirin treatment is stopped.

A fourth patient was treated at first with sodium salicylate and sodium bicarbonate in equal doses of 20 gr. (1.3 g.) four-hourly. The initial clinical response was satisfactory, but on reducing the dosage a relapse occurred and treatment was changed to aspirin. A second relapse followed aspirin withdrawal, and a further course was given. The relationship of relapse to oxygen consumption is shown in Fig. 4. It is seen that recrudescence of symptoms occurred when the oxygen consumption had fallen to low levels, either in reduction of dosage or withdrawal of salicylate.

A comparison was made of the effects on oxygen consumption of single 3-g. doses of sodium salicylate and aspirin and single 5-g. dosage of the *para*- and *meta*-hydroxy isomers of salicylate. The tests were carried out on the same convalescent patient, and the results are shown in the Table. Sodium salicylate and aspirin caused respectively a 12% and 11% maximal increase in oxygen consumption, while the two isomers were without significant effect. Two convalescent patients were given the isomers over a four-day period in doses of approximately 2 g.

four-hourly. There was no significant increase in oxygen consumption with either *para*- or *meta*-hydroxybenzoate (Figs. 5 and 6).

Discussion

Barbour (1919) and Barbour and Devenis (1919) stated that salicylates increase the metabolism in afebrile subjects but lower it in febrile patients. These workers used a Benedict respiration chamber, and observations were made after the ingestion of single 1-g. doses of aspirin. It would

seem that the pharmacology of salicylate, and in particular the effect of the drug on oxygen uptake, would be most profitably studied where full therapeutic doses are being given and are having the desired beneficial effect, as in the present study.

The metabolic rate rises in fever, and it has been estimated that it increases 7% for every degree F. of fever. In the patients studied the acute stage of rheumatic fever was associated with a raised metabolic rate. It is assumed that in an untreated case undergoing natural remission the fall in temperature and subsidence of symptoms would be accompanied by a parallel reduction in the level of oxygen consumption. In the treated rheumatic patients it has been shown that the level of oxygen uptake either increases or remains at an elevated level, while the temperature falls and symptoms are relieved. It is only on stopping salicylate therapy or on reducing dosage that the oxygen uptake falls to normal or near normal levels. There would seem to be

no doubt that salicylate has a metabolic stimulating effect in the febrile acute rheumatic patient; the increase in metabolism due to the drug is equal to or greater than the decrease in metabolism due to the lowering of temperature, and the net result is the maintenance of a high metabolic rate while full therapeutic doses are being given.

It is important to determine if the metabolic stimulating effect of salicylate is an essential part of the therapeutic action of the drug. It has been shown that the effect is not shared by the closely related salicylate isomers, *para*- and *meta*-hydroxybenzoate. There is no significant increase in oxygen consumption when these substances are given over a four-day period in amounts equivalent to full therapeutic dosage of salicylate. The salicylate isomers are known to be quite ineffective in the relief of acute rheumatic manifestations.

Further work is in progress to attempt to elucidate the therapeutic importance and the nature of the metabolic stimulating property of salicylate.

Summary

It has previously been shown that full doses of salicylate greatly stimulate the metabolic rate of normal and subacute rheumatic subjects. The present study concerns the metabolic effect of full therapeutic doses of salicylate in the treatment of acute rheumatic fever. Fall in temperature and relief of symptoms are associated with the maintenance of the original high level of oxygen consumption, and the level falls only when the drug is withdrawn or dosage reduced. It is concluded that salicylate has a metabolic stimulating effect in the acutely ill rheumatic patient.

The isomers of salicylate, *para*- and *meta*-hydroxybenzoate, which are without effect in the relief of the acute rheumatic state, do not significantly alter the metabolic rate of convalescent patients.

I am greatly indebted to Professor Sir John McNee and Dr. James Reid for their constant help and criticism.

"FAILED FORCEPS": A REVIEW OF 100 CASES

BY

R. LISLE GADD, M.B., Ch.B., M.R.C.O.G.

First Assistant, St. Mary's Hospitals, Manchester

Occipito-posterior positions and deep transverse arrest of the head accounted for over 50% of "failed forceps" cases investigated at the Birmingham Maternity Hospital by Freeth (1950), who found that the maternal death rate was 2% and the total foetal loss was 34%. Earlier, Miller (1928) reviewed a larger series with a maternal death rate of 10% and a total foetal loss of 64%. The reduction in the mortality from failed forceps over two decades has therefore been considerable.

To confirm Freeth's findings and to see if a similar reduction in mortality has taken place in another large maternity hospital, all cases of failed forceps admitted to St. Mary's Hospital, Manchester, during the period January, 1943, to December, 1951, have been reviewed.

Undilated cervix (39%) was the commonest cause of failure. The maternal death rate was 2% and the total foetal loss was 28%.

Incidence

The number of cases admitted each year fell from 17 in 1943 to 1 in 1951 (Table I). As the total number of emer-

TABLE I.—Incidence of Failed Forceps Cases

Year	No. of Cases	% of Total Emergency Admissions

1950	6	1.9
1951	1	0.5

gency admissions varied considerably from year to year, the failed forceps cases have been expressed as a percentage of the total emergency admissions. There is a decrease from 3.2% in 1943 to 1.5% in 1948, followed, after an increase in 1949, by a fall to 0.5% in 1951.

Aetiology

The causes of failure fall into eight groups, and each group is analysed separately (Table II). In certain cases more than one possible cause for failure was present. When this occurred the case has been classified under the more

important cause. Thus in the presence of incomplete cervical dilatation along with an occipito-posterior position, the case has been classified under the former condition. When spontaneous delivery occurred shortly before or after admission the cause of failure could not be verified. Such cases have been allotted to Group 8.

Group 1—Cervix Not Fully Dilated (39 Cases).—All cases were treated expectantly in the first instance (Table III). If full dilatation of the cervix did not occur, caesarean

section or forceps extraction after craniotomy was carried out, depending on whether the foetus was alive or dead. Natural dilatation of the cervix occurred in 33 cases. Of these, six were subsequently delivered by natural forces. In 27 cases forceps were applied. This high proportion is partly accounted for by the 10 cases of occipito-posterior position (including deep transverse arrest), and in the other 17 cases there was perhaps a tendency to apply forceps rather readily in the belief that, once failure with forceps has occurred, it is safer—for the baby—to deliver as soon as possible. The onset of foetal distress in one multipara with a rim of cervix was unsuccessfully treated by internal version and breech extraction.

Group 2—Occipito-posterior Positions (22 Cases).—In one case associated with a funnel-shaped pelvis caesarean section was resorted to when attempts at manual rotation failed. In cases in which the foetal heart was still audible at the

time of admission there were two stillbirths and two neonatal deaths from intracranial haemorrhage. The maternal death, which was attributed to shock, occurred after manual rotation and mid-forceps extraction.

Group 3—Deep Transverse Arrest (11 Cases).—All the cases in this group were treated by manual rotation and mid-forceps extraction. Shoulder dystocia caused the only stillbirth among babies alive on admission.

Group 4—Brim Disproportion (7 Cases).—The size of the baby—average weight 9 lb. 4 oz. $\pm$ 11.3 oz. (4.2 kg. $\pm$ 85 g.)—rather than contracted pelvis was the major factor in causing disproportion. In one case with a normal pelvis the baby, which was dead on admission, weighed 13 lb. (5.9 kg.). The treatment of choice for brim disproportion with a living baby is caesarean section. The poor results with the alternative, high forceps, are shown in Table V.

Group 5—Outlet Contraction (7 Cases).—In seven cases, all primiparae, contracted outlet was stated as the reason

for failure. In only one case, in which the single foetal loss occurred, was pelvic outlet contraction definitely established by the recorded measurements. In this case the intertuberos diameter was 3½ in. (8.3 cm.) and the posterior sagittal diameter 2 in. (5 cm.). With great difficulty an 8 lb. 4 oz. (3.7 kg.) stillborn foetus was delivered with for-

ceps. In the other cases moderate traction with forceps effected delivery. In all the occiput was anterior and in none had episiotomy been performed before admission. I believe that soft-tissue resistance, rather than bony disproportion, caused the failure or was an important contributing factor.

Group 6—Hydrocephalus (3 Cases).—The diagnosis was made by the size of the head and the great width of the cranial sutures on vaginal examination. Treatment was by craniotomy. Bilateral episiotomies had been made in one case in which the greater part of the head lay above the brim, but such moulding had occurred that it was also visible at the vulva.

Group 7—Brow Presentation (2 Cases).—One of these cases was treated by caesarean section and the other by craniotomy, as the baby was already dead. In the latter case even after craniotomy great difficulty was encountered in delivering the head. Exploration of the uterus revealed an extensive rupture of the lower segment which was treated by supravaginal hysterectomy. The patient's recovery was complicated by a temporary uretero-vaginal fistula, but this closed by the twentieth day and she eventually did well.

Group 8—Aetiology Unknown (9 Cases).—Normal delivery or an easy low forceps extraction successfully terminated the labour in eight cases. The ninth ended fatally (Table VI). After failing to deliver with forceps the family

medical attendant performed internal version and unsuccessfully attempted breech extraction. On admission the dead baby was delivered up to the head, and maternal shock was present. The after-coming head was delivered easily by the Mauriceau-Smellie-Veit manœuvre under a general anaesthetic, the third to be administered. The uterus was not explored and the third stage was normal. Twelve hours later the patient's condition deteriorated and death occurred 24 hours later. Necropsy revealed a ruptured uterus which was unsuspected until the general condition was such that surgical intervention was no longer feasible.

Munro Kerr and Chassar Moir (1949) say, "Version (after failed forceps) is never worth while; not one in two children

is saved, and more than 10% of mothers are lost from rupture of the uterus, shock, or sepsis."

Prophylaxis

Many cases could be prevented if the accoucheur constantly kept in mind the criteria for a successful forceps delivery—namely, (1) no cervix palpable; (2) the head deeply engaged; and, if the forceps is to be applied in the home, the head should be visible on separating the labia; (3) the occiput anterior; (4) no marked contraction at the pelvic outlet; and (5) the bladder and rectum empty.

Even with a visible head the abdomen should always be examined to exclude the hydrocephalic which has so moulded that the greater part is above the brim yet is visible at the vulva. If the cervix is palpable (so often said to have re-formed) after the induction of anaesthesia, the interests of mother and baby are best served by graceful retreat without applying forceps. (An exception, however, may be made in respect of a multipara with a rim of cervix which responds easily to manual dilatation.)

Principles of Treatment

Once failure occurs the treatment of shock, if present, should be the first consideration. In this event it is advantageous in domiciliary practice to call an obstetrical flying squad, which should then assume responsibility not only for resuscitation but also for the subsequent delivery.

Failure to deliver with forceps, using moderate traction, should not be regarded with shame. On the other hand, persistent attempts to deliver by brute force constitute bad practice.

Whenever possible the doctor should accompany his case to hospital, giving full particulars of the labour, with special reference to the time of full dilatation, number and type of anaesthetics administered, and the previous obstetrical history. If this is neglected, drowsiness of the patient may lead to the failure to elicit vital information.

In hospital the patient is admitted to a "suspect" ward, as every case must be regarded as potentially infected. (In the present series the incidence of notifiable pyrexia was 18%.) The interests of the individual in such a case demand antibiotics. Unfortunately, however, the routine administration of these drugs may lead to the subsequent production of resistant strains.

It will often be advisable to set up a 5% glucose intravenous drip as soon as possible, in view of the fact that many cases are suffering from acidosis and dehydration. It should also be borne in mind that all of these patients have had some form of anaesthesia, and many have had more than one anaesthetic. It is therefore important to ensure that any further anaesthetic is given by a skilled person, that chloroform is avoided, and that it is the last anaesthetic required. With the latter end in view it is considered advisable after delivery to explore the uterus to discover if any damage has occurred.

Discussion

The fall in the annual number of cases is ascribed to three factors: (1) Improved antenatal care, which has reduced the number of home confinements of such abnormalities as brim disproportion, hydrocephalus, and outlet contraction. (2) The stress laid in the modern teaching of obstetrics on the criteria for successful forceps delivery. (3) The appointment of new consultants in the outlying districts since the advent of the National Health Service in 1948. The number of patients confined in hospital was not a factor in the fall, as there were fewer hospital confinements in the Manchester area in 1951 than in 1945.

Contrary to Freeth's findings, the commonest cause of failure in this series was application of the forceps before the cervix was fully dilated, and in at least 50% of the cases the forceps was applied too soon. Unlike Freeth (1950) earlier reviewers (Feeney, 1947; Stacey, 1931) came

to a similar conclusion. Ovarian tumour, constriction ring, or breech or face presentation were not observed, although Freeth found one of each abnormality.

A maternal mortality of 2% and a foetal loss of 28% are similar to Freeth's figures. In the last 25 cases reviewed the total foetal loss was only 8% and all the mothers survived.

Reference to Table VII demonstrates the progressive improvement in the maternal mortality since 1928. Analysis of the deaths in Miller's series suggests that the reduction

TABLE VII.—Review of Earlier Series

Gadd	Manchester	1952	100	2	28	14	2
Freeth	Birmingham	1950	100	2	34	10	—
Feeney	Dublin	1947	77	16.9	60	56	6
Munro	Glasgow	1933	70	7	51	?	?
Kerr	Sheffield	1931	154	15	52	29	7
Stacey	Manchester	1928	558	10	64	23	8
Miller	Glasgow	1928	558	10	64	23	8

* Does not include any cases in which normal delivery or low forceps without complications to the mother occurred.

in maternal loss is due to the advent of antibiotics and blood transfusion rather than to greater obstetrical skill. Miller's deaths occurred from sepsis (37), ruptured uteri (8), post-partum haemorrhage and shock (6), pneumonia (3). Excluding the deaths from sepsis and pneumonia, maternal deaths were only 2.5%, a figure similar to the two recent series in which none of the four deaths occurred from sepsis.

A similar reduction occurred in the total foetal loss. The minimal foetal loss is the percentage of babies dead on admission. Excluding Feeney's series there has been a change for the better in the type of case. In Miller's and Stacey's series the babies dead on admission were over twice as many as in the two later series. Subtracting the minimal foetal loss from the total foetal loss gives the "actual" loss of babies in hospital. In Stacey's series this was 23% and in the present series 14%. This difference may be accounted for by the more confident and safer use of caesarean section to-day for inertia, brim disproportion, and difficult occipito-posterior positions. Caesarean section was employed only for brim disproportion in Freeth's series, with the result that his "actual" foetal loss in hospital was 24%—1% higher than Stacey's figures 20 years previously.

Summary

A review has been undertaken of 100 consecutive failed forceps cases admitted to St. Mary's Hospital, Manchester, during 1943–51.

The incidence of such cases fell from 3.2% to 0.5% of the total emergency admissions, and reasons for this decline are suggested.

The commonest cause of failure was the undilated cervix (39%).

The maternal mortality was 2% and the total foetal loss was 28%.

Pyrexia was notifiable in 18% of the cases.

A comparative survey of earlier series is presented, and reasons are suggested to explain the gradual improvement noted in the results.

I wish to thank Dr. E. A. Gerrard, Professor W. I. C. Morris, and Dr. J. W. A. Hunter for help and advice in the preparation of this article.

CRISES IN CONGENITAL SPHEROCYTIC ANAEMIA (ACHOLURIC JAUNDICE)

BY

J. L. EMERY, M.D., D.Ch.

Pathologist, Children's Hospital, Sheffield; Lecturer in Pathology, University of Sheffield

AND

D. W. LEMMON, M.B., B.Chir.

Registrar in Pathology, Children's Hospital, Sheffield

Since the observation by Owren in 1948 that in the crises of "acholuric jaundice" the bone marrow showed hypoplasia of the erythron there have been confirmatory reports in America (Dameshek and Bloom, 1948) and on the Continent (Cremer, 1950; Gasser, 1950). Other than an annotation in the *British Medical Journal* (1949) there has been extremely little comment in this country. Whitby and Britton (1950) merely note Owren's views without comment. Changes in the bone marrow as a cause of "crisis" have by no means reached general clinical assent.

Details of the marrow changes in four crises in three children are presented here, and the probable aetiology of the anaemic crisis is discussed.

Case 1

The patient was first admitted to hospital at the age of 1 month with extreme pallor and a history of icterus neonatorum lasting 20 days. Her haemoglobin was 5.2 g.% and she was thought to be a case of congenital hypoplastic anaemia. A blood transfusion was given and she was discharged. When readmitted two months later with further anaemia (Hb 5.6 g.%) her reticulocytes varied between 2.5

Fig. 1.—Case 1. Showing changes in haemoglobin and reticulocyte level during the first crisis. M = marrow biopsy.

and 4% of 2,250,000 red cells. Spherocytes were seen in the film. She was given a further transfusion and discharged.

She attended the out-patient department for about a year, during which her haemoglobin remained around 8 g.% and her reticulocytes between 3 and 6%.

She then had a crisis. This followed a period of restlessness, fretfulness, cough, and nasal discharge for two weeks, during which time she was seen to become increasingly pale. The course of the crisis may be seen in Fig. 1. No reticulocytes were seen for five days; they then appeared, and increased steadily in numbers over the next nine days, her general condition then returning to the pre-crisis state. Marrow biopsies were taken at the onset of the crisis and after recovery. Marrow pictures were based on counts of

approximately 1,000 cells; the cells were:—At crisis: myeloblasts, 1.0; promyelocytes, 4.0; neutrophil myelocytes, 7.75; eosinophil myelocytes, 0.25; neutrophil metamyelocytes, 8.0; eosinophil metamyelocytes, 0.25; neutrophil polymorphs, 18.5; eosinophil polymorphs, 1.25; basophil polymorphs, nil; lymphocytes, 13.0; mononuclears, nil; proerythroblasts, 3.0; eosinophil normoblasts, 2.0; intermediate normoblasts, nil; late normoblasts, nil; unidentified cells, 2.0; haematogones, 37.0; plasma cells, nil; reticulo-endothelial cells, 1.0; mitotic cells, 0.25. After recovery from crisis: myeloblasts, 0.25; promyelocytes, 1.25; neutrophil myelocytes, 7.0; eosinophil myelocytes, 1.0; neutrophil metamyelocytes, 9.0; eosinophil metamyelocytes, 0.25; neutrophil polymorphs, 4.5; eosinophil polymorphs, 0.75; basophil polymorphs, 0.25; lymphocytes, 6.0; mononuclears, nil; proerythrocytes, 3.25; early normoblasts, 11.0; intermediate normoblasts, 22.0; late normoblasts, 29.25; haematogones, 2.5; plasma cells, nil; reticulo-endothelial cells, 1.0; mitotic cells, 0.75.

The distribution of primitive cells in the erythron (Fig. 2) shows a general depression in the crisis period.

FIG. 2.—Case 1. First crisis. Showing the percentage of cells of the erythroid series seen in the marrow during the crisis period and later in the recovered state ("usual").

marrow again showed hypoplasia of the erythron. Her erythrocyte count fell from 3,800,000 to 2,500,000 in five days, the haemoglobin from 8.2 to 5.5 g.%, and the reticulocytes from 133,000 (3.5%) to 35,000 per c.mm. (1.4%). Her reticulocytes remained low for the next four days and then steadily rose during the next week to 350,000 per c.mm. and the blood count steadily returned to its pre-crisis level of between 8 and 9 g. Hb% with 4,000,000 to 4,500,000 erythrocytes. Her marrow again showed hyperplasia of the erythron—that is, the changes seen in the previous crisis were repeated.

Her spleen was then removed. Since that time her haemoglobin has remained in the order of 10 to 12 g.%, and she has shown no anaemic crisis.

Other Investigations.—During her anaemic crisis no changes were seen in her leucocyte count. Erythrocyte saline fragility curves showed haemolysis commencing in 0.67% and complete in 0.4% saline. Coombs's test was negative. The serum bilirubin during the second crisis was 1.3 mg. per 100 ml., a single level done in a quiescent phase being 1.1 mg. per 100 ml. The child's mother has a spherocytic anaemia with abnormal saline fragility, but gives no history of recurrent anaemic crises.

Comment.—This child, who had typical familial spherocytic anaemia, was observed through two crises. Both episodes were preceded by a clinical disorder, the first by an upper respiratory infection, and the second by an intestinal disturbance which may have been an infection. In both crises the usually hyperplastic erythron was replaced by extremely hypoplastic tissue and there was a great fall in peripheral reticulocytes. The first crisis was severe, and was associated with a depression of the bone marrow which lasted at least 10 days. The second crisis was much less severe, and the duration of the hypoplasia seemed to be less. In both instances

recovery was spontaneous. No depression was seen in the leucocyte either in the peripheral blood or in the bone marrow. During the crisis the child was pale and yellowish but not notably jaundiced, and the blood bilirubin did not appear significantly raised from the resting level. Splenectomy effected a clinical cure.

Case 2

This child was admitted in "crisis" at the age of 6½ years. She had been one of twins and had had spastic quadriplegia since birth. No history of anaemic episodes was available.

Examination revealed severe pallor, Hb 3.4 g.%, R.B.C. 1,300,000, and reticulocytes 5,200 per c.mm. The erythrocytes showed marked spherocytosis. Her saline fragility curve was typical of hereditary spherocytic anaemia; haemolysis began in 0.75% and was complete in 0.40% saline. No evidence of serological blood incompatibility was found. Her bone marrow on admission showed considerable depression of erythropoiesis, particularly in the late normoblast stage (Fig. 3).

Immediately after the marrow puncture she was given a blood transfusion; this raised her haemoglobin to the region of 10 g.%, and coincidental with this her reticulocytes rose to 224,000 per c.mm. and remained at about this level for several days.

Marrow puncture at this time showed hyperplasia of the erythron and a picture similar to that seen in subsequent studies before splenectomy.

The leucocyte counts throughout the crises were above what appeared to be a normal level for the child. She was subsequently discharged for a few weeks and then readmitted for splenectomy, after which her reticulocyte count fell to normal levels, although her fragility curve remained abnormal. She has since then shown no anaemia. Faecal bilirubin excretion during the period of crisis was 19 mg. a day. Later when she came in for splenectomy the level was 62 mg. a day.

Comment.—We were unable to follow the whole course of the crisis in this child. She showed, however, three features: (1) reticulocytopenia and marrow hypoplasia during the crisis; (2) an apparent immediate reticulocyte response to the administration of 2 pints (1,140 ml.) of blood; (3) a relative diminution of faecal bilirubin excretion during the crisis period.

Case 3

This child was first seen when aged 6 years, and was admitted with a history of increasing pallor for about 48 hours. She was extremely pale with a faint yellowish tinge. Her blood bilirubin was 1.8 mg. per 100 ml. Her haemoglobin was 1.3 g.%, R.B.C. 900,000, platelets 47,000 per c.mm., and reticulocytes 14,000 per c.mm. Her erythrocytes showed marked spherocytosis and increased saline fragility. (Haemolysis began in 0.75% and was complete in 0.40% saline.) Her bone marrow showed extreme hypoplasia of the erythron with a few giant proerythroblasts.

A blood transfusion given immediately after the marrow puncture produced a dramatic change in her appearance. Before the transfusion it was a point of bedside discussion whether or not she was icteric; after the transfusion she looked so like the other children in the ward that the question of icterus did not arise.

Her subsequent course is illustrated in Fig. 4. Her platelet count rose within six days to her normal figure, while her reticulocyte count did not rise until several days later.

FIG. 4.—Case 3. Showing the changes in reticulocytes, platelets, and haemoglobin during the crisis. Blood transfusions were given at the points marked B.T.

Later marrow studies showed hyperplasia of the erythron (Fig. 5). Bilirubin studies could not be carried out. Her mother's erythrocytes showed increased fragility in saline, but she gave no history of anaemic crises.

After the child's spleen was removed her reticulocytes fell from their apparent usual level of 200,000 to 8,000 per c.mm. Her haemoglobin remained around 14 g.%. She has since then shown no clinical symptoms.

Comment.—This girl was admitted in a severe anaemic crisis which, but for a blood transfusion, would probably have been fatal. Her severe anaemia clinically unmasked her continually raised serum bilirubin, giving her a mild yellow tinge. After transfusion this disappeared. Her marrow showed extreme hypoplasia of the erythron during the crisis, compared with hyperplasia in her usual state. The return of platelets in her peripheral blood preceded the return of reticulocytes. The latter may have been postponed by the adequate blood transfusion.

Discussion

In the three children described here four crises were seen. All of these crises were associated with a reticulocytopenia in the peripheral blood and a period of hypoplasia of the erythroid element of the bone marrow. In the case most carefully studied the two crises were preceded by a period of symptoms suggesting an infection and both crises resolved spontaneously. The other two cases showed more severe anaemia and required blood transfusion. From a biochemical point of view the one case in which faecal bile elimination was studied showed diminished excretion during the crisis period, and in one other case the blood bilirubin was not significantly raised during the crisis.

Owren (1948), in a study of six cases of crises in acholuric jaundice, saw reticulocytopenia in five of them. In one case he followed the marrow picture through the complete crises. He observed that in the crises the red blood cell count fell to about a half of the original level in about six

days. He noted a reduction in serum bilirubin and diminution in urinary urobilin excretion. In the bone marrow he saw a spontaneous recovery of the erythron, beginning on the ninth day of crises. He considered that the aplastic phase of the bone marrow was able of itself to account for the blood changes during the crises. The finding of marrow aplasia during the period of crises was confirmed by Dameshek and Bloom (1948), but they considered the crises to be due to a phase of hypersplenism in which the spleen produced an inhibitory effect on the bone marrow and at the same time itself increased its own haemolytic activity. The aplastic factor in the crises was also confirmed by Gasser (1950), Cremer (1950), and Hermansky (1951). Schrumpf (1950) summarized a group of papers read at the Société Européenne d'Hématologie at Montreux by saying "... it is advised to remove the statement from most textbooks of increased reticulocytic number during haemolytic crises. What really happens is that the number is lowered during the crisis."

It was soon noted that similar aplastic crises occurred in sickle-cell anaemia (Singer, Motulsky, and Wile, 1950; Chernoff and Josephson, 1951). In this condition hypersplenism does not seem to occur and removal of the spleen does not influence the course of the disease.

In discussing the cause of the anaemic crises the most important single factor would seem to be the length of life of the individual cell. It has been shown that whereas the life of a normal red cell is about 100 days that of a red cell in a case of hereditary spherocytosis is about 14 days (Dacie and Mollison, 1943; Owren, 1948). Thus if there was an absolute cessation of red cell production for a period of 10 days in a normal person the effect on the peripheral blood would be a reduction of about 10% of the peripheral count for 100 days. In a case of spherocytosis, on the other hand, a similar cessation of cell production would result in a precipitous fall in red cells. If the aplasia lasted 14 days it would theoretically result in there being no peripheral surviving cells at all. It is this feature which would seem to account for the presence of anaemic crises in spherocytic and sickle-cell anaemia.

Clinically the crises often appear to have a very rapid onset, but this is compatible with the view that the anaemia is due to aplasia. The clinical acute pallor will be associated with a fall of haemoglobin from the regions of 5 g. to around 3 g. This can easily occur owing to the elimination by the spleen of surviving spherocytes in 36 to 48 hours. It is interesting to observe that in Case 1 of our series the two crises were of different severity, the second crisis being much less severe than the first. The milder crisis was associated with a less marked reticulocytopenia.

Three mechanisms that need discussion in the production of the crises are (1) the role of increased haemolysis, (2) hypersplenism, and (3) marrow aplasia.

There is virtually no evidence of increased haemolysis in cases recently studied and reported during crises. No increase in bile excretion occurs. Owren noted an absolute diminution in jaundice and blood bilirubin during the crises. The name "acholuric" attached to the disease is on simple clinical observation that in this type of jaundice an increase in bile elimination does not occur. The theory of two forms of bilirubin used to explain the anomaly is probably false (Gray and Whidborne, 1947).

The role of hypersplenism was largely adopted by Dameshek and Bloom; they had no evidence that the spleen itself produces the marrow aplasia. They noted a relative increase in the number of spherocytes in the peripheral blood during crises and suggested that this was due to splenic activity. A more likely explanation is that in crises there is a relative increase in older and hence spherocytic cells. The presence of aplastic crises in sickle-cell anaemia, in which hypersplenism does not seem to occur, necessitates a different explanation of the crises in the two similar diseases. Further, Freund (1932) refers to cases in which splenectomy did not prevent later death from anaemia.

The evidence suggests that the aplasia of the erythron can itself account for the clinical presentation of an anaemic crisis. In that case why the aplasia?

It has been considered that the crises in spherocytic anaemia are often precipitated by infection (Murray-Lyon, 1935; Scott, 1935; Dameshek, 1941; Horne, Lederer, Kirkpatrick, and Leys, 1945), and recently it has been recognized that certain infections, notably diphtheria and infectious mononucleosis (Gasser, 1950; Chernoff and Josephson, 1951), may be associated with a transient hypoplasia of the erythron.

In spherocytic anaemia we have to consider the effect of an infection upon a bone marrow in a state of prolonged and profound compensatory hypertrophy and therefore especially liable to a conditioned nutritional deficiency. The diversion of essential protein which is thought to be responsible for the anaemia of infection (Cartwright and Wintrobe, 1952), could thus be exaggerated in effect, and a relatively acute deficiency could occur, with resulting aplasia.

Such an explanation would seem to us more likely than the postulation of a hypothetical hypersplenism, and would also account for the apparently increased tendency to crises during pregnancy.

Summary

Four crises in three children with spherocytic haemolytic anaemia were studied.

All crises were associated with reticulocytopenia and with hypoplasia of the erythron in the bone marrow.

Recovery from crises was associated with the reformation of the usual hypertrophic marrow.

No evidence of increased haemolysis was seen in the crises.

It is suggested that the marrow aplasia is the primary cause of the anaemic crises and that the aplasia is due to conditional deficiency states induced by the presence in the body of an infection on a marrow undergoing prolonged compensation hypertrophy.

We are indebted to Dr. T. Colver and Professor R. S. Illingworth, the paediatricians in charge of the cases reported here.

The C.W.S. Retail Co-operative Society of Manchester was fined £120, with 10 guineas costs, at Hastings, Sussex, on March 18 on five summonses in respect of the condition of premises used for food storage at St. Leonards. The society pleaded guilty to summonses accusing them of (1) failing to provide a sufficient supply of water for persons employed there; (2) failing to see that the walls, ceilings, and doors of the room had been purified; (3) failing to give notice that an infestation of rodents was present in the room; (4) failing to protect food stored in the room; and (5) failing to see that the walls, ceilings, floors, and windows were kept in a proper state of repair. The premises were used for the storage of cereals, rice, and beans in sacks and packages. A spokesman for the society said they deplored this matter and now had very good premises.

FURTHER TRIAL OF AUREOMYCIN IN THE TREATMENT OF CHOLERA*

BY

S. C. SEAL, Ph.D., M.B., B.S., D.P.H., F.A.P.H.A.

AND

S. C. GHOSAL, M.B., B.S., D.P.H., D.B.†
Lately Professor of Bacteriology, School of Tropical Medicine, Calcutta

In a previous communication (Seal, Ghosal, and Ghosh, 1951) the results of a preliminary trial of aureomycin, administered intravenously, in the treatment of cholera cases were reported. These being unsatisfactory it was suggested that the oral route might be chosen for the administration of the drug if further trial was undertaken in future. Accordingly a trial was organized in the same institution at Calcutta, this time during the prevalence of cholera epidemic in the city between April 30 and July 20, 1951. Only frankly typical cases were chosen at random and were divided into three groups: experimental, sulphaguanidine control (control 1), and saline control (control 2), the number of cases treated in each group being 50, 35, and 35 respectively, total 120. The subjects were all males and were admitted in a stage of collapse, generally within 24 hours of the onset of symptoms, and had received little or no treatment prior to admission to hospital.

Treatment

Dosage.—The drug was supplied in capsules, each containing 250 mg. In the previous study the dosage used for intravenous administration was 100 mg. every six hours, and in a few cases 50 mg. every three hours, the total quantity used being generally 300 mg. Some untoward symptoms were noted with 100 mg., but not with 50 mg. per adult dose. With this experience, and in the absence of any previous knowledge of the dose which would be suitable for oral administration in cholera patients, it was tentatively decided to try one capsule of 250 mg. every three hours. This amount was easily retained with no untoward effect referable to the drug. A few cases which showed complications during the course of the disease will be discussed later. Of the 43 cases which recovered 8 were clinically severe, 23 moderately severe, and 12 were mild, the average doses received by these groups being 6.65 g., 5.5 g., and 4.875 g. respectively. From the nature of response obtained by oral administration of the drug it appears that 500 mg. every three hours or 250 mg. every one and a half hours may be tried as an initial dose, whichever is found convenient, and if the drug is effective at all the total amount actually needed for recovery may be much less than has been used in the present investigation, perhaps about 3 to 5 g., depending upon the severity.

Other Treatments.—As in the previous trial, all cases brought to the hospital in a state of dehydration and collapse were given intravenous saline and glucose in varying

*Presented before the Medical and Veterinary Section of the Indian Science Congress Association at its annual meeting held at Lucknow in January, 1953.

†Dr. S. C. Ghosal has died since the paper was written.

doses before the administration of the experimental drug. In severe cases, this treatment was further supplemented by alkaline saline, coramine, and atropine whenever necessary.

Treatment of Controls.—Two groups of control cases were simultaneously treated, one receiving sulphaguanidine in place of aureomycin and the second receiving no specific drug, the "other treatments" being the same in all the three groups. The initial dose of sulphaguanidine was 4 g., the total doses varying from 4 to 36 g. (average 25 g.) in the cases which recovered.

Laboratory Examinations

Examination of Stool Samples.—The procedures adopted by Chaudhuri *et al.* (1950) were followed for the collection and examination of stool samples, and only specimens collected by means of a sterile rectal rubber catheter or on a burnt earthenware vessel and removed to the laboratory in sterile borate-buffered salt solution were accepted for cultural examination. This had twofold advantages. It eliminated the use of a bed-pan, which could give spurious results due to imperfect washing and sterilization or to the presence of some residual antiseptics; secondly, it gave more reliable

data about the period of excretion owing to the greater chance of isolating *V. cholerae*, if present, by this method than by others. A case was considered bacteriologically negative when at least three consecutive stool samples inoculated into the enriched medium proved negative to *V. cholerae*. Seventy-five or 62.5% of the patients were vibrio-positive, yielding Inaba type in 64 cases, Ogawa in 10 cases, and both Inaba+Ogawa in one case. The vibrio-positive cases were equally distributed in the three groups (see Table II).

Examination of Blood Samples for Non-protein Nitrogen.—As in the previous trial the examination of blood samples from the cholera patients for non-protein nitrogen was carried out in the Biochemistry Section of the Calcutta Medical College. The estimation could be made only in 28 patients, 12 from the aureomycin group and 8 each from the two control groups; these tests were done mostly in the earlier period of the investigation; the difficulty arose out of the gas-workers' strike in Calcutta during the months of May to July, 1951. The amount and distribution of non-protein nitrogen in different groups of cases, according to the nature of complications, are given in Table I.

TABLE I.—Amount and Distribution of NPN (mg./100 ml.) in the Blood of Cholera Patients According to the Nature of Complications in Different Experimental Groups.

Group Treated With	Uraemic Cases		Lung Complication		Typanitis		Jaundice		Vasomotor Failure		Without Complication	
	No. of Cases	Blood NPN in Cases Tested (mg./100 ml.)	No. of Cases	Blood NPN in Cases Tested (mg./100 ml.)	No. of Cases	Blood NPN in Cases Tested (mg./100 ml.)	No. of Cases	Blood NPN in Cases Tested (mg./100 ml.)	No. of Cases	Blood NPN in Cases Tested (mg./100 ml.)	No. of Cases	Blood NPN in Cases Tested (mg./100 ml.)
I	2	3	4	5	6	7	8	9	10	11	12	13

TABLE II.—Showing the Clinical States and Progress of the Three Groups of Cholera Patients Treated with Aureomycin (Oral), Sulphaguanidine, and Saline Respectively.

Clinical States	Aureomycin (Oral)-treated Group	Sulphaguanidine-treated Group (Control 1)	Saline-treated Group (Control 2)
Number of cases treated	50	35	35
Age distribution (in years)	10-50 (average 30.5 years)	12-60 (average 31.2 years)	14-80 (average 31 years)
Duration of illness before admission (hours)	14-48 ¹ (average 9.6 hours)	34-48 ² (average 15 hours)	4-72 ³ (average 17.2 hours)
Sp. gr. of blood on admission	1062 (3), 1062 (14), 1063 (3), 1064 (10), 1065 (3), 1066 (9), 1067 (1), 1068 (7); average 1064.2	1061 (1), 1062 (8), 1063 (1), 1064 (8), 1065 (1), 1066 (11); 1068 (3); average 1064.5*	1062 (7), 1063 (2), 1064 (5), 1065 (4), 1066 (10), 1067 (3), 1068 (4); average 1065
Clinical types	Severe 15 (30%); Mod. 23 (46%); mild 12 (24%)	Severe 8 (22.9%); Mod. 16 (45.7%); mild 11 (31.4%)	Severe 11 (31.4%); Mod. 16 (45.7%); mild 8 (22.9%)
Condition of urine on admission	Suppressed 32 (64%); scanty 18 (36%)	Suppressed 16 (45.7%); scanty 19 (54.3%)	Suppressed 19 (54.3%); scanty 16 (45.7%)
Duration of suppression of urine (hours)	6-36 (average 16.0 hours, SD 2.219)	3-34 (average 16.3 hours, SD 2.103)	11-36 (average 22.75 hours, SD 2.207)
Complications	Uraemia 5; lung complications 2; jaundice 2; total 9 (18%)	Uraemia 4; typanitis 1; vasomotor failure 1; jaundice 1; total 7 (20.0%)	Uraemia 1; typanitis 1; total 2 (5.7%)
Blood NPN (mg./100 ml.)	Done in 12 patients (15, 16, 20, 22, 25, 38, 39.2; 42, 56, 60, 86, and 95 mg.—average 42.85 mg.)	Done in 8 patients (18, 24, 28, 39.2, 45, 53, 72.8, and 90 mg.—average 46.25 mg.)	Done in 8 patients (25, 24, 25, 26, 28, 34, 62, and 86 mg.—average 38.75 mg.)
Vibrio positive or negative	Vibrio + 31 (62%); Vibrio - 19 (38%); Inaba 27; Ogawa 3; In. + Og. = 1	Vibrio + 22 (63%); Vibrio - 13 (37%); Inaba 20; Ogawa 2	Vibrio + 22 (63%); Vibrio - 13 (37%); Inaba 17; Ogawa 5
Excretion of vibrios (average duration)	2-75 days (SD 0.132)	3-72 days (SD 0.164)	3-72 days (SD 0.271)
Average number of stools during the first 5 days of admission	10.9 (SD 0.919)	12.3 (SD 1.611)	14.1 (SD 1.902)
Average duration of illness (acute stage)	37.1 hours, SD 1.611 (average of 43 cases); 37.4 (including the dead)	39.7 hours, SD 2.249 (average of 29 cases); 39 hours (including the dead)	47.3, SD 3.530 (average of 29 cases); 43 hours (including the dead)
Average amount of saline used (pints)	6.0 (average of all cases); 5.96 (excluding the dead)	6.0 (average of all cases); 5.7 (excluding the dead)	6.2 (average of 34 cases); 6.3 (excluding the dead)
Specific drugs	4 to 36 capsules (250 mg. each); average 23 capsules (excluding the dead)	4-36 g.; average 26 g. (excluding the dead)	Nil
Number died	7† (14.0%)	5 (14.3%)	5 (14.3%)
Period between admission and death or cessation of acute stage	28.3 hours (excluding the dead); 28.8 hours (all cases)	28.0 hours (excluding the dead); 28.4 hours (all cases)	30 hours (excluding the dead); 27.2 hours (all cases)
Average length of stay in hospital (days)	5.5 (excluding the dead); 6.2 (all cases)	6.5 (excluding the dead); 6.2 (all cases)	5.9 (excluding the dead); 6.8 (all cases)

* Sp. gr. of two cases not estimated.

† One case had only 1 capsule and died within 3 hours of admission and another had 2 capsules and died within 4 hours of admission. Fatality rate excluding the first case = 12.2%.

¹ 48 hours—1 case; ² 48 hours—3 cases; ³ 48 hours—3 cases, and 72 hours—1 case.

Reactions after Oral Administration of Aureomycin

Five cases in the aureomycin-treated group developed uraemia, two cases lung complications, and two cases jaundice, total nine cases (18%). Similarly in the sulphaguanidine-treated group four cases developed uraemia, one case tympanitis, one case vasomotor failure, and one case jaundice with pain in the abdomen, total seven cases (20%). In contrast with this only two cases (5.7%) in the saline-treated group showed complications. It is thus a question whether these complications were in any way the results of drug treatment. Though the appearance of jaundice in two cases and uraemia in five cases treated with aureomycin may be considered as some evidence for the toxic action of the drug it is doubtful whether the latter was directly responsible for the complications: not only did the amounts of the drug administered to the patients who developed complications vary widely—namely, 1, 1.75, 4.5, 4.75, and 7.25 g. in the uraemic cases, 3.5 and 4.75 g. in the jaundiced cases, and 5.25 and 6 g. in cases with lung complications—but also all those who received as much as 9 g. each (two severe, three moderate, and one mild), recovered without any complication. This question will be discussed again later.

Results

The data relating to the clinical states and the progress of the patients in the aureomycin-, sulphaguanidine-, and saline-treated groups are summarized in Table II. As will be seen, the cases in the three groups are fairly well distributed in regard to age, clinical stage at the time of admission, specific gravity of blood, condition of urine, and positive isolation of *V. cholerae*. In so far as the end-results are concerned there is no appreciable difference between the three methods of treatment, but in regard to certain minor points aureomycin treatment showed some advantages.

Unlike the previous trial by the intravenous route the blood non-protein nitrogen was generally within the normal range in the majority of cases treated by aureomycin, being high only in two of the twelve cases examined. The same was true of the control groups. The average duration of the suppression of urine in the aureomycin group was significantly less than that of the saline-treated group by 6.8 hours ($t=2.099$ with 41 d.f., as against 2.021 with 40 d.f. at 5% point of t), but there was very little difference between the aureomycin and the sulphaguanidine groups in this respect ($t=0.105$ with 39 d.f. and 90% point of t with 40 d.f.=0.126).

So far as complications, such as uraemia, lung symptoms, jaundice, and tympanitis, are concerned, the advantage was definitely in favour of the saline controls, there being hardly any difference between the aureomycin and the sulphaguanidine groups. However, a significant advantage of the aureomycin group over the saline controls is found in respect of the duration of excretion of vibrios. Although the difference is small it is statistically significant ($t=3.514$ with 43 d.f., as against 3.551 with the same d.f. at 0.1% point of t). The same advantage is found over the sulphaguanidine group ($t=2.417$ with 45 d.f. and 2% and 5% point of t with the same d.f. are 2.423 and 2.021 respectively). Similarly the average duration of the acute stage was curtailed by 10 hours in the aureomycin group compared to the saline group ($t=2.919$ with 69 d.f. and 1% point of t with 60 d.f.=2.660). In this respect the sulphaguanidine group gave nearly the same results as the aureomycin group. The average number of stools during the first five days of hospital treatment was also less in the aureomycin-treated group than in the sulphaguanidine- or the saline-treated group, though the difference is not statistically significant. Some difference was also noted in the average length of stay in hospital of patients in the three groups, the advantage being in favour of the aureomycin group, but the discharge of the patients from the hospital was not strictly guided by the condition of the patient. There was no difference, however, in the fatality rates of the three groups of patients.

Comments

Although no appreciable reduction in the fatality rate of patients treated with oral aureomycin was obtained, the findings of this investigation are nevertheless interesting. Firstly, the toxicity seen after intravenous administration was practically eliminated, the toxicity being no greater than was observed in the cases treated with sulphaguanidine. It is true, complications were much less without any chemotherapy, but treatment with aureomycin had certain advantages. For instance, there was a significant reduction in the average period of suppression of urine as well as of the acute stage of the disease. Perhaps more important than this, from the point of view of epidemiology and international quarantine laws, is the fact that the patients became vibrio-free earlier than with sulphaguanidine or saline treatment. However, judging from the fatality rates and from the average amount of saline used in each group it is difficult to avoid the impression that the drug had no influence upon the course of the disease. This would appear to support Lahiri's (1951) view that no specific drug has yet been found in cholera. We do not, however, fully subscribe to this. In the experience of one of us (S. C. S.) in the field trial of sulphaguanidine (Seal, 1947) it became quite clear that the secret of success in the treatment of cholera cases lay in their early treatment; once dehydration and collapse set in, the administration of a vibrio-static drug is of no help without saline treatment; and treatment with a vibriocidal drug becomes sometimes positively harmful owing to the release of a large quantity of endotoxin at a stage when the patient is already at a serious disadvantage owing to the extreme loss of fluid.

Another difficulty is the great individual variation in the behaviour of patients against cholera infection. Some people are more apt to develop vasomotor failure or uraemic symptoms than others, and such cases generally do not respond easily to treatment. Again, the fatalities mostly occur in the earlier part of the epidemic and there is proportionately greater chance of recovery in cases occurring after the peak period. Thus, in the present study, deaths in all the three groups occurred during the first two weeks of May, 1951—that is, the early weeks of this investigation. In fact no fatality occurred amongst 35 patients treated with another antibiotic during the period between May 22 to July 18, 1951. The failure of any drug in the advanced stages of cholera does not necessarily mean that it has no action on the cholera vibrio. Aureomycin is vibriocidal *in vitro*, and the quicker disappearance of the organism from the convalescent cases indicates that the drug is also effective *in vivo*. The dose of aureomycin capsules used in the present investigation was probably high. A lower dose of 3 to 5 g. according to the stage of the disease may be found sufficient.

Summary

1. In a trial of oral aureomycin for the treatment of cholera, 50 patients were treated with aureomycin capsules, 35 with sulphaguanidine, and 35 with saline, the last two groups acting as controls.
2. There was no difference in the fatality rates among the three groups, which were all about 14%. In the group receiving aureomycin the acute stage was shorter, and the duration of suppression of urine and the period of excretion of vibrios were reduced. There were no serious toxic effects.
3. The results are discussed.

Thanks are due to Dr. A. K. Dutta Gupta, Principal, Nilratan Sircar Medical College, for kindly providing facilities for this investigation and to Dr. M. Chakrabarti, Professor of Physiology, Medical College, Calcutta, for carrying out the blood examinations for the estimation of N.P.N.

Medical Memorandum

Spontaneous Perforation of the Colon Due to Alkaline Medication

The following case is reported because, although it is almost unique, it results from a very common combination of circumstances.

CASE REPORT

A man aged 68 was admitted to hospital complaining of severe lower abdominal pain. He had been investigated in another hospital six months previously because a duodenal ulcer was suspected, but a barium meal examination did not confirm this. Subsequently he had taken an unidentified alkaline preparation. On the morning of March 4, 1950, he paid a routine visit to his doctor. There he collapsed with severe lower abdominal pain which led to his admission to hospital. He gave a history of increasing constipation during the previous few months with occasional bleeding at stool.

Examination showed an old man with evidence of recent weight loss. There was a slight degree of shock with cold extremities and perspiration. The temperature was 96.8° F. (36° C.), pulse 66, respirations 20, and blood pressure 140/95. The lower abdomen was very tender, with muscle spasm almost amounting to rigidity. Rectal examination showed the bowel to be full of large hard faecal masses. Immediate laparotomy was advised, though it was some hours before the patient would consent to this.

Under general anaesthesia the abdomen was opened through a right lower paramedian incision. There was a moderate quantity of turbid fluid with a faecal odour in the peritoneal cavity. In the pelvic colon there was a perforation about 1 cm. across on the antimesenteric border. Around its edges was a ring of necrotic tissue about 1 mm. in width. Through the perforation a hard faecalith was protruding. This proved to be a very hard spherical whitish lump of faeces with a rough gritty surface. Palpation showed the whole of the descending and pelvic colon and the rectum to be full of similar material. The perforation was temporarily closed by suture, and the loop in which it lay was then exteriorized through a separate incision in the left iliac region, where it was fixed by passing a glass rod through its mesentery. The temporary suture was then removed so that the perforation became a colostomy opening. Exteriorization was performed under some tension owing to the shortness of the mesosigmoid. The abdomen was closed with drainage of the pelvis.

Intravenous fluids were given and gastric aspiration was continued for four days, and streptomycin, 1 g. twice daily, was administered. The patient progressed satisfactorily until the eighth day, when there was a small secondary haemorrhage from the colostomy, possibly due to the tension of the colon over the glass rod. Bleeding recurred and was fatal on the eleventh day.

Post-mortem examination confirmed the operation findings. In particular, the colon, both throughout its length and at the site of perforation, was normal. The condition was a perforation of an acute stercoral ulcer due to faecal impaction, presumably caused by alkaline medication, and occurring in an otherwise normal colon.

DISCUSSION

Spontaneous perforation of the colon—that is, perforation not due to external injury—is familiar to all surgeons with experience of abdominal emergencies. In discussing the aetiology, apart from malignant disease, Koucky and Beck (1940) mention diverticulitis, foreign bodies, nemata, compressed air, tuberculous ulceration, ulcerative colitis, typhoid, and dysentery, to which may be added simple ulcer of the ascending colon (Wilkie, 1937). Woodruff's 1952 review, apart from mentioning Brown's (1944) case, described below, adds no new predisposing cause to these.

Spontaneous perforation of the colon in the absence of any of these factors is very rare. The only cases at all similar to the present one are those of Brown (1944) and of Hoffert (1946). Brown's patient was a man of 30. A few minutes after rising he had a sudden abdominal pain of great severity. On admission to hospital he was shocked and had the signs of generalized peritonitis. At operation the abdomen contained thin turbid fluid. "In the pelvis was a small quantity of faeces. On the antimesenteric border of the pelvic colon close to the pelvi-rectal junction there was a laceration in the long axis of the bowel about 1 cm. long and with a mass of faeces protruding through it. The edges of the laceration were irregular and the bowel wall, apart from involvement in the general inflammation, was macroscopically normal." This patient recovered, and subsequent radiological examination failed to show any evidence of diverticula or foreign body. Brown was unable at that time to trace any similar case in the literature.

Hoffert's case, described two years later, is very similar to Brown's and almost identical with the case now reported. A male patient aged 63 was receiving treatment for duodenal ulcer. He developed signs of peritonitis, and x-ray examination showed free gas in the abdomen. At operation there were solid faeces throughout the left half of the transverse colon and descending colon. Two faecal balls were lying in the pelvis and there was a 2-cm. perforation in the sigmoid. This patient survived following a Paul-Mikulicz resection of the segment containing the perforation.

These two cases and the present one are remarkable in that the perforation occurred in a normal colon and in the absence of trauma. The mechanism of perforation in Brown's case is unexplained, but the fact that the patient was being treated for duodenal ulcer in the other two cases points to a previously unrecognized danger of alkaline medication. The site of the perforation on the antimesenteric wall in two of the cases suggests that this type of perforation is due to impaction of faeces causing tension gangrene, which appears first at that part of the wall with the poorest blood supply. Constipation is a well-known complication of certain alkaline powders, especially bismuth salts and aluminium hydroxide, and patients who have had these medicines prior to partial gastrectomy often develop post-operative diarrhoea due to faecal impaction in the rectum, a complication which may also occur if operation follows soon after a barium meal.

Even without the interruption of rectal function which follows an operation, old and constipated patients may develop faecal impaction while receiving alkaline powders, as another recent personal case shows. Hunt (1950) says: "Aluminium hydroxide and aluminium silicate are constipating and tend to produce dry hard stools with, in some cases, even troublesome faecal impaction. Magnesium trisilicate, on the other hand, in sufficient dosage to be effective in relieving pain is laxative and irritant to the intestine, so that colic borborygmi and intestinal flatulence make it difficult to use. A mixture of these two is rational . . . and probably the best of the antacids available."

The same principle is already familiar in the balancing of bismuth and magnesia in the older powders. Although this stasis seldom leads to perforation of the colon, minor degrees of impaction, irritation, and even ulceration are probably quite common. It is suggested, therefore, that if alkaline powders play any part at all in the treatment of peptic ulcer the two substances mentioned should be combined with liquid paraffin and a mild aperient (a combination likely to reduce calcium intake); or, better, an alkali which has a mild aperient action, such as magnesium carbonate or trisilicate, should be included in the mixture.

I wish to thank Mr. J. B. Oldham for help and advice in the preparation of this paper.

Reviews

PRINCIPLES OF PUBLIC HEALTH

The Health of the Community: Principles of Public Health for Practitioners and Students. By C. Fraser Brockington, M.A., M.D., D.P.H., B.Chir.(Cantab.), M.R.C.S.(Eng.), L.R.C.P.(Lond.). With a foreword by Sir John Stopford, M.D., Sc.D., LL.D., F.R.C.P., F.R.S. (Pp. 415. 32s.) London: J. and A. Churchill Ltd. 1954.

This is a well-written and timely book. Professor Brockington has wide experience of the public health service and has maintained over the years a close interest in academic teaching and field research. This book has the great quality of being a personal document. Although much of his material is highly compressed, he never hesitates to use vivid illustrations from his own experience. In fact this is a first-rate example of how to write a short book on a large subject without making it synoptic and dull. It is vivid and interesting, comprehending much in few words. Professor Brockington handles figures with ease, and he might have been tempted to produce acres of tables; instead of this he weaves the figures into the pattern of the story in such a way as to add to their interest. He goes a step further indeed: "The use of numbers in epidemiology," he says wisely, "(and in a book about people) is unavoidable, and, although they may at first sight seem to be impersonal and lacking in human qualities, to those who come to understand them figures are in reality as full of meaning and poignancy as any descriptive writing; each is the record of a human life and in the aggregate of groups of people or of the whole nation."

He is not afraid of verbal imagery even when he is using words with the utmost economy. In discussing mental ill-health, for example, he says, "A large fraction of the time and energy of the State is concerned to cope with the end results—hospitals, institutions, clinics, home care, and supervision; the operation of courts of law in crime, delinquency, and divorce; the problem of absenteeism from work—yet this may be proportionately not more than the visible part of an iceberg is to the whole floating mass." Sometimes the compression is too great, and a comma or two become displaced, with curious results. The reader may be a little startled by the remark about medical officers of health: "He cannot like his colleague, the family doctor . . . until he discovers that the sentence is governed by what follows: 'apply whatever treatment he thinks appropriate.'"

This book is an admirable statement of principles and the author never loses sight of his main objects. He may be a trifle optimistic about the future unification of the health services, but he states his case cogently and shows evidence of a deep understanding of the position as a whole. He restates with great skill and restraint the scope and functions of the medical officer of health, and does battle valiantly to secure the general practitioner in his rightful place. This book should be read by all who are interested in the development of the public health service and particularly in the health of the community in its broadest sense. The blemishes are trivial in a book at once so interesting and comprehensive.

J. M. MACKINTOSH.

GENERAL PRACTITIONERS' SYMPOSIUM

Clinical Medicine in General Practice. Edited by John Fry, M.B., B.S., F.R.C.S. With a foreword by Sir Henry Cohen, M.D., D.Sc., LL.D., F.R.C.P. (Pp. 436. 27s. 6d.) London: J. and A. Churchill Ltd. 1954.

This book is a symposium by eight general practitioners and edited by Dr. J. Fry. The first chapters describe the management of a practice and the work done by rural and urban practitioners. Chapters on cardiovascular diseases (Dr. C. Papp), rheumatic disorders (Dr. A. Talbot Rogers), and the common fevers (Dr. G. O. Barber) are written by experts who are good teachers as well as general practitioners. The reader's enjoyment is slightly marred by some tiresome misprints in the chapter on rheumatic disorders.

It appears that clinical medicine in general practice is based on the same principles as in hospital practice. It is stressed that the general practitioner has special difficulties and responsibilities because he is the first to see the patient and has to distinguish between the trivial and the serious.

Dr. Watts, writing on nervous disorders, insists on the importance of diagnosis. He cuts a path clean through the jungle of psychological undergrowth that besets the general practitioner. One can but marvel at his ability to label his specimens so neatly. It seems too good to be true. Writing on obstetrics he is disappointing. He repeats the hospital teaching on antenatal care, including a fearful pamphlet handed to the expectant mother, and believes the general practitioner's chief function in a normal confinement is to act as anaesthetist to the midwife.

Dr. Fry on respiratory diseases nicely illustrates how a general practitioner is able to take the long view of his patients' disorders. His description of the development of bronchitis and emphysema in a patient over twenty years is of great interest, but he commits the error of dividing the respiratory tract into upper and lower. Nowhere is it mentioned that this particular patient had his nasal sinuses x-rayed. Dr. Fry and Dr. Pinsent on skin disorders and Dr. Barber on drugs in general practice show that treatment can be rational and yet simple and inexpensive.

The general practitioner is seen at his best in two chapters on children (Dr. Lindsey W. Batten) and the aged and incurable (Dr. Finer). Dr. Lindsey Batten in particular happily combines a scientifically detached attitude of mind to the problem with a really imaginative sympathy with the child—and his mother. If he is not already teaching medical students he certainly should.

This is an uneven book. It is, however, a laudable attempt to show how the general practitioner can be of value to clinical medicine.

C. W. WALKER.

SYNOPSIS OF CHILDREN'S DISEASES

A Synopsis of Children's Diseases. By John Rendle-Short, M.A., M.B.(Cantab.), M.R.C.P., D.C.H. (Pp. 620; illustrated. 32s. 6d.) Bristol: John Wright and Sons Ltd. 1954.

Now that paediatrics has become recognized in many universities as a fourth major subject, equal in importance to medicine, surgery, and obstetrics, it is both fitting and timely that a companion volume to Tidy's *Medicine*, Wakeley's *Surgery*, and Bourne's *Obstetrics* should appear in this outstanding synopsis series. This newcomer is particularly welcome, for there is no volume of comparable size available for final-year students revising their paediatrics, or for D.C.H. or M.R.C.P. candidates, and the standard of the contents is admirably suited to these ends. *A Synopsis of Children's Diseases*, which might perhaps better have been entitled "Synopsis of Paediatrics," is a courageous attempt to follow in the steps of the three other masters.

Inevitably a first edition such as this must invite some criticisms, but these are slight. There are commendably few errors and the text is remarkably up to date. Although the author says in the preface that the book is intended for paediatric house-physicians and general practitioners as well as for examination candidates, the details of treatment are, in the main, too sketchy to be of value to residents and general practitioners. The most helpful section, perhaps, is that on diseases of the respiratory system. There are twenty-one tables of differential diagnosis, and these will prove most useful. It is a pity, however, that one of these is devoted to the differentiation between mongolism and cretinism, although this is following tradition. Mongols and cretins are so unlike, and each has such distinguishing characteristics, that there should be no need for this table in future editions.

There is one severe criticism—and that is the use of "etc." This appears—usually more than once—on almost every one of the 554 pages encompassing the 174 chapters. And it is a very bad example to examinees. The height of synopsis is reached in Chapter 168, which reads: "Gonorrhoea. In girls—see p. 393. In boys—very rare. Signs, symptoms and

treatment etc. as for adults." Why the etc.? On page 150, in the indications for tonsillectomy, no mention is made of the importance of enlargement of the tonsillar glands. On page 20, in the treatment of Hirschsprung's disease, ephedrine sulphate 2 gr. is the dose recommended. As no reference is made to the age of the child so to be treated this is certainly a dangerous recommendation.

This is really a most valuable book and is certain of a wide circulation.

WILFRID GAISFORD.

THE CHRISTIE CASE

Medical and Scientific Investigations in the Christie Case. By Francis E. Camps, M.D. Foreword by the Attorney-General, Sir Lionel Heald, Q.C., M.P. (Pp. 244; with 47 diagrams and photographs and 6 coloured plates. 30s.) London: Medical Publications Limited. 1953.

The case of John Reginald Halliday Christie was unusual in several respects, but especially because of the number of women who died from violence in one house. That the details of medico-legal investigation adopted in such cases should be recorded is of high importance for reference and other purposes. In this monograph the story of the finding of the bodies and the ensuing scientific and police investigations, together with the medical evidence, are fully explained. It is a welcome addition to volumes which have already treated similar subjects. Throughout the text and in many illustrations the methods used are fully described. The reader cannot fail to be impressed by the scrupulous care taken by the investigators not only in the collection but in the evaluation of the evidence.

In this case, as in others within recent times, the anatomist plays a predominant part. The appendix to the book, in which the methods of estimating stature from long bones are not only fully described but compared, is of very considerable value to all whose work is concerned with such an undertaking. The formulae devised by Karl Pearson, Dupertuis and Hadden, and Trotter and Gleser are discussed and their comparison illustrated by their application to five subjects. The author indicates that the Pearson formulae underestimate the true height and that those of Trotter and Gleser give the best results. In this work Dr. Camps has received the able assistance of Dr. Richard J. Harrison, reader in anatomy, University of London, and of Professor A. E. W. Miles, professor of dental pathology, University of London, and of others.

Throughout the text the findings are carefully described, and, more important still, the methods whereby the results were obtained are recorded. This record will be of benefit in any future similar investigation. To the medico-legal consultant, pathologist, police surgeon, lawyer, and indeed to all concerned with medico-legal problems this volume will prove of high value. The author and his collaborators are to be congratulated. The illustrations are numerous and well produced and the production is of a high standard, for which the publishers should be complimented.

J. GLAISTER.

RADIOLOGY OF BONE DISEASES

The Radiology of Bones and Joints: An Introduction to the Study of Tumours and other Diseases of Bone. By James F. Brailsford, M.D., Ph.D., F.R.C.P., F.I.C.S.(Hon.). Fifth edition. (Pp. 875; over 725 illustrations. 90s.) London: J. and A. Churchill. 1953.

Radiology, though still a young branch of medicine, is now sufficiently mature to span easily a man's whole professional life. This point cannot be better illustrated than by reference to the book under review. In the preface to the new edition the author writes: "The book now comprises a digest of the work of the author since he was appointed to the staff of the Pathological Department of the University of Birmingham forty-six years ago." The work has grown in size and maturity concurrently with the experience of the writer. The first edition was published in 1934, and this one, the fifth, is about twice as long and contains about twice as many illustrations.

The general structure has changed but little since the last edition five years ago. Rather more space has been devoted to bone tumours, the problem perhaps of greatest interest to the author and that to which he has made his most important contributions. On this theme he has always been stimulating and provocative. There are probably few more worrying problems in the whole of medicine than the accurate diagnosis and correct treatment of bone tumours. Classical medical teaching leads us to rely on the veracity of histological reports, but we are liable to become disillusioned if the subject is a possible bone tumour. When three expert pathologists all differ in their opinion—as can happen—on one section, and when each may ultimately be proved to be wrong, a strong case can be made out for the expert bone radiologist having a casting vote. Dr. Brailsford has done much to reorientate our views in this respect, and for that alone his name would be important. Bone tumours are likely long to remain difficult diagnostic problems, partly because they are sufficiently rare for more than a few to gain sufficient experience to develop a mature judgment.

Brailsford's work is too well known, not only to the English-speaking world, but also to the Spanish, into which language it has been translated, to require further comment. It is a pleasure to see that first-class paper is now being used again so that the blocks may be reproduced to their best advantage, so important particularly for bone lesions.

J. W. D. BULL.

THE NATIONAL HOSPITAL

The National Hospital, Queen Square: 1860-1948. By Gordon Holmes, M.D., F.R.S. Foreword by Sir Ernest Gowers, G.C.B., G.B.E. (Pp. 98; illustrated. 10s. 6d.) Edinburgh and London: E. and S. Livingstone Ltd. 1954.

The introduction of the National Health Service marked the end of an epoch, and has naturally led to the recording in book form of the past histories of many of those hospitals which won international fame while still on a voluntary basis. In this well-produced and readable book Sir Gordon Holmes has written the story of the National Hospital, Queen Square, of which he himself has been such a distinguished ornament. The National Hospital was not only the first hospital to be established solely for the treatment of nervous diseases, but for many years it was, and we believe it still is, the leading centre for neurological teaching and research.

It began in a small way. Miss Johanna Chandler, finding that it was difficult to obtain hospital treatment for paralysed persons, determined to remedy the deficiency, and, though not wealthy herself, by her persistent efforts succeeded in getting such a hospital established. It started with only 12 beds, but it filled a need and inevitably grew in size and importance. At present it has about 200 beds and splendid out-patient and research departments. It is in addition a great centre of teaching as a postgraduate school and is recognized as a unit of the University of London.

The author has inserted short biographies of all the chief physicians and surgeons who have been associated with the hospital in the past and are no longer living, and these impress one with the large proportion of truly distinguished men who have worked there. It is an inspiring story, and these great men are not likely to be forgotten. We hope also that the memory of Miss Johanna Chandler will be kept alive.

ZACHARY COPE.

In *Medicine in Oxford* (Basil Blackwell, 10s. 6d.) Dr. Maurice Davidson discourses pleasantly on the general history of the University of Oxford, emphasizing those events and statutes that specially affected the development of the medical curriculum. He draws attention to the "Laudian code" of 1636 and sympathetically portrays the personality of Archbishop Laud (1573-1644). A particular feature of these FitzPatrick Lectures, delivered before the Royal College of Physicians of London in 1952-3, is the very fine series of portraits. The book should be a useful companion to H. M. Sinclair and Robb-Smith's *History of Anatomical Teaching in Oxford*, Oxford, 1950.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 27 1954

GOOD GENERAL PRACTICE

This week the Nuffield Provincial Hospitals Trust publishes in book form a report¹ by Dr. Stephen Taylor of a survey of 30 general practices in England and Wales. This survey was commissioned three years ago "at a time," as the foreword of the report says, "when there was not perhaps as sympathetic an attitude as now seems usual towards the problems and opportunities of general practice." The survey was to be non-statistical and, also in contradistinction to that carried out by Dr. S. Hadfield on behalf of the B.M.A.,² not of a random sample of practices but of a selected number of good practices. The whole purpose of the report is, in a sense, an attempt to define and describe good practice, and therefore those practices were chosen which were generally regarded by other practitioners as outstanding. It is encouraging to read that such practices proved "surprisingly easy to find." In the 30 practices there were 94 doctors, of whom 81 were principals and 13 were assistants. Dr. Taylor was guided in his investigation by a steering committee under Sir Wilson Jameson with Dr. G. Barber, Sir Ernest Rock Carling, Sir Henry Cohen, Mr. Leslie Farrer-Brown, Dr. J. Revans, Dr. A. Talbot Rogers, and Sir James Spence as members. This was an active body, and though the observations in the report are those of an individual the conclusions drawn from them are not.

Surveying the pattern of general practice, the report comes down firmly in favour of the capitation method of payment. It is said that it avoids the disadvantages of both salary and fee for service in a type of occupation where "checking of work done is undesirable and indeed impossible"; and, again, "the independence of mind and spirit of the G.P.s visited has been a striking feature . . . in substantial measure, this appears . . . to be associated with payment by capitation fee." As might be expected, a notable difference in the amount of work per patient per year and in the daily volume of work per doctor was observed in the practices surveyed—variations as great as 3.5 to 9.6 items of service per patient per year and 24 to 87 items of service per doctor per day.

"On a basis of general observation" it appeared to Dr. Taylor that fatigue and decline in efficiency started to show itself in the surgery after 15 to 20 patients had been seen and on the round after 10 to 15 visits. From this it is estimated that the average number of services a day should be between 40 and 55, and, on the assumption of an average of 5.3 services per patient per year, this suggests that the "average optimal maximum list is between 2,500 and 3,000."

Of the practices visited in the survey, fourteen had three or more members, and of these fourteen ten were conducted from a single practice house and thus fulfilled what is taken as one of the main criteria of a true group practice. The making of a group practice, its advantages and disadvantages, and the details of its administration are carefully examined. While acknowledging that there are many first-class individual practices and partnerships Dr. Taylor gained the impression that doctors in a successful group almost always supply a better medical service than they would if dispersed. Defining a health centre as "a building where general practitioners carry out their work under the same roof as the local authority clinics" the report goes on to say that there is no point in providing health centres for the sake of any abstract dogma. Policy must be adapted to the nature of the need in areas of different types. Where there are keen and competent general practitioners who undertake maternity and infant welfare work there is a diminishing need for clinics, and to build expensive health centres would be foolish. Where there are good clinic buildings actively at work the report says that it is clearly unnecessary to replace them by new health centres. In such places, mainly industrial areas, it is thought that the need is for group practice buildings and for functional links between the general practitioners and the clinics. Where, however, both the clinic buildings and the general practitioners' premises are poor or non-existent, such as the new towns and housing estates, the case for building health centres is strong.

The section devoted to the thorny problem of the general practitioner's place in hospital work will be read with special interest. It is suggested that the development of clinical assistant posts on the widest possible scale is likely to become the key to the whole problem, provided that these posts are regarded as training appointments and as a means of forging personal links between general practitioners and the local specialists and hospitals rather than as an easy way of supplying an extra pair of hands to the hospital. Of general-practitioner beds the experience in the survey suggests that, where general practitioners have

their own beds available and a general hospital with full specialist staff, the use made of general-practitioner beds is very small. From this comes the conclusion that instead of increasing the number of general-practitioner beds where specialist services exist it would be better to improve the facilities for domiciliary care—by increasing, for instance, the home-nursing and home-help services, and through housing policy. But, the report adds, there is no reason why the general practitioner should not look after his own maternity cases in hospital or nursing-home beds. Almost every general practitioner should regard obstetrics as completely within his sphere. The specialist must be prepared to leave normal midwifery to the general practitioner (except for the training of midwives), and general practitioners on their side must be ready to call in the specialist whenever the need arises. No evidence of anything but good relations between the midwives and general practitioners was found in the course of the survey. Arrangements for normal deliveries, on the whole, were found to be good, and there were several examples of excellent co-operation during the antenatal period. Of the health visitor, it is said that if she is to make a useful contribution towards the care of the general sick in the home as well as of mothers and children she must take her instructions from the general practitioner. No systematic attempt was made in the survey to take evidence from medical officers of health, and any picture gained of the local authority health service was seen through the eyes of the general practitioners interviewed. Criticism of the medical officer of health was less common than complete ignorance of him and all his works, but in one county borough general practitioners and the medical officer of health had set up a joint liaison committee. The report considers that this sort of thing can prove successful, but the initiative for co-operation must come from the medical officer of health.

These are but samples of some of the matters dealt with in considerable detail in a long report on the vast and ever topical subject of the day-to-day work of the general practitioner. A whole chapter and an appendix, for instance, are given to a favourable description of rota systems. Much useful information is given about the use of ancillary help and the planning of the surgery accommodation, and about the scope of the general practitioner's work, together with a section on laboratory work in general practice. The report concludes with an attempt to foretell the future. Remarking that medically the greatest change brought about by the National Health Service has been the diffusion of salaried specialists throughout

the country, with a resulting new homogeneity in general practice, it says that "almost all general practitioners must now make domiciliary and consulting-room medicine their primary activity." A future "rich with opportunity" for general practice is envisaged. Open access to the laboratory, to much of the x-ray department, and perhaps to some physiotherapy will enlarge the scope of practice. Within the past fifteen years, it is pointed out, technical advances have so greatly extended that to-day the general practitioner in the gloomiest slum practice can treat pneumonia more effectively than most specialists were able to do before the war. "What has happened once," the report says, "may surely happen again." A society which is changing with increasing speed, and against which the future of general practice must be set, in itself will present new problems and growing points, which will, as the report foresees, occupy the general practitioner to the extent that he has the time, energy, and initiative to cope with them. Of the risks to the future of general practice three are singled out. First, that the general practitioner may become lazy in his work. Next, that he may become a relatively unimportant outpost of the hospital service: this risk is a predisposing cause of the first, and many have seen it as the gravest danger to general practice. Lastly, there is the risk to personal freedom and personal integrity which is liable to develop inside any large-scale organization. It is noticeable that nowhere in the report are administrative details discussed. This is in keeping with the attitude of mind with which the survey was approached—namely, that good general practice begins with the good general practitioner and that its quality depends upon the men and women who are actually doing the job. Organization is described as a means to the end of bringing together those who are sick and those specially trained to help them. Beyond this, organization must not be exalted, for this is the way to a tyranny all the more dangerous because it is cloaked with good intentions. The future safety of the doctor's freedom, as the report sees it, lies in his own hands. By their standards of work general practitioners must deserve to be free—"that is the challenge to general practice to-day."

The declared function of the Nuffield Trust is not to pronounce policies but to make accurate experimental studies of various aspects of the health services so that all concerned may benefit. This report fulfils the traditions of the Trust, and, one may add, is a tribute to the tradition of the branch of medicine which it sets out to describe. It is not always clear which conclusions are based on the observations of the practices surveyed and which come from the

¹ *Good General Practice*, 1954, Oxford University Press, London.
² *British Medical Journal*, 1953, 2, 683.

consideration of other evidence or from the opinions of the steering committee itself. However, this need not detract from the value of an important document which starts with certain assumptions and then by every means possible sets out to find if these were true or false. Taken in conjunction with Dr. Hadfield's survey, to which in many important respects it is complementary and in broad agreement, this latest Nuffield Report will do much to restore confidence in the future of general practice and is likely to achieve the author's hope that many, particularly the young practitioner, may profit from it. It is a report which all general practitioners should read and digest.

ADOLESCENCE

The period of adolescence is one fraught with immense importance for the individual lad and for the community. It is a period of instability, of development and transition, physical and psychological. There is good reason why this period of change should be beset with difficulty for the young people concerned, striving as they are to adapt themselves to the new freedom—and the new restrictions—inherent in the change from school to employment, facing a host of new interests and new temptations, groping for new values, and all the while developing personality. The approach to youth problems in the depressed years of the 'thirties was inevitably overshadowed by the spectre of unemployment. Cameron¹ and his co-workers found that under the circumstances of those times demoralization was at its worst among young adults of poor social background, and they considered that irretrievable damage had often already been done during the first few years after leaving school. Morgan,² in a report to King George's Jubilee Trust, concluded that the voluntary youth movement had so clearly demonstrated the necessities and the possibilities of providing creative leisure activities for youth that its work must go on. "The vague clamour for national fitness," he wrote, "will have meaning when the nation as a whole grasps the fact that only on the bedrock of youth can we lay the foundations of real national fitness." Is it more difficult now for a youth to pass successfully from boyhood to manhood than it was a generation ago? In some ways it probably is; for, while it has never been easier for the school-leaver to step into a comparatively well-paid job, it is equally certain that many of the jobs so readily available are bad, gilded

with a thin veneer of apparent attractiveness. Two important new factors have been introduced: one, the raising of the minimum school-leaving age to 15; the other, the introduction of compulsory National Service. The motives behind the raising of the school-leaving age a few years ago were wholly benevolent, but there appears to be some room for doubt whether facilities yet exist in all parts of the country to provide an attractive and useful training for the young people thus kept at school for a further year. For some of them retention at school may be little more than an unsatisfying frustration. Of the introduction of compulsory National Service it may be argued that Service training and discipline will have a steadying value in a period so often characterized by instability; on the other hand, Service life may be a disturbing influence, possibly aggravating the insecurity of adolescence and deterring youth from settling down to a career. There is not yet available any reliable body of evidence on the subject—an extraordinary deficiency, which should surely be remedied.

The transition from school to industry offers at once new problems to the lad and immense opportunities to the sociologist. Osler deplored the attitude of his day which surrounded the child with protective care, only to throw him, on leaving school, more or less by chance into a maelstrom of hazards that could often scarcely fail to undermine the stoutest constitution. Of recent years things have improved in this respect, and the International Labour Review³ has described the growth of legislation designed to protect the young worker in Britain and other industrial countries; but there is still urgent need for enlightened vocational guidance. Fortunately most young people are likely to be able to do most jobs that come their way nowadays, though some at the extremes of fitness do require help. The crisis of school-leaving is never repeated, and if a young person gets into the wrong kind of work at that stage it is very difficult to get him back on to the rails again. The task of the Youth Employment Counsellor is not an easy one. He has to fit the ability and inclination of the boy to a job in which he is likely to be reasonably happy and successful; and he has to find the appropriate job quickly, for if it is not forthcoming soon there is a probability that the boy may drift into the first opening offered. Among the criteria of success that have been applied to young people in this age group are the ability to get, and to hold, skilled employment; to obtain work which satisfies the young person himself and which he is prepared to accept as his permanent job in life; and ability to conform to the

ordinarily accepted standards of social conduct and to use leisure in a reasonable and intelligent manner. Ferguson and Cunnison⁴ found that, no matter which of these tests is applied, young people who come from a good home get on best.

Fortunately the teenagers enjoy comparative freedom from illness; incapacity for work is lower in this age group than at any later age, though tuberculosis is a problem among these young people. In their series of 1,315 boys who had left school at the earliest permitted age, Ferguson and Cunnison found that 54 had already, three years after leaving school, some degree of disability liable to influence their future working capacity. In a representative group of 74 18-year-old lads studied on the eve of call-up for National Service, Logan and Goldberg⁵ have reported that 43 were stable and well adjusted, 19 were maladjusted in some respect, while 12 were "clearly disturbed"—"emotionally so disturbed that psychiatric help would have been advisable." This is probably a higher proportion than that found by most doctors in the student health services of our universities, though the circumstances are different; and there may be room for difference of opinion about the degree of emotional disturbance that calls for psychiatric help. The problems of youth are many-sided and compelling. To their solution medicine has a contribution to make: this is surely above all in the sphere of the family doctor.

ALCOHOL AND ROAD ACCIDENTS

The drunken driver gets short shrift from both public opinion and the law in Britain nowadays, and there seems also to be a growing awareness that the drinking of quite small quantities of alcoholic liquor can seriously impair judgment.^{1,2} But the extent to which alcohol causes road accidents is unknown; indeed, it can hardly be guessed at. The police are reluctant to assign alcohol as the cause of an accident unless they have good evidence, and the evidence of whether people involved in an accident have alcohol in their tissues is not often obtained in this country. Even if it were, the question whether the amount found was sufficient to account for the accident would often be difficult to answer—impossible sometimes with any certainty. In road accidents recorded as due to drink or drugs 1,278 people in Great Britain were injured during 1952; these were 0.61% of the total road casualties. The corresponding figures for 1951 were 1,704 and 0.79, and for 1949 they were 1,269 and 0.72. These figures must seem surprisingly small in relation to the amount of travelling to and from convivial gatherings to be seen of an evening, whether by car, bicycle, or on foot—for the drunken pedestrian is also a menace. An analysis of the road accidents attributed to drink or drugs in 1951 carried out at the

Road Research Laboratory of the Department of Scientific and Industrial Research³ shows that these accidents composed 0.62% of all road accidents in England, 0.85% in Wales, and 1.98% in Scotland. Of the 1,704 casualties, 636 (37%) were pedestrians; in these 636 cases the pedestrian was to blame in 497 (78%). There were 233 bicycle casualties (14%), and in 180 (77%) of these the cyclist was the culprit. The worst period of "drink or drugs" accidents was Saturday 10 p.m. to Sunday 1 a.m., when 21% of the week's total occurred. The closing of public houses on Sundays in Wales and Scotland was found to be associated with a statistically significant lowering of the Sunday drink accident figures for these countries in comparison with those for England. Such in outline is one part of the rather shadowy background to the many telephone calls that doctors are apt to receive, just as they are dropping off to sleep, asking them to come and examine a man at the local police station. What the doctor should do when he gets there is the subject of a useful booklet published this week by the British Medical Association.⁴

In June, 1951, the Association appointed a special committee to revise and bring up to date two of its previous reports on road accidents and drunkenness, published in 1927 and 1935. The chairman of the committee was Professor E. J. Wayne, and among members were experts in many branches of medicine, including general practitioners, as well as authorities from outside the profession. After explaining the law on intoxication the committee describes in detail the examination of a person detained by the police on the suspicion of being under the influence of alcohol. The report includes guidance on such necessary preliminaries as gaining the person's consent, such questionable concomitants as the presence of a police officer, and such worrying consequences as the giving of written or verbal evidence. Most of this is procedure well tried in practice and here well expressed, a concise record of the exceptionally wide experience which the committee's members have of different aspects of the subject.

The more novel feature of the report is its discussion of estimating the alcoholic content of body fluids. In practice urine is found to be the most suitable fluid to analyse, but considerable experience of the procedure is necessary and facilities are not yet available in every district. Though no particular proportion of alcohol in urine or blood is recognized by the law of this country as signifying that the suspect was culpably drunk or not, an estimate of it can nevertheless, as the report points out, be of value for several reasons. First, a suspect may be conclusively exonerated, and the committee recommends that a suspect who protests he has taken little or no alcohol should be given the opportunity of having his word confirmed by a test of his urine. Secondly, it affords some indication of the trustworthiness of the suspect; and, thirdly, alcohol estimations may point not to a living suspect, for instance, but to a dead victim. Even so, any alcohol estimation could be

misleading if the possibility was overlooked that another drug might have been taken as well. The most likely one is a barbiturate, and there is some evidence that it potentiates the effects of alcohol, though the combination if only additive would clearly be a grave risk.⁵

Confining itself to issues of more immediately practical importance, the report does not venture more than a glance at the arguments whether or not a particular level of alcohol in the blood or urine of a person in charge of a motor vehicle should be evidence that he was culpably intoxicated. In this country it is probable that the degree of intoxication below which conviction will not be obtained corresponds to a blood level of about 0.15%. In some countries figures have been agreed at which it is an offence to drive a vehicle. In Norway, for example, it is 0.05%, in Denmark 0.1%, in Sweden 0.15%, and in some states of America 0.15%. Opinion in Britain has usually veered away from making the blood level of alcohol a fixed measure of culpability, and preferred to dwell rather on the fact that people vary much in their response to different quantities of alcohol. Perhaps this has led to some neglect of the value of routine alcohol estimations (of urine) as additional evidence. If so, this report, admirable as a manual of instruction, may also serve the useful purpose of arousing interest in this debatable subject.

ANTIHAEMOPHILIC GLOBULIN

It is now believed that in the early stages of coagulation thromboplastin is formed in the blood itself as the result of a complicated interaction between a factor or factors derived from the blood platelets and several plasma factors—namely, antihæmophilic globulin, Factor V, Factor VII, and the Christmas factor.¹ In addition, contact with a water-wettable surface and the presence of ionized calcium seem to be essential. As its name suggests, one of the plasma components, antihæmophilic globulin (A.H.G.), is the substance which is absent or grossly deficient in true inherited hæmophilia. The exact nature of A.H.G., which is present normally only in very small amounts in the plasma, is unknown; it mostly separates with the fibrinogen fraction (Cohn's fraction I) when plasma is fractionated by chemical methods of precipitation.

The only effective way of treating hæmorrhage in hæmophilia is to administer A.H.G. intravenously. This can be done by whole-blood or plasma transfusions. Large volumes are necessary—several pints of blood or plasma being required for an adult—and as A.H.G. is somewhat labile the blood or plasma should be administered within 24 hours of collection. Lyophilized fresh plasma or plasma frozen as soon as possible after collection may be used provided they are administered immediately they are reconstituted. Alternatively, the fibrinogen fraction of plasma may be administered, if available: it is this preparation that has loosely been referred to as "antihæmophilic globulin." This has the theoretical advantage of containing A.H.G. in a concentrated form. Unfortunately preparations of high and

standard potency are difficult to prepare, and at present it seems best to use freshly obtained plasma, even if this means administering much larger volumes.

NEW FELLOWS OF ROYAL SOCIETY

Though the list of twenty-five Fellows elected to the Royal Society last week did not contain the names of any medical men, some of the distinguished scientists accorded the honour have made far-reaching contributions to the advancement of medicine. Prominent among them is Professor A. Bradford Hill, professor of medical statistics at the London School of Hygiene and Tropical Medicine. In recent years Professor Hill has been foremost among those workers engaged on the evaluation of new therapies. The large number of drugs produced in the last decade or so, often several for a single disease, such as tuberculosis, made some accurate assessment of their worth imperative. In devising the methods for doing this in conjunction with his colleagues of the Medical Research Council, Professor Hill not only put medical men and their patients in his debt but set standards of therapeutic research in Britain that have not yet been adopted on the same scale in any other country. Some years ago Professor Hill collected and analysed data for the Spens reports; more recently his name has been well-known outside medical and scientific circles for his work with Dr. R. Doll showing the link between smoking and cancer of the lung. Professor C. Rimington, who is particularly distinguished for his work on the synthesis of porphyrins, is professor of chemical pathology at U.C.H. Medical School, London. The author of many papers on blood pigments and their chemistry, Professor Rimington served the Medical Research Council as a biochemist from 1937 to 1945. Before that he had worked in the South African veterinary services for several years. Canada is honoured in the person of Professor F. C. MacIntosh, one of its foremost scientists and professor of physiology at McGill University. Professor MacIntosh formerly worked for a time at the National Institute for Medical Research, London. His researches have been concerned with the physiology of the nervous system, including the transmission of the nervous impulse. Dr. Rosalind Pitt-Rivers, who is a biochemist at the National Institute for Medical Research, has worked for some years on products of the thyroid gland, and in the last two years particularly has carried out research into thyronine. Dr. F. Sanger is a biochemist at Cambridge, a colleague there of Professor F. G. Young's. He has played a prominent part in the biochemical researches into insulin that have distinguished that laboratory, and is also an authority on the amino-acid structure of proteins. Dr. M. F. Perutz is a lecturer in biophysics at Cambridge and director of a Medical Research Council unit there for research into the molecular structure of biological systems. He is carrying out research into the structure of proteins by means of x-ray diffraction, and much of his work has been on hæmoglobin, some of it in connexion with sickle-cell anaemia.

CLINICAL PATHOLOGY IN GENERAL PRACTICE THE ASSESSMENT OF ADRENAL CORTICAL ACTIVITY

BY

F. T. G. PRUNTY, M.D., F.R.C.P.

Physician to St. Thomas's Hospital; Reader in Chemical Pathology, University of London

In the investigation of patients with altered adrenal cortical function there are certain routine laboratory tests which may show deviations from normal and be of subsidiary value, and other specially designed tests aimed at more precise diagnosis. In this article the former will be discussed first, and then the more specific tests such as the Kepler test, the estimation of the urinary 17-ketosteroids, and the trial of A.C.T.H. Before dealing with these, however, it is convenient to review the important conditions in which changes in adrenal cortical function occur. The following is a brief classification for this purpose.

Decreased Adrenal Cortical Function

Acute.—(1) *Waterhouse-Friderichsen syndrome* (the diagnosis of this condition should be regarded as a clinical problem and it is inserted here only for completeness) and (2) *crisis in Addison's disease*.

Chronic.—(1) *Addison's disease* due to tuberculosis, "adrenal cortical atrophy," and rarely to invasion by tumour, amyloid disease, etc. (2) *Anterior hypopituitarism* may be due to post-partum necrosis (Simmonds's disease), chromophobe adenoma, craniopharyngioma, and other rarer lesions. In these patients partial atrophy of the adrenal cortex occurs owing to lack of adrenocorticotrophin secretion by the pituitary. (3) In rare cases children with *adrenal virilism* may have accompanying Addison's disease owing to lack of secretion of cortisone and hydrocortisone by the glands.

Increased Adrenal Cortical Function

Adrenal Virilism.—Pre- or post-pubertal, due to "hyperplasia" or tumour of the adrenal cortex.

Male Feminization.—Rare cases associated with adrenal cortical tumours.

Cushing's Syndrome.—A small proportion of these cases may be due to primary tumour of the adrenal cortex.

Laboratory Investigations of Subsidiary Value

Blood Counts

In increased adrenal cortical activity of the type seen in Cushing's syndrome a characteristic blood picture is often encountered. Haemoglobin and red-cell counts are usually raised, a haemoglobin level of 110% Haldane, even in women, being expected. The total white-cell count is not demonstrably abnormal, but there is a definite tendency for the polymorphs to rise and the lymphocytes to fall, changes which are best evidenced in the fall in lymphocytes to levels below 25%. The direct eosinophil count may be of value in showing a reduction in the number of these cells to the lower limits of normal or below. (Their usual range is between 25 and 300 cells per c.mm.) For this determination the blood should be collected freshly by the pathologist.

Although all these changes tend to be reversed in Addison's disease and hypopituitarism the values seldom deviate very significantly from normal levels. A few patients with hypopituitarism are found to have a mild macrocytic type of anaemia.

Carbohydrate Metabolism

A proportion of patients with Addison's disease show a tendency to hypoglycaemia on fasting. This may be appar-

ent after the lapse of 24 hours and is gradually progressive with a longer duration of fast. If this tendency is present these patients respond unfavourably to fasts of this duration and may drift into a crisis. Blood-sugar levels below 50 mg. per 100 ml. may occasionally be reached with the development of hypoglycaemic crisis. Patients with hypopituitarism also possess this tendency in a variable degree. Both these groups of patients respond profoundly to the injection of small doses of insulin; for example, a dose of 4 units of soluble insulin may be a large one to the rare patient developing severe diabetes in the presence of Addison's disease. This emphasizes that the standard insulin-tolerance test based upon the injection of 0.1 unit per kg. body weight intravenously is apt to be dangerous, promoting a profound fall of blood sugar which the patient is unable to overcome. Such investigations should never be carried out outside hospital, and substandard doses of insulin must be employed. The administration of oral glucose to these patients results nearly always in a "flat" type of tolerance curve where only low levels of blood sugar are reached after half an hour and one hour. Thus in extreme cases the blood-sugar level may never rise above 100 mg. per 100 ml.

Patients with Cushing's syndrome often show decreased tolerance to carbohydrate; glycosuria, fasting hyperglycaemia (blood sugar greater than 120 mg. per 100 ml.), and a diabetic type of oral glucose curve may all be apparent.

Basal Metabolic Rate

A decrease in the basal metabolism, as would be expected from the secondary hypothyroidism, is nearly always found in patients with hypopituitarism, and values down to minus 40% found in myxoedema are encountered. In Addison's disease there is a tendency to a secondary decrease in the basal metabolism, the average lying within the lower limit of the normal range of minus 15%.

Changes in Blood Chemistry

In Addison's disease characteristic changes in the serum electrolytes are found in the more advanced stages of the disease. The constant renal leak of sodium from decreased tubular reabsorption of this ion results, especially if the intake is insufficiently high, in a decrease of extracellular fluid volume and of its total sodium content. Continued shrinkage of this fluid entails depletion of the volume of blood plasma and the concentration of sodium in both these fluids. This process is accompanied by a rise in the packed cell volume (haematocrit) if the patient is not too anaemic to mask it. This rise in packed cell volume is likely to indicate an impending crisis and can be of value in following the efficacy of intravenous replacement therapy. The low values for serum sodium (below 135 mEq per litre or 310 mg. per 100 ml.) are accompanied by a similar drop in the serum chloride below 95 mEq per litre (560 mg. per 100 ml. expressed as NaCl, or 365 mg. per 100 ml. expressed as Cl). A further finding which may be of corroborative assistance is a rise in the level of serum potassium above 5.5 mEq per litre (or 22 mg. per 100 ml.). In performing estimations for this ion it is essential that the serum be separated from the blood within an hour and that no haemolysis should be present, since the red cells contain very much greater concentrations of potassium than the plasma. In Addisonian crisis these changes tend to be at a maximum and the carbon dioxide combining power of the

¹ Biggs, R., et al., *J. Physiol.*, 1953, 122, 538.

plasma rises slightly. The accompanying dehydration results in a moderate rise in the blood urea and non-protein nitrogen values.

In hypopituitarism there is also a tendency to lowering of the serum sodium and chloride levels, but this is not so marked as in Addison's disease, so that the changes are not easily apparent and the investigation is not worth while. In Cushing's syndrome a curious imbalance is encountered, so-called hypochloreaemic alkalosis. The chloride level falls and the carbon dioxide rises to a small degree. There is an accompanying tendency for the potassium level to fall below 3.5 mEq per litre (14 mg. per 100 ml.). These alterations are of very subsidiary value in the diagnosis of the syndrome.

The Water Test (Kepler Test)

In patients with appreciable decrease of adrenal cortical activity due either to Addison's disease or to hypopituitarism it is found that the excretion of urine follows a more uniform pattern through the day than in normal persons. As a consequence of this the decreased ability to economize in urine volume during the night and to show a diuresis during the day is made use of in the investigation proposed by Robinson, Power, and Kepler at the Mayo Clinic (Kepler test). This test is relatively simple to perform and is one of the most valuable screening tests in the diagnosis of these syndromes. It may be of great value in suggesting the possibility of adrenal cortical insufficiency in the absence of pigmentation. It should never be applied to patients suffering from renal disease or oedema due to any cause.

The test is divided for convenience into two parts. For its performance the patient should be in bed, but admission to hospital is not necessary if adequate facilities can be arranged to make and measure accurately the necessary urine collections over timed periods. The co-operation of the patient in complete emptying of the bladder at the end of each period is also necessary. The first part is carried out by withholding all fluids and food after 6 p.m. After emptying the bladder at 10.30 p.m. urine is collected from 10.30 p.m. until 7.30 a.m. the next morning. The patient is then given 20 ml. of water per kg. body weight (9 ml. per lb.) to drink during 45 minutes. Urine collections are made at 8.30, 9.30, 10.30, and 11.30 a.m. and at 12.30 p.m. If the largest volume of urine excreted during a single hour between 8.30 a.m. and 12.30 p.m. ("day urine") exceeds the volume of the 10.30 p.m. to 7.30 a.m. specimen ("night urine") the result is negative for adrenal cortical insufficiency. If the reverse is true the test is positive. Several shortened and more convenient versions of this test have recently been proposed, but their use is not advised for the data for their interpretation are at present lacking.

The accuracy and specificity of the test are greatly enhanced if the second part is also carried out. This involves obtaining, before the water is administered to the patient, a specimen of oxalated blood for chloride and urea determinations. A specimen of the "night urine" with a note of its volume and the volume of "day urine" should also be sent to the pathologist. The test depends upon the fact that the clearance of chloride is increased in cortical insufficiency and the clearance of urea tends to be decreased. These variables (expressed in mg. per 100 ml.) are multiplied to the urine volume observations thus:

$$\text{Factor} = \frac{\text{Night urine urea}}{\text{Blood urea}} \times \frac{\text{Plasma chloride}}{\text{Night urine chloride}} \times \frac{\text{Volume of day urine}}{\text{Volume of night urine}}$$

Adrenal cortical insufficiency may be regarded as present if the factor is less than 25.

The results of both parts of the test can be interpreted only in an all or none fashion, as they give no information about intermediate degrees of failure. If the second part is applied many less false-positive results are obtained and the number of false negatives diminished. The two parts together, when used for the first time, are positive in about

80% of cases of Addison's disease, but occasional false positives are also obtained in patients with liver disorders, hyperthyroidism, anorexia nervosa, gastric lesions, and sprue, so that the results can be interpreted only in the light of other known factors. The test, however, has the advantage that treatment of the patient with deoxycortone does not alter an abnormal test for adrenal cortical insufficiency into a negative one. Treatment with cortisone can of course effect this change.

Urinary 17-Ketosteroid Determinations

There are excreted in the urine a large number of metabolites of adrenal cortical hormones. The determination of one group of these, the 17-ketosteroids, in which a ketone grouping ($\text{C}=\text{O}$) is present at the seventeenth carbon position in the steroid "nucleus" in ring D, may be considered to be a basically reliable procedure. Substances of the same type and giving the same chemical reaction are excreted as the end-products of the metabolism of testosterone, itself secreted by the interstitial cells of the testes. There is no significant corresponding source of 17-ketosteroid in women, so that this must be taken into account in interpreting the results. A further factor is the variation of technique employed in different laboratories. It is to be hoped that this difficulty may be mitigated by the publication of a recommended technique from the Committee on Clinical Endocrinology of the Medical Research Council.* In my laboratory, which may be taken as a guide, the normal range for adults between the ages of 20 and 40 is taken as 8-23 (average 14.5) mg. a day for men, and 5-18 (average 9.5) mg. a day for women. In older individuals these values fall away by 50% at the age of 70. In children of both sexes up to the age of 8 the excretion is up to approximately 1 mg. a day; up to the age of 12 it rises to 4 mg. a day, and then after puberty is established adult values are reached. Day-to-day variations of up to approximately one-third may be encountered in a given person.

Careful 24-hour collections of urine are required. The patient is instructed to empty his or her bladder at the start of the collection and discard the urine. All the urine excreted during the subsequent 24 hours, including the specimen passed at the conclusion of the period, is collected. The urine is preferably acidified (by adding 10 ml. of dilute hydrochloric acid B.P. to the collection). A note of the total volume and a sample of about 200 ml. should be sent to the pathologist undertaking the estimation.

The determination of 17-ketosteroids may be of ancillary value in the diagnosis of Addison's disease. Values are usually less than 7 mg. a day, with a definite tendency for lower values in women than in men, as would be expected. In the presence of normal values the diagnosis is likely to be wrong. In interpreting reductions of this order it must be remembered that any chronic illness may lead to similar changes. It is advisable not to have the patient on cortisone therapy, but again deoxycortone does not interfere. In hypopituitarism values are often lower and approach zero in both sexes, so that the diagnostic value is greatly increased. This is partly owing to the fact that in the male the testicular component is also reduced in this condition. Patients with anorexia nervosa, the differentiation of which from hypopituitarism may be difficult, sometimes have normal values or they may be decreased to Addisonian levels as a result of the inanition.

Increased adrenal cortical activity due to hyperplasia and producing adreno-genital or virilizing syndromes always results in a rise in 17-ketosteroid excretion. This is most pronounced in adults who have developed virilism before puberty, in whom values up to approximately 100 mg. a day may be reached. The post-pubertal variety of this syndrome in girls has to be differentiated from "idiopathic hirsutism" and may show only quite moderate rises in excretion to about 40 mg. a day. In some of these patients with a similar clinical picture the underlying lesion may be

*Lancet, 1951, 2, 585.

an adrenal cortical tumour, an uncommon lesion. In about half the cases this is accompanied by the excretion of large amounts of 17-ketosteroid, and many biochemists feel that a level in excess of 100 mg. a day is likely to be indicative of tumour. It is possible by applying colour reactions for dehydroepiandrosterone and its relatives to obtain some further assistance. A proportion of tumour cases show an increase in the excretion of this steroid. Unfortunately the cases in which there is most difficulty, those with lower levels of 17-ketosteroid excretion, are the least likely to show a rise in dehydroepiandrosterone.

In Cushing's syndrome the help obtained from 17-ketosteroid excretion is much less. This clinical picture may also be due to increased adrenal cortical activity or to a tumour. In the former case a minority of patients show a small elevation of 17-ketosteroids to about 30 mg. a day. The findings in the tumour cases are similar to those discussed for tumours causing the virilizing syndromes. It is inadvisable to have any of the patients in these groups receiving cortisone when 17-ketosteroids are determined. When interpreting a rise in 17-ketosteroid excretion it should be remembered that the rare interstitial tumour of the testes causes a large increase for the age of the patient and a rise may also result from arrhenoblastoma in women.

Trial of A.C.T.H.

The attempt to stimulate the activity of the adrenal cortex by the use of A.C.T.H. and measure the response obtained may be of the greatest value in the diagnosis of Addison's disease and helpful in cases of anterior hypopituitarism. In advanced Addison's disease it seems that destruction of the adrenal cortex is complete. In less severe cases and cases of hypopituitarism destruction is not complete, so that some degree of stimulation of the cortex is possible. There are two ways of using A.C.T.H. that may be helpful.

Eosinophil Test.—At about 10 a.m. an eosinophil count is made in the peripheral blood and 25 international units of lyophilized A.C.T.H. injected intramuscularly. After four hours the count is repeated. Normal individuals show a pronounced fall in the eosinophils under these conditions. If the test shows a decrease of less than 50% in the count the patient is likely to have Addison's disease or severe hypopituitarism. Repetition of the test makes the diagnosis much more certain. Patients with a small degree of cortical destruction or atrophy may give a normal response. The validity of the test is interfered with in some patients with eosinophilia, and tests in which the initial eosinophil count is very low (below 50 cells per c.mm.) should be disregarded.

Excretion of 17-Ketosteroids.—The most stringent diagnostic test for complete adrenal cortical insufficiency is to measure the change in 17-ketosteroid excretion after adequate adrenal cortical stimulation. Several methods have been proposed for the procedure, but one of the best seems to be as follows. The 17-ketosteroid excretion is measured in two consecutive 24-hour periods and the patient is then given 20 units of A.C.T.H. gel intramuscularly 12-hourly for 48 hours. The 17-ketosteroid excretion is measured again for the last 24 hours of the period. A significant increase (exceeding 50% of the baseline level) indicates that the adrenal cortex is responsive. This test is elaborate and will probably have to be carried out in hospital. Both these tests are at present subject to the restricted supplies of A.C.T.H. available.

Conclusions

It will be appreciated that the use and interpretation of laboratory tests in these conditions require careful judgment. In order to draw the correct inferences all the facts, especially the clinical findings, must be given their due weight. For instance in this article the discussion has been limited to the question of deciding whether adrenal cortical function shows serious deviations from normal. Decreased function results from either a primary lesion of the gland or secondary atrophy due to diminished pituitary function. In the latter event evidence of decreased function of other

endocrine glands, particularly the gonads, should be forthcoming. Rarely the differentiation of the two conditions may be a difficult matter. Some of the procedures described would be better carried out in hospital. They are considered here partly to remind the reader of their interpretation, which may be of value when hospital reports on patients are received.

It will be appreciated that most of the tests considered afford only indirect evidence of the behaviour of the adrenal cortex and that other factors may intervene between the secretion of this gland and the final manifestation measured in the test. For this reason measurements of steroids, perhaps in blood, may be the most valuable test in the future. It is evident that 17-ketosteroid determinations have their limitations. It is hoped that other measurements of adrenal cortical steroids and of other metabolites may be more definitive. Several techniques have been proposed for this—for example, determinations of "11-oxosteroids" and "reducing steroids"—but at present no method has been developed which may be regarded as satisfactory for routine use and which can be recommended in this article.

Next article on Clinical Pathology.—"Serological Tests in Diagnosis," by Professor E. T. C. Spooner.

RECOGNITION OF INTOXICATION

With the publication this week of a report on "The Recognition of Intoxication," the B.M.A.'s Committee on Alcohol and Road Accidents* has completed the first half of its work. Appointed in June, 1951, the Committee was instructed to revise and bring up to date the Association's Reports on Tests for Drunkenness (1927) and The Relation of Alcohol to Road Accidents (1935). The Committee is awaiting results of experimental work now in progress on the physiological effects of alcoholic intoxication before revising the report on road accidents.

"The Recognition of Intoxication" is intended as a guide for those who are called upon to examine persons detained by the police on the suspicion of being under the influence of alcohol. The examiner is often a general practitioner, and the report is written primarily to help general practitioners in the discharge of this difficult and anxious task.

The Medical Examination

First comes a brief explanation of the Law relating to alcoholic intoxication. The Road Traffic Act, 1930, makes it not simply a question of deciding whether a person is drunk in the popular sense, but whether he "is under the influence of drink or a drug to such an extent as to be incapable of having proper control of the vehicle." Then follow two important sections on the medical examination itself. The first deals with points of procedure, such as obtaining consent and the degree of privacy that may reasonably be expected. One of the main purposes of the examination is to exclude other causes of unusual behaviour, and if such are present to decide how far they influence the clinical picture. A fairly comprehensive list of these is given, with some tips to help in differential diagnosis. There is advice on taking specimens for the estimation of alcohol content, and on making a second examination at a later date. Finally there is a word about what information should be given to the detained person and to the police. The second section consists in a "model scheme" of medical examination. Making the examinee walk along a straight line is condemned. The examiner is warned to base his opinion on the results of the whole examination, and not to draw conclusions from isolated features.

*Professor E. J. Wayne (chairman), Dr. Robert Forbes, Dr. E. A. Gregg, Dr. F. E. Camps, Dr. E. A. Carmichael, Dr. Macdonald Critchley, Dr. A. B. Davies, Colonel A. H. Farley, Dr. T. C. N. Gibbens, Dr. J. A. Gorsky, Professor A. St. G. Huggett, Dr. J. C. Matthews, Dr. T. W. Morgan, Mr. F. R. J. Peel, and Professor R. J. V. Pulvertaft.

Evidence in Court

After dealing with the form in which a doctor called by the police should record his opinion, the report goes on to consider the evidence which may have to be given in court. "Whether called for the prosecution or the defence (the doctor) should present, without bias, the medical opinion he has formed . . . and, with his scientific knowledge, help the court to arrive at the facts of the case." He should take care not to act as a partisan witness nor to be drawn into legal arguments. It is for the court alone to decide whether the accused person has committed an offence.

Estimation of Alcohol in Body Fluids

Among the data which may help the doctor to estimate the degree of intoxication is the concentration of alcohol in the body fluids. The report recommends the use of urine for this purpose. Urine samples are easier to collect than blood if the subject is obstreperous, and the results equally useful. An estimate of the urine alcohol level may help the court in one or more of four ways: it may conclusively exonerate the person charged; it can serve as a useful check on his veracity, as the alcohol content of the tissues is generally accepted as an accurate indication of the minimum quantity consumed; it may show that it was the victim of an accident who was intoxicated rather than the driver; and, lastly, it may be used—with circumspection—as indirect evidence of incapacity to control a vehicle. The report discusses some of the evidence linking blood alcohol levels with performance, but it is careful to stress that the responses of different individuals to the same concentration of alcohol vary widely. The Committee is continuing its consideration of this problem and will deal with it more fully in its second report.

TABLE I

Minimum Intake of Ordinary Beer or Stout as Calculated from the Alcohol Content of the Urine
(For a male of body weight of 11 st. (70 kg.) and assuming beer and stout to contain 14.7 g. alcohol per pint.)

Urine Result in mg./100 ml.	Intake in Pints	Urine Result in mg./100 ml.	Intake in Pints
24	$\frac{1}{4}$	367	7 $\frac{1}{2}$
49	$\frac{1}{2}$	391	8
73	$\frac{3}{4}$	416	9 $\frac{1}{4}$
97	1	439	9 $\frac{3}{4}$
123	1 $\frac{1}{4}$	464	10 $\frac{1}{4}$
147	1 $\frac{1}{2}$	488	10 $\frac{3}{4}$
171	1 $\frac{3}{4}$	513	10 $\frac{3}{4}$
196	2	537	11
220	2 $\frac{1}{4}$	561	11 $\frac{1}{4}$
244	2 $\frac{1}{2}$	587	12
268	2 $\frac{3}{4}$	611	12 $\frac{1}{4}$
293	3	635	13
317	3 $\frac{1}{4}$	660	13 $\frac{1}{4}$
343	3 $\frac{1}{2}$	684	14

TABLE II

Minimum Whisky or Gin Intake as Calculated from the Alcohol Content of the Urine
(For a male of body weight of 11 st. (70 kg.) and assuming whisky and gin to contain 8.98 g. per fluid ounce.)

Urine Result in mg./100 ml.	Whisky* in fl. oz.	Urine Result in mg./100 ml.	Whisky* in fl. oz.
30	$\frac{1}{4}$	420	14
60	$\frac{1}{2}$	430	15
90	$\frac{3}{4}$	480	16
120	1	510	17
150	1 $\frac{1}{4}$	540	18
180	1 $\frac{1}{2}$	570	19
210	1 $\frac{3}{4}$	600	20
240	2	630	21
270	2 $\frac{1}{4}$	660	22
300	2 $\frac{1}{2}$	690	23
330	2 $\frac{3}{4}$	720	24
360	3	750	25
390	3 $\frac{1}{4}$	780	26
400	13 $\frac{1}{4}$ (= 1 bottle)	800	26 $\frac{1}{4}$ (= 1 bottle)

* 1 whisky = $\frac{1}{2}$ fl. oz. approx. 1 double whisky = 1 fl. oz. approx.
Note.—1 pint = 0.6 litre : 1 fl. oz. = 28 ml.

The last section of the manual is based on the report of a panel of the Royal Institute of Chemistry, which the Council of the Institute appointed to help the Committee. It deals with the technical aspects of determining the blood and urine alcohol concentrations. Detailed instructions are given on how to collect specimens, and the chemical analyses are described in two appendices. This section also discusses the translation of the results of these laboratory investigations into terms of pints of beer or ounces of spirits consumed. Two conversion tables are given (Tables I and II) relating the urine alcohol level to intake for an 11-stone man. These tables show the minimum amount of alcohol in the body; in the average case the amount would undoubtedly be rather higher—it certainly could not be lower. For this reason the Tables cannot be used to estimate the probable urine or blood alcohol content from a knowledge of the amount of alcohol taken.

Factors for differences in body weight and sex are provided. For women the answer in pints of beer or ounces of spirits must be multiplied by $\frac{3}{5}$. If blood alcohol figures are used instead of urine alcohol figures the result must be multiplied by $\frac{4}{3}$.

The report ends with a list of offences in which "drunkenness" plays a part. These are the offences, in addition to those under the Road Traffic Act, in respect of which a doctor might be asked to express an opinion on the sobriety of the defendant or other persons. They range from being "drunk in any street and guilty of any riotous or indecent behaviour therein" to being a drunken person who refuses or fails to quit licensed premises "upon being requested to do so."

The report may be obtained from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1. It is free to members of the medical profession; to others it costs 1s. (including postage).

PAUL EHRLICH AND EMIL VON BEHRING

CENTENARY CELEBRATIONS

Over 600 men and women from different parts of the world gathered together in Frankfurt am Main a fortnight ago to do homage to the memory of Ehrlich and von Behring, the subject of commemorative articles in last week's *Journal*. The hosts were the Paul Ehrlich Institute, the Philipps University of Marburg a. d. Lahn, and the Johann Wolfgang Goethe University of Frankfurt. Generous hospitality was provided by the Farbwerke Höchst A.G. The opening ceremony in the Paulskirche (no longer a church) began and ended with music and was presided over by Dr. Theodor Heuss, the President of West Germany, who in his address recalled his meeting many years ago with Einstein, whose birthday fell on the same day as Ehrlich's. Two of Ehrlich's daughters and two grandsons were present, as well as descendants of von Behring. The solemnity of the proceedings was heightened by the magnificent robes of the Rectors of Frankfurt and Marburg Universities—Professor O. Gans and Professor W. Walcher, and somewhat marred by the ubiquitous photographer and the glaring lights of the cinematographer. In fact when Professor Gans bestowed the Ehrlich Prize on Professor E. B. Chain a horde of camera-men prevented the audience from witnessing the principal event of the morning. After a word of greeting from Professor R. Prigge, director of the Paul Ehrlich Institute, speeches were made by the Minister of Education of Hesse and the Minister for Internal Affairs of West Germany.

The Ehrlich Prize Oration

Professor Chain, in acknowledging the prize, made handsome acknowledgment to the numerous workers who had played a part in the discovery of penicillin. After a tribute to Ehrlich's work and to the discovery of prontosil in 1935 by Domagk, the orator said that a new era began when,

†Kent-Jones, D. D., and Taylor, G., *Analyst*, 1954, 79, 121.

in 1940, Florey, himself, and their co-workers isolated penicillin at Oxford as a metabolic product of *Penicillium notatum*. But before the turn of the century Pasteur and others had observed the antibacterial action of substances obtained from bacteria and moulds. Fleming's discovery in 1929 of what he then named penicillin, and of the inhibiting effect of a filtrate on the growth of staphylococci, passed for the time being unnoticed. Fleming suggested that his culture extract could be applied in the local treatment of infected wounds, but the instability of penicillin made its use impracticable. Three years after Fleming's discovery Raistrick tried, without success, to isolate the active principle from filtrates of *Penicillium notatum*. Professor Chain emphasized that Florey and he began their work a year before the outbreak of war from a purely biochemical angle, and did not expect to find a preparation which could be applied clinically. To-day one could state that penicillin was the most active and least toxic of chemotherapeutic remedies. The only side-effect was an allergic reaction in about 5% of treated cases. Staphylococci did not develop resistance against penicillin. Staphylococci not affected by penicillin were those which produced penicillinase. Penicillin killed off bacteria only when they were actively growing, thus differing from most other antibacterial substances. After a review of other antibiotics, Professor Chain suggested that the expression "broad spectrum" was not altogether happy—the wider the spectrum of an antibacterial substance the less was its specificity and the greater its toxicity. In other words a "broad spectrum" implied a general protoplasmic poison. He concluded by saying that the search for new antibiotics must go on, especially for the treatment of tuberculosis and virus infections. Further progress would be achieved only through the aid of chemical microbiology as a department of biochemistry.

Ceremony at Marburg

Marburg, an old university town, provided a charming contrast to bustling, largely rebuilt Frankfurt. The university, dating from 1527, was the first protestant university to be founded. After the procession of university authorities entered the Hall to the music of Handel, the Rector, Professor W. Walcher, gave an address and bestowed the von Behring prizes for 1948, 1952, and 1954 on Professor H. Schmidt, Sir Macfarlane Burnet, and Professor M. Heidelberger respectively.

Allergy and Immunity

In a lecture on the relations of allergy to immunity Professor Schmidt recalled the first fatal case in 1896 resulting from the prophylactic injection of an antitoxic serum. It was logical to assume that infection would be followed by allergy to the infecting micro-organism and its antigens. Two main questions posed themselves: (1) How far were the characteristic symptoms of an infectious disease due to the characteristic symptoms of an infectious disease due to allergy? (2) What was the relation between allergy and immunity? The body became allergic to tubercle bacilli immunity? The body became allergic to tubercle bacilli immunity? A focus of infection containing living bacilli existed in it, if a focus of infection containing living bacilli existed in it, and what was known as Koch's phenomenon prevented and what was known as Koch's phenomenon prevented superinfection from becoming a progressive disease. On this basis von Behring tried to protect cattle against tuberculosis with a vaccine prepared from human tubercle bacilli. In principle, Professor Schmidt claimed, von Behring's method corresponded to that of Calmette in the prophylactic use of B.C.G. in man. Was the protection afforded by B.C.G. vaccination due to the concomitant allergy? Experiments with guinea-pigs made tuberculin-allergy? Experiments with sheep blood cells adsorbed positive when immunized with sheep blood cells adsorbed with tuberculin showed that the course of tuberculous infection in them was the same as in normal guinea-pigs. But this did not prove that immunity and allergy were independent of each other, for tuberculin was but a partial antigen. If it were possible to immunize non-infected man with the complete antigens of the tubercle bacillus, the immunity could not last so long as that provided by B.C.G., but, with repeated injections, could be made more effective. Passive immunization with sera of healthy individuals previously

hyperimmunized might be of therapeutic value. "And here," concluded Professor Schmidt, "I am falling into line with von Behring's aim of preparing an antitoxic serum in the treatment of tuberculosis."

Viruses, Enzymes, and Genetics

Sir Macfarlane Burnet briefly described the work on viruses in progress in the Walter and Eliza Hall Institute in Melbourne. During the recent war work was concentrated on means of immunizing against influenza, "with the ever-present fear that the experience of 1918-19 might be repeated." The methods of handling influenza virus in chick embryos were worked out, largely in his laboratory. Then Hirst in New York discovered the haemagglutinating activity of the virus. The war over, they decided to make a systematic attack on the problems presented by haemagglutination. Until 1941 they had understood that viruses acted only on susceptible cells and that their existence could be recognized only by the lesions or symptoms produced as a result of intracellular multiplication in susceptible tissues. Hirst showed that the haemagglutination was a function of the virus particles themselves, the particles adhering firmly to the cell surface. A single virus particle attached to two cells acted as a bridge holding them in contact and helping to build up the visible clumps seen in an agglutinated suspension. Another basic feature of the reaction shown by Hirst was that after a time the virus elutes off the cells, leaving them inagglutinable by fresh virus, the eluted virus, however, retaining the power to agglutinate fresh cells. Hirst was clear that the virus acted as an enzyme, and the first phase of the work at Melbourne was to seek the nature of the virus enzyme. After seven years' work, Sir Macfarlane continued, he could now say that during the past year his colleague Dr. Gottschalk had shown that the virus acted as an amidase, breaking the CO-NH₂ link between 2-carboxy-pyrrole and hexosamine, both of which are present as part of 200 or more prosthetic groups on each macromolecule of certain mucoproteins. Chemical, physical, and biological techniques enabled them to build up a picture of the cell surface—in the first instance of the erythrocyte in its relation to the viruses that attached to it. Over the surface of the virus particle there were many enzymically active groupings, each of which could unite with and, in appropriate conditions, destroy the substrate receptors scattered over the length of the mucoprotein macromolecules. As soon as a virus particle collided with the cell surface many bonds were formed which together held the particle firmly on the cell. But as each pair of reactants developed an appropriate mutual orientation the corresponding bond was broken by enzymic action and a new bond could be then formed elsewhere. "We can almost picture the virus particle browsing like a sheep over the receptors of the cell surface until the concentration of the substrate group becomes too low to hold the virus and the cell in physical contact."

One of the implications of the enzymic attack pictured by Gottschalk was that with each splitting of a receptor an amino group was exposed and a positive electric charge added to the cell—which in practice meant a diminution of its net negative charge.

The surface reactions described were equally important in relation to cells susceptible to attack by the influenza virus. It could be shown that the influenza virus was adsorbed to the cells lining the allantoic cavity of the chick embryo or the respiratory epithelium of the mouse lung, and that the adsorption was to the same type of receptors as were present on the red cell.

As an accidental result of experiments in 1949 they had, Sir Macfarlane said, since then concentrated on the study of virus genetics. First they were concerned to see what happened when a neurotropic influenza virus was inoculated in the mouse brain with a non-neurotropic virus of different serological type. If the amount of the latter was much larger than that of the former no illness resulted—a typical interference phenomenon. But at the level where delayed illness resulted it was often possible to isolate from

After the scientific sessions the visitors had the alternatives of visiting the works and laboratories of Farbwerke Höchst A.G. or of listening to a chamber concert of string quartets of Schubert, Haydn, and Mozart. A feast of good food and wine brought the day to an end.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Ion-exchange Resins

SIR,—I have read with interest your leading article on the ion-exchange resins (*Journal*, March 13, p. 633), but I am surprised to find the statement that "it is questionable whether resin treatment should be used at all" in Type II nephritis. Nephrotic oedema is notoriously resistant to treatment, and in the ion-exchange resins we have a new weapon which appears to produce very good results. The fact that these resins are potentially dangerous in the presence of renal failure is no argument against their careful use when renal function is normal. In the uncomplicated case of Type II nephritis there is little more risk than in the normal person of producing severe acidosis, hyperkalaemia, or complications due to increased ammonium absorption. Your leading article mentions a further possible danger, that of causing or aggravating structural damage in the kidney, and this is considered a possibility, because granular casts may occur in the urine even in healthy subjects taking cation exchange resins. If renal function is normal, the urine of patients on the resin is highly acid. Granular casts can readily be found in such acid urine and are not evidence of structural damage to the kidneys. Their occurrence was noted in the highly acid urine of patients treated with sodium mandelate and ammonium chloride, and it was shown that they disappeared when the urine was no longer so acid.

The medical profession is divided on the advisability of using mercurial diuretics in Type II nephritis, for these drugs are known to act by impairing tubular function. Such evidence as we possess at the present time suggests that ion-exchange resins are a very promising form of treatment for nephrotic oedema, and it would be unfortunate if your leading article were taken as a serious warning against their use even in patients whose urea clearance is not seriously impaired.—I am, etc.,

London, W.C.1.

Pre-operative Anticipation of Thrombo-embolic Episodes

SIR,—In his medical memorandum on a possible method of pre-operative anticipation of thrombo-embolic episodes Mr. John Dutton (*Journal*, March 6, p. 566) makes several interesting points. He states that if it could be foreseen which patients were liable to thrombo-embolic phenomena active measures for their prevention could be taken. The guide for this prophylaxis is to be based on the response of the clotting mechanism to an injection of adrenaline. Unfortunately this test involves the performance of eosinophil counts and clotting times at half-hourly intervals over a four-hour period, which will preclude its universal application to all patients undergoing surgery in a general hospital. If Mr. Dutton has found six cases of post-operative thrombo-embolism in his first 50 cases he has been fortunate, in a statistical sense, for the general incidence of such complications must be very much lower. The rational basis for using an accelerated clotting response as a reason for active anticoagulant prophylaxis in an otherwise healthy patient remains unproved.

Waugh and Ruddick,¹ Silverman,² and Rosenthal,³ using sensitized coagulation time tests, have all noted accelerated clotting in patients who showed no evidence of thrombosis. Accelerated clotting (interpreted as a clotting time less than the minimum of a normal range based on 100 controls) has been noted with the heparin-retarded plasma clotting test also in a variety of states with no clinical manifestation of thrombo-embolism.⁴ These include acute inflammation post-

haemorrhagic states as well as the majority of a series of 40 patients who underwent a group of common operative procedures. On the other hand, of 50 cases of recent thrombo-embolism, 37 demonstrated accelerated clotting.⁵ Thus, although it may be deduced that thrombosis is associated with a shortened clotting time the reverse does not necessarily follow.

It is to be hoped that Mr. Dutton's research will produce valuable results in the prevention of these tragic consequences of surgical trauma. However, the danger of reliance on an *in vitro* laboratory test without reference to the clinical state and the all-important vascular factors in thrombosis cannot be allowed to pass unnoticed.—I am, etc.,

Catterick.

Anaesthesia in Hospital Breech Delivery

SIR,—I have read with great interest the article (*Journal*, March 6, p. 562) "Anaesthesia in Hospital Breech Delivery" by Dr. R. G. Law and Dr. Shila G. Ransom. The point which interests me chiefly is the statement that forceps on the after-coming head is a procedure which the authors "strongly advocate in all cases." I should like to know the reasons for this. During the time I was in the active practice of obstetrics as a G.P. in the country I never found this procedure necessary. Incidentally, I attended a large number of breech cases and only had one foetal death (if my memory serves me aright), and this was not due to any difficulty in delivery of the head but due to rupture of the cord *in utero* during the manipulations necessary in bringing down extended legs and arms behind the head. This case was during the war, with hostile planes overhead and consequent difficulties, lighting, etc.

All my confinements were done in cottages by the light of a paraffin lamp with an open coal fire. Hence chloroform was the anaesthetic of choice, and it often had to be given by myself, though not when I could get assistance, which was not always and not in the case quoted. Perineotomy was not often practised by me. I heartily approve of it, and wish I had used it more frequently. The method I used for the after-coming head in all cases, without difficulty, was when the baby was born as far as the umbilicus, legs were brought down, unless they were, as was often the case, already delivered, and then both arms were brought down. I then inserted the middle finger of my left hand into the mouth, thus flexing the head. I got the midwife or whoever was present to press on the abdomen just above the pubes to help flex the head, then seizing the legs with a circular swing the head was easily delivered. All my cases with one or two exceptions were delivered in the left lateral position. Needless to say, anaesthesia was always used and, of course, aseptic precautions taken.

I shall be most grateful if Dr. Law would let me know what the advantages of forceps on the after-coming head are. That it is used frequently and successfully I know from experience with reference to a relative of mine.—I am, etc.,

Petworth.

DAN C. DRUITT.

Utero-tubal Insufflation

SIR,—Mr. Stanley A. Bond's letter (*Journal*, March 13, p. 646) states that "all the work of Rubin and Sharman is based on the proven fact that the information obtained is definitely attributable to the fallopian tubes alone." I am sure that Rubin and Sharman would not claim that all their work is based on this "fact." That it is not a fact is easily shown. Just as good oscillations can be produced by insufflation of a hysterectomy specimen with no peristalsis or spasm visible. The oscillations are just what one would expect of gas passing through a fine tube filled by a sticky medium.—I am, etc.,

Newcastle-upon-Tyne.

FRANK STABLER.

The Thyroid

SIR,—In response to requests to amplify my letter (*Journal*, March 6, p. 584) perhaps you will permit me, in the interests of scientific accuracy, to deal briefly with the points raised in the review of my book, *The Thyroid* (February 27, p. 503).

(i) "There is no reference to controls done, for instance, on post-mortem material from euthyroid patients."—This is incorrect. A reference to the index would have saved the reviewer from this error. On page 112 I state: "A separate study of the changes in the life history of the normal thyroid gland has led me to add support to the finding that 5 to 10% of apparently normal glands contain collections of lymphoid tissue." The discussion on these controls is then elaborated further. The normal thyroid gland is discussed further on pages 68 and 284, and figures 197 and 198. Even electron microscopy of the normal thyroid in the euthyroid patient is discussed and illustrated (p. 21).

(ii) "We cannot tell from the tables whether the designated state refers to the patient at the time of the operation or many years previously."—On page 110, under the title heading "Age," I state: "Taking account only of the age at which the patient presents herself for operation, I find that the diffuse lymphoid hyperplasia or lymphadenoid goitre patient was at operation, on an average, 43 years old, the fibro-lymphoid hyperplasia of Hashimoto 48 years, and the fibrosis of Riedel 56 years." Any further comment becomes unnecessary.

(iii) "Hypotheses . . . [reading] as statements of fact."—In such a swiftly advancing subject, speculation is sometimes necessary. Throughout the book I have been careful to indicate any departure from the conventional views. It is not fortuitous, therefore, that both the sentences to which the reviewer, in his penultimate paragraph, takes exception are preceded in the book by "My own interpretation is" (p. 39) and "I would suggest that" (p. 31). Even thyrotropin, in the quotation, appeared in inverted commas in the book to emphasize the uncertainty of its nature and action; similarly the word "collagenin" is qualified in the book as an "unidentified factor" (p. 39).

(iv) "With regard to the diagnosis of mild toxicity . . . Mr. Levitt's enthusiasm and belief in his thesis have led him to strain fact to fit theory."—Chapter XIV (p. 186) is almost entirely devoted to the recognition and exclusion of a number of conditions simulating mild thyrotoxicosis; it is emphasized in the book that "instances of mild thyrotoxicosis in this series underwent very strict scrutiny" (p. 198). The clinical data including mild thyrotoxicosis were there also subjected to a critical statistical assessment (pp. 48-59 and 144).

(v) "We have no idea how the proportion of lymphatic to epithelial tissue was assessed, whether by cell counts or measurement of cellular areas."—On page 4, I state that "in evolving a reliable criterion for a basic classification I have felt that the final criterion must be the microscopical appearance of the gland." Emphasis is laid throughout on the assessment of cellular areas (pp. 66-77). Nowhere in this book is there any mention whatsoever of cell counts.

(vi) "We are not told whether the selection of blocks was done on an anatomical basis or on appearance."—On page 2 it is emphasized that it is "always possible to assess the dominant phase either from the clinical, the macroscopical or microscopical aspect," which was done in selecting blocks of characteristic thyroid tissue. On page 4 I state that "the naked eye view gives a useful, if crude, estimate of the relative quantities of epithelial and lymphoid tissues." The multiplicity of profusely illustrated macroscopic pictures of the gland, seen in the natural state at operation as well as in the formalin-fixed specimen, stresses the importance given to general macroscopical appearance in the selection of the blocks. The danger of an anatomical selection of blocks is also emphasized on page 527.

(vii) "The patients are designated as mild, moderate, or severe thyrotoxic, but the criteria used to separate the cases studied are not given."—On page 187 in *The Thyroid* I say: "The assessment of mild, moderate and severe toxicity is often a purely personal problem, necessitating repeated observations of all the stigmata by the same investigator." The paramount importance of a clinical assessment has been stressed throughout the book. Laboratory tests (pp. 188-90), radioiodine tests (pp. 477-93) are shown to help to corroborate the clinical diagnosis especially in a difficult borderline case. So protean have the manifestations of

the different degrees of thyrotoxicity been shown to be that hard-and-fast rules have, as indicated in the book, been eschewed.

(viii) "Nor are we given the average weights of the resected thyroid tissue."—This desideratum of the reviewer cuts right across the principle of surgical treatment as discussed in pages 388-9, and noted and illustrated on pages 536-7. Its use as a scientific criterion is shown in the book to be outmoded, unnecessary, and of no statistical significance.

T. LEVITT.

Continuous Caudal Analgesia

SIR,—Our experience here of caudal analgesia in disordered uterine function confirms that of Mr. G. Trevor Johnson (*Journal*, March 13, p. 627). May I add a comment in favour of the nylon catheter technique? It is true that nylon tubing has to be obtained by devious means, but it is worth the trouble. In our hands it has reduced the percentage of failures. We sometimes find when the needle seems to have been properly placed that the catheter will not pass beyond its point, or will pass on only half an inch or so. Under these circumstances, continuing with the injection of the anaesthetic solution hardly ever produces satisfactory results. The free passage of the nylon for a few inches beyond the needle-point, on the other hand, is certain confirmation that it is correctly placed. Thanks mainly to this test, we have had only three failures in our last fifty cases.

I agree that polythene is not strong enough and its sterilization unreliable. Nylon tubing can be boiled or autoclaved and used three or four times. It is easier to seal off from the perineum with waterproof plaster than are the hub of the malleable needle and the pressure-tubing. It can be led under a strip of plaster to a more accessible part of the body and end under a sterile dressing, leaving the patient free to move about in bed without displacing it.

The cases in which one fails to place a caudal needle correctly need not be deprived of extradural analgesia; in the three cases mentioned above, one patient had the catheter inserted in the lumbar region through a Tuohy needle, and the other two had between them four lumbar extradural injections of 1/600 cinchocaine with 1/100,000 adrenaline, each injection providing four hours of analgesia.—I am, etc.,

Cambridge.

H. R. YOUNGMAN.

Hibernation Anaesthesia

SIR,—Drs. Frank S. Preston and Hugh Y. Wishart (*Journal*, March 13, p. 645) describe an interesting case as "prolonged hypotension following hibernation anaesthesia." From their detailed description it would appear that it was really a case of shock following inadequate anaesthesia. In our opinion the dosage of drugs used, 12.5 mg. of chlorpromazine, 12.5 mg. of promethazine, and 25 mg. of pethidine, together with an aliquot mixture of nitrous oxide and oxygen by inhalation, is unlikely to protect an aged patient from such a severe surgical procedure. It would seem obvious that, as "a few ml. of a 1/250,000 solution of L-noradrenaline" produced a marked rise in blood pressure, the effect of the small dose of chlorpromazine had disappeared. One of the most striking attributes of this drug is its anti-adrenergic action, and at the stage when the noradrenaline was administered a state of shock had supervened. The fact that atropine and neostigmine had no effect supports this view. We feel that if the drugs had been given in adequate dosage to produce "hibernation" anaesthesia this complication would not have arisen.—We are, etc.,

London, N.W.1.

ANGUS SMITH.
J. G. FAIRER.

Methylpentynol

SIR,—Whilst recent contributions to your correspondence columns have dealt chiefly with the use of methylpentynol for premedication, at Warlingham Park Hospital we have been using it for the past nine months as a hypnotic with alcoholic patients. Alcoholics are not infrequently addicted to other drugs as well as to alcohol, or they may become drug addicts when they stop taking alcohol. According to *Alcohol, Science, and Society*,¹ "there is no wholly satisfactory sedative" for the alcoholic. Barbiturates, probably the most widely used sedatives, have recently been alleged to have harmful effects in certain cases when used concurrently with alcohol.² So far, no evidence has been produced that methylpentynol itself may lead to addiction.

Methylpentynol has, up to the present, been given to more than 50 alcoholics in this hospital, who received no other sedative or hypnotic drug except myanesin during the day for a few days following admission. On the whole, our experiences with methylpentynol have been not unsatisfactory. Apart from difficulties during the first night, our patients had five or more hours of sleep in the great majority of cases, and woke up refreshed with no after-effects. The dosage varied from 1 to 5 capsules (250 to 1,250 mg.). Whilst onset of sleep has been said to follow administration of methylpentynol usually within one hour,³ in our patients sleep commonly did not follow until one to two hours afterwards, so that we now give it two hours before bedtime. The minority of patients who experienced wakeful periods during the night stated that even then they felt calm and relaxed under the influence of the drug and consequently went to bed less fearful of possible sleeplessness.

No harmful side-effects or after-effects were noted. Liver and renal function tests and full blood counts, taken repeatedly with patients who took the capsules for longer than a few weeks, failed to show any pathological changes. Most of the patients, however, easily gave up taking the capsules after a few days or weeks, and slept without sedation. No systematic inquiry regarding its use by discharged patients has so far been carried out, but we have not heard that any of them who remained sober have continued taking methylpentynol or any other hypnotic.—I am, etc.,

Warlingham, Surrey.

Medical Treatment of Peptic Ulcer

SIR,—Your leading article on the medical treatment of peptic ulcer (*Journal*, March 13, p. 632) is important for the stress it lays on the uncertainty both of aetiology and the effects of treatment. As regards the former and the greatly increased incidence of the condition I often think that insufficient regard may be given to changes of fashion in treatment. We all know now that many of the classical symptoms of chronic nephritis were, in fact, due to the treatment given and not to the disease itself. Lord Horder¹ hinted at the effect of the premature outmoding of sodium bicarbonate for indigestion as a possible factor in the increase of digestive disorders. I have long thought that the sudden suppression of bismuth at the beginning of the last world war may similarly have contributed to the incidence of more serious disease.

Professor Alstead² gave reasons for believing that bismuth carbonate was at best a feeble antacid, and Professor Brindle³ has *in vitro* recently extended and largely confirmed his results. But, though raising the pH of the gastric contents will relieve pain, this is far from covering the whole of the complex function of the stomach or the causation of peptic ulcer. Bismuth empirically has been used for digestive troubles for over a century, and it is unlikely that our very acute clinical ancestors were entirely wrong in their observations. Having qualified in 1915 I

was a convinced believer in the use of bismuth in 1939 and continued to use it with satisfaction throughout and since the war. One doctor's experience may be of little value, but I must say that I am constantly surprised to find the small number of peptic ulcers I have to treat compared with that of other general practitioners. I do not think this is altogether due to inability to diagnose the condition, for I take full advantage of consultants and x rays. I rather think that my continued use of bismuth may have much to do with it.

I have not used the massive doses recommended by some advocates of bismuth therapy, and Dr. Kemp,⁴ of Copenhagen, certainly has an impressive list of apparent cures by this method followed up for many years, which you rightly stress is the only useful criterion. I am here more concerned to point out the possible effect of moderate doses in indigestion preventing more serious trouble. It is, in my experience, almost specific in relieving the symptoms of mild appendicitis, but its use is not limited to that.

There are many things we still do not know about bismuth and its effects. It was, for instance, stated by Mr. R. L. Stephens,⁵ in the discussion on Professor Brindle's paper, that bismuth will inhibit the digestive action of pepsin at as low a pH as 2.0 instead of the usually accepted 4.4. If this is so a new outlook may be given to the use and abuse of "antacids." Certainly there is room for much more research—and research which, from its nature, may be quite outside the usual pharmacological and out-patient fields. They should illuminate what is and has been found in general practice, and, though I would not have general practitioners or professors chasing will-o'-the-wisps, I think treatment might improve and peptic ulcers diminish if our academic brethren kept before them the precept constantly dinning into me at Cambridge—the immense difficulty of proving a negative. This is more true of medicine even than the pure science in which I was taught it.

In writing this I do not overlook the fact that a peptic ulcer may seem to develop quite suddenly, though, as with coronary thrombosis, I fancy this suddenness is more apparent than real and means that the patient has neglected to seek advice for clear premonitory symptoms.—I am, etc.,

Winsford, Cheshire.

Danger of Slow Combustion Stoves

SIR,—I think it is important that attention should be drawn to the dangers of installing, without adequate precautions, any of the new forms of slow combustion stove inside a house, whether for cooking food or heating water, if such installation entails the use of an existing chimney.

The danger arises within the chimney, where the gases from the slow combustion eddy and attack the mortar or cement between the bricks, eventually permitting the noxious gases, especially carbon monoxide, to seep into rooms and diffuse throughout the house. The danger to health, as so often pointed out by the late Sir Bernard Spilsbury, comes from the insidious nature of the effects of chronic poisoning from the non-smelling carbon monoxide. He emphasized that there was no distinctive clinical picture associated with chronic monoxide poisoning, but that its effects were to bring out any weakness or idiosyncrasy in the individual, whether respiratory, cardiac, or alimentary.

Recent cases here have redrawn my attention to this genuine danger. The more modern chimneys have to be constructed with an approved lining, but this is not imperious in time to the action of the gases evolved in the process of slow combustion. I am informed by technical experts that the only completely safe protection is a sealed (joint by joint) asbestos stackpipe inside the existing chimney, carried up sufficiently to avoid any risk of equal height chimney pots receiving the gases; in new chimneys the liner

should be a salt-glazed pipe. I have myself not seen any scientific proof of this assertion. It is, however, important that the profession should know of this danger and be warned of the symptoms to which these slow combustion stoves may give rise.—I am, etc.,

Chipping Campden, Glos.

C. B. HEALD.

Gastro-intestinal Fuso-spirochaetosis

SIR,—The presence of *Spirochaeta vincenti* and *B. fusiformis* in large numbers in the faeces of patients suffering from diarrhoea and abdominal pain has been reported by the author in 1945¹ and 1947,² and its aetiological significance discussed. Subsequent observations have shown that these organisms are commonly found associated with three groups of symptoms: (a) Recurrent bouts of diarrhoea at intervals of a few weeks. The patient loses weight and often complains of a peculiar burning sensation in the anal region and rectal mucous membrane. Pain is colicky and severe. The faeces show a pH on the acid side—6.0 to 6.6. Arsenical preparations like carbarsone and acetarsol by mouth give relief, but recurrences are common when arsenic is stopped. Penicillin orally gives more lasting relief. (b) Acute diarrhoea simulating cholera. These cases go on to dehydration and collapse, and, if not energetically treated with intravenous saline, may end in death. Repeated saline infusions failed to improve the condition of one of them who had anuria. Neoarsphenamine, 0.3 g. in the next intravenous saline, resulted in a quick recovery. These two groups have been fully described in the two earlier papers. (c) Pain in the epigastrium. It is often worse after food, not relieved by alkalis, and accompanied by a burning sensation. It is very severe in character and there is tenderness over the area. Vomiting is occasionally present, but does not relieve the pain. Fractional test meal shows total and free acidity within normal limits and the gastric contents show blood and mucus with great regularity. The organisms are present in the gastric contents, though not in the large numbers seen in the faeces of the same cases. There is no diarrhoea, as a rule. Response to arsenicals is immediately good, but the trouble recurs when arsenic is stopped. Penicillin orally is more effective.

Details are given below of a case which has been investigated and followed up over a period of five years. The patient is himself a medical officer. He came under observation in March, 1948, with a history of unbearable pain in the epigastrium for the last two months with occasional vomiting. Previous history included an attack of amoebic dysentery in 1924 treated with a full course of emetine injections, appendicectomy in 1926, and recurrence of diarrhoea with two or three loose motions daily and amoebic cysts in the motion in 1928. Acetarsol tablets orally stopped the diarrhoea and the cysts disappeared. During this attack he noticed acid eructations and "hunger pains" for the first time, both being promptly relieved by alkalis. Subsequently he used to get the hunger pains frequently, lasting for two to three weeks at a stretch. In 1943 he was examined at Madras. Fractional test meal report was "slight increase of acidity, with mucus in all the specimens and blood in the later ones." X-ray report: "No evidence of active lesion. Suggestive of healed ulcer." His condition was becoming gradually worse. The usual dietetic and alkaline treatment did not give even temporary relief; in fact, food, especially when hot, aggravated the pain. Tenderness was marked over the area, and he used to roll about in the bed due to the severity of the pain.

In March, 1948, microscopic examination revealed the presence of *Spirochaeta vincenti* in the smears from the gums, in the resting gastric juice, and in the faeces. The gum smears showed *B. fusiformis* also. The saliva and faeces were both on the acid side, the pH varying from 6 to 6.6. Repeated examinations of the faeces were made but did not show any evidence of the old amoebic infection. No pathogenic organisms were isolated. A fractional test meal on March 15 showed total and free acidity within normal limits, but blood and mucus were present in all the specimens.

He was started on acetarsol tablets on March 21, 1948. Within a week the pain disappeared and he found he could take a normal diet with impunity. The gum smears and faeces did not show any spirochaetes after March 30, 1948. After a fortnight, when he was no longer taking acetarsol, there was a recurrence of pain. He was then put on a course of penicillin tablets of 50,000 units, one daily for 12 days. Then pain completely dis-

appeared and he has been free for a period of five years—that is, till April, 1953. There was a slight recurrence which made him take another course of 12 penicillin tablets, with the satisfactory results expected. Fractional test meals were repeated on him in June, 1948, and March, 1950. Blood was absent in all specimens on both occasions. The total and free acidity values were within normal limits but higher than in March, 1948, with, however, no pain.

Smoking and Mouth Cancer

SIR,—Miss Marion H. Russell, in her interesting article on "Cancer of the Tongue, Mouth, and Pharynx" (*Journal*, February 20, p. 430), puts forward several lines of inquiry to investigate sex differences in prognosis following radiotherapy. While supporting her suggestions, I would add that analysis should be made of the smoking habits of patients with cancer of these organs. "Radium National Form No. 1, Malignant Disease of the Tongue and Mouth," compiled in 1929–30 by the Radium Commission and others,¹ required a note on "Tobacco" for completion of records, showing that an association was recognized or suspected at that time, and much valuable information should be available after 20 years.

Doll and Bradford Hill,² in their work to which you refer (p. 445), have jolted us into keeping careful records of the smoking habits of our lung cancer patients, and it seems no less important that we should continue to investigate and record the same information in relation to patients with malignant disease anatomically in closer relation to the cigarette or other source of possible chronic irritation. Prognostic differences which appear to be linked with sex or age could be due, wholly or in part, to differences in smoking habit and/or to duration of smoking.—I am, etc.,

London, W.C.1.

"Status Lymphaticus"

SIR,—Risking the charge of levity, may I add to the discussion of this condition the story of a meeting held not long after the first world war, where the anaesthetists were pressing for recognition as such. The plaint was repeated *ad nauseam* that they had no "status." Eventually, a surgeon—was it Sir D'Arcy Power?—rose to say that, while he had the greatest sympathy with the anaesthetists' plea, they had a status not enjoyed by any other members of our profession—that is, the status lymphaticus.—I am, etc.,

Sunderland.

W. GRANT WAUGH.

SIR,—I read with bewilderment Dr. H. B. Dodwell's statement (*Journal*, March 6, p. 582) that I have described a syndrome consisting of "anatomical anomalies, recurrent asthma, lymphocytosis, and evidence of the breaking down of the nuclei of lymphocytes" (*Journal*, February 13, p. 398). Like Dr. Dodwell I do not know of such a syndrome, especially as the two last-mentioned findings exclude each other as evidenced by the fact that adrenocortical deficiency is accompanied by lymphoid hyperplasia and lymphocytosis, whereas injection of cortical hormone leads to depletion of the lymphoid stores, lymphopenia, and increased "urinary excretion of uric acid which is presumably formed by the breakdown of lymphatic nuclei." All I did was to draw attention to the obvious similarity between "status lymphaticus" and the state of adrenocortical deficiency to which neither anatomical anomalies nor recurrent asthma nor lymphatic breakdown bear any relationship. I cannot deny, however, that Dr. Dodwell's misrepresentation and lack of understanding have alarmed me.—I am, etc.,

London, W.1.

H. UCKO.

Medical Auxiliaries

SIR,—May I be permitted to reply to Mr. S. S. Knight's letter (*Journal*, February 27, p. 520) on the subject of medical auxiliaries? His claim that the training afforded by the Physiotherapists Association is comparable to that of the Chartered Society of Physiotherapy calls for comment. Candidates for training in schools recognized by the Chartered Society must first submit evidence of a standard of education which would enable him/her intelligently to grasp the basic sciences which form the background of treatments by physical methods. Instruction in these essential sciences and their practical application is carried out by experienced teachers, both physiotherapists and members of the academic staff of medical schools, where the emphasis throughout is on education, and facilities are adequate for this purpose. Throughout the whole three years of training, not only is the application of the practical skills acquired by the students to the treatment of patients very carefully supervised, but the students are also under constant guidance and instruction from really experienced teachers. The examinations are searching and thorough, and are conducted by members of the medical profession and teachers of the Chartered Society. Post-registration courses and congresses ensure a maintenance of that high standard of work that has come to be expected of the chartered physiotherapist.

The intensive training in principles over a short period, mentioned by Mr. Knight, is educationally unsound, and the standard of work produced by such "crammed" training is generally inferior to that where adequate time is allowed for absorption. The expression of aims of the Physiotherapists Association is most commendable, but until there is evidence that those aims are really achieved it is perhaps misleading to claim equality of standards.—I am, etc.,

London, S.E.1.

S. M. EVANS.

Recruitment of Nurses

SIR,—May we have the advantage of your columns to give a brief account of a scheme for the recruitment of nurses in York, which has been in operation since last September and which shows good promise of success? In conjunction with the education authority a course of evening classes has been organized by the hospital management committee in the nurses' training school of one of our general hospitals for young people of either sex under 18 years who have left school and who are already in full employment in other spheres. The lectures are on a wide variety of subjects which bear on biological problems, medicine, surgery, and nursing care, and are given by consultants, family doctors, the sister tutor, and experts in various ancillary branches of medicine and other social services.

The course is designed to occupy a two-year interval between leaving school and the age of 18, when full training may begin. Lectures, which are loosely integrated in subject matter, are given once a week and are divided up into two winter terms each year, each term of about 13 weeks' duration. The lectures are followed by relaxation with cups of tea and buns, and are interspersed with visits to special departments of the hospital, and with instruction in bandaging, invalid cookery, films, and demonstrations of nursing techniques and discussion periods. By holding the courses in the nurses' training school, the student is brought at once into the atmosphere of the school and into contact with the personnel of the hospital, so that any feeling of diffidence or apprehension on entering may be overcome before the candidate is called upon to make a final decision on whether she wants to enter for a nurse's training or not.

The course was publicized in the local press and by the education authority to school-leavers through the youth employment officers, and to youth clubs, and the response was most enthusiastic—double the number of applicants that could be assimilated being forthcoming. Thirty were accepted, two of whom were boys. The applicants were selected on the following grounds—that they intended to take up a nursing career and that they were physically and mentally fitted to do so. Selection was made

by the sister tutor in conjunction with a representative of the education authority, who was in possession of their school records of ability and character.

Enthusiasm for the course has continued unabated, as shown by the attendances, which have been full except when affected by sickness or bad weather. The four girls nearing 18 have all decided to sign on for training as soon as eligible, and from next autumn, when the course starts on its second year, it seems likely that there will be a steady stream of nursing recruits as and when the older ones reach the age of 18. After one year as a pilot experiment it has been decided to plan a second course on exactly similar lines so that both general hospitals will be running similar courses, one starting at the beginning while the other is half-way through. At the same time each course has been planned so that a new entrant could start at the beginning of any one term without feeling the effects of missing the subjects of the preceding term.

The shortage of nurses in training bids fair to be the biggest stumbling block to any plan for the expansion of the hospital service, and in publishing this scheme for a night school for the young people who might take up nursing as a profession we hope that hospitals elsewhere may find in it something of value towards the solution of this pressing problem. The expenses incidental to the course have been largely defrayed by the Ministry of Education, but a great part of the work has been done voluntarily, especially by the sister tutor and by the members of the medical profession, who have given their lectures without fee.—We are, etc.,

A. E. WILLSON-PEPPER.
J. K. WILLSON-PEPPER.

York.

Child Life and Health

SIR,—I have read with interest the study presented by Professor Charles McNeil on the above subject (*Journal*, March 6, p. 533). I saw the service grow in my own district almost from scratch (when a voluntary body had charge of it) to present unimagined proportions.

According to Freudian teaching on the psychopathology of mental and neurotic illness in the adult, the seeds of such are laid in the frustration of the biological needs of the infant. The physical aspect of child health is undoubtedly extremely important, and my training in and practice of paediatrics stressed the sensible, though broad-minded, routine of feeding, "potting," sleeping, and playing in the life of the infant in order to produce its health and happiness. In latter years, however, I became interested in the psychological aspect of health and disease, and it seemed to me that it was almost axiomatic that a contented mother had a contented child and that a stable mother had less illness in her family than a harried, worried, fidgety mother. It may be a matter of genetic inheritance that stability breeds stability, but there would seem to be something more involved—an ingredient which ensures that the right food is digested properly, and that the sleep is tranquil, and that the other biological needs are not only satisfied but happily satisfied. That ingredient is not visible; it is an atmosphere of tranquil security which surrounds the infant, setting its mind at rest and ensuring harmonious working of its bodily functions. In other words, the body is dependent on the mind, so that the mental state of the infant is of paramount importance to its physical well-being. Even though the infant mind is not consciously working, it is intensely impressionable.

According to this thesis, therefore, I would suggest that in child health of to-morrow there should be psychiatric sessions attached to each child welfare centre with the specific objective of supportive therapy for the emotionally unstable mother, which would cater also for the needs of the antenatal mother, since much physical and mental trouble is laid up for the offspring during the period of gestation. I would also suggest the great value to child health of the establishment of marriage guidance clinics in the setting of the child welfare centre; at these the man or girl to be married could discuss important premarital problems, and also parents in emotional difficulties might be helped, to the immense benefit of the household and the prevention of much neurotic illness among their children.—I am, etc.,

Morpeth.

J. H. THOMPSON.

Emotions and the Nose

SIR,—Personal experience prompts me to offer two observations upon the papers of Mr. P. Reading, Mr. K. Malcomson, and Dr. D. O'Neill (March 6, pp. 552 and 554). Is it really necessary to invoke anything so recondite as physiology and interference with regulation of body temperature to explain aggravation at night? Will not the blanket allergens of wool and bacteria suffice for most people, or even the homely possibility of the horizontal posture affecting mucous membrane blood vessels? Repeated caravan holidays have taught me the value of eating the antihistamine tablet before both the morning and the evening blanket-tossing.

The psychiatric study, although suggestive, suffers inevitably from the absence of controlled observations. Case 10 found that her nose cleared during the excitement of walking out with her boy friend. Mine used to clear regularly under the excitement of visiting my E.N.T. consultant. Could the sneezing of Case 10, while evacuated to the country, have been due to musty hay or any other rustic allergen? This study, as presented, scarcely warrants a more specific conclusion than that "when the investigation of post-war urban Britishers is carried far enough and deep enough, then some frustration or anxiety will usually be uncovered."—I am, etc.,

Doncaster.

CEDRIC C. HARVEY.

Herpes Simplex Virus in Infantile Eczema

SIR,—Dr. G. I. Barrow's article on "The Herpes Simplex Virus in Infantile Eczema" (*Journal*, February 27, p. 482) reminds me of two cases which connect with his series.

On August 25, 1953, a 4-months-old baby was vaccinated. A typical vaccinia resulted and the scab had already cleanly separated when her mother—never vaccinated before—fell suddenly ill, on September 17. She showed three vaccinia-like lesions on the edges of the eyelids and a phlyctenular lesion on the sclera of the right eye, with severe cellulitis of the eyelids and cheek and a considerable painful adenitis in the pre-auricular region and neck. She felt ill, she had much pain, and her temperature was 101.2° F. (38.4° C.). She had been suffering from ulcerative colitis, but had no skin conditions. One week later her other child, 18 months old and also never previously vaccinated, developed a large herpetic eruption in the right groin, again with marked cellulitis and lymphadenitis, fever, etc., followed within a few days by further 5-6 groups of vesicles in the vicinity. Her skin was clear, but she had just recovered from pityriasis rosea. Both cases were treated with systemic penicillin and ung. chloramphenicol; both took over three weeks to recover. There is a slight residual scarring in both cases, and the mother has partial loss of eyelashes.

A third child, 4 years old, had erythema nodosum with strongly positive Mantoux test two years ago.—I am, etc.,

Tutbury, Staffs.

J. I. HOFMAN.

Burns and the Adrenal

SIR,—In your annotation of March 6 (p. 572) you spoke of the "gross inadequacy of all methods of assessing the activity of the adrenal cortex." A reliable chemical method suitable for routine use was described to the Heberden Society in December, 1952, and first published in *Nature*.¹ Using a simplified form of the method,² a technician can assay six to eight specimens a day. The subject of steroid assays is too complex to discuss in a letter. What matters is that the assay of 17-ketogenic steroids in urine, referred to above, does answer our everyday needs.

Dr. Simon Sevvitt's paper (p. 541), with which your annotation is concerned, does little to clarify the indications for cortisone therapy in the treatment of severe burns. There is good evidence that adrenaline will cause a fall in the eosinophil count in the absence of the adrenals, and that intravenous adrenaline does not give rise to an increased output of adrenocortical steroids.³ It should not be difficult to follow the daily output of 17-ketogenic steroids in severely burned patients and to find out whether in fact adrenal failure is responsible for death in some cases. Alternatively

it would be simple to add hydrocortisone or cortisone aldehyde to the transfusion fluids of a controlled series of patients.—I am, etc.,

Sheffield, 3.

SIR,—Dr. Simon Sevvitt (*Journal*, March 6, p. 541) seeks to revive the adrenaline test of adrenocortical function. Your annotation (p. 572) appears to support the suggestion implicit in Dr. Sevvitt's article that 0.3 mg. adrenaline given intramuscularly or subcutaneously is an adequate adrenal cortical stimulant. The annotation, however, carefully refers to intravenous adrenaline acting on the pituitary to stimulate the production of A.C.T.H. It further refers to three of Dr. Sevvitt's patients in whom intravenous adrenaline was ineffective. Dr. Sevvitt, however, gave adrenaline to his patients by the intramuscular or subcutaneous route. On p. 543 he quotes evidence that intravenous adrenaline produces an increase of adrenocortical activity, and on the next page states that his adrenaline test stimulus consisted of 0.3 ml. of 1 in 1,000 adrenaline B.P. injected subcutaneously or intramuscularly. The route of administration is not mentioned thereafter, so presumably all the tests were done as described.

There must be few who regard subcutaneous or intramuscular adrenaline as an adequate adrenocortical stimulus. Dr. Thorn, who was largely responsible for the introduction of both A.C.T.H. and adrenaline as clinical tests of adrenocortical responsiveness, has amplified his earlier views. To quote¹: "The four-hour A.C.T.H.-eosinophil test is a useful screening procedure in eliminating Addison's disease or acute adrenal failure if a 70 per cent fall or over is observed. Failure to observe a satisfactory fall in circulating eosinophils must not be construed as necessarily indicative of adrenal cortical failure since (1) on occasion A.C.T.H. administered subcutaneously or intramuscularly may be inactivated or destroyed locally, and hence never reach the adrenal; (2) the single administration of 25 i.u. of A.C.T.H. intramuscularly does not place the adrenal cortex under maximum stimulation; and (3) a fall in eosinophils is after all an indirect indicator of adrenal cortical activation in contrast to the measurement of changes in adrenal oxysteroid and 17-ketosteroid excretion. It is also essential to recognize the fact that an initial control level of 100 or more eosinophil cells per c.mm. is necessary if a significant fall is to be detected. Despite these limitations the four-hour eosinophil response to A.C.T.H. remains a useful and highly reliable screening test for the rapid evaluation of adrenocortical responsiveness. These observations refer to the use of A.C.T.H. and not epinephrine."

It would be unfortunate if the adrenaline test as now described were to be accepted without further evidence of its validity. In so far as your annotation appears to lend support, it should be withdrawn.—I am, etc.,

Edinburgh.

Diagnosis of Thyrotoxicosis

SIR,—Dr. E. Montuschi (*Journal*, March 6, p. 584) raises the interesting point that sinus arrhythmia is absent in thyrotoxicosis. For some years past this test has been in common use in Dublin for suspected hyperthyroidism. It is a test which is open to certain fallacies. Sinus arrhythmia is more easily elicited in younger patients, and hence the test is less valuable in patients over 50 years of age. In menopausal tachycardia, when, if reliable, it would be very helpful, the results are less satisfactory, as, while its presence is strong evidence against hyperthyroidism, its absence is not so easily interpreted. The value of this and other signs of thyroid disease will be incorporated in a communication at a later date.—I am, etc.,

Dublin.

D. K. O'DONOVAN.

Obituary

H. W. MARETT TIMS, O.B.E., M.D.

Dr. H. W. Marett Tims died at Lower Bourne, near Farnham, Surrey, on March 4, eight days before his 91st birthday. All through his professional career his interests ranged widely over the whole field of biology, and he was perhaps best known as professor of biology at the Royal Veterinary College.

Henry William Marett Tims was born at Calcutta, the son of Dr. T. Lamb Tims, and was educated at Reading School and at Edinburgh University, where he had an outstanding career as a student. He obtained first-class honours in anatomy, surgery, and clinical surgery and graduated M.B., C.M. in 1887. Three years later he proceeded to the M.D., with commendation. After graduation he held the appointment of assistant demonstrator in anatomy and physiology in Edinburgh University, and then, in 1889, he came to London to continue his postgraduate studies at St. Thomas's Hospital. Then for a number of years in the late 'eighties and early 'nineties he was employed as a medical officer under the London County Council. In 1892 he became lecturer in biology and comparative anatomy at Westminster Hospital Medical School, an appointment he held until 1901, when he took up a similar post at the Charing Cross Hospital Medical School. A few years later he became reader in zoology at the Bedford College for Women in London University, and in 1908 was appointed to the chair of biology at the Royal Veterinary College. To these two appointments he devoted a good deal of his time until the outbreak of the first world war in 1914, when he relinquished his civilian duties to serve in the R.A.M.C., in which he attained the rank of lieutenant-colonel. For his war work he was appointed O.B.E. in 1919, and in the following year he was awarded the Order of St. Sava by the King of Yugoslavia.

For many years Dr. Marett Tims acted as examiner in physiology and biology for the Society of Apothecaries of London and in elementary biology for the London Conjoint Board. After the war he was for a time reader in zoology and comparative anatomy in London University and lecturer in comparative dental anatomy at the Royal Dental Hospital of London. Always keenly interested in odontology, he contributed a number of important papers on the subject to various scientific publications. He also edited the seventh and eighth editions of *Tomes's Dental Anatomy*. He had been recorder and vice-president of section D of the British Association, and while resident in the Channel Islands, where he lived for a time after the first world war, he was chairman of the Jersey Division of the British Medical Association in 1924-5. In 1888 he married Miss Alice M. M. Findlay, who died in 1950. There was one son and one daughter of the marriage.

Dr. AMBROSE EMERSON, who was in general practice at Eastbourne for many years, died suddenly at his home at Vennes-sur-Lausanne, Switzerland, on January 28 at the age of 78. Ambrose Emerson was born on January 15, 1876, and was educated at Cambridge University and at University College Hospital, graduating M.B., B.Chir. in 1901. He proceeded to the M.D. three years later. He held appointments at the Stanley Hospital and the Hospital

for Women, Liverpool, before moving to London, where he worked successively as house-physician at the East London Hospital for Children and as clinical assistant to the ophthalmic out-patients department at the London Hospital. In 1906 he entered a partnership at Eastbourne, where he remained until he retired in 1922, except for the period of his service as a temporary captain in the R.A.M.C. in Italy and France in the first world war. In 1923 he was appointed a cavalier of the Order of the Crown of Italy for distinguished services rendered during the war. In 1922 he took up residence in Switzerland and remained there until his death, except for the major part of the last war, when he was in England. He is survived by a widow, two sons, and three daughters.

Dr. EDGAR STEVENSON, who died at his home at Hoylake, Cheshire, on February 3 at the age of 86, was for many years well known as an ophthalmic surgeon in the Liverpool area. He studied medicine at Aberdeen, graduating M.B., C.M. in 1889, and proceeded to the M.D., with commendation, three years later. After a period of study at Strasbourg he returned to his home at Birkenhead. In 1892 he was appointed house-surgeon to the Liverpool Eye and Ear Infirmary, becoming assistant surgeon two years later, as well as honorary ophthalmic surgeon to Toxteth workhouse. At the beginning of the century he was appointed to the honorary staff of the Eye and Ear Infirmary—to which he later became consulting ophthalmic surgeon—and also demonstrator in ophthalmology in University College, Liverpool, a post he held for a number of years. At Liverpool he was in partnership first with Dr. Edgar A. Browne, a son of Hablot Knight Browne, better known as "Phiz," the illustrator of books by Charles Dickens, and later with Dr. F. B. Chavasse, son of the second Bishop of Liverpool. During the first world war Dr. Stevenson served as an ophthalmic surgeon attached to the 1st Western General Hospital. Later he became ophthalmic surgeon to the Ministry of Pensions Hospital at Liverpool. Among his many contributions to the medical literature was a paper on the treatment of corneal opacities by electrolysis which appeared in this *Journal* in 1896. After his retirement he went to live at Hoylake. For relaxation he enjoyed fishing, and only recently had contributed an article to the *Fishing Gazette*. His wife, formerly Miss Helen D. L. Gunn, had predeceased him by only two weeks.

Dr. G. H. GRILLS, formerly medical superintendent of the County Mental Hospital, Chester, died at his home at Lymm on February 16 at the age of 82. Galbraith Hamilton Grills was born on April 17, 1871, and was educated at the old Queen's College, Belfast, and at Liverpool University, graduating M.B., B.Ch. at the former Royal University of Ireland in 1899. He proceeded to the M.D. in 1902, and was awarded the diploma in mental and nervous disorders of the University and the Gaskell medal and prize of the Royal Medico-Psychological Association. Dr. Grills spent practically the whole of his professional life at the County Mental Hospital, Chester, where he first went in the early 1900's as assistant medical officer. He later became medical superintendent and held the post for many years, retiring in 1945, when he went to live at King's Norton, Birmingham. Last year, however, he returned to the county he had served so well and took up residence at Lymm, where he died.

J. H. M. writes: Having been associated with Dr. Grills for well over 30 years, I find it hard to realize that he has passed on. Somehow I regarded him as one who had discovered the secret of perpetual youth. His unceasing vitality, his boundless enthusiasm, and his boyishness of spirits never suggested that he should grow old, although he lived to the good age of 82. He was a doyen and a pioneer among medical superintendents. All his vigour of mind and body was given wholeheartedly to his life's work, which he loved and in which he spent 45 years of active service. His sympathy, kindness, and knowledge were ever available to his patients as well as to his junior colleagues, who mourn the passing of a great and lovable gentleman.

He was invariably in the van in the use of new treatments. His hospital was among the first to introduce malarial therapy, diathermy, sun-ray lamps, electric shock treatment, etc. His motto was "To stand still is to recede." He genuinely felt for his patients. My own feeling is that he regarded it almost as an injustice that they should be so sorely afflicted. "What better are we," he used to say, "that we should escape?" Material improvements during his tenure of office were many and included a new annexe (12 wards) with operating theatre, a handsome home for nurses, and the complete modernizing of the (then) 100-year-old building. He had no hobbies as such. He was devoted to his family and home. He was a profound thinker, always seeking after truth. Books dealing with matters metaphysical and mystical were his joy, and it was a sheer delight to listen to his discoursing on these and kindred subjects. From him I learnt much. He is survived by his wife and daughter and three grandchildren, to whom we extend our sympathy in their sudden and sad bereavement.

Dr. C. B. COHEN, a well-known general practitioner at Oxted, Surrey, died in St. Thomas's Hospital on February 10 at the age of 59. Charles Benjamin Cohen was born on August 15, 1894, the son of the late Sir Benjamin Cohen, K.C., and was educated at Rugby School and at Trinity College, Cambridge, before entering St. Thomas's Hospital as a medical student in 1916. He qualified M.R.C.S., L.R.C.P. in 1918, and after holding a house appointment at St. Thomas's served as a captain in the R.A.M.C. in the first world war. After demobilization he obtained further experience as a house-surgeon at his own teaching hospital and as a house-physician at the Brompton Hospital. He graduated M.B., B.Chir. in 1920 and proceeded to the M.D. four years later. After a period of practice at Brighton and at New Malden, Surrey, he became, in 1931, a junior partner in a practice at Oxted, where his father had moved in 1914. He soon established himself as a very competent general practitioner and was appointed surgeon to the local cottage hospital, in which, from the time of his appointment until shortly before his death, he was responsible for a large proportion of the emergency surgical work. He was also lecturer to the local branch of the British Red Cross Society and medical officer to most of the schools in the district. He is survived by his widow, a son, who is a doctor, and a daughter, who is a trained nurse.

J. F. S. writes: Dr. C. B. Cohen, known to a large circle of friends as Charles, will be badly missed, as he was a very conscientious doctor, nothing ever being too much trouble: he was always available and good at relieving the anxieties of relations. These were his great characteristics—his competence and his conscientiousness—and he will long be remembered in Oxted and Limpsfield for them.

Dr. U. W. N. MILES died at his home at Bewdley on February 11 at the age of 82, and the borough has lost a well-loved figure and a doctor of the old school. Born at Farnworth, Lancashire, on January 22, 1872, Usher William Newton Miles was the son of a country parson. After leaving Rossall School he became a student at King's College Hospital, London. In 1896 he qualified M.R.C.S., L.R.C.P., having been trained by such men as Burney Yeo, Rosc, Carless, and Frederick Silk. After holding resident appointments at various hospitals he became assistant to his uncle, H. L. Miles, at Kidderminster, where he remained until he bought a Bewdley practice in 1901. From that date until his retirement in 1946 he was in general practice, coupling with it the appointments of medical officer of health of the borough, a post he held for 45 years, and honorary anaesthetist at the Kidderminster and District General Hospital, an appointment which spanned the years 1917 to 1946. Being a man of broad mind and wide interests, Dr. Miles did not let himself get into a rut of professional life. For a time he was interested in the Church Lads' Brigade, and in 1909 he started the Boy Scout movement in Bewdley, remaining an active scout until 1914. At the end of the first world war he was made president of the newly formed local associa-

tion of Boy Scouts, a post which he filled with great pride to himself and to everybody else's great satisfaction until his death. He was also a keen sportsman, being a good shot and fisherman, a life member of the local rowing club, and a founder member of the tennis club. In quieter vein he was fond of gardening, showing special interest in the growing of chrysanthemums. In his heyday Dr. Miles was a tall, well-built man, and his character fully matched his physical stature. Forthright and plain spoken, he had all the courage of his convictions, but nobody suffered hurt thereby. His was a deeply religious nature, and this brought all the gentleness and goodness of religion into his activities and his dealings with his fellow men. Indeed, he was built four-square. And all these attributes, welded with a sound professional skill and wisdom, made him what he was—a family doctor *par excellence*. To his widow, after the joy of a golden wedding anniversary, his children, and his grandchildren must go the sympathy of all who knew him.—C. P. P.

Dr. D. B. KENNY died on February 13, in a motor accident, at the age of 34. Douglas Boal Kenny was born on February 1, 1920, and was educated at Campbell College, Belfast, and at Queen's University, where he graduated M.B., B.Ch., in 1945. After graduation he held appointments as house-surgeon at the Belfast City Hospital and the Dreadnought Seamen's Hospital, London. A period as a ship surgeon followed before he joined Dr. J. G. Johnston in practice at Lisburn, Northern Ireland. A quiet and kindly man, Dr. Kenny was rapidly building up a reputation as a first-class general practitioner, and he will be greatly missed by his friends, colleagues, and patients. He is survived by his widow, to whom we extend our sympathy.

Dame GRACE THYRZA KIMMINS, who devoted her life to the care and training of crippled children, died on March 3 at the age of 83. Many who benefited by her help and encouragement and the training she was able to provide will feel a sense of personal loss by her death. From the time of her own girlhood the sight of the neglected poor, the blind, and the crippled child had inspired in her a feeling of deep compassion and a longing to help. The Heritage Craft Schools and Hospitals at Chailey, in Sussex, although now incorporated in the National Health Service, is a fitting memorial to her and to the work she undertook so willingly, work which was spread over two generations. She was the founder of the schools, and the children received from her all the devoted and loving care that could be desired. Dame Grace Kimmins opened the first hospital school for cripples at Chailey in 1903, but such an establishment must have been in her mind much earlier when, in 1894, she convened a meeting which resulted in the foundation of the Guild of Brave Poor Things. It was from the guild that seven boys were drawn to become the first inmates at Chailey, and they were housed in old buildings already condemned. Forty years later the school was accommodating more than 500 boys and girls in modern buildings. This magnificent result was achieved through the remarkable determination of a remarkable woman. In her work she had the whole-hearted support of her husband, Dr. C. W. Kimmins, whom she married in 1897, and who was chief inspector of the education department of the London County Council from 1904 to 1923 and deputy vice-chancellor of London University in 1933-4; he died in 1948. The work at Chailey received support from people in all walks of life, from royalty downwards. It had the approval and encouragement of the late Queen Mary, and other members of the Royal Family have honoured the school with their patronage. Dame Grace Kimmins was appointed C.B.E. in 1927 and promoted Dame Commander four years ago.

Dr. JAMES BRYAN HERRICK, the distinguished American cardiologist, died in Chicago on March 7 in his ninety-third year. He was born at Oak Park, Illinois, and spent four years as a school teacher before beginning an association

with Rush Medical College which lasted from 1886 until his death. He graduated in medicine at Rush in 1888, and served as instructor in medicine (1890-4), adjunct professor (1894-1900), professor (1900-27), and finally professor emeritus. He was attending physician at the Presbyterian Hospital, Chicago, from 1895 until he died. In 1910 Herrick was the first to describe sickle-cell anaemia, which he had observed in a negro six years before. In 1912 he published what has become a classical account of coronary thrombosis with myocardial infarction, diagnosed during life; he also showed that sudden coronary occlusion need not always terminate fatally. Besides making numerous contributions to the periodical literature, he was the author of a *Handbook of Medical Diagnosis* (1895), *A Short History of Cardiology* (1942), and an autobiography, *Memories of Eighty Years* (1949), which reflects the kindness, sympathy, and leadership which made him such an outstanding teacher. He was founder and first president of the Chicago Society of Medicine, president of the Institute of Medicine of Chicago, and, in 1927, president of the American Heart Association, which presented him with the Gold Heart Award in 1951. He was also awarded the Kober Medal of the Association of American Physicians in 1930 and the Distinguished Service Medal of the American Medical Association in 1939. *Circulation*, the journal of the American Heart Association, published a special number in honour of Herrick in 1950. A tribute he paid to Nathan Smith Davis might equally have been said about himself: "Men succeed because of native ability and in small measure because of chance, but chiefly through hard work, through a knowledge of their special vocational subject, and through their ability to apply this knowledge."

Medico-Legal

INJECTION INTO ARTERY

Fulham and Kensington Hospital Management Committee in the Queen's Bench Division on March 18 accepted liability for negligent treatment of a patient's fractured left forearm at Fulham Hospital in 1948. Mr. Justice Pearce awarded £8,254 damages, with costs, to the patient, Mr. Ernest Sidney Peters, a 50-years-old Thames waterman and lighterman.

Mr. Peters's complaints were that during an operation for resetting the arm the anaesthetist, Dr. M. R. Rifaat, injected thiopentone into an artery instead of a vein; when a remedial injection of heparin caused swelling of his left arm the plaster cast was not removed until too late, causing the onset of Volkmann's ischaemic contracture; the fracture was set in the wrong position; and all these matters were concealed from him, thus depriving him of an opportunity to seek other medical advice.

Mr. Peters also sued Mr. J. L. Temple, surgical registrar at the hospital in 1948, who was in charge of the operation, and R. G. Odell, Ltd., of Walton Bridge, Shepperton, Middlesex, owners of the Thames barge *Magpie*, on which he was working a winch when his arm was fractured. Both these defendants were dismissed from the suit without costs.

Mr. Peters's case was that he suffered a fracture of the left radius on October 12, 1948. The same evening Mr. Temple was in charge of an operation for setting the arm at Fulham Hospital. Mr. Peters was given an injection of thiopentone in his right arm, but during the operation it was discovered that the anaesthetist, Dr. Rifaat, had injected into an artery instead of a vein. As the effect of thiopentone was to coagulate the blood there was a danger of thrombosis developing and a crisis was created. Mr. Temple recollected reading an article describing what should be done in such a situation. He sent for the article, and, following its advice, the patient was injected with heparin. The heparin accentuated the bleeding around the muscles of the left arm caused by the manipulation of the bones in setting. As

soon as it was injected, the plaintiff contended, the plaster ought to have been removed. Although the arm swelled that evening and was extremely painful, the plaster was not removed until another doctor arrived at 11.30 the next morning and advised its removal at once. The damage had then been done.

The bones were said to have been set out of alignment, so that when Mr. Peters saw an orthopaedic surgeon in May, 1949, the arm had to be plated permanently in that position. Everybody agreed that the hand was now completely useless and that Mr. Peters would be better off without it.

Heroic Measures

Giving evidence for R. G. Odell, Ltd., and the plaintiff, Sir Hugh Griffiths, consultant surgeon, said it was imprudent to leave the plaster on the fractured arm after the injection of heparin. In his view, by the time the plaster was removed much of the muscle fibre was already dead. Certain orthopaedic treatment might have prevented some of the deformity, but it was impossible to say that any useful function could have been restored. He did not think the condition of Mr. Peters's arm could have been brought about by arterial spasm following the fracture itself. He agreed that the crisis caused by the injection into an artery called for "heroic measures." The surgery on the right arm was brilliant. In the circumstances, he did not think the failure to remove the plaster was negligence, though it was an error of judgment. He also agreed that the malalignment of the bones occurred some days after the operation and was not the result of faulty work by Mr. Temple.

Dr. O. H. Belam, a consultant anaesthetist, said in evidence that no competent anaesthetist should inject thiopentone into an artery if he was careful.

Mr. St. John Dudley Buxton, consultant in orthopaedic surgery, gave evidence on behalf of the management committee. His opinion was that the condition of Mr. Peters's arm was due partly to arterial spasm following the original blow and partly to manipulation of the bone in setting. No one could say to what degree one factor or the other was responsible for the condition. He considered that everything necessary to produce ischaemic contracture was present in the arm before the anaesthetic injection was given and the arm was placed in plaster.

Parties Come to Terms

At a resumed hearing Mr. Gerald Gardiner, Q.C., for the plaintiff, told his lordship that the parties had come to terms. He said: "When something goes wrong in a hospital it is not easy for the patient to tell what has gone wrong, and naturally he can only place the blame where he sees it. In these circumstances, apart from allegations made against the anaesthetist and others who later treated my client, he also complained that the surgeon, Mr. Temple, who manipulated the limb under an anaesthetic, should, in view of an injection of heparin, have at once removed the plaster. Having had an opportunity of hearing the evidence which has so far been given, I should like to withdraw that allegation." The hospital management committee had accepted liability for everything the plaintiff had suffered, including the original injury by the winch. His lordship would be asked, however, to assess the damages which should be paid to Mr. Peters.

Commenting that this was a very just result, the judge assessed damages at £6,000 in addition to special damages of £2,254.

The Medical Defence Union instructed Messrs. Hempsons, solicitors, to act for Mr. Temple.

RETICENT HOSPITAL

Recently a patient claimed damages from a hospital management committee and house-surgeon for injuries received when a hypodermic needle broke in his back during a lumbar puncture examination. The defendants contended

that the patient had received the correct treatment but had jerked suddenly when the needle was inserted, although he had been fully warned what to expect. The judge accepted the defendants' version, found no negligence or lack of skill on the doctor's part, but made no order as to costs. He added: "I have certainly not overlooked the reticence of the hospital authorities in reporting back to the patient's doctor. They had everything to gain and nothing to lose by frankness at that stage. Instead they remained for a time silent. If I had drawn an adverse conclusion from this they would have had only themselves to blame."

Medical Notes in Parliament

Smoking and Cancer of Lung

Mr. J. R. BEVINS, Parliamentary Secretary to the Ministry of Works, replying on behalf of the Lord President of the Council, whom he represents in the Commons, stated on March 16 to Lieutenant-Colonel M. Lipton that the tobacco companies' offer of £250,000 for investigation into the relationship between smoking and lung cancer was accepted by the Medical Research Council at its meeting on February 19. The donation would be made available to the Council in seven equal annual instalments, the first of which had been received.

Lieutenant-Colonel LIPTON asked how this money would be spent, in view of the Minister's previous assurances that research had never been hampered by lack of funds. Mr. BEVINS said the work of the Medical Research Council was already subsidized to the extent of £15,000 a year by the Department of Scientific and Industrial Research. That was additional to the £35,000 a year from the tobacco companies, and there was a total of about £400,000 spent on cancer as a whole by the Medical Research Council. Dr. STROSS said the original statistical work by the Medical Research Council, conducted by Dr. Doll and Professor Bradford Hill, cost only £7,000, and was a magnificent piece of work which showed where the problem lay. This additional sum should be welcomed, because it should prove ample for all the further work needed to elucidate the problem.

Cancer Registrations

Mr. N. DODDS asked the Minister of Health on March 18 what progress had been made in ensuring the complete registration of all cases of cancer. Mr. IAIN MACLEOD informed him that effective registrations of new cases in hospitals in England and Wales, which were 23,239 in 1945, 40,333 in 1947, and 49,110 in 1948, were expected to be about 58,000 for 1953. This figure was estimated to be about half the total probable number of new cases of cancer in 1953 in England and Wales. He had recently issued a circular encouraging hospitals to make still greater efforts to achieve the registration of all cases, and had asked for progress reports by June 30.

Mr. DODDS asked whether the records were kept on a voluntary basis or a compulsory basis; and, if voluntary, why. Mr. MACLEOD said that it was still being done on a voluntary basis. He had recently been advised by the Standing Advisory Committee that, for a variety of complicated reasons, it was best that it should continue on a voluntary basis.

Air Pollution Report

Mr. ERNEST MARPLES, Parliamentary Secretary, Ministry of Housing and Local Government, answering a number of questions on March 16 about air pollution, said that he understood the Beaver Committee expected to present a further report before the end of the summer. The committee's interim report contained a clear statement of the main facts at present known about air pollution and the preventive measures already in operation, and he asked the M.P.s to await its next report on possible further action.

Prescribing Costs

Mr. A. BLENKINSOP asked on March 18 when the Minister of Health expected to introduce area averages of prescribing costs in England and Wales, in view of the commencement of a similar scheme in Scotland. Miss PAT HORNSBY-SMITH, the Parliamentary Secretary, stated that the matter was under discussion with the chemists and with the Joint Pricing Committees, and the Minister was not yet able to give a date. Mr. BLENKINSOP said that they were sufficiently far forward with pricing to make this a reasonably practical proposal. Did the Minister appreciate the importance of giving the extra responsibility to doctors to check their own prescribing costs as probably one of the best ways of keeping costs down? Miss HORNSBY-SMITH said that she recognized that, but it was essential to clear arrears first before starting on a new and complicated scheme.

Miss PAT HORNSBY-SMITH supplied Mr. SOMERVILLE HASTINGS on March 18 with the following figures of the Health Service prescriptions dispensed by retail pharmacists and chemist contractors supplying appliances in successive years since 1949:

Year	Total Cost	Average Cost per Prescription
1949	£30,331,303	36.04 d.
1950	£34,804,535	38.47 d.
1951	£41,662,354	43.91 d.
1952	£43,768,599	48.63 d.
1953 (first six months) ..	£23,898,821	49.15 d.

Flour Improvers

Dr. BARNET STROSS asked the Minister of Food on March 15 whether he could make a statement on the change-over from agene to some other substance as a flour improver; and what were the substances that had been investigated. Major LLOYD-GEORGE replied that he understood that the Medical Research Council had reported on the tests carried out on certain flour improvers. Its report would be considered by the appropriate subcommittee of the Interdepartmental Standing Committee on Medical and Nutritional Problems, and he must await its recommendations. The following were the methods of improvement which had been investigated: agene, chlorine dioxide, the aeration process, ascorbic acid, and potassium bromate.

Prison Treatment of Sexual Offenders

Sir DAVID MAXWELL FYFE, the Home Secretary, was questioned by Mr. LESLIE HALE about the treatment in prison of persons convicted of sexual offences. He replied on March 16 that prisoners convicted of offences of a sexual nature were specially investigated by prison medical officers, who were instructed to recommend for psychiatric treatment those likely to prove susceptible to it. A prisoner would not benefit by such treatment unless he had a sincere desire for it and a genuine anxiety about his condition. Such adverse factors as low intelligence, advancing years, and a history of persistence in the commission of offences reduced the number of suitable cases. In England and Wales there were three centres—Wakefield, Wormwood

Scrubs, and Holloway—to which selected prisoners were sent to receive special treatment from visiting psychotherapists. The precise nature, extent, and duration of treatment in a particular case were determined by the doctor carrying out the treatment. The forms of treatment used included both individual and group methods, assisted, as occasion required, by special procedures. There was also treatment of a less formal kind, especially in training establishments, in which the medical officer played a valuable part as a member of a team. The numbers of prisoners convicted of offences of a sexual nature who were under regular treatment by a visiting psychotherapist for a period exceeding six months in the years 1951, 1952, and 1953 were 25, 26, and 27 respectively. He would hesitate to speak of cure in homosexual cases, and any attempt to give figures of supposed cures could only be misleading.

Vital Statistics

Week Ending March 13

The notifications of infectious diseases in England and Wales during the week included pneumonia 755, scarlet fever 1,476, whooping-cough 2,093, diphtheria 22, measles 2,213, dysentery 1,001, acute poliomyelitis 22, paratyphoid fever 96, and typhoid fever 2.

Infectious Diseases

The largest variations in the trends of infectious diseases in England and Wales during the week ending March 6 were increases of 350 for measles, from 2,099 to 2,449, and 97 for dysentery, from 910 to 1,007, and decreases of 160 for acute pneumonia, from 869 to 709, 84 for scarlet fever, from 1,463 to 1,379, and 64 for whooping-cough, from 2,098 to 2,034.

The largest rises in the incidence of measles were 239 in Norfolk, from 396 to 635, 101 in Cumberland, from 119 to 220, and 52 in Staffordshire, from 207 to 259; the only large decrease in incidence was 59 in Kent, from 94 to 35. The largest variations in the trends of scarlet fever were a rise of 27 in Yorkshire West Riding, from 163 to 190, and a fall of 31 in Lancashire, from 187 to 156. The chief features of the returns for whooping-cough were a rise of 39 in Derbyshire, from 35 to 74, and a fall of 40 in Kent, from 114 to 74. 34 cases of diphtheria were notified; these were 23 more than in the preceding week and were the largest total for the past 67 weeks. The largest rises were from 4 to 10 in Lancashire (Liverpool C.B. 9), from 0 to 5 in Durham (Stockton-on-Tees M.B. 4), from 0 to 3 in Devonshire (Plymouth C.B. 3), from 0 to 3 in Oxfordshire (Henley R.D. 3), and from 1 to 4 in Staffordshire.

The notifications of paratyphoid fever increased from 5 to 15. This rise was contributed by an outbreak with 11 notifications in Glamorganshire (Cardiff C.B. 7, Penarth U.D. 3, Swansea C.B. 1).

The number of notifications of dysentery reached the highest level for nearly three years. The largest rise during the week was 89 in Lancashire. The largest centres of infection were Lancashire 324 (Eccles M.B. 97, Bolton C.B. 56, Preston C.B. 43, Ormskirk U.D. 33, Liverpool C.B. 23, Salford C.B. 18), Yorkshire West Riding 124 (Leeds C.B. 38, Keighley M.B. 34, Bradford C.B. 15, Royston U.D. 12), London 94 (Islington 23, Finsbury 11, Hackney 10), Middlesex 71 (Enfield U.D. 21, Ealing M.B. 12), Leicestershire 64 (Leicester C.B. 60), Essex 58 (Walthamstow M.B. 17), Staffordshire 58 (Cannock U.D. 46), Kent 37 (Tonbridge R.D. 19), Surrey 25 (Chertsey U.D. 10), Norfolk 24 (Norwich C.B. 24), Gloucestershire 22 (Bristol C.B. 21), and Warwickshire 20 (Birmingham C.B. 19).

The notifications of dysentery in Scotland are the largest for three years. During the week the largest centres of infection were Glasgow 179, Edinburgh 35, Lanark county 29, and Dundee 16.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ————. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 6 (No. 9) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrar-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

* Measles not notifiable in Scotland, whence returns are approximate.

† Includes primary and influenzal pneumonia.

‡ Includes puerperal pyrexia.

Medical News

New Chair of Anaesthetics.—Dr. W. W. Mushin has been appointed as the first holder of a new Chair of Anaesthetics in the University of Wales. Dr. Mushin qualified in 1932 from the London Hospital, and was then for a time first assistant in the Nuffield Department of Anaesthetics at Oxford. In 1947 he became director and lecturer in anaesthetics at the Welsh National School of Medicine, Cardiff, his present appointment. He is also adviser in anaesthetics to the Welsh Regional Hospital Board. In 1948 he was elected F.F.A.R.C.S.

Faculty of Anaesthetists' Dinner.—The Faculty of Anaesthetists of the Royal College of Surgeons of England held its sixth anniversary dinner in the library of the College on March 17. The Dean, Dr. Bernard Johnson, presided, and among the guests were the High Commissioner for South Africa, the High Commissioner for Ceylon, the Acting High Commissioner for the Federation of Rhodesia and Nyasaland, Sir Russell Brain, P.R.C.P., Sir Cecil Wakeley, P.R.C.S., Mr. A. A. Gemmell, P.R.C.O.G., Sir John Charles, Chief Medical Officer of the Ministry of Health, Sir Philip Morris, Vice-chancellor of the University of Bristol, Sir Gordon Gordon-Taylor, and Dr. G. Godber. Sir John Charles proposed the toast of the Faculty, and in his acknowledgment Dr. Johnson reviewed the year's work and particularly the educational aspects of it. He referred with gratitude to the gift of £1,000 which the Faculty had received from the Association of Anaesthetists to start a foundation fund for the proposed department of research. The health of the guests was proposed by the Vice-dean, Dr. T. Cecil Gray, and replied to by Sir Philip Morris.

Centenary at Queen's University, Ontario.—In February, 1854, at the home of Sir John A. Macdonald, the father of confederation in Canada, plans were laid for a Faculty of Medicine in the 13-year-old Queen's University at Kingston, Ontario. The centenary is commemorated by a special issue of the *Canadian Medical Association Journal* (the March issue) which has on its cover the armorial ensigns of the university. Inside, all the scientific articles have been contributed by members of the teaching and research staff, and there is a guest editorial by Dr. Austin Smith, editor of the *Journal of the American Medical Association*, who is himself a graduate of Queen's. Queen's University was established by a Royal Charter issued by Queen Victoria in 1841, its foundation being sponsored by the Presbyterian Church of Canada, which remained its legal owner for 71 years. Since 1913 there has been a corporation of trustees, staff, graduates, and benefactors, which receives substantial support from the government of Ontario and, more recently, Ottawa. There are some 4,000 students, of whom about one-tenth are medical.

Professorial Appointments at Sheffield.—Dr. D. H. Collins has been appointed to the Chair of Pathology at Sheffield in succession to Professor H. N. Green. Dr. Collins graduated from Liverpool in 1930, where he was subsequently junior lecturer in pathology. In 1934 he was appointed first Rheumatism Research Fellow in the University of Leeds. During the war Dr. Collins was in the Emergency Pathological Service. In October, 1946, he returned to Leeds as reader in clinical pathology, his present appointment. Dr. Collins is especially interested in diseases of the bone, and he has published a book on spinal disease. He is an assistant editor of the *Journal of Pathology and Bacteriology*. Professor Green has gone to Leeds to take up the Chair of Experimental Pathology.

Another professorial appointment at Sheffield is that of Dr. G. M. Wilson to the Chair of Pharmacology and Therapeutics, which becomes vacant at the end of this month as a result of Professor E. J. Wayne going to Glasgow as Regius Professor of the Practice of Medicine. Dr. Wilson graduated at Edinburgh in 1940, obtaining the M.D. with gold medal in 1950. During the war Dr. Wilson was in the

medical branch of the R.A.F., where he was a medical specialist. In 1947 he became an assistant to the medical unit at St. Mary's Hospital, London, and in 1950 went to Sheffield as lecturer in therapeutics. During 1952-3 he held an Eli Lilly travelling fellowship at Harvard University. Dr. Wilson's main publications have concerned the peripheral circulation and the part played by hormones in metabolic and cardiovascular disorders.

Silliman Lectures.—This year's Silliman Lectures at Yale University mark the fiftieth anniversary of the famous series given by Sir Charles Sherrington in 1904 which culminated in his classic *The Integrative Action of the Nervous System*. The lecturer this year is Professor Ragnar Granit, from Stockholm, whose subject is "Receptors and Sensory Perception." The lectures will be given on April 29 and 30 and May 3 to 7.

Vade-mecum on Transfusion.—Notes on Transfusion, a pamphlet intended primarily for the junior medical staff of hospitals, has been revised and reprinted. It is issued by the Ministry of Health on behalf of the National Blood Transfusion Service, and is distributed free of charge by regional boards and transfusion centres. In 16 pages the pamphlet gives concise and practical advice on the main difficulties that a houseman is likely to encounter. It deals with choice of fluid; storage of blood and plasma and criteria of fitness for use; volume and rate of transfusions; blood grouping and compatibility testing; administration of transfusions; transfusion records; complications and dangers of transfusion; investigation of transfusion reactions; and, lastly, the Rh factor.

Grants for Research at the Tavistock Clinic.—Dr. John Bowlby's work on the effects of separating young children from their mothers is receiving financial support from the following organizations: Trustees of Elmgrove (a private British fund—£1,650), European Office of W.H.O. in conjunction with the International Children's Centre, Paris (£3,900), and the Josiah Macy Jr. Foundation (£3,900 per annum for three years). The Foundations Fund for Research in Psychiatry (U.S.A.) has made a three-year grant of approximately £2,000 a year to Dr. H. Eziel for research on analytic technique. Both Dr. Bowlby and Dr. Eziel are working at the Tavistock Clinic, London.

Royal College of Surgeons in Ireland.—At the annual general meeting of the Association of Graduates, Royal College of Surgeons in Ireland, which was held recently in the College, the following officers were elected for the year 1954-5. *President*: Dr. J. D. H. Widdess; *Vice-President*: Dr. J. Lewis; *Hon. Secretaries*: Dr. P. C. D. MacClancy and Mr. T. O'Grady; *Hon. Treasurer*: Dr. D. Riordan.

Readerships at the Royal Free.—London University has announced the following appointments to University readerships tenable at the Royal Free Hospital School of Medicine: Dr. D. N. Baron to the readership in chemical pathology; and Dr. Eleanor J. Zaimis to the readership in pharmacology.

Family Doctor.—The April *Family Doctor* is now out. The main medical articles are on air travel (Sir Harold Whittingham), tuberculosis (by the secretary-general of the National Association for the Prevention of Tuberculosis, Dr. Harley Williams), hypertension (a continuation of Dr. W. C. Alvarez's series), hysterectomy ("There Need be No Fear about Hysterectomy"), blood transfusion—questions answered by Dr. R. A. Zeitlin, and the sensible use of the clinical thermometer (Dr. W. Edwards). The cover picture of a little girl in her bath is one of the best so far.

Sir Russell Brain, F.R.C.P., is to receive the honorary degree of D.C.L. of Durham University at Newcastle on July 3.

Dr. C. E. Dent, reader in medicine at University College Hospital Medical School, London, has been elected a Fellow of University College.

Mr. Michael Harty, F.R.C.S., has been appointed assistant professor of anatomy in the Graduate School of Medicine, University of Pennsylvania.

COMING EVENTS

Professor D. M. Dunlop will deliver the Lumleian Lectures on April 6 and 8 at 5 p.m. at the Royal College of Physicians. His subject will be "The Complications of Diabetes."

Association of Clinical Pathologists.—The 52nd general meeting will be held in Harrogate from April 8 to 10. Further information may be obtained from the honorary secretary of the association, Dr. W. H. McMenemey, Maida Vale Hospital for Nervous Diseases, London, W.9.

Institute of Biology.—A meeting is to be held on April 21 and 22 at the Royal Geographical Society, Kensington Gore, London, S.W.7, to discuss the training of biologists. A programme will be available from the general secretary, Institute of Biology, Tavistock House South, Tavistock Square, London, W.C.1.

Dartford Hospital Group.—A refresher course intended for general practitioners will be held at the Southern Hospital, Dartford, weekly on Fridays from 3.30 p.m. to 6 p.m. from April 23 until July 2. Further information may be obtained from Dr. J. C. Hogarth, Southern Hospital, Dartford.

Wessex Rabere Club.—The spring dinner will take place at the Royal Clarence Hotel, Exeter, on April 24. Mr. H. Jackson Burrows will be the guest of honour. Further details may be obtained from Mr. A. Daunt Bateman, 11, The Circus, Bath.

Seminar on World Health Organization.—The World Federation of United Nations is holding a seminar, for doctors, public health workers, and medical students, on the work of W.H.O., from May 3 to 15 at Geneva. Those attending the seminar will be able to go to the meetings of the seventh World Health Assembly, which is taking place at the same time, as well as to lectures and discussions led by senior W.H.O. officials. Further details may be obtained from W.F.U.N.A., 1, Avenue de la Paix, Geneva.

International Diabetes Federation.—The second congress will be held in Cambridge from July 4 to 8, 1955. Sir Lionel Whitby will be honorary president of the meeting.

NEW ISSUES

Thorax.—The next issue (Vol. 9, No. 1) will be available in a week's time. The contents include:

THE TREATMENT OF PULMONARY TUBERCULOSIS IN ADULTS BY RESECTION. H. T. Thompson, T. Savage, and T. H. L. Rosser.
THE PRODUCTION OF PLEURAL ADHESIONS BY KAOLIN INJECTION. James Maxwell.
EBSTEIN'S DISEASE. W. E. Medd, M. B. Matthews, and W. R. R. Thurnfeldt.
NERVE SUPPLY TO THE CRURA OF THE DIAPHRAGM. J. Leigh Collis, L. M. Seichwell, and L. O. Abrams.
MALIGNANT CELLS IN SEROUS EFFUSIONS COMPLICATING BRONCHIAL CARCINOMA. Arthur J. Spriggs.
ENDOGENOUS LIPOID PNEUMONIA WITH SPECIAL REFERENCE TO CARCINOMA OF THE LUNG. S. De Navasquez and G. A. D. Haslewood.
AIR CONTAINING CYSTS OF LUNG. J. R. Belcher and A. H. M. Siddons.
PULMONARY MANIFESTATIONS IN THE DIFFUSE COLLAGEN DISEASES. Philip Ellman and L. Cudkovic.
LINGULAR BIOPSY IN MITRAL STENOSIS. J. B. Enticknap, B. B. Milstein, and Charles Baker.
A CRITICAL DISCUSSION OF THE RECORDED FORM OF THE FAST VITAL CAPACITY RECORD. L. Bernstein.
UNILATERAL ELEVATION OF THE DIAPHRAGM IN DYSTROPHIA MYOTONICA. J. E. Caughey and W. G. Gray.
A CLINICAL, RADIOGRAPHIC, AND PATHOLOGICAL STUDY OF PULMONARY EMBOLISM. J. C. Macleod and I. W. B. Grant.
INSTRUMENTAL PERFORATION OF THE OESOPHAGUS AND PERFORATED DUODENAL ULCER. James S. Davidson.
THE TREATMENT OF HYPERTROPHIC EMPHYSEMA BY PNEUMOPERITONEUM. Bertram Mann and Edmond A. Murphy.

Published quarterly; annual subscription £2 2s., single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

British Journal of Venereal Diseases.—The next issue (Vol. 30, No. 1) is now available.

Medical and Biological Illustration.—The next issue (Vol. 4, No. 1) will be available in a week's time.

Issued quarterly; annual subscription £2 2s.; single copy 12s. 6d.; obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, March 29

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor A. B. Nutt: Significance and Surgical Treatment of Congenital Ocular Palsies.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—6.15 p.m., Mr. Harold Edwards: Intestinal Diverticula.

Tuesday, March 30

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. A. R. French: Medico-Legal Problems and the Dermatologist.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. Harvey Jackson: Diagnosis and Treatment of Orbital Tumours; 6.30 p.m., Mr. C. P. Wilson: Malignant Disease of the Superior Maxilla.
● ROYAL SOCIETY OF ARTS.—5.15 p.m., Sir Arthur Porritt: Experiment of a State Medical Service in New Zealand.
ROYAL STATISTICAL SOCIETY: STUDY CIRCLE ON MEDICAL STATISTICS.—At Westminster Medical School, 6 p.m., Mr. N. T. J. Bailey: Queueing for Medical Care.
WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., neuro-radiological demonstration by Dr. D. Gordon.

Wednesday, March 31

INSTITUTE OF DERMATOLOGY.—5.30 p.m., Dr. H. Haber: Cytodiagnosis in Dermatology.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. G. F. Rowbotham: Surgical Aspects of Injuries to the Head; 6.30 p.m., Professor A. M. Boyd: Claudication.
ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Mr. W. E. Tucker: Injuries in Sport.

Thursday, April 1

FACULTY OF HOMOEOPATHY.—5 p.m., Dr. J. C. Mackillop: Some Aspects of Homoeopathic Case-taking.
ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.30 p.m., Otolaryngology Lecture by Mr. G. A. Mason: Diagnosis, Treatment, and Prognosis of Tumours of the Lung.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—6.30 p.m., Dr. Wilfrid G. Oakley: Diabetes in Surgery.
ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.—5 p.m., Symposium: Photosensitivity. Speakers: Dr. W. N. Goldsmith, Professor C. Rimington, and Dr. A. D. Porter.

Friday, April 2

LEEDS AND WEST RIDING MEDICO-CHIRURGICAL SOCIETY.—Sir Francis Walsh, F.R.S.: Some Lessons Learned in Consulting Practice.
● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Professor T. Pomfret Kilner: Reproductive Surgery in the Treatment of Complications following Radiation; 6.30 p.m., Professor J. Trueta: Osteoarthritis of the Hip.
● SOCIETY OF CHEMICAL INDUSTRY: FINE CHEMICALS GROUP.—At King's College, Strand, W.C.2, 7 p.m., annual general meeting; 7.30 p.m., Dr. D. S. Morris: Chorea acrophthalmica.
WHIPPS CROSS HOSPITAL MEDICAL SOCIETY.—8.30 p.m., Professor A. Wilson: Peculiar Prescriptions. Members of the South-west Essex Division, B.M.A., are invited.

Saturday, April 3

KENT PAEDIATRIC SOCIETY.—At Royal Star Hotel, Maidstone, 3 p.m., Sir William Hamilton Fyfe: Some Platitudes on Education.
MIDLAND TUBERCULOSIS SOCIETY.—Visit to St. Wulstan's Hospital, Malvern. Clinical meeting.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Happel.—On March 16, 1954, at Alton General Hospital, Alton, Hants, to Margaret, wife of Dr. John S. Happel, D.Obst.R.C.O.G., of Ropley, Alresford, Hants, a daughter—Susan Margaret.

DEATHS

Beane.—On March 5, 1954, at Moretonhampstead, Devon, Robert Leonard Beane, M.R.C.S., L.R.C.P., aged 87.
Cormack.—On February 27, 1954, at Nairobi, Kenya, Robert Fairman Cormack, O.B.E., M.B., Ch.B., D.T.M.&H., D.P.H., Brigadier (retired), R.A.M.C., late Senior Medical Officer, Colonial Medical Service, Kenya.
Cumming.—On March 3, 1954, at Springfield House, Sutton-on-Hull, East Yorks, John Cumming, M.B., C.M.
Farrant.—On March 3, 1954, at his home, Charles Farrant, D.S.O., T.D., M.R.C.S., L.R.C.P., of Boldre, Lymington, Hampshire.
Fraser.—On February 28, 1954, at Craigroyston, Strathpeffer, Ross-shire, John James Fraser, M.B., C.M., aged 87.
Gupta.—On January 31, 1954, Subodh Chandra Gupta, M.B., F.R.C.S.Ed., of Calcutta, India.
Hare.—On March 5, 1954, at Cheltenham, Glos., Edward Christian Hare, M.R.C.S., L.R.C.P., D.P.H., Lieutenant-Colonel, I.M.S., retired, aged 90.
Jackson.—On February 28, 1954, at Feock, Cornwall, Gordon Alexander Jackson, M.B., B.Ch., Surgeon Lieutenant-Commander, R.N., retired, aged 72.
Lyon-Smith.—On February 28, 1954, at his home, Spaxton, Bridgewater, Somerset, George Lyon Lyon-Smith, M.B., M.R.C.P., aged 61.
McGlasgow.—In February, 1954, John Thomas McGlasgow, M.B., Ch.B., of Canonbie, Dumfriesshire.
Thms.—On March 4, 1954, at Eldon House Nursing Home, Lower Bourne, Farnham, Surrey, Henry William Marcet Tims, O.B.E., M.D., aged 90.
Umney.—On March 3, 1954, at 9, The Knoll, Beckenham, Kent, William Francis Umney, M.D., aged 87.
White.—On March 2, 1954, at Merthyr Vale, Glamorgan, Charles Richardson White, D.S.O., T.D., M.D.
Yealland.—On March 2, 1954, at 103, Clarence Gate Gardens, London, N.W., Louis Ralph Yealland, M.D., F.R.C.P.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Bodies for Dissection

Q.—A patient wishes to leave his body for dissection, and has asked my advice on what steps he must take to do this. How should I answer him?

A.—Strictly speaking no one can bequeath his own body, for as soon as he dies the legal right to dispose of it passes to his next-of-kin or the executor of his will. The body can be sent to a medical school for anatomical dissection only if the near relatives agree. Accordingly, if your patient wishes his body to be used for this purpose he should: (a) Ascertain that no objection will be raised by his nearest relatives. (b) Place with his papers a written statement of his wish to benefit medical education in this way. (c) Apply for the necessary forms and instructions to H.M. Inspector of Anatomy, Anatomy Office, Ministry of Health, Savile Row, London, W.1.

All expenses connected with the removal and subsequent burial of the body are borne by the medical school concerned, but if anything more than the very simple funeral provided by the medical school is desired then the executor or next-of-kin is expected to meet the expenditure.

Screening Test for Anaemia

Q.—What are the details of the copper sulphate test which is used by the Blood Transfusion Service as a screening test for anaemia? How reliable is it?

A.—A range of solutions of copper sulphate are prepared as described by R. A. Phillips *et al.*,¹ each being of known specific gravity. These can then be used to estimate the specific gravity of plasma or whole blood in the following way.

A drop of the plasma or blood is dropped into the solution, where it becomes encased in a sac of copper proteinate. Its momentum carries it 1 to 2 cm. below the surface, but in about 5 seconds the momentum of the fall is lost and the drop then begins to rise, becomes stationary, or continues to fall. The gravity of the drop relative to that of the solution remains constant for another 10 to 15 seconds and during this time its behaviour is noted. If it is lighter than the standard it will rise, perhaps only a few millimetres, and may then sink immediately. If the drop remains stationary for a few seconds its gravity is the same as that of the test solution; if the drop is heavier, it continues to fall. From comparison of plasma specific gravities with protein concentration calculated from Kjeldahl analyses an equation can be derived which permits the determination of protein concentration in normal plasma with an error of less than 0.1 g. per 100 ml. plasma (D. D. Van Slyke *et al.*²). The difference between the specific gravities of whole blood and plasma can be used to calculate the blood haemoglobin concentration, and, if one assumes a normal plasma protein concentration, the specific gravity of whole blood can be used to measure the haemoglobin concentration. Van Slyke *et al.*,³ using the latter method on blood from normal individuals and from subjects with anaemia due to iron deficiency or blood loss and comparing the results with those of a precise gasometric method of haemoglobin determination, observed an error of ± 0.5 g. haemoglobin per 100 ml.

A screening test, using a copper sulphate solution of specific gravity 1.053, allows a separation of those with haemoglobin concentrations above 12.5 g. per 100 ml. of blood (that is, about 85% Haldane) from those with lower

concentrations. The accuracy of the method within the limits mentioned depends upon the close observance of certain points. The solution must be properly prepared. The surface film must be clean and free from fragments; occasionally a part of a drop of blood remains attached to the surface film and might interfere with the passage of subsequent drops. The drops must be free of even minute air bubbles, which would make them float. The solution must be allowed to reach room temperature before use; if the solutions are used while warming, convection currents may interfere with the determination. The difference in temperature between the copper sulphate and blood should not exceed 5° C.; however, the error caused by dropping blood immediately after collection from a syringe or capillary tube is very small, because when the drop enters the solution the drop approaches the temperature of the solution so rapidly that the effects of several degrees of initial difference are nearly eliminated. A volume of 100 ml. of the test solution should not be used for more than 50 determinations. The solution must not be allowed to evaporate, for obvious reasons.

The limits of accuracy of this test have also been the subject of a field investigation, the results of which correspond very closely to those of Van Slyke *et al.*, quoted above. It does, however, occasionally happen under field conditions that a few donors are rejected who have in fact concentrations of haemoglobin above the limiting values.

This test is used by transfusion services in many parts of the world and has proved to be a reliable method for rapid examination of large numbers of individuals. Those persons whose haemoglobin concentration is shown by the copper sulphate test to be in the region of, or below, the critical level are usually tested by another method.

Treatment of Still's Disease

Q.—In what way does the treatment of rheumatoid arthritis in children (Still's disease) differ from that of adults? Is hormone therapy particularly indicated in children?

A.—The principles to be observed in treating children with rheumatoid arthritis are no different from those to be followed in adults, but there are many small differences in their application. The major factors in successful treatment of both children and adults are five in number: (1) care of general health, (2) relief of pain by suitable analgesics, (3) maintenance of muscle tone and joint movement by active and passive exercises preceded by heat, with assistance by the masseuse or in a therapeutic pool, (4) prevention of deformity by adequate splinting, and (5) the maintenance of function and morale by adequate employment.

Deformities occur very rapidly in children, and once knee contracture has developed it may take many years of orthopaedic endeavour to regain even limited function. It is most important, therefore, to avoid absolute immobilization, and even in patients who are running considerable fever we endeavour to control this with salicylates and keep the children up and moving about for at least a short time every day. During rest periods, splints are necessary.

There is no specific cure for rheumatoid arthritis either in children or in adults; salicylates in various forms, phenylbutazone, cortisone, hydrocortisone, and corticotrophin (A.C.T.H.) are all useful for diminishing pain and increasing function in conjunction with a regime planned along the lines outlined above. Hormone therapy will sometimes bring a child back to a point where he can lead a normal life and, less frequently, maintain him at that level for a long period of years. It is a little too early yet to know whether these results are better in the long run than those obtained with agents such as salicylates. Hormone therapy is particularly indicated in children who do not respond adequately to the usual regime or whose disease for some

reason or the other has become more active, possibly as the result of an infection or trauma. In view of the slightly better prognosis in children compared with that in adults, it might be maintained that hormones are particularly useful in children.

Multiple Meibomian Cysts in Children

Q.—A girl, aged 4½, since birth has had no less than eight Meibomian cysts removed from all four eyelids at various times. What can be done to prevent their formation?

A.—Children do sometimes suffer from repeated Meibomian cysts. In some instances marginal blepharitis appears to predispose to these cysts. Therefore the lid margins should be kept clear of dried secretion. If no blepharitis can be detected, there is no method of successful prophylaxis, but spontaneous cessation is the rule, and the eyelids hardly ever show any lasting damage from the cysts.

NOTES AND COMMENTS

Pharaoh's Ants.—Mr. H. E. Cox (Infestation Control Division of the Ministry of Agriculture and Fisheries, Hook Rise, Tolworth, Surbiton, Surrey) writes: We were pleased to see the publicity given to the treatment of a hospital infestation of Pharaoh's ant (*Monomorium pharaonis* L.) with chlordane ("Any Questions?" February 20, p. 471). We are in full agreement with the information given in your answer. We hope it would not be out of place for us to suggest that it might be emphasized that not only is treatment with chlordane an efficient control of Pharaoh's ant, and also for cockroaches, which are a common infestation of hospitals, but that the use of chlordane is an easy process. It is only too likely that the attitude of hospitals to infestations of Pharaoh's ant in the past has been rather controlled by the difficulties of the treatments recommended, which, although effective, require poison baiting with a prebaiting technique. No doubt the staff responsible for carry-out treatments in the past found it a tiresome process, with the inevitable result. We are always ready to give advice, particularly in difficult cases.

Phenylbutazone and Pulmonary Tuberculosis.—Dr. W. S. Wilson (Huddersfield) writes: Your answer to this question states that there is no contraindication to therapy ("Any Questions?" February 20, p. 471). About a year ago you published a letter of mine relating to the possible toxic effect of this drug in tuberculosis. The patient was given phenylbutazone for a severe ankylosing spondylitis; on investigation for the latter complaint, an old-standing "quiescent" tuberculosis of the lung was discovered. After about four to six weeks' treatment with phenylbutazone, there was an acute flare-up of the tuberculosis. Although absolute proof is lacking, it is difficult to ignore the clinical impression of phenylbutazone toxicity in this case.

THE CONJOINED TWINS OF KANO

BY

IAN AIRD, Ch.M., F.R.C.S.

Professor of Surgery, University of London; Director of Surgical Studies, Postgraduate Medical School of London, Hammersmith Hospital

(WITH SPECIAL PLATE)

The term "conjoined (Siamese) twins" is usually applied to twins who are united bodily but possessed of separate personalities. It has therefore been used to include a great variety of twins monstrously joined, and has included partners who have shared various combinations of trunk and limbs. Those of surgical interest include the so-called "symmetrical conjoined twins," though this term is perhaps unfortunate in that conjoined twins are seldom completely symmetrical; they differ from each other usually to some degree in appearance, and their internal organs may partly or wholly each be a mirror image rather than a replica of their partner's.

Formation of Conjoined Twins

It is usually assumed that conjoined twins are monovular and due to fission of an embryo. If fission occurs at the stage of the inner cell mass before the embryonic disk has separated, separate twins result. If the twinning occurs after separation of the embryonic disk, there is only one amniotic sac. If the centres of axial growth are at this stage far enough apart there are separate twins in a single amniotic sac. If the centres of growth were not sufficiently separate the intermediate area between the two centres of axial growth might be shared and conjoined twins result (Potter, 1952).

It has never been completely proved that conjoined twins are in fact monovular. It is conceivable that separate twins might become joined from fusion of the closing edges of the neural grooves, for example, or from fusion of some other epithelial surfaces with their underlying mesodermal masses; but this would require disappearance of intervening amnion, a rare accident, as well as fusion of the twins. It is certainly curious that conjoined twins always differ from each other slightly in size and appearance, and are seldom so precisely identical as separate monovular twins are. Seventy-three per cent. of conjoined twins exhibit mirror imaging, while separate one-egg twins show this abnormality in only 22%, the mirror imaging taking the form of a degree of *sinus inversus viscerum*, which has never been explained satisfactorily. I have a record, obtained directly from a traveller, of Chinese conjoined twins, one of whom was a eunuch. There is also a report of twins joined at the pelvis, one of whom suffered from hypertension (Jones *et al.*, 1948). In one reported pair there was a hare-lip deformity in the case of one only, and, as in the Townsend twins of Alberta (Allin, 1953), the heart is often normal in one twin but the seat of Fallot's tetralogy or some other congenital cardiac defect

in the other. In this connexion it should, however, be remembered that in parabiosis of any kind one partner always becomes dominant. If two identical twins from a normal litter are artificially joined by parabiosis one almost invariably outgrows the other, contributing more to the total organism and taking more from the total organism than its partner. If conjoined twins were ever the result of the fusion of binovular embryos it would be likely that on some occasion a blood-group chimera would occur; this has never been demonstrated, but it apparently has never been sought.

Types of Twins

Conjoined twins may take the form of an *omphalopagus* (joined at the navel); a *xiphopagus* (joined at the lower sternum); a *thoracopagus* (joined in the chest); a *craniopagus* (joined by the heads); or a *pygopagus* (joined at the pelvis). The bridge of fusion may include an important internal organ. An *omphalopagus* may have a fusion of the two small intestines, or of the stomach, or of the liver. A *craniopagus* may have the two brains joined by a bridge of nervous tissue. When union is at the pelvis, urogenital organs may be shared, or if union is at the sacrum the spinal cords may be single at the level of the union. Rarely, one twin is included in the body cavity of the other as an "included foetus" (Farris and Bishop, 1950).

The frequency of occurrence of conjoined twins is difficult to ascertain. Potter reports one specimen of symmetrical joined twins in the Chicago Lying-in Hospital in 60,000 deliveries; during the same period there was no example of such union in embryos or foetuses. The frequency of reports of conjoined twins is increasing, but it would seem that this is due to the increasing accessibility of very large populations in Asia and Africa, to the greater possibility of the successful birth of conjoined twins in improved modern obstetrical circumstances, and to the lessening likelihood now of conjoined twins being sacrificed as monsters at birth. My belief is that we may expect each year, over the world as a whole, the birth of half a dozen or more conjoined twins capable of separation. A number of survivors from the operation of separation of Siamese twins have come to my notice in the past few months, and not all of these have been reported in the medical press.

Only a minority of conjoined twins seem to cause dystocia, though at least one case of obstructed labour from this cause is reported (Roxburgh, 1946).

Some Historical Examples

A number of conjoined twins have become historically famous. The earliest case on record seems to be that of the "Biddenden Maids" born in A.D. 1100 in England, united from hips to shoulders and with only one pair of upper and one pair of lower extremities shared between them. The "Florentine Twins," born in the fourteenth century and the subject of a bas-relief in the Church of La Scala and of a sonnet of Petrarch's, seem to have had three lower extremities between them and three upper, though successive mediaeval authors vary in their descriptions and illustrations (Belloni, 1950). The "Scottish Brothers," joined from the waist down but separate above it, lived for 28 years at the Court of James III of Scotland in the latter part of the fifteenth century. The opposite abnormality—one head and chest and a double abdomen and pelvis, with four inferior extremities—has also been described (Rohrbach, 1950). In the sixteenth century female conjoined twins with three legs, the central one equipped with ten toes, lived at Middleton, in England (Rueff, 1554), and during the same century there was a similar monster, carrying, however, only five toes on each of the three lower extremities, alive at Viaban in France. The "Hungarian Sisters" were born at Szorny in 1701 and survived in a convent for 22 years. The famous "Siamese Twins," Chang and Eng (1811–74), have been fully documented elsewhere (Luckhardt, 1941). Born of Chinese parents in Siam in 1811 as a xiphopagus, they were discovered at the age of 13 by a British merchant. Removed to North America, they were shown in his circus by Barnum, married English sisters, and settled down as farmers in North Carolina under the name of Bunker. As in the case of most other conjoined twins, when one died the other refused separation. Other conjoined twins include the "Sardinian Sisters" (1829–?), the Negro slave sisters Millie-Christine (1851–?), the "Bohemian Sisters" Rosa-Josepha Blazek (1878–1922), and many subsequent examples (Newman, 1942). There are at least three dozen fully documented instances in the literature of conjoined twins born alive. Hindu twins, Guarabai and Guaganbai, were on exhibition at the Paris Exposition of 1931. The Godino twins, born in the Philippines, applied for United States' citizenship. They were perplexed when the official response to their application was a warning that military service would be required of them; their sacral junction would have rendered it impossible for them both to have obeyed marching orders simultaneously (*N.Y. St. J. Med.*, 1937).

Previous Operations

Scammon (1925) recorded and described the operations performed for the separation of conjoined twins, including that performed by Doyen in 1902 for the separation of the Radica-Doodica sisters, one of whom had developed active tuberculosis: the tuberculous sister died, but the healthy survived. The earliest attempt at surgical separation is said to have been made by Dr. Farius, of Basle, in 1689, but I have not traced the record of this operation.

In October, 1912, conjoined twins were successfully separated at the Military Families Hospital, Portsmouth, by a R.A.M.C. officer whose name cannot now be traced. One of the sisters of this pair is alive to-day, age 41, and the scar of her operation can be seen on the lateral aspect of the hip. The other sister died of pneumonia at the age of 4 months, but there are no records to show whether or not she in fact had congenital heart disease. This would appear to be the first successful separation of conjoined twins.

Dr. Holm, of Minnesota, successfully separated conjoined twins joined by the xiphoid cartilage on January 8, 1927, and they were alive and well nine years later (Holm, 1936). Dr. D. W. McLaren (1936) also successfully separated conjoined twins of a Hausa woman in the Sokoto Emirate of Nigeria on June 16, 1935, and the separated twins are alive and well to-day (McLaren, 1953). Here again the junction was of skin, subcutaneous tissue, and cartilage at the level of the xiphoid process. Three further separations were recorded last year in America in the medical and lay press. In one of these (Carolyn Anne and Catherine Anne Mouton) the junction was pelvic and both girls survived, one with an artificial anus. The second example, in Cleveland, Ohio, was a separation of twins joined by cartilage at the xiphisternum, both again surviving (Reitman *et al.*, 1953), and the third (Grossman *et al.*, 1953) was a craniopagus, with a common sagittal sinus which necessitated the sacrifice of one child, the other surviving. In 1953 a craniopagus was born in Bonn, Germany, but operation was, I understand, refused. A xiphopagus born in Molenend in Friesland awaits operation. A thoracopagus born in Greenock, Scotland, on March 20, 1954, survived for rather more than a day, and conjoined twins born in Hamburg, Germany, on the same day, are still alive at the time of writing.

Hazards of Operation

Surgical success is most likely to be obtained when the union between conjoined twins is only of skin, subcutaneous tissue, and perhaps cartilage. I have recently been informed of several cases in which an umbilical junction of minor extent has been successfully separated just after birth and the event not thought worthy of medical record. The chance of success should also be high in twins joined at the xiphisternum by skin and cartilage only. Where a vital organ is shared—the liver or the brain—the division of that organ may render operation hazardous. The Edendale twins shared a common ileum (Tibbit, 1951). Pelvic junctions also offer particular difficulties, for frequently the generative organs, urethra, or rectum may be single (Fox and Barnes, 1950), or may be so closely associated with each other that surgical separation is extremely difficult. Sacral unions can be divided often only with sacrifice of one spinal cord at that level. Cranial unions may involve the division of brain substance (Smellie and Starr, 1950), or the loss to one infant of a blood vessel vital to the survival of its brain. In any event, and however great the risk of the death of one or both children, it would seem that operation should nearly always be undertaken if the children are known each to have a full complement of the organs and tissues necessary for separate life. In very extensive union there may be no prospect at all of separation, as in those historical monsters who lack a full complement of limbs, or who share a single pelvis or an even more extensive length of trunk.

In the case of a stillborn premature thoracopagus which I had an opportunity to dissect in February, 1954, by the courtesy of Dr. T. K. Owen, of Bournemouth, union was exceedingly complex. A bridge extended from just below the chin to the navel and the chest cavities and abdominal cavities were shared. Each foetus had a mouth, pharynx, and larynx, but there were a single oesophagus, stomach, duodenum, and small intestine down to the level of Meckel's diverticulum; here there was a dilatation from which the lower ileum passed to each foetus, and each foetus had a complete colon. There were only one heart and thoracic aorta, and one liver—a misshapen organ lying vertically in the middle of the bridge with only one common bile duct and portal vein, and with one pair of hepatic veins. The urinary tracts were normal and separate. There was a single trachea terminating in an arborization of bronchi which ended blindly, and the lungs were represented by multiple islands of solid tissue which had no communication with the bronchi. Such monsters could in no circumstances have survived to live separately.

The diagnosis of conjunction, usually made during labour, has only twice been made before labour has begun (Graber, 1945; Becker, 1950).

On March 22, 1954, a thoracopagus was born at Hastings, Sussex. The mother's previous obstetric history was of a miscarriage at 12 weeks gestation in 1947 and a full-time pregnancy in 1949. There was a history that the paternal grandmother had had three sets of normal twins. There was a pre-natal diagnosis of twins, both presenting by the head. Labour began at term on March 22. One head presented at the vulva next morning, but further progress was arrested and traction was in vain. The presenting baby died during these efforts to deliver it. The obstetrician (Mr. John F. Foulkes) was summoned, and his examination revealed the presence of conjoined twins. In view of their size delivery by the abdominal route was undertaken and accomplished, both babies being now dead. The mother has made a good recovery.

These twins were joined from the sternum at the level of the third costal cartilage to the umbilicus. The lower part of the communicating bridge took the form of a substantial exomphalos through the wall of which four umbilical veins, one pair on each aspect of the bridge, could be seen passing from a single placenta, diverging from each other on each aspect of the bridge and coursing together again, appearing to join at the edge of the exomphalos. Dissection of the specimen showed that each infant had an oesophagus and stomach, but that the two pyloric canals entered a single duodenum which was continued as a single small intestine to a point about half-way along the small intestine, where there was a pouch resembling a Meckel's diverticulum, though placed at a much higher level than usual; and from this pouch two separate enteric channels continued, one to each infant. The large intestines were normal. The liver was joined and no gall-bladders could be found. There appeared to be two sets of bile passages and each infant had a pancreas. A single heart, anatomically abnormal in a complex way, served both infants, and only one of the infants was possessed of an aorta. In the other infant no vessel or vessels suitable to take the place of the aorta could be found. These infants, though externally not substantially dissimilar to the conjoined twins of Kano, could not have been separated with any hope of the survival of both, and it seems unlikely that even one of them would have survived operative intervention. The complexity of their union shows the need for the most extensive possible investigation before the surgical separation of conjoined twins is attempted.

The Kano Twins

The conjoined twins which are the subject of the present paper were born in Kano, Nigeria, to a mother of Ibo race, on July 25, 1953. They were rotated at birth with respect to each other; one presented as a vertex, the other as a breech. A diagnosis of plural birth had not been made. The twins were successfully and safely delivered by a pupil midwife. Their weight at birth was 7 lb. 13 oz. (3.5 kg.) They were nursed at the breast, the mother learning to support them both in a suitable position for feeding together.

X-ray examination after the feeding of barium to one twin showed already while they were in Nigeria that the alimentary tracts were separate.

The twins were admitted to Hammersmith Hospital on Friday, November 13, 1953. Both were then in good health, and their joint weight was 19 lb. 1 oz. (8.7 kg.). One twin, Wariboko, was noticeably larger and more active than the other, Tomunotonye, and the facial appearance of each was quite distinct. They were not in the literal sense identical even though presumably uniovular.

The twins were joined by a bridge which extended from the sixth costal cartilage to the navel. The bridge was 14 cm. in its long vertical diameter and 37 cm. in circumference. There were a single common navel and an umbilical hernia which depended from the lowest part of the bridge (Fig. 1). This hernia could be invaginated, the invaginating finger passing easily into both peritoneal cavities (Fig. 2), which showed that the peritoneal cavities communicated at least in

the lower part of the bridge. There was a firm ring of muscle around the neck of the hernia, which admitted two fingers, and it thus seemed certain that the bridge had a substantial muscle wall in its greater part. In its lower part the bridge could be compressed between finger and thumb (Fig. 3) so that its two walls met. In its uppermost part the bridge contained a hard tissue which was deduced to be cartilage: it seemed to arch over the upper part of the bridge formed by the fusion of the sixth, seventh, and eighth costal cartilages, and the lower part of the sternum. Even below palpable cartilage the bridge could not be fully compressed in its upper half.

A heart beat could be heard over the chest of each child, but it was impossible on auscultation to decide whether the beat was separate. The children breathed in unison and consequently sucked synchronously when fed. This was a matter at first of some apprehension, in case the diaphragms should be extensively intermingled and the pericardial cavities perhaps in communication with each other. It was then recalled, however, that animals artificially joined in parabiosis breathe synchronously, apparently as a matter of convenience, and it was hoped that synchronous breathing was a matter of convenience in these twins rather than a sign of seriously extensive anatomical union of their respiratory organs. It is perhaps of psychological interest that each infant sucked her own and her sister's thumb almost indiscriminately and with equal and mutual satisfaction.

A series of special investigations was undertaken to decide whether operative separation afforded any prospect of success.

X-ray Examination

A straight x-ray film failed to demonstrate visibly the cartilage bridge between sternums and ribs. (This feature can be seen in Figs. 4, 5, and 6.) Both spines were lordotic from the infants constantly straining away from each other, and the sternums both sloped forward towards each other from the upper to the lower ends. The heart shadows were clearly separate from each other. In repeated x-ray examinations the intestines filled the lower part of the bridge, but in none of the very numerous plates were hollow viscera seen to occupy the upper third of the bridge. In the very uppermost parts of the bridge a clear gap was observed between the two livers and the outlines of the opposing faces of the two livers were thought to be distinguishable; yet there remained a rather hazy shadow between these two outlines, and a bridge of liver tissue crossing from one infant to the other could not be excluded.

An opaque-meal examination was undertaken in Nigeria, barium being fed to one infant. This showed clearly that stomach (Fig. 4), small intestine (Fig. 5), and colon and rectum (Fig. 6) were separate for each child. It showed in addition that the pylorus of one child lay at least 3 in. (7.6 cm.) from the pylorus of the other, and therefore it was assumed that the two duodenum were substantially separate from each other, and consequently that at least the lower ends of the common ducts were separate too.

Cholecystography was next performed. The gall-bladders were both visible, well separate from each other. Consequently it was deduced that the common ducts must be separate at their upper ends and, since their lower ends were also considered above to be separate, presumably throughout their whole length. It was assumed that if the bile ducts were separate the portal veins would be separate also.

Intravenous pyelogram was performed at the same time as blood and circulation studies were done in order to preserve at least one great saphenous vein in each baby to be used for transfusion at the time of operation. An intravenous catheter was in each infant passed by way of the saphenous vein into the common iliac vein. A pyelogram showed that each infant had two kidneys placed well back in the paravertebral region. From this it was deduced that the renal arteries, and probably therefore the aortas, were in their

normal situations. Anomalies of the great vessels are frequent in conjoined twins and a common ventral aorta was to be feared. The pyelogram seemed to exclude this particular danger. The bladders were well outlined, separate from each other, and there was no visible junctional canal between them, as might be found by the union of one allantois with the other.

Electrocardiography

Electrocardiographic studies were undertaken by Dr. T. Counihan. They proved to be of special cardiological interest sufficient to require separate description, and Dr. Counihan's description of the electrocardiographic changes and discussion of their implications will be described in a separate paper. The individual electrocardiographs of both children were essentially normal. In the joint electrocardiograph (Fig. A) the Wariboko complex was inverted, and

FIG. A.—Joint electrocardiograph. Wariboko complex inverted. Heart rates different.

this infant was shown later to have a dextro-rotation of the heart. This joint tracing showed clearly that the heart rates were different.

Investigation with Radio-isotopes

Mr. N. Veall, formerly of the Radiotherapy Unit, and Dr. P. L. Mollison, of the Transfusion Research Unit, of the Medical Research Council, both situated in Hammersmith Hospital, undertook a study of the circulatory connexion between the two infants: A known dose of radioactive red cells was injected by intravenous catheter into twin I. Gradually the injected cells, circulating across the bridge, mixed with the circulating blood of twin II. The concentration of radioactive blood in twin I consequently gradually fell, and the concentration of radioactive blood in twin II, as measured in successive specimens by Geiger-Müller counter, gradually rose, until equilibrium was reached with complete mixing. From the rate at which the proportion of radioactive cells in twin II increased the rate of blood flow across the bridge could be deduced. Mr. Veall prepared a graph (Fig. B) which showed the rise in radioactivity in the blood of infant II and the fall in that of infant I. The curve is, as was expected, an exponential one, but it will be seen that there is a slight time-lag in the early part of the curve. This would be compatible with the blood in the injected infant having to complete nearly the whole circle of the circulation, passing through not only pulmonary and systemic capillary beds but also the hepatic

sinusoid bed before crossing the bridge. Mr. Veall's curve shows that complete mixing was obtained in 29 minutes, and half-mixing was reached in 5 minutes. The logarithmic curve and formula for determining the rate of crossing is given in Fig. C. It is thought desirable here to publish Mr. Veall's pre-operative report in full.

Consider two tanks A and B each having an equal volume V ml. They are connected together so that there is a flow of

FIG. B.—Graph showing rise in radioactivity in blood of infant II and fall in infant I.

FIG. C.—Logarithmic curve and formula for determining the rate of crossing.

v ml./minute between them. A marker substance is added to tank A and its concentration C is measured in both tanks as a function of time. Assuming perfect mixing, the concentration of the marker in each tank is given by the equations:

$$(1) C_A = C_F (1 + e^{-\frac{v}{V}t}); \text{ and } (2) C_B = C_F (1 - e^{-\frac{v}{V}t})$$

where C_F is the final equilibrium concentration after mixing is complete. The two curves have the form shown in Fig. B, one being the mirror image of the other. By plotting the logarithms of either $(C_A - C_F)$ or $(C_F - C_B)$ against time a straight line is obtained (Fig. C), whose slope gives the value of the ratio v/V . Finally the volume V can be calculated from the value of C_F and a knowledge of the amount of marker added, so that the flow v can be calculated.

Two assumptions were made:

(1) That the blood volumes of the infants were equal: this assumption greatly simplifies the mathematical treatment and within the limits of the experimental data available appears to be reasonable.

(2) That there is perfect mixing: in the first two or three minutes this is certainly not true, so the very early points cannot be relied on for determining the slope of the logarithmic plot.

Injection of labelled red cells was made into infant I. Only two well-timed samples were obtained from that infant, and one sample which was uncertain because of catheter blockage. Six well-timed samples were obtained from infant II, and these gave a value for the ratio of v/V of about 1/7. The one-minute sample was ignored for this purpose (see assumption (2) above). A reliable value of C_F was obtained by means of samples from both infants when mixing was almost complete. This gave a combined blood volume, using the normal procedure and corrections, of 600 ml. for the thoracopagus, whence V (blood volume of each twin) equals 300 ml. Hence the blood flow, v , between the two infants is 40 ml. per minute in each direction. This figure is thought to be accurate to within $\pm 10\%$.

It will be seen that the actual points in figure B, except for the first and the last, do not fit the exponential curve which suits a half period of five minutes; the other points can be fitted by another exponential curve which extrapolates back to a value of 1,400 c.p.m. instead of zero. It is therefore necessary to account for a relatively sudden influx of labelled red cells, sufficient to increase the activity of the blood in infant II by about 1,400 c.p.m. and occurring at about one minute after injection.

A reasonable interpretation of this phenomenon would be as follows:

Assume that one-third of the cardiac output (blood volume) passes to the liver—that is, 100 ml. When the labelled red cells are injected no appreciable mixing will have occurred, and one-third of the labelled red cells will pass into the liver circulation of infant I as a wave. If 30 ml. of the liver flow then passes directly to the liver from infant II, and thence into the circulation, then the effective increase in concentration in infant II will be given by $14,800 \times \frac{1}{3} \times 0.3 = 1,500$ c.p.m.

This effect takes about one minute to manifest itself at the sampling point, a time consistent with the length of the circuit involved.

If the above assumption about liver flow is true a completely common liver circulation, with a common portal vein, would give about 50/50 partition. The implication of the figures obtained is that about 60% of the liver tissue is shared.

It thus emerged from the circulation studies that 41 ml. per minute of blood crossed the bridge in each direction. It was a guess that perhaps 5 to 10 ml. per minute might cross in the skin and muscle of the bridge. There was thus 30 to 35 ml. per minute to account for by a cross-circulation in some tissue other than skin and muscle. Assuming the liver circulation to be one-third of the total circulation it might be taken that 100 ml. per minute passed to each liver, or to each half of a shared liver. For 30 to 35 ml. to cross the bridge in each direction by way of the liver would mean that there was substantial mixing in the central 60% to 70% of a shared liver. The presumption that liver lay in the bridge was thus extremely strong.

Decision to Operate

The investigations seemed to show that both infants were fully equipped with all the organs necessary for separate life. It was not possible to predict whether the separate organs

would necessarily function adequately after separation, but it was unfortunately not anticipated at this point that one of the pair might be contributing more, and one less, than the other to the total endocrine production. The only hazard of operation would seem to be the liver union which was confidently predicted; but this was not felt to be an insoluble barrier, though division of a common liver might well add to the shock of the operation. There was no previous record of the successful separation of twins so extensively conjoined. The investigations seemed to have shown that the portal veins and common bile ducts were separate. It was decided to operate without further loss of time to avoid increasing the spinal lordosis and the forward angling of the sternums.

The Operation

The mother was prepared for operation in case a vein or fascia graft or temporary skin cover by homograft should be required.

INSTRUMENTS

Only two special instruments were included in our armamentarium, a liver tourniquet of fine soft rubber (Penrose) tubing, as used by Dr. Allin, of Edmonton, who lent his film of a previous separation, and Schumacher intestinal clamps for application to the liver bridge if it was narrow enough.

ANAESTHESIA

Since the vascular communication across the bridge gave complete mixing of the twins' blood only after 29 minutes it was obvious that both must be separately anaesthetized, and two anaesthetic teams were arranged. Nitrous oxide and oxygen anaesthesia was chosen, and each infant was to be separately intubated and to be anaesthetized by means of a separate anaesthetic apparatus.

For an operation of such magnitude on babies so young blood transfusion was obviously essential, and Dr. P. L. Mollison, Director of the Medical Research Council Transfusion Research Unit, catheterized the remaining saphenous veins so that transfusion would be entirely dependable.

The twins were placed on an operating table with the headpieces and footpieces dropped, and the double anaesthetic was induced without difficulty. A remarkable phenomenon was observed during the induction of anaesthesia. As has already been stated, the respiration of the twins before operation was synchronous. As the induction of anaesthesia proceeded, and while the children were breathing still voluntarily, each through its own anaesthetic apparatus, the character of the breathing changed, and a kind of saw-saw respiration developed, one baby inspiring as the other exhaled. Gradually the tempo of respiration again changed, until each settled down at its own pace. The explanation of these respiratory changes must be exceedingly complex. Once induction was complete intubation proceeded and was effected without difficulty.

TOWELLING THE TWINS

The special arrangements for towelling were learnt also from the Canadian film. A team of nurses supported the twins horizontally over the operating table and well clear of it, while the skin of the whole trunk of each, and of the bridge between them, was cleaned. A series of four towels were then applied to the babies, one towel wrapping the head and upper chest of each, and the others the lower extremities. The towelled babies were then placed on the operation table. Two surgical teams were in readiness, each consisting of surgeon, assistant, and instrument nurses, the two surgeons to separate the twins and then each to conduct one closure. Other specialists were additionally available to advise in the solution of unexpected problems in particular fields, and an anatomist to help unravel internal anatomi-

cal abnormalities, especially the complicated and varied venous plexuses sometimes present in such twins on the under surface of the liver.

INITIAL PHASES

It was decided first to explore the bridge directly through its presenting obverse surface, the incision being made initially from the cartilage bridge to the navel. The alternative would have been to start at the lower limit of the bridge, dividing the parietes on both obverse and reverse aspects, and closing the two abdomens from below upwards *pari passu* with the division. This might have been less shocking, but would have been clumsy and slow, and control of escaping viscera might have been awkward. The anterior approach to the abdominal cavity and to the liver, leaving the parietes on the far side undivided until the end of the operation, would, it was thought, permit the intestines to be easily packed off throughout the whole period of operation. The number of hands in the operation field was restricted to four, which ought to be sufficient for control of the abdominal contents and for retraction. A multiplicity of hands is a hindrance in the neighbourhood of so small a wound.

The skin having been divided, a reasonably thick sheet of abdominal muscle presented, equal to the whole thickness of the normal infantile abdominal wall, though not separated in layers. When this was divided, peritoneum appeared in the lower part of the wound and the liver bridge could be detected in the upper part. A cushion pad of suitable size inserted under the bridge was now found to enhance the exposure substantially.

Since it was known that there was a common peritoneal cavity, extending at least across the lower part of the bridge, where the hernia could be invaginated, the peritoneal cavity was first opened here. It was now clear that the peritoneal cavities communicated only at the lowest extremity of the bridge in the neighbourhood of the hernia. The peritoneal incision had in fact entered the peritoneal cavity of baby I. It was extended now up as far as the liver, and it was clear that the peritoneal cavities communicated freely below, but above were separated by a slender dividing veil which stretched across the whole thickness of the bridge. The peritoneal cavity of baby II was now opened in the same way.

The intestines were now packed off carefully, the packs being inserted along the surface of the peritoneal partition to reach the abdominal wall on the far side of the bridge. The nature of the peritoneal partition was now clear. Above, it was attached to the liver; and inferiorly it had a crescentic edge concave downwards. Its attachment to the near and far walls of the bridge extended down to the navel, and to its surfaces were attached the falciform ligaments. The upper part of this partition, just below its attachment to the liver, was now divided, together with the falciform ligaments. There was the expected plexus of veins in relation to the under surface of the liver and the falciform ligaments, but this gave less trouble than was expected. Care was nevertheless taken to clamp carefully the peritoneal folds of the liver before their division.

THE LIVER

It was now clear that the central part of the common liver could not be satisfactorily exposed for division until the bridge of cartilage which crossed from one chest wall to the other had been at least partly divided. It proved to take the form literally of a bridge or arch, being concave downwards in the coronal plane and forming a cartilage roof over the upper part of the common liver. It cut easily with the knife, but was really so rigid that it was surprising to recollect that the babies had been twisted through 90 degrees at birth. After the bridge had been divided to a point beyond its summit, the remaining cartilage on the far side yielded sufficiently for a much better view of the liver to be obtained. Care was taken not to distract the two infants

from each other. It was felt that stretching of the liver after the loss of its cartilage protection might exert dangerous traction on the hepatic veins and on the diaphragm. The division of the cartilage did, however, give a much wider view of the presenting surface and of the inferior surface of the common liver, and the two gall-bladders could be demonstrated in the situations where cholecystography had shown them to lie. Obviously the next stage of the operation must be division of the liver through its centre in the bridge. No obstruction was met to a finger passed round the bridge to reach the lower edge of the liver on the far side.

At this stage of the operation it soon became clear to us how valuable was the method of liver control devised in Edmonton at the operation on the Townsend twins. In passing the forceps which would later guide the tourniquets round the liver bridge it was clearly desirable to keep as far as possible, on each side, from the centre of the liver. If the tourniquets lay too close together on the far side of the bridge they might easily slip through the cleft in the divided liver when liver division was completed. Consequently each artery forceps was induced to find its own separate way round the far side of the liver as far as possible from the median plane of the bridge. Each Penrose rubber drainage tube followed easily the path of its guiding forceps, and the tension made by this tubing when finally controlled by clip was very comfortable. It was estimated that the tourniquets lay 5 or 6 cm. from each other on the far side of the liver, and that there would not be much danger of their slipping when liver division was completed. It was found more convenient to divide the liver by knife and scissors than to tear through it with forceps, though the consistency of the liver varied from place to place: in one place it would be easy to tear through soft liver substances, while in another it was necessary to use sharp dissection.

When liver division had proceeded through approximately three-quarters of the bridge a thin band of liver tissue remained on the far side, and it proved easy to apply a Schumacher clamp and to divide the remaining liver between the clamps: though a variety of clamps were in readiness, this particular type was, as had been expected, the most suitable for the purpose. By rotation of the clamps towards the operator the raw surface of the liver of baby I could now be inspected. It was easy to distinguish open blood vessels and bile ducts, and these sustained the application of artery forceps surprisingly strongly without tearing. Indeed the impression was obtained that the divided vessels on the cut surface of the liver of this baby were easier to control than are those of the adult liver.

It had been intended to trim the cut surface of the liver to a concave shape so that its edges could be sutured together by stitches through Glisson's capsule, and the liver surface was inspected while consideration was given to this step. It was felt highly desirable to close the raw surface in this way lest bleeding should occur with the increase in liver flow which follows operation, and to avoid the oozing of bile into the peritoneal cavity, so commonly followed in babies by subphrenic abscess. In fact the question did not arise, for the liver tissue proved to be so flexible and elastic that the cut edge of Glisson's capsule on the far side of the raw surface could be brought quite readily forwards for suture. After division of the liver the abdominal contents had to be packed off again on each side to afford a view of the undivided peritoneum on the far side of the bridge. Division of the remaining cartilage link was now completed, and the soft tissues on the far side of the bridge were divided from within outwards.

CLOSING THE ABDOMINAL WALL

In closure of the abdominal wall a single layer of stitches was employed for muscle and peritoneum. In the upper part of the closed abdominal wound the heart could be seen beating through the opening in the diaphragm, where diaphragmatic muscle had presumably been united across

the bridge under cover of the cartilage roof. That part of the cartilage bridge which now appertained to each child protruded in an unsightly way and had to be trimmed, but care was taken in trimming not to leave too much of the pericardial sac exposed. The procedure was now identical for the two children at the two separate tables except in so far as the liver of baby II had still to be sewn over after the moment of separation. The last stage in closure was to trim the skin over the hernia that had been present in the lower part of the bridge, and to excise on each side what remained of the hernial sac. The quality of the muscle in both babies was rather poor at this level, and the muscle closure at the lower end of the wound, though complete, gave rise to some doubt of its strength.

As separation approached completion the second team came into play. This proved to be really quite a complicated manoeuvre. Its abdominal contents kept in place by packs and manual pressure, the baby, complete with transfusion apparatus, had to be carried to the second table, the anaesthetist moving over with his apparatus too. The manoeuvre was completed without mishap.

It might be said at this point that all pre-operative predictions were, as has been seen, fulfilled as the operation proceeded, and the plan of the operation proved reasonably sound. There was, however, one fault in the planning which should be considered when this operation is repeated—the difficulty of an accurate swab count at the end of the operation which starts as a single operation and finishes as two operations performed by two separate teams. This did not occur either to the surgical or to the nursing planners until the time came to count the swabs at the end of the operation, when for a few minutes it proved extremely difficult to establish that no swab was missing.

The abdomen of the second baby was now closed, and the total operating time from the first incision to the insertion of the last stitch in the second baby was one hour and thirty-five minutes.

Thus at the end of the operation two apparently normal and separate babies were obtained. Their general condition was good, and the circulation of each was entirely satisfactory. The babies were in as good shape as any babies of that age are after an abdominal operation. The babies were returned from theatre to ward in a double oxyginaire specially constructed by the Oxyginaire Company to contain both. On their return to the premature baby unit, still in good shape, they were transferred to separate oxygenaires.

Collapse of Tomo

One hour after their return, while still under close inspection, Tomo suddenly collapsed. The chest was opened and the heart massaged for an hour. A ventricular rhythm returned but no normal beat. Post-mortem examination showed no cause for death. There had been no bleeding and the liver closure was perfect. There was no cardiac or other abnormality. The lungs were airless and oedematous, as is usually observed *post mortem* after artificial respiration with oxygen through tracheal tube and cardiac massage. The only possible cause of death lay in the adrenal gland. This was only about one-third of its normal weight as measured by the adrenal/renal weight ratio. It is possible that the surviving twin had been responsible in life for the greater part of the production of cortisone for the pair, and that the dead twin had insufficient adrenal-cortical tissue to withstand the shock of the operation. When this operation is done again it would be wise to give both twins cortisone, for usually in such a partnership one twin is dominant, providing more for, and taking more from, the joint organism. It is notable that after Holm's successful separation of twins conjoined only by skin, muscle, and cartilage one infant was noticed to be particularly pale and collapsed.

The Surviving Twin

The surviving baby's wound was well healed on the tenth day of her post-operative course (Fig. 7), and it gave rise to no anxiety whatever. There remained a weakness of the lower end of the wound, and this baby has the umbilical hernia which is exceeding common among Nigerian babies. There is a protuberance also where the cartilage bridge was divided, and this is to some extent due to the rather acutely sloping sternum, the children when joined having striven always to pull away from each other, a fact which led to distraction of the xiphisternum on each side forward in front of the upper part of that bone. X-ray examination of the surviving baby (Fig. 8) shows now dextro-rotation of the heart. But the electrocardiogram was not that of a situs inversus; there was therefore no true mirror-imaging of the twins present. The surviving baby and her mother left hospital to return to Nigeria on December 21, eighteen days after operation.

ACKNOWLEDGMENTS

I must express my gratitude to Dr. A. O. Sasegbon, of Kano Hospital, for offering us this rare surgical problem, and for the excellent clinical notes which he furnished of the birth and early life of the twins in Nigeria. I must also pay public tribute to Dr. Eardley S. Allin, of Edmonton, for sending us his film of the operation on the Townsend twins; we learnt much from it.

I am indebted to many colleagues for assistance with the management of these twins. Professor Alan Moncrieff supervised the paediatric problem they presented in his Premature Baby Unit at Hammersmith Hospital. Dr. R. Steiner was responsible for the radiographic detail. The anaesthetic arrangements were supervised by Dr. H. Woodfield-Davies, with the assistance of Dr. A. Ryan. Dr. T. Counihan undertook the electrocardiographic studies. For the precise prediction of the size of the liver bridge we are indebted to the radio-isotope work of Mr. N. Veall, formerly of the Medical Research Council Radiotherapeutic Unit at Hammersmith Hospital. All the intravenous work before and during the operation was undertaken by Dr. P. L. Mollison, of the Medical Research Council Blood Transfusion Research Unit at Hammersmith Hospital; Dr. Mollison's previous experience of infant transfusion made his services invaluable on this occasion. Mr. Selwyn Taylor co-operated with me in the operation on the babies and was responsible for the closure of one of them. Professor W. J. Hamilton, Professor of Anatomy at the Charing Cross Hospital Medical School, advised us on the vascular anatomy to be expected in the bridge, assuming a common liver. I am grateful to Dr. I. Doniach for his report on the post-mortem findings in the case of the twin who died.

The return journey Kano-London-Kano of baby and mother, together with nurse, was defrayed by the United Africa Company. The cost of their treatment as private patients in Hammersmith Hospital was borne by an anonymous donor.

TREATMENT OF PERNICIOUS ANAEMIA WITH VERY SMALL QUANTITIES OF PYLORIC MUCOSA AND VITAMIN B₁₂

BY

E. MEULENGRACHT, M.D., LL.D.

(From the Medical Department B, Bispebjerg Hospital, Copenhagen, and the Biological Chemistry Laboratories of the Medicinalco)

Recently I described investigations into the localization of the anti-anaemic factor ("intrinsic factor") in the pig's stomach (Meulengracht, 1952a, 1952b). It was shown that even minute amounts of the pyloric mucosa of the pig's stomach can be therapeutically active when combined with one or other source of the "extrinsic factor" under suitable conditions regarding preparation and blending.

In the present work this advance, which arose from a fortuitous discovery, has been pursued further, and it has been proved that an apparently full therapeutic effect can be obtained with doses of the intrinsic factor far smaller than had hitherto been imagined, when these are suitably combined with vitamin B₁₂.

Technique

The source of the intrinsic factor used was the dried mucosa of the pyloric region of the pig's stomach prepared as previously described (Meulengracht, 1952a, 1952b). The vitamin B₁₂ used was an ordinary commercial product, controlled spectrographically.

Patients suffering from untreated pernicious anaemia were used in the investigation. The reticulocytes were counted daily in wet preparations. The reticulocyte maxima for the different forms of dosage were plotted against the number of erythrocytes at the beginning of treatment, for comparison with Bethell and Goldhamer's (1933) standard for the expected reticulocyte maxima after adequate intravenous and oral treatment with liver extract.

The erythrocytes were counted at weekly intervals. The rises during the first three weeks for the different forms of dosage were plotted against the number of erythrocytes at the beginning of treatment, for comparison with Schiødt's (1939) standard for the expected erythrocyte rises after adequate oral treatment with liver extract, "ventriculin," and (in accordance with my own experiences) "pylorin." Schiødt's standard was recalculated for 21 days.

Experiments With Very Small Doses of Pyloric Mucosa Administered Alone

Some orientating experiments were first made with very small amounts of pyloric mucosa given alone in the form of weighed powder. Preliminary tests showed that such doses were not entirely inactive, at any rate when given in close association with meals, which, in fact, on the ordinary mixed diet, must contain requisite amounts of the food factor.

Twelve experiments were made. In nine the dose of pyloric mucosa was 0.1 g. of dried substance thrice daily, and in three it was 0.2 g. thrice daily. In some of the experiments the administration was at meal-times—that is, at 9 a.m., 1 p.m., and 6 p.m.—in other experiments it was between meals, at 8 a.m., 11 a.m., and 9 p.m.

The following results were obtained. In one isolated case there was no demonstrable effect. In the majority there was some response, but it was not complete, since only a weak and protracted reticulocyte reaction occurred without a full rise in the haemoglobin and red cells, and with subsequent secondary reactions after adequate injection treatment with liver extract or vitamin B₁₂. Lastly, in two or three experiments there was a more pronounced effect.

The experiments showed practically no difference between the two dosages. Nor is it possible to decide definitely whether administration at meal-times or between meals played any part, although the effect seemed to be more pronounced when the pyloric mucosa was given at meal-times. It is possible that a rather more suitable planning of the experiments might produce clearer evidence on this point; thus it might be arranged that, in the case of the dosage between meals, the stomach and the upper part of the intestinal canal should be empty at the time of the administration—for example, by resorting to nightly administration. The importance of the times of oral intake of the intrinsic factor in relation to meals has never been

TABLE I.—Reticulocyte Maximum and Erythrocyte Rise in 12 Patients After Oral Administration of Small Amounts of Pyloric Mucosa Alone

No.	Pyloric Mucosa Orally	Reticulocyte Maximum	Three Weeks' Erythrocyte Rise
180	0.1 g. × 3	4.6%	0.65
181	0.1 g. × 3	5.4%	0.10 (14 days)
184	0.2 g. × 3	7.8%	0.60
186	0.1 g. × 3	10.8%	0.80
192	0.1 g. × 3	13.3%	0.40 (14 ..)
194	0.1 g. × 3	7.8%	0.35 (14 ..)
196	0.1 g. × 3	5.2%	0.80
197	0.1 g. × 3	4.6%	0.30
200	0.1 g. × 3	1.8%	0.10* (14 ..)
1	0.2 g. × 3	16.8%	1.15*
3	0.2 g. × 3	21.0%	0.60
5	0.1 g. × 3	10.6%	0.20 (14 ..)

*Blood transfusion.

properly grasped. An attempt was therefore made to elucidate this point, but, as intimated, the technique of the experiment was scarcely satisfactory for this purpose.

The results of these orientating experiments with very small doses of pyloric mucosa given by itself are shown in Table I and Fig. 1. Both the reticulocyte maxima and the three-weeks erythrocyte rises after adequate oral administration are far below the expected increases in each case.

Experiments With Very Small Doses of Pyloric Mucosa and Vitamin B₁₂

In this series of experiments the same very small amounts of pyloric mucosa were combined with vitamin B₁₂ in the proportion of 0.1 g. of dried pyloric mucosa and 5 µg. of vitamin B₁₂ in weighed powder.

There were 10 experiments in all. In the first three the mixture was given three times daily, the daily dose being 0.3 g. of dried pyloric mucosa and 15 µg. of vitamin B₁₂. In the following experiment the combination was given twice daily, the dose then amounting to 0.2 g. and 10 µg. respectively. In the rest of the experiments the compound was given only once a day, so the daily dose was narrowed down to 0.10 g. and 5 µg. respectively. It will be seen from Table II and Fig. 2 that the reticulocyte maxima and the three-weeks erythrocyte rises are now greater and approach the standards for adequate oral treatment in spite of the dosage in most of the cases being restricted to 0.1 g. of dried pyloric mucosa and 5 µg. of vitamin B₁₂.

In two of the experiments the erythrocyte rise is clearly unsatisfactory. Both of these experiments fall into the group in which the dose was reduced most drastically.

Preliminary Experiments with a Commercially Prepared Substance, "Cycloplex Mco"

Our knowledge was now so far advanced that it was decided to adopt the method in the routine treatment of pernicious anaemia.

FIG. 1.—Three weeks' erythrocyte rises in 12 patients after oral administration of small amounts of pyloric mucosa alone in comparison with Schiødt's standard.

When it is remembered that at the time the treatment with dried stomach was first introduced large amounts were administered, it must seem surprising, indeed almost sensational, that such small doses as those used in the above experiments can be effective.

For the earlier preparations the following scheme of dosage was usually recommended in the treatment of fresh cases:

Ventriculin	20 g. thrice daily
Pylorin	10 g. " "
Exo-pylorin	5 g. " "

In view of the experiments described above, it would seem that we ought to be able to come right down to centigram doses, provided that the material is taken from a site in the pig's stomach where the intrinsic factor occurs in a concentrated form—that is, the pyloric mucosa (Meulengracht, 1934; Meulengracht and Søbørg-Ohlson, 1934).

As has so often happened on previous occasions, it became apparent that, when one proceeded to the commercial production of a preparation various obstacles of a technical nature had to be overcome if uniformity and stability were to be guaranteed.

In the commercial preparation the mixture of dried pyloric mucosa and vitamin B₁₂ was put into small gelatin capsules. Each capsule contains 0.05 g. of dried pyloric mucosa and 5 µg. of vitamin B₁₂. The vitamin B₁₂ content is thus greater than that in the above-described orientating experiments. The preparation has received the name "cycloplex mco."*

Therapeutic experiments with this commercial preparation have been carried out in my hospital department and, at the manufacturer's request, in the medical departments of a number of other hospitals in this country. The dosage has been three capsules daily, corresponding to a daily dose of 0.10 g. of dried pyloric mucosa and 15 µg. of vitamin B₁₂. The four curves from my department are reproduced in Figs. 3, 4, 5, and 6, in which the reticulocyte reaction and the rises in Hb and red cells are recorded. The total number of experiments—both my own and those from the various other

*Cycloplex (Pharmacopoeia danica)=vitamin B₁₂.

medical departments—are recorded, with the permission of the manufacturers, by graphic presentation of three-weeks erythrocyte rises (Fig. 7).

In my four experiments subjective recovery, rapidly ensuing reticulocyte reaction with a high narrow form of curve, and a big rise in the number of erythrocytes were observed. When one is used to judging the reactions in different kinds of treatment, the rapidity and abruptness with which they set in become striking. The three-weeks erythrocyte rises for all the cases, which are plotted in Fig. 7 in comparison with Schiødt's standard, display an even distribution around the latter.

Commentary

Combined preparations—that is, preparations in which an attempt has been made to combine the intrinsic and extrinsic factors in a suitable manner—are nothing new in the treatment of pernicious anaemia. The most commonly used preparation in Denmark,

exo-pylorin, is just such a combination: each 5-g. carton contains 3.5 g. of dried and pulverized pig's total pylorus and 1.5 g. of "liver remains" as the sources of the intrinsic and extrinsic factors respectively (Meulengracht, 1941).

‡Complicated by fever (pyuria, phlebitis).

FIG. 2.—Three weeks' erythrocyte rises in 10 patients after oral administration of small amounts of pyloric mucosa and vitamin B₁₂ in comparison with Schiødt's standard calculated for 21 days.

The bringing to light or, indeed, identification of the two factors which has gradually taken place, particularly the generally accepted identification of the extrinsic factor with vitamin B₁₂, has led to the production of combined preparations from concentrated sources of the two factors. In practice this means a concentrate of the intrinsic factor from the pyloric portion of the pig's stomach, where this factor, according to earlier experiments, is principally localized (Meulengracht, 1934; Meulengracht and Søborg-Ohlsen, 1934), and the pure crystalline vitamin B₁₂ which is now easily procurable commercially.

FIG. 3.—E. V. L., a woman aged 64. Treated with cycloplex mco three capsules daily. Bispebjerg Hospital, Dept. B.

FIG. 4.—M. K. B., a woman aged 74. Treated with cycloplex mco three capsules daily.

FIG. 5.—M. B., a woman aged 53. Treated with cycloplex mco three capsules daily.

FIG. 6.—H. N. J., a woman aged 53. Treated with cycloplex mco three capsules daily.

FIG. 7.—Three weeks' erythrocyte rises in 16 patients after oral administration of cycloplex mco three capsules daily in comparison with Schiødt's standard.

Such combined preparations suggest themselves, and indeed they have recently been put on the market in different ways in a series of preparations in some countries, including Denmark (Hoff-Jørgensen *et al.*, 1952). As the source of the intrinsic factor in these preparations extracts of stomach have been used, by which means a reduction in weight can be arrived at, although rather complicated technical procedures and the probability of waste are involved. Much more simply, however, with regard to both preparation technique and accuracy, can one resort to very small—in fact, in relation to previous dosage, minimal—amounts of pyloric mucosa for the source of the intrinsic factor, as demonstrated in the investigations above. One is thereby spared an elaborate and incalculable technical process, and can be content with a statement of the weight of the substance of the organ dried at a low temperature; while, as regards the testing of the activity of the preparation and the determination of the dose, one can keep to the approved methods, using fresh cases of pernicious anaemia.

It seems as if extremely small doses are usually adequate. Profiting by earlier painful experiences (Meulengracht, 1933)—there an attempt was made to cut down the dose and to individualize it—it was felt to be more rational that the dose should be fixed in excess of what is absolutely needed, so that each patient might be covered and protected against unpleasant surprises in the form of incomplete compensation of the anaemia or a myelopathy attack.

Since the economic factor is less important than hitherto, I would recommend, as a result of the experiences here recorded, that the initial dose in fresh cases be fixed at two capsules three times daily, but the maintenance dose has yet to be fixed by further experiments.

With regard to the plan of dosage, I have endeavoured to give these between meals in order not to mix up the small quantities involved with a large meal; but whether this is reasonable and appropriate I honestly do not know, for there is no evidence in favour of this procedure, and I cannot conclude anything definite from my own experiments.

Summary

It has been shown that even very small doses of dried pyloric mucosa from the pig's stomach given alone exert a definite but, in comparison with Bethell and Goldhamer's and Schiødt's standards, slight anti-anaemic effect.

It has also been demonstrated that the same very small amounts of pyloric mucosa, when combined with vitamin B₁₂ in quantities which in themselves are inactive when given orally, exert a strong anti-anaemic effect which is practically the same as the standards referred to.

A commercial preparation, cycloplex mco, in daily dosage of 0.15 g. of dried pyloric mucosa and 15 µg. of vitamin B₁₂, exerts a strong anti-anaemic effect which corresponds to the standards cited. In the routine treatment of pernicious anaemia patients, in order to be well on the safe side, a dosage is recommended which corresponds to 0.3 g. of dried pyloric mucosa and 30 µg. of vitamin B₁₂ for the initial doses. The maintenance dose has yet to be fixed.

The "Odium Fund," recently set up by the National Association for Mental Health through the generosity of Dr. Doris Odium and others, is to be used as a permanent fund for the production of pamphlets by the association. The fund, which amounts to about £1,000, will enable the association to consider the possibility of publications without reference to its general finances. In its annual report for 1952-3 the association states that its financial position, extremely serious at the beginning of the year, has now greatly improved. The report gives a short account of considerable and varied activities. An inquiry into the necessity for a change in the law for dealing with aggressive psychopaths has reached the stage where discussions with the Home Office are imminent. In the case-work department the number of advisory cases referred during the year was 1,650.

DOMICILIARY OBSTETRICS*

A SURVEY AND COMMENTARY

BY

IVOR COOKSON, M.B., D.Obst.R.C.O.G.
D.C.H., M.M.S.A.

General Practitioner, Clinical Assistant, Gloucester
Maternity Hospital

Domiciliary midwifery is gradually diminishing in spite of the ample evidence that good results are compatible with a high proportion of domiciliary deliveries. Delivery in hospital is no panacea, and is expensive. It may be that for the same expenditure better results can be obtained by improving the domiciliary services than by expanding maternity hospitals, for the former make greater use of the patient's own resources; but it is difficult to say how improvements could be made, or how cases should be selected for hospital delivery, for the literature relating to domiciliary work is very small.

This survey is a superficial study of 4,441 births, with the primary object of collecting information on which can be based the selection of cases for hospital delivery so that the remainder will consist of those who can be delivered at home in reasonable, if not absolute, safety. It is also intended to indicate the type of obstetrical problem likely to be met in general practice, and to show whether maternity cases may safely be supervised by a practitioner who has consultant support but no post-graduate experience.

Material

The patients of a general practitioner with a list of 2,500 (rather more than average) will produce only about 40 babies a year. Approximately half will be born in hospital, and some of the remainder may be attended entirely by midwives. It is evident that a general practitioner cannot study domiciliary midwifery effectively in his own practice alone, for on an average he would take ten years to accumulate records of 150 cases. Therefore, in addition to a small personal series, two much larger groups have been studied, the survey con-

TABLE I.—Number of Primiparae and Multiparae in Each Group, and Place of Delivery

sisting of (1) 168 confinements of patients of a general practitioner between 1946 and 1952; (2) 3,273 confinements of residents in a city in 1949, 1950, and 1951, either at home or in hospital; and (3) 1,000 domiciliary deliveries in the surrounding district but outside the city boundary in the early months of 1952.

These three groups are called "personal," "city," and "county" cases respectively. The inclusion of hospital and nursing-home cases (Table I) makes it possible to study domiciliary cases in relation to the group from which they were selected, and to consider all the cases for which a general practitioner could assume responsibility.

*A revised version of the Sir Charles Hastings Clinical Prize essay for 1953.

Obstetrics in a Community

The city series consists of almost all births, at home or in hospital, to residents in the City of Gloucester over a period of three years. As it includes 97.4% of all births to city residents, and also 97.1% of all stillbirths and neonatal deaths, it is believed to give a true account of obstetrics in that area, a community of about 67,000 inhabitants.

Supervision of the majority of the 1,484 domiciliary deliveries was carried out by midwives, for practitioners arranged in advance to attend only 242, representing 29.8% and 11.8% respectively of those primiparae and multiparae who were delivered at home. Medical aid was requested during pregnancy, labour, or the puerperium in 26% of all cases.

TABLE II.—Total Numbers of Certain Types of Case in the City Group, and the Proportions Delivered at Home

Type of Case	Total No. of Such Cases	Delivered at Home	
		Cases	% of Total
All deliveries	3,273	1,484	45.3
Multiple pregnancy	39	16	41.0
Stillbirth	69	30	43.4
Neonatal death	69	29	42.0
Babies under 5½ lb. (2.5 kg.)	219	93	42.4
Mature stillbirth or neonatal death	62	20	32.2
Ante-partum haemorrhage	29	6	20.7
Post-partum	95	32	33.6
Manual removal of placenta	47	8	17.0
Primiparae	1,387	368	26.6
Primiparae breech	102	32	31.3
" episiotomy	43	7	16.2
Multiparae	1,686	28	1.6
Multiparae breech	15	11	73.3
" episiotomy	68	24	35.2
" episiotomy	40	4	10.0

Selection of cases for home delivery, shown in Table II, was, of course, dependent on the force of circumstance and the whims of the patient, as well as on the advice of the attendants. It seems that primiparae and breech presentations were to some extent selected for hospital delivery, but the district took almost its full proportionate share of twins and premature deliveries, and, perhaps in consequence, of stillbirths and neonatal deaths. It is axiomatic that a high foetal risk necessitates delivery under the best possible conditions, and it appears that, although over 50% of deliveries took place in hospital, too many cases in which the baby was in danger were delivered at home. If, however, it had been possible to arrange for all premature babies to be delivered in hospital, the number of babies lost after delivery at home would have been reduced from 59 to 20, a combined stillbirth and neonatal death rate of only 14.2 per thousand.

Table II also shows that only a small proportion of the cases having episiotomies were delivered at home. As the types of case needing forceps delivery and episiotomy are very similar the relatively low proportion of the latter on the district is likely to be due to management rather than to case selection.

The additional 1,000 domiciliary deliveries collected from the county of Gloucestershire include abnormalities in proportions similar to those in the city series, except that the proportions of premature birth, stillbirth, and neonatal death were lower, presumably owing to case selection. Primiparae had apparently been selected for hospital delivery on a rather larger scale, for only 17.6% of the deliveries were primiparous, compared with 24.5% of the city domiciliary cases. Of the county cases, 3% had been induced, either medically or surgically; 30.2% had blood examinations during pregnancy;

and 2.8% were admitted to hospital after delivery, half of them for either prematurity or post-partum haemorrhage. The proportion of domiciliary deliveries attended by a doctor, either by prearrangement or in response to calls for medical aid, was 15.6%.

Obstetrics in a General Practice

The personal series consists of the booked maternity cases from a practice rather larger than average, over a period of six years. During that time there were 168 cases booked for delivery under the practitioner's care, either at home or in nursing-homes or hospital, the last being possible only during a period of clinical assistantship and relating to 29 patients. Fourteen patients developed abnormalities and had to be transferred to a hospital where they could not remain under the practitioner's direct supervision, but they have not been excluded from the series on that account. It follows that some forceps deliveries, surgical inductions, and the like were not performed personally.

The average number of antenatal examinations was 8.3, and the two most common abnormalities during pregnancy were breech presentation and hypertension (over 140/90 mm. Hg), with 18 and 14 cases respectively. There were six cases of retroverted gravid uterus, five being corrected by the insertion of a large rubber ring as recommended by Sinclair (1900), and the sixth bimanually. Other abnormalities were multiple pregnancy 3, thrush vaginitis 4, trichomonas vaginitis 1, pyelitis 2, fibroids 2, pelvic tumour (a retroperitoneal fibrolipoma) 1, mitral stenosis 1, anaemia (Hb below 70%) 4, and ante-partum haemorrhage 4. It is notable that there were only two cases of pelvic contraction and that both patients were born prior to the 1914-18 war.

Consultations.—Consultant opinion is easily obtainable either at local clinics or, when necessary, in the home, and there were 33 consultations, for the following reasons: suspected multiple pregnancy 5, breech presentation 2, high head at term 6, toxæmia 4, post-maturity 5, previous obstetric history 4, and 1 each for pelvic tumour, mitral stenosis, retroverted gravid uterus, recurrent pyelitis, deficient perineum, vulval varices, and uterine inertia.

Transfers to Hospital Before Delivery.—Fourteen of the 114 domiciliary and 1 of the 24 nursing-home bookings were transferred to hospital. The principal reasons were collapse of domestic arrangements, and toxæmia, which accounted for two cases each; with one each for uterine inertia, premature labour, mitral stenosis, ante-partum haemorrhage, contracted pelvis, deficient perineum, pelvic tumour, unstable lie, vulval varices, triplets, and suspected diabetes. The cases of unstable lie and triplets account for three of the six babies lost in the whole series so that before labour began it was possible to arrange hospital delivery for half the babies so destined. Of the other three, one was a premature stillbirth, labour being so rapid that transfer was impossible, and the remaining two had gross deformities.

Difficult Cases Delivered at Home

There were, in addition to the cases transferred to hospital, 24 domiciliary or nursing-home cases which were actually or potentially difficult, some of which were the subject of consultation as above. There were nine in which it was decided that a surgical induction was necessary (Table III), and it was decided with some reluctance to deliver one breech and two sets of twins at home. All these could, of course, have been transferred to hospital, or induced at hospital and returned home for delivery. In fact, all but one had uneventful deliveries, the exception being a twin delivery which produced an intra-partum haemorrhage due to premature separation of the first placenta. It was possible to extract the second baby quickly, and a transfusion was not necessary at the time, but a pint (570 ml.) of blood was given during the puerperium.

Two cases of ante-partum haemorrhage were not transferred to hospital. One was a loss of about 4 oz. (110 ml.) at low membrane rupture for post-maturity, but labour

TABLE III.—A General Practitioner's Booked Maternity Cases Between 1946 and 1952. Details Relating to Labour and Delivery

	Place of Delivery		Total

Manual removal	1	0	1
Blood transfusion	3	0	3
Pulmonary embolus	1	0	1
General anaesthesia	5	2	7

started at once and delivery was normal. A second patient lost 1 oz. (28 ml.) at 35 weeks, at a time when she had raised blood pressure. This subsided completely with rest, and she went to term without further loss.

There were three persistent occipito-posterior cases, but all were multiparae, and two delivered themselves easily before the diagnosis was made. The third succeeded after an episiotomy.

Three post-partum haemorrhages were relatively slight and were controlled by ergometrine. The fourth followed a manual removal at which a combination of chloroform and amyl nitrite was used, and the uterus became so atonic that there was heavy loss. No fluid was necessary at the time, but a transfusion was given during the puerperium. The patient could have gone to hospital for the manual removal, but was dealt with at home at her own request.

Finally there were three forceps deliveries. In two cases the head was on the perineum, and in the third only a little higher, and the occiput was anterior in all three. All were fairly easy extractions; but one patient, who had a mild pyrexia for most of the first week, had a small pulmonary embolus on the 18th day, after she had been getting up for a week. Apart from a baby with haemolytic disease whose rhesus-negative mother had been labelled positive, this was the only patient admitted to hospital after delivery, and she was not too upset by the experience to have another baby, normally, two years later.

Post-natal Examination

At post-natal examination, which since the introduction of an appointment system has been attended by 98% of patients, it was noted that failure to restore the perineum completely occurred once in four cases after a tear, but only once in eighteen after an episiotomy. The two primiparae with stress incontinence (Table IV) both had episiotomies, for forceps and breech delivery respectively, and both regained continence.

TABLE IV.—Abnormalities Noted at Post-natal Examination Six Weeks After Delivery

	Total Exams	Cervical Erosion	Pro-lapse	Deficient Perineum	Stress Incont.	Retro-version	Hyper-tension
Primiparae	43	2	6	7	2	6	7
Multiparae	99	4	13	17	5	20	3
All cases	142	6	19	24	7	26	10

trol after faradism. During the two and a half years for which records have been kept of the number of babies entirely breast-fed at the time of post-natal examination, the proportion has been 77.2% and 55.5% for primiparae and multiparae respectively.

Forceps Delivery

The forceps rates shown in Table V illustrate the well-recognized difference between primiparae and multiparae, the rates being 1 in 10 and 1 in 128 respectively. The caesarean section rate in the area is 1.06%.

TABLE V.—Forceps Rates, and the Number of Babies Lost After Forceps Delivery

	Primiparae				Multiparae			
	Total Cases	Forceps Cases	Rate %	Babies Lost	Total Cases	Forceps Cases	Rate %	Babies Lost
Personal series	50	5	10.0	2	118	0	0	0
City and county domiciliary cases	541	55	10.1	4	1,943	19	0.9	1
All city cases	1,257	102	8.1	9	2,016	15	0.7	1

It would be useful to be able to predict the probability of a forceps delivery either before the end of the first stage of labour or, better still, during pregnancy. Table VI, which refers only to the primiparae of the county series, shows what would have been the effect on the number of primiparous forceps deliveries at home if certain groups of these patients had been selected, either before the onset of labour or during the first stage, for delivery in hospital.

TABLE VI.—The Probable Effect on the Number of Primiparous Forceps Deliveries at Home if Certain Groups of Those Patients Delivered at Home Had Been Transferred to Hospital for Delivery

If the Types of Patient Below had been Transferred to Hospital for Delivery	The Total Number Transferred Would Have Been	The Number of Primiparous Forceps Deliveries	
		Among Those Transferred	Among Those Remaining at Home
All primiparae	176	23	NH
Primiparae over age 30	12	6	17
Primiparae with delayed 1st stage:	6	3	20
Over 24 hours	20	8	15
36 " "	8	4	19
Primiparae over age 30 or with 1st stage over 24 hours	30	12	11

The admission of all primiparae shows a poor return for the number of beds taken up. Each of the other groups has a forceps delivery rate of more than 1 in 3, and there seems to be a good case for recommending hospital delivery for primiparae over 30 years of age, and for those not fully dilated after 24 hours in labour, if it is desired to avoid forceps delivery at home. But the home rate would not have been reduced below 1 in 15, and the only patient who lost her baby would still have been delivered at home.

Table VII refers to the domiciliary cases in the city series, and compares the forceps delivery rates and the length of

TABLE VII.—Comparison of Forceps Rate and Average Length of Second Stage in Forceps Cases, in Maternity and Midwifery Cases in the City Domiciliary Series

	Primiparae				Multiparae			
	Total Cases	Forceps Cases	Average 2nd Stage		Total Cases	Forceps Cases	Average 2nd Stage	
Maternity cases	109	19	17.9	1 hr. 53 min.	133	5	3.7	1 hr. 35 min.
Midwifery cases	256	13	5.0	3 " 16 "	986	6	0.6	2 " 21 "

the average second stage in "maternity" and midwifery cases, maternity cases being those in which a practitioner had arranged in advance to attend the delivery.

In comparison with that for midwifery cases, the forceps rate for maternity cases is more than three times as high for primiparae and six times for multiparae. Even when allowance is made for the time taken to call a doctor, 3½ hours is long for the average second stage, and the extreme was 5 hours 40 minutes.

In addition to the long second stages ending in forceps delivery, there are many ending in normal birth, and the number of second stages exceeding various lengths has been determined in the primiparae of the county series, being shown in Table VIII.

TABLE VIII.—Showing the Number of Patients, out of the 176 Primiparae of the County Series, Whose Second Stage of Labour was Prolonged, and the Number Eventually Delivered with Forceps

	Length of Second Stage of Labour in Hours				
	2 or More	2½ or More	3 or More	4 or More	5 or More
Total cases	44	32	23	9	3
Forceps deliveries	20	18	14	4	0

Many would think it unwise to tolerate a high proportion of long second stages, and, even without resorting to a high forceps rate, it may be unnecessary to do so. Table IX compares the primiparous forceps and episiotomy rates, and the proportion of primiparae having second stages of over three hours and four hours in the county series, with the corresponding figures for personal cases; it appears that a large proportion of long second stages can be eliminated by episiotomy.

TABLE IX.—Comparison of Forceps and Episiotomy Rates in Primiparae of the Personal and County Series, Showing the Proportion of All Cases Having a Long Second Stage

	Forceps Rate %	Episiotomy Rate %	Length of Second Stage	
			Over 3 Hours	Over 4 Hours
County cases	13.0	7.4	13.0%	5.1%
Personal cases	10.0	36.0	2.0%	Nil

It is possible that some of the forceps deliveries might also have been eliminated by preliminary episiotomy, for Table X shows that an episiotomy was carried out in less than one domiciliary forceps delivery in four.

TABLE X.—Condition of Perineum After Forceps Delivery at Home

	Forceps Deliveries	Condition of Perineum			
		Intact	Episiotomy	Tear	Third-degree Tear
Primiparae	55	16	15	24	4
Multiparae	19	9	2	8	0
All cases	74	25	17	32	4

Suturing was avoided in only 25 cases out of 74, and at a cost of four third-degree tears. This alone seems too high a price to pay; in addition there is the greater difficulty of repairing tears as compared with episiotomies, and there may be concealed vaginal lacerations and stretched levatores ani in those cases in which the perineum is intact. Four primiparae and two multiparae were delivered face to pubes without episiotomy, but as these account for only one of the third-degree tears it is not enough to perform the episiotomy only when the baby is so delivered. It appears that episiotomy is a desirable preliminary to most if not all forceps deliveries, and, performed before an anaesthetic is given in those cases in which the head is on the perineum, it may make forceps delivery unnecessary.

Breech Presentation

Breech delivery can be foreseen and, to a great extent, prevented. The domiciliary obstetrician can, if he chooses, reduce the breech delivery rate to very small proportions, and he can arrange in advance for the inevitable cases to be delivered in hospital. This survey includes 51 breech deliveries at home, with the loss of 23.5% of the babies. Not all were lost as a result of breech delivery itself, but, after excluding all babies weighing less than 5½ lb. (2.5 kg.) and all in whom there was an obvious cause of death other than breech delivery, the percentage loss remains formidable, and is shown in Table XI, where it is compared with results obtained in hospital.

TABLE XI.—Proportion of Babies Lost, Either by Stillbirth or Neonatal Death, Following Breech Delivery, After Eliminating all Babies Weighing Less than 5½ lb. (2.5 kg.) and All in Whom There Was an Obvious Cause of Death Other Than Breech Delivery

	Corrected Loss %		
	Primiparae	Multiparae	All Cases
Domiciliary cases	25.0	10.2	13.7
Hospital "	11.1	9.0	10.0

These figures suggest that there would still be a very considerable mortality after breech delivery if all such cases were delivered in hospital. Cox (1950) has shown that the mortality for mature babies after breech delivery can be much lower than this, but the figure of 5.2%, extracted from his findings, may not be universally attainable, for it related to a centre dealing with a large number of cases, and involved a caesarean section rate of 12.4%. A low mortality in a small centre might be dependent on a high breech delivery rate to provide the staff with enough practice in breech delivery, and this would tend to cancel the gain due to a lower mortality. It does not appear that the problems of breech delivery can be solved merely by the transfer of cases to hospital.

In the personal series, version was performed whenever a breech presentation was diagnosed after the 30th week, and there were only two inevitable breech deliveries—a rate of 1.19%. Abercrombie (1952) performed version as soon after the 30th week as he felt that it was becoming difficult, and had only two breech deliveries in 249 cases. Dalley (1952) quotes a series of 576 booked cases in which early version resulted in a breech delivery rate of 0.86%. If the breech delivery rate in the city had been reduced to 1%, the number of babies lost would probably have been halved, allowing for the mortality of version. Since this would achieve the same saving in babies' lives, without the risks of a caesarean section rate of 12.4%, as would reduction of mortality to Cox's figure, it suggests that the primary aim in a small centre should be not the reduction of mortality but the elimination of breech delivery itself.

The Perineum

It is difficult for the general practitioner to observe a large number of normal primiparous deliveries, because the number delivered at home is small, and before 1948 he could attend normal cases only if the patient could afford to pay private fees. Table XII records the fate of the perineum in all the personally observed normal primiparous deliveries during a period of six years, including a few not qualified for inclusion in the personal series. These cases can be

TABLE XII.—Fate of Perineum in 40 Personally Observed Normal Primiparous Deliveries

No Delay on the Perineum			Delay on the Perineum		
Intact	Tear	Episiotomy	Intact	Tear	Episiotomy
10	16	2	0	2	10

divided into three groups: (1) no undue delay and an intact perineum, 25%; (2) no undue delay but a torn or incised perineum, 45%; and (3) delay on the perineum, 30%.

The delay in most of the cases having an episiotomy for delay was very considerable, for many date back to a time when episiotomy was used reluctantly. In retrospect it is thought that at least one, and possibly two, of the forceps deliveries in the personal series could have been avoided if an incision had been made before the patient and the uterus had become too exhausted to make full use of it. If this is correct, second stages of over three hours could have been eliminated from the personal series, at the same time reducing the primiparous forceps rate to 6%. These results suggest that nearly one-third of primiparae need episiotomy to avoid delay on the perineum, and to avoid the forceps delivery that may result if the perineum resists until the patient and the uterus are exhausted.

Table XIII shows tear, episiotomy, and suture rates in cases having a normal delivery. Episiotomy was rarely used in the absence of a doctor, and in multiparae the absence of a doctor reduced the incidence of recorded tears by nearly a half, although it is likely in all cases, and quite certain in the personal ones, that the actual delivery was almost invariably controlled by the midwife.

TABLE XIII.—Fate of Perineum in Normal Domiciliary Deliveries, Showing Effect of the Presence of a Doctor

	Primiparae			Multiparae		
	Tear Rate %	Episiotomy Rate %	Suture Rate %	Tear Rate %	Episiotomy Rate %	Suture Rate %
County and city cases:						
Doctor present	38.7	14.4	53.1	25.6	2.2	27.9
Doctor not present	34.1	3.0	37.1	13.3	Nil	13.3
Personal cases	36.3	27.2	63.5	25.6	5.1	30.7

Post-partum Haemorrhage

The post-partum haemorrhage rate in domiciliary cases varied with parity, being 2.6% for primiparae and 6.9% for patients with a parity of five or more. A much greater difference, however, is that between normal and forceps deliveries (Table XIV), possibly due to the use of chloroform, which, in the city series, was certainly used in 67% of forceps deliveries, and possibly in 87%.

TABLE XIV.—Post-partum Haemorrhage Rate in Domiciliary Cases, Showing the Difference Between Forceps Deliveries and Normal Deliveries

	Total Cases	Post-partum Haemorrhage	
		Cases	Rate %
All deliveries	2,484	70	2.8
Forceps deliveries	74	10	13.2
All deliveries, excluding forceps	2,410	60	2.4

Lister (1950) suggested that the use of ergometrine at the end of the second stage should be practised only under hospital conditions, where team-work is possible. To explore the possibility of using it routinely in domiciliary work, the intention recently has been to give it to all cases in the personal series. Over a series of 48 consecutive domiciliary deliveries it was found possible to give an intravenous injection between the time of head crowning and of birth of the anterior shoulder in 64%; it is considered that, after elaborating a routine and working with the same midwife, the proportion could be raised to 80%. In domiciliary practice, where blood transfusion is not readily available, it is particularly important to prevent post-partum haemorrhage, and there is no doubt that the use of intravenous ergometrine is a great advance in this direction. If it cannot be given in all domiciliary cases it seems most important to make the attempt in all cases of forceps delivery, and in all those with a parity of five or more.

Hypertension in Pregnancy

Hypertension has been studied only in the personal series in which patients were normally examined monthly from the time of booking up to 32 weeks, at 34 weeks, at 36 weeks, and then weekly until delivered. Where necessary, several readings were taken to eliminate labile pressures. The cases

TABLE XV.—Hypertensive Patients of Personal Series Divided Into Three Groups According to Highest Pressure Reached in Late Pregnancy. Bracketed Figures Show the Number Developing Albuminuria

	Total Cases	Highest Pressure Recorded in Late Pregnancy		
		Between 130/85 and 140/90	Between 140/90 and 150/100	150/100 and Over
Primiparae	50	9 (0)	7 (4)	7 (5)
Multiparae	118	7 (1)	7 (2)	1 (1)

have been divided into three groups according to the highest stable pressure recorded in late pregnancy (Table XV): 14% of primiparae and only 1% of multiparae qualify for the highest group, which is 87% primiparous, confirming the higher incidence of toxæmia in primiparae. In 46% of primiparae a pressure of 130/85 occurred at some time during late pregnancy, and 18% developed albuminuria.

Of the first six primiparae in the personal series, two developed toxæmia severe enough to require admission to hospital and premature induction, both having a considerable amount of albumin. In retrospect it was thought that insufficient attention had been paid to slight early rises of pressure in these cases, and since then the following regime has been instituted.

Stage 1.—Blood pressure over 120/80. No work except light household duties. Rest from 2 to 3 p.m. Bed at 9 p.m.

Stage 2.—Blood pressure over 130/85. As Stage 1, but bed until 10 a.m. Rest from 2 to 4 p.m. Phenobarbitone, ½ gr. (32 mg.) three times a day.

Stage 3.—Blood pressure over 140/90. Complete rest in bed. Phenobarbitone 1 gr. (65 mg.) three times a day.

This regime has been varied a little to suit individual cases, according to parity, age, the lowest pressure recorded in mid-pregnancy, and the presence of albumin or oedema. It has not prevented 45% of primiparae from developing a pressure of 130/85 or more, and 25% have required rest in bed. Four (9%) eventually passed the 150/100 level, but only two needed induction before term. There were no babies under 6 lb. (2.7 kg.) in weight, and none appeared to be in real danger on account of toxæmia. The number of cases is, of course, so small that a similar result might well have been obtained by chance.

Induction of Labour

McKiddie (1949), using figures for Aberdeen, showed that the stillbirth rates for patients delivered in the second, third, and fourth weeks after term were about 1 in 60, 1 in 30, and 1 in 15 respectively. The neonatal death rates were unaffected. McKeown and Gibson (1951) showed that the stillbirth rate in Birmingham in 1947 was 11.5 per thousand for babies born in the 41st and 42nd weeks, and 25.5 for babies more than two weeks post-mature.

In the personal series the policy has been to induce at about two weeks after the expected date, if that seemed reliable. In addition, patients with a raised blood pressure were rarely allowed to go past term. This has led to a very high induction rate, and the proportion of patients successfully induced was 21.4% (Table XVI).

For post-maturity 13% of all patients were induced, and for toxæmia 16% of primiparae and 1.7% of multiparae. There was only one stillbirth in the whole series, this baby being five weeks premature and not induced. Only one baby was lost after induction, this being the neonatal death of a post-mature monster.

The results so far recorded in this small series do not indicate the need for a change in the policy regarding in-

TABLE XVI.—Medical and Surgical Induction in Personal Series

	Total Cases	Medical Induction			Surgical Induction	Induction Rate (Successful Cases Only)
		Total	Failed	Successful		
Primiparae	50	14	4	10	10	40.0%
Multiparae	118	19	12	7	9	13.5%
All cases	168	33	16	17	19	21.4%

duction, but a simple calculation based on McKeown and Gibson's figures shows that, if the average general practitioner eliminates post-maturity of more than two weeks' duration from his domiciliary practice, he will save the lives of only 1.5 babies in his lifetime.

Stillbirths and Neonatal Deaths

McKeown and Gibson (1951), who investigated all births in the City of Birmingham in 1947, suggested that babies born more than four weeks before the expected date should be delivered in hospital whenever possible. They showed that such babies had a collective mortality of 1 in 3, but the mortality for babies born in the 36th and 37th weeks was 150 and 94 per thousand respectively. This suggests that, for babies born prematurely, a dividing line between suitability for hospital and home delivery might be placed at an expected mortality of 100 per thousand. The line would not necessarily be at the same level for other types of case, for the difference in the relative safety of hospital and home delivery may vary. It would, for instance, be very considerable for a primiparous breech delivery, and almost non-existent for a normal patient having her second baby. It has not been possible in this survey to attempt to compare the results of hospital and home delivery of identical cases, but Table XVII shows the total mortality, stillbirths, and neonatal deaths together, for certain types of patient and for certain abnormalities.

TABLE XVII.—Total Mortality, Stillbirths, and Neonatal Deaths Together, for Certain Types of Patient and for Certain Abnormalities

	Babies Lost per 1,000 Births	
	All Domiciliary Cases	All City Cases
All first births	45.7	52.7
Other	29.5	34.7
Babies over 5½ lb. (2.5 kg.)		
First births	17.9	26.7
Other	14.9	16.0
Forceps deliveries		
All cases	67.5	85.4
First births	72.7	88.8
Breech deliveries		
All cases	235.2	207.2
First births	250.0	232.5
Over 5½ lb.	139.5	144.3
Multiple births		
All cases	229.1	191.5
Over 5½ lb.	100.0	111.1
All babies under 5½ lb.	330.8	347.0

Many of these groups are composite, and, if the total numbers had been large enough, might have been broken down into smaller groups with varying mortalities. For instance, twins in a multipara, if both were presenting by the vertex and were expected to be over 5½ lb. (2.5 kg.), might be expected to have a mortality appreciably lower than 100 per thousand. With such reservations, it seems that all breech, multiple, and premature deliveries should take place in hospital. First births, however, if the baby is mature, are relatively so innocuous that it seems ridiculous to suggest that primiparity alone is a reason for hospital delivery, for the rate for those at present selected for home delivery is at the low figure of 17.9 per thousand, and is only 3 per thousand higher than the corresponding figure for multiparae.

The General-Practitioner Obstetrician

When the National Health Service was introduced the conception of the general-practitioner obstetrician appeared

to be one who had postgraduate experience of obstetrics, examined his patients at 12 weeks, 36 weeks, and 6 weeks after delivery, and, apart from that, merely attended abnormal cases at the request of the midwife. By and large, unless his midwives are exceptional, this type of practitioner will not see anaemia of pregnancy in time to cure it without transfusion, hypertension in its earliest stages at a time when it may be possible to prevent serious toxæmia and to avoid premature induction, breech presentation in time for early version, or multiple pregnancy in time to advise on the avoidance of premature labour. Post-maturity will not be eliminated, his primiparae and their foetuses will endure unnecessary hours of the second stage, little will be done to prevent post-partum haemorrhage, and the vulval orifices of his multiparae will enlarge a little at each delivery because minor tears will be left unsutured.

If the results of domiciliary midwifery have been bad in the past, it is important, before attempting to improve matters by introducing a special obstetric list, to inquire why it was so, and whether the same causes would operate in the future. One cause, possibly the major one, was that the family doctor could undertake only the maternity work for which his patients could afford to pay—and that in many practices was very little. Many patients who did engage him wished to pay not for antenatal and post-natal care, but only for analgesia at the delivery. This gave the family doctor very little experience of the normal and little opportunity of practising preventive obstetrics, but, on the other hand, arrangements for consultant help were often inadequate, so that he was obliged to undertake difficult abnormal cases in response to midwives' requests for help. Local authority schemes, when introduced, allowed the practitioner to examine his patients at 12 and 36 weeks, but did not permit him to be paid for any other attendance on normal cases. The result was that, having seen little of the normal, and having had little opportunity of preventing the abnormal, he was obliged to deal with the latter when it occurred.

Since 1948 it has been possible for the family doctor to give adequate attention to all cases, normal and abnormal. Specialist opinion is easy to obtain, and the opportunity exists for the next generation of family doctors to acquire adequate experience of normal midwifery, to learn to recognize the abnormal at an early stage, and often to prevent the occurrence of dangerous conditions. If this is likely to happen, it is not at all certain that the maternity services will be improved by regulations aimed at making the patient forsake her family doctor for a stranger with a little more experience of abnormal obstetrics.

In any discussion of the competence of the newly qualified practitioner it will inevitably be said that he has no experience of forceps or breech delivery. In practice, as the average family doctor has only one imperative forceps delivery in two years, and as most are either able to carry out a forceps delivery or have the help of a competent colleague, it is no more necessary for the inexperienced single-handed practitioner to apply forceps himself than it would be for him to remove an appendix on the kitchen table. The number of such cases is so small that he need not hesitate to call a consultant. As for domiciliary breech delivery, it is too dangerous to be justified, and the inability to conduct a breech delivery, an abnormality which can be foreseen, does not prevent the family doctor from being an adequate domiciliary obstetrician if he aims at the avoidance of breech delivery altogether, handing the inevitable cases over to hospital.

It may be true, as Farquhar Murray (1952) says, that there are insufficient forceps deliveries to permit the student to perform even one before qualification, but the same explanation cannot be offered if he has not sutured a perineum, for there are about a quarter of a million to repair per annum in England and Wales. It is an essential accomplishment for the domiciliary obstetrician, but it can, and should, be taught before qualification.

In dealing with hypertension, the inexperienced practitioner who knows a few simple rules and sees his antenatal

patients regularly will see serious cases of toxæmia so rarely that the postgraduate obstetric experience necessary to decide when to induce before term, or when to carry out a caesarean section, would rarely be of use to him. When the need arose—say once in two or three years—the help of a specialist could be obtained.

It does not need postgraduate obstetric experience to select for hospital women who have had many previous deliveries and those with a history of an abnormal third stage, or to prevent pregnancy anaemia, or to give an intravenous injection when the head crowns. Students are familiar with intravenous infusion, and any enthusiast who has provided himself with ergometrine, suitable fluid, and a "giving" set, can greatly reduce the incidence and danger of post-partum haemorrhage, and, in the occasional difficult case, keep the patient in good condition until the flying squad arrives.

The possibility of disproportion causes much concern, but, because rickets in childhood has been eliminated almost completely, pelvic contraction is rare and likely to become more so. The only two cases in the personal series were aged 37 and 41, an incidence of 6% in patients over 35 and nil in younger patients. If consultant opinion is available the family doctor should not meet serious trouble with disproportion.

These are some of the more common abnormalities with which the domiciliary obstetrician has to deal. There are many others, but in domiciliary practice most of them are rare. The number of years for which the average family doctor would have to practise to see a case among his domiciliary patients is, for prolapsed cord, 10 years; transverse presentation in labour, 10 years; mento-posterior presentation, 40 years; brow presentation, 50 years; hydatidiform mole, 50 years; ruptured uterus, 300 years; inverted uterus, 600 years. Averages cannot be applied to individuals, but they help to keep a sense of proportion. General practice would be impossible if one of the qualifications for it were postgraduate experience of abnormalities unlikely to be encountered in 10 years of practice.

There are good reasons for making adequate experience in obstetrics an essential qualification for practice in remote country districts, but it appears equally clear that any family doctor who is interested in obstetrics, and who, as a student, has had adequate instruction in the aspects of midwifery likely to be met in general practice, can be allowed to supervise maternity cases in any area where consultant support is available, without the risk of serious consequences for his patients. The role of practitioners with postgraduate obstetrical experience should be to practise either in country areas where consultant help is not readily available or as members of a group, where, by helping their colleagues with difficult cases and by providing a liaison between them and recent advances in obstetrics, they can help to maintain a high standard throughout the group, without taking the day-to-day care of maternity cases out of the hands of the family doctor.

Summary and Conclusions

An inquiry has been made into the practice of obstetrics (1) in a general practice over a period of six years; (2) in a community of 67,000 inhabitants over a period of three years; and (3) in a further 1,000 domiciliary deliveries.

In group 1 the case records were those of a medical practitioner, and in groups 2 and 3 those of midwives. The following suggestions are offered.

Premature delivery, breech delivery, and multiple birth carry a stillbirth or neonatal death rate too high to be acceptable for domiciliary delivery. The rates for first births do not suggest that normal primiparae should be delivered in hospital.

Domiciliary forceps delivery is inevitable in a small proportion of cases, but the risks are not great. The proportion can be reduced considerably if hospital

delivery is arranged for primiparae who are over 30 years of age or who are not fully dilated after 24 hours in labour.

More frequent use of episiotomy in domiciliary work would reduce the forceps rate and the incidence of severe tears, and would avoid many long second stages of labour.

Toxaemia can be controlled to a very great extent if blood pressures are observed frequently and if adequate attention is paid to slight rises.

Intravenous ergometrine at the end of the second stage can be used with advantage in domiciliary practice, particularly in forceps deliveries.

Interest in obstetrics and adequate instruction as a student are the only essential qualifications for the family doctor who wishes to practise obstetrics in an area where consultant support is available.

Acknowledgments are due to the medical officers of health who made available the records of their midwives.

CONDITIONS ASSOCIATED WITH THE GROWTH OF BOYS, 1950-1

BY

W. T. C. BERRY, M.D.

AND

P. J. COWIN, M.R.C.S., D.P.H.

(From the Ministry of Health, Savile Row, London, W.1)

The changes which have taken place over the years in the growth of children are generally, and we think rightly, attributed to improvements in their food. Whereas during the slump years dietary surveys showed a grossly deficient diet, a study made in 1949 by Beltram and Bransby (1950) of children from the lowest income group (parent earning £4 10s. or less a week) showed average intakes which compared "satisfactorily" with the recommendations of the B.M.A. Committee on Nutrition (1950) in respect of all nutrients with the exception of vitamin D, the requirement of which at school age is still a matter of complete uncertainty. If this was the case for the lowest income group, then it could be argued that an actual margin of safety existed in higher income groups. It is, of course, obvious that about half of the group surveyed by Beltram and Bransby must have had intakes below the B.M.A. recommendations, but nutritional "standards" are set, deliberately, on the safe side of the optimum, and it is at least questionable whether many boys, even in this group, consumed too little of any nutrient.

There is, too, evidence from the past to suggest that schoolboys' diets may now be adequate. The last large milk-feeding experiment, carried out for a year on 2,800 children in 1934-6, showed gains in height and weight

in all groups; but they were small and none was statistically significant; the opinion that they were, in fact, real was formed on the grounds that they were consistently found in all of the groups. Since then, not only has milk been added to the diet of school-children, but their diet has been enormously improved in other respects. Again, a feeding experiment carried out during the war (Bransby, Burn, Magee, and MacKecknie, 1946) tested the effect of a supplement of vitamins A and B₁, riboflavin, nicotinamide, ascorbic acid, and vitamin D on 800 children for a year. No effect was observed on growth, strength, endurance, or absenteeism.

It is of interest, then, to note that well-marked differences in stature still exist in children, not only between the lowest income group and the one above it, but fairly evenly throughout most of the social scale.

Cause of Differences in Stature

In view of the evidence cited above, it is worth while to consider the other possible causes for these differences in stature. The first is that these differences are hereditary. But the considerable changes in stature that have occurred as a result of environmental change should make us very wary of accepting this. The finding of Weir (1952) that "secular changes in growth are similar to the differences in growth associated with differences in social condition" adds point to this.

Another possibility is that the rate of growth is inexorably set as a result of conditions in the early years of life, and if these are adverse no subsequent improvement can lift the child out of his "growth channel." This has been shown to be the case in underfed pigs by McMeekan (1940), and in his study certain changes in skeletal proportion occurred, which, as Leitch (1951) has pointed out, are similar to skeletal differences to be found between children of different social classes. But application of the findings of animal experiment to man needs always to be made with caution. Moreover, Bransby (1953), studying the diets of 461 children over 6 months and under 5 years in 1951, found that in high income groups the nutrient intake was just as often below the optimum in some respect as it was in the low income groups; yet, at any rate by the age of 6, differences in stature can be demonstrated in association with social class. Nevertheless, the work of Yudkin (1952b), in which a liver supplement fed to small children on an otherwise excellent diet enhanced growth, reminds us that all may not yet be known concerning the essentials for growth.

A further possibility is that some factor other than diet may operate to an important degree to-day. This has never been adequately explored because, as Cruickshank (1951) has put it, "heredity and environmental factors—nutrition, poor housing, lack of sleep, infectious disease—are inextricably interrelated in determining the growth and development of children." The only instance, so far as we know, in which a non-dietary factor has been demonstrated to affect the growth of children in the mass was reported by Widdowson (1951). German orphans, she found, grew better when the matron in charge of them was motherly and kind than when she was severe, though their diet remained the same. Other non-dietary factors have never been studied in isolation. For example, no one can be confident that the environment of our great industrial cities is favourable to the growth of children, and it is in these, typically, that growth rates are least.

We may presume that the answers to all these problems will ultimately be writ clear in the stature of future generations. There are, too, long-term research studies afoot which may somewhat anticipate the event. But in the meantime we do not even know whether there may not be conditions affecting the stature of large numbers of children and thus preventing them from benefiting fully from im-

provements in their diet. The public health aspects of this question appeared to us of sufficient importance to warrant a reconnaissance.

The Investigation

The plan of investigation was as follows. In Beltram and Bransby's survey the intakes of Salford schoolboys were analysed separately and found on the whole to be slightly higher in most nutrients than the rest. Salford is an industrial city, with mean crowded houses, and much smoke and rain. Here, therefore, non-dietary conditions might be expected to operate at a maximum, and dietary ones at a minimum. The stature and physique of Salford boys, at three age levels, were therefore compared with those of boys at Kingston-on-Thames, a sunny pleasant town. At each place, each age group was examined at one season and in the same year. At Bristol a study was carried out on a larger group of 14-year-old boys, and the findings were analysed in terms of social class and similar factors. Our aim was to test whether the differences between stature and physique in industrial and other areas were similar to the differences that occur between different social groups—in effect, an extension of Weir's dictum quoted above.

In addition, we obtained at Bristol as much information as we could about dietary and non-dietary factors. Before the war Bristol built a large housing estate for families who had previously lived under slum conditions in the city. Data on these boys were compared with those on boys still living in the heart of the city. Thus the environmental differences between these groups reflected *in parvo* those seen *in magno* in Salford as compared with Kingston. Since we interpreted Widdowson's study as showing the effects of mental stress, we analysed separately the weights, in Bristol, of boys from "broken homes," in which category we include parental death and divorce and illegitimacy. We also compared boys whose mothers went out to work with those whose mothers did not, for it had been retailed to us elsewhere that children often came home to an empty house, or even had to wait outside a locked door, and that they were on occasion sent to school when they should really have been in bed, because the mother could not afford to lose her day's work; we therefore felt that in this group some form of mental stress might operate. One further point was tested: in our surveys in previous years it had been the practice to record the number of boys who had a "tired expression." Inquiry had shown that a high proportion of them shared beds, and, to judge by their looks, did not get enough sleep. We therefore analysed our findings in terms of those who did and those who did not share beds.

Physical Findings

Stature and Physique.—Table I gives the mean heights and weights of boys in the different groups, and the numbers involved. The children at all ages are lighter and

TABLE I.—Weight and Heights of Boys in Different Parts of Britain

	Age	No.	Weight in kg.	Height in cm.
Salford ..	6 years	149	20.83 ± 2.45	114.38 ± 5.08
Kingston ..	6 "	197	22.63 ± 2.72	118.00 ± 5.69

A public school	14 "	76	51.63 ± 6.71	166.50 ± 7.82

shorter at Salford than at Kingston, and at Bristol the modern-school boys are lighter than the grammar-school boys, who are in turn lighter than public-school boys. We compared the height/weight ratio in the different groups to test whether they showed the tendency, reported by Weir,

towards a slimmer build where mean growth was greater. No consistent or statistically significant differences were found. As a further test, we expressed the biacromial and bitrochanteric diameters, and the chest girth, as percentages of height (Table II). It will be seen that in every set of comparisons the group shown in Table I to be taller and heavier is also slimmer.

TABLE II.—Biacromial, Bitrochanteric, and Chest Measurements Expressed as a Percentage of Height

	Age	Bitrochanteric	Biacromial	Chest Circumference

Development.—Following on Greulich's work in America, Ellis (1947) showed that Barnardo boys who became pubertal early grew more rapidly than their fellows. The differences here were presumably genetic in origin, but data collated by Stuart (1946) show that improved socioeconomic circumstances accelerated the onset of puberty. We therefore studied the stage of puberty in our 14-year-old boys. We held that because we knew the plan of our study, and the place of our different groups in it, unconscious bias could creep in, and we therefore concentrated on the physical index of puberty which we considered the least subjective—namely, the condition of the pubic hair. We felt our groups were large enough to offset the errors due to the use of a single criterion. We recorded four degrees; complete absence of hair (PH-), a few downy hairs (PH±), an intermediate stage (PH), and a well-developed escutcheon (PH+). At Bristol we were fortunate in having as a check the findings of Drs. Irving-Bell and Fraser, of the Bristol school medical service, on the same boys. They used a system of classification to which they were accustomed, with three grades only, but the trend of their findings clearly confirms our own (Table III). There is a lag in puberty in Salford compared with Kingston, and in Bristol modern compared with grammar schools.

Pallor.—Yudkin (1952a) reported that pallor was associated with underdevelopment. Differences in lighting, etc., made it impossible to compare our groups with one another, but a comparison could be made within each group. Only about 20 boys in each group were recorded as pallid, but in each case they were on average lighter than their fellows. The difference was on average about 4%. On the other hand, no consistent difference whatever was recorded in height.

Fat Covering.—Because pallor is an early sign of under-nutrition, data on the skinfold thickness of our groups are of interest. There were no statistical differences between the mean readings of comparable groups, but when

we separated in each group the "thin" boys (with readings below the norm for all boys of their age group) and others, the former showed consistently lower mean weights, and, with the exception of one group, the Kingston 6-year-olds, in which there were only 28 "thin" boys, consistently lower mean heights. It is to be expected that the "thin" boys would be slighter, but it is surprising that they should also be shorter. Details both of these findings and of those relating to pallor are omitted for reasons of space.

Environmental Conditions Associated with Difference in Stature

In relating environment to stature, weight only was taken into account. Height varied similarly, but in less degree, and there was therefore no point in including it. The data given below are from Bristol only. In a few cases in which the information provided was inadequate the boy was excluded from that part of the analysis.

Diet

It was not practicable to carry out detailed dietary surveys of such large numbers of boys. Instead, each boy was questioned about the frequency with which meat or fish was provided for him, upon the number of times a week that he ate fresh fruit, and on the amount of milk he consumed, which was checked by determining the amount delivered daily for the family, and making allowances for the other members (their ages were known); the amount drunk at school was known. The whole of this work was done by Miss C. M. Wood, nutritionist on the staff of the M.O.H., Bristol. The diets have been classified as "poor," "average," and "good," in the case of each of the three indices, on the following basis: "Poor" = Meat or fish once or less a day; milk less than half-pint daily; fruit less than every other day. "Good" = Meat or fish for more than two meals daily; milk one pint daily or more; fruit daily. The average diet was intermediate between these. Obviously the biochemical content of the diet cannot be assessed by this means. But an indication is provided of the extent to which variety enters into the diet, and it is axiomatic that the greater the variety the greater the likelihood that the diet is balanced.

As the graph shows, whatever criterion is used the mean weight increases progressively from "poor" to "good." The differences between the extremes are statistically significant in the case of meat and fish, and of milk.

Non-dietary Conditions

Parental Care.—Each boy's home was visited by a health visitor and an assessment made of the standard of parental care. The mean weight of 122 boys with "very good" parental care was 51.63 kg.; of 220 with "normal" parental care it was 47.16; of 17 with "bad" parental care it was 46.26. The first of these differences is statistically significant, and the second is in keeping with the trend of the data.

Parent's Occupation: Type of School.—The Registrar-General's classification was used (here written R.G. I to V in

Graph showing association between dietary pattern as indicated by number of servings of various foodstuffs, and weight. —, Meat and fish. ---, Milk., Fruit.

descending social order). There was a relation between R.G. category and weight, in grammar schools the means (in kg.) being R.G. I and II, 52.95; III, 49.86; IV, 48.87; V, 47.38; and in modern schools 47.64, 46.89, 46.85, and 46.37 respectively. It may be noted that in every case grammar-school boys are heavier than modern-school boys of the corresponding R.G. group. In general, grammar-school boys have passed, and modern boys have failed, an examination at the age of 10-11 years, and the implied difference in "intelligence" is presumably also to be found in their parents. We feel that the R.G. classification, the type of school, and the assessed parental care should be regarded merely as different indices of the care given to the welfare of the child.

Bed-sharing.—A relationship, if any, with bed-sharing needed to be separated from the factors shown above to be associated with stature. Therefore (1) the mean was found for all boys who shared beds, and (2) this was "matched" by a mean made up of boys who did not, but were otherwise identically placed as regards the environmental factors noted above. The mean of 100 boys who shared beds was 45.6 kg.; the figure for the matched mean was 47.8. Formal tests of significance could not be applied to this difference because of the complexity of factors concerned, but the difference is large and showed up with great consistency throughout the process of analysis. We therefore think that it is real.

Open Surroundings.—Sixty-three boys who lived in the heart of Bristol were compared with a "matched sample" who had lived almost all their lives in the open surroundings of a modern housing estate. The difference, 1.41 kg. in favour of the latter group, is too small in view of the size of the sample to enable an inference to be drawn.

"Broken Homes."—Twenty-eight boys from broken homes had a mean weight of 48.7 kg. as compared with a mean of 48.5 kg. for a matched sample from unbroken homes. This sample is small, but we may add that we were also unable to demonstrate any difference in this respect in either Kingston or Salford.

"Mother Goes Out to Work."—The mean weight of 105 children whose mothers went out to work was 49.8 kg. That of a matched sample was 47.0 kg., a difference so great as unlikely to be a "chance" occurrence. In the case of boys from modern schools it was permissible to make a direct comparison without resorting to matching, because there was little difference between the mean weights of R.G. groups in modern schools. In the modern schools, 65 boys whose mothers went out to work had a mean weight of 48.9 $\pm$ 9.33 kg., compared with 145 boys with mean weight 45.8 $\pm$ 8.13. These differences are statistically significant.

Independence of Dietary and Other Factors

The mean weight (kg.) of grammar-school boys on "poor," "average," and "good" diets was 47.6, 50.3, and 52.0 respectively. For modern schools it was 46.1, 46.4, and 48.1. The corresponding figures for good parental care were 48.5, 51.6, and 52.1, compared with 46.6, 46.4, and 48.4 for average parental care. For R.G. I and II they were 49.0, 52.7, and 54.0, compared with 46.9, 47.0, and 50.0 for R.G. III, IV, and V combined. Whatever the social criterion used, those assessed as "good" stand well above their fellows of the corresponding dietary pattern. The data above are for consumption of meat and fish. The other dietary indices gave a similar picture.

Discussion

Physical Findings

This work confirms the report of Weir that where the stature of children has increased the physique is slimmer. The findings on puberty are in harmony with those cited by Stuart upon the effect of good social conditions in accelerating the onset of puberty.

The differences between Salford and Kingston are similar in character to those between the different social groups in Bristol. This, we hold, extends the implication of Weir's work comparing secular change and social differences.

Environmental Factors

Certain negative points are best cleared up first. We adduce no evidence that mental stress affected the stature of our groups; in fact, one of our "stresses" was associated with exactly the opposite result. We cannot say whether residence in open surroundings confers any advantage over residence in the heart of a city, for the fact that the difference found was small does not mean that it may not have been real. Whether the association between weight and bed-sharing was in fact causal could only have been proved by the provision of beds.

The inquiry was not designed to throw light on the effect, in after years, of environmental conditions affecting the growth in early childhood, and some of the contrasts in weight that we have recognized may simply be the result of factors which operated then. For example, there was little difference in the dietary pattern of boys whose mothers worked and of those whose mothers did not work, but it does not follow that differences did not exist in early years, particularly if those having working mothers were left for any part of their pre-school life in the nutritionally excellent environment of a day nursery.

The association between dietary pattern and weight shown in this study does not support the hypothesis put forward at the outset concerning the adequacy of schoolboys' diets. There are, of course, possibilities other than the obvious one. (1) The "poorer" diets may be adequate for growth at 14, but boys on them may also have lived on poorer diets earlier when their rate of growth was relatively greater. (2) Since the provision of a varied diet is a function of a good parent, it may be that we are merely recording degrees of parental care which were not shown up by the social criteria which we used in this study.

The relation, at all dietary levels, between weight and "very good" and "normal" parental care is reminiscent of Widdowson's demonstration of the influence of the motherly matron on the orphans in her care. Here too, however, other possibilities exist, because our dietary criteria are not exact, nor do they provide information about the diet at other seasons or earlier in life.

The problems raised in this study would not have been resolved had the same approach been used but with greater detail and exactitude. For example, even using the conventional (and costly) method of dietary survey, doubt would have arisen whether any association found between growth and diet was in fact causative. This study suggests that non-dietary factors cannot be ignored as a potential cause of checks to growth, and further progress in this direction would seem to depend upon the development and testing of working hypotheses on how such factors may operate. Presumably they either act "centrally"—for example, through the endocrine system (in which case, for lack of knowledge, no guess can be hazarded regarding the way in which they work)—or there is some disturbance in the equilibrium between intake and the needs of energy and of growth. From clinical studies in time of hunger, and from animal experiments, notably by Young (1945) and by Greenbaum and Maclean (1953) it may be concluded that under certain conditions competition between growth and energy requirements does occur. There is, too, some evidence that this may occur in everyday life. For example, Macy and Hunscher (1951) have reported that for some children the voluntary intake level is not sufficient for "satisfactory" weight gain or nitrogen retention, and that these may be secured by increases of total intake of 10 calories per kg. body weight. Similarly, Hubbell and Koehne (1934) report improved nitrogen, calcium, and phosphorus retention in children whose calorie intake was increased 16-18% by the addition of sugar.

The finding of Yudkin (1952a) that pallor was related to poor development (but not to haemoglobin level), which we confirm in respect of weight, is of interest in this connexion, for pallor is an early sign of undernutrition. A possible explanation is that over long periods of life the

equilibrium between growth, activity, and appetite is set at a low level, owing to some factor affecting the last of these. Whether "undernutrition" of this nature could affect growth without effect on the surface fat, or with such small changes only as we have reported, is unknown; it is not the role, and may not even be the prime, function of the surface fat exactly to make good deficits of intake.

There are, as already noted, long-term growth studies in progress, some of them on the general public. The practical value of these will depend in part upon the success with which the factors affecting growth are recognized at a time and their intensity is gauged. This is impossible in the case of non-dietary factors without working hypotheses regarding their *modus operandi*. Hence these considerable speculations. We would suggest, among such hypotheses, at such things as a varied and tempting diet, adequate sleep, and regular bowel habits, and similar attention to the needs of the child, may affect appetite and therefore growth rate.

Summary

Recent published evidence on schoolboys' diets and stature has been reviewed. Possible reasons for the differences in stature which still persist are discussed, and a field study of a reconnaissance character is described.

The findings confirm the report by Weir (1952) that increase in growth rate is associated with slimmer physique.

Differences in physique between boys in an industrial area and others elsewhere are similar to the differences in boys of different socio-economic environment.

Boys with pallor were found on average to be lighter, confirming a part of Yudkin's (1952a) findings on the significance of pallor. Thin boys were found to be lighter and also shorter than others. The possibility that these findings mean that in some individuals growth is checked because appetite is inadequate is discussed in the light of American work.

Varied diets, as indicated by frequency of consumption of meat and fish, milk, and fruit, were found to be associated with higher weights.

There was a relationship, independent of the association between weight and diet, between weight and the standard of parental care, social class, and type of school.

We wish to express our gratitude to the Medical Officers of Health of Salford, Kingston, and Bristol for their help. We are much indebted to Miss C. M. Wood, Dr. R. J. Irving-Bell, and Dr. A. M. Fraser, of the Bristol Public Health Services, and to many health visitors, school nurses, and others in the three areas for their kind collaboration.

ENTERIC PNEUMATOSIS

BY

F. J. C. MATTHEWS, F.R.C.S.Ed.

(From the Hospital of St. Cross, Rugby)

Enteric pneumatosis is characterized by the occurrence of gas-containing cysts, either sessile or pedunculated, arising in the submucous and subserous layers of the small intestine. They attain the size of a grape and tend to appear in local masses, which in turn may be multiple. They are classically more common on the mesenteric aspect of the bowel and are confined to the small intestine and proximal half of the large intestine.

These cysts are similar in appearance to lymphangiomas, having a thin translucent wall, and are composed of delicate connective tissue lined, at least partially, by endothelium and with evidence of giant-cell formation. The entire microscopical appearance supports the view that the longevity of these cysts is not so much the result of their own perpetuity as of continual replacement due to some influence not understood. The contents are gaseous, being composed mostly of nitrogen with smaller proportions of oxygen and occasionally carbon dioxide, hydrogen, and methane.

Theories on the Cause

Various theories of the evolution of this condition have been expounded, and Masson (1925) has examined these in some detail. It has been thought that these collections of gas are caused by gas-producing organisms, but experiments have failed to produce a similar condition. Further work has been done to investigate possible penetration of intestinal mucosa, associated with increase in intestinal pressure such as may occur in vomiting, coughing, or constipation, but this theory in turn has been disproved, as the cystic gas has not shown the same constituents as intestinal gas.

It is now accepted that this condition is in fact one of gaseous dilatation of lymphatic channels. Masson has investigated the causation of this phenomenon, and concludes that the fundamental pathology lies in lymph stagnation in tortuous or obstructed lymph vessels. He further states that absorption of carbon dioxide and lactic acid from the intestinal mucosa occurs into blocked lymphatics, and that this is followed by liberation of the carbon dioxide, and by diffusion of nitrogen, oxygen, and occasionally methane from capillaries; the resultant ratios of the gases being adjusted by the laws of diffusion governing the partial pressures of gases.

Masson and others have suggested that enteric pneumatosis occurs in association with digestive disturbances, and especially those due either to gastric or to duodenal ulceration, although the cause for this is not clear. Various other authors assert that it is associated with such conditions as intestinal tuberculosis, acute and chronic appendicitis, colitis, and many others, but these seem to be purely coincidental.

Koss (1952), in a review of the literature, has noted the clinical course of this disease. He asserts that the disease may develop within a relatively short time, as confirmed by operative findings. There is also considerable evidence to show that these cysts may disappear spontaneously, but certain complications have been noted. Pneumoperitoneum may occur owing to spontaneous rupture of the cysts, but intestinal obstruction seems to be the most likely complication. The obstruction may be precipitated by blockage of the bowel lumen by submucous cysts, by volvulus induced by a cyst mass, or by extrinsic obstruction due to pressure by cysts or adhesions arising as a result of the condition. Koss reported one case of intussusception due to gas cysts.

This disease has been described as occurring in the vagina during pregnancy, and the first, albeit inadequate, descrip-

tion of its occurrence in man is claimed by English authors to be that of John Hunter (1728-93) and by French authors to be that of Duverney (1648-1730).

In 1825 Mayer described a case occurring in the intestine and peritoneum of a pig, but the first full account of the disease in humans is attributed to Bang (1876), who found this condition at necropsy in a female who died of volvulus of the colon. In 1899 came the first report of the condition by Hahn, who found it in the living subject. Since that time, according to Koss, who has reviewed the available literature very fully, 213 cases have been reported, the vast majority from Central Europe.

A further case, reported below, shows the classical features as described, with the exception that the condition was found to be present in the distal colon—a rare site in a rare disease.

Case History

A married woman aged 49 was first seen in January, 1952, complaining of the passage of bright red blood intermittently on defaecation and associated with diarrhoea and lower abdominal pain. The pain was not severe, but the whole syndrome had been present for 18 months. She had no other complaints apart from long-standing constipation before the onset of the present symptoms, and her weight was steady at about 11 st. (70 kg.). Her previous history contained nothing relevant—an appendicectomy at the age of 19 and hysterectomy at 39. She had been a chronic sufferer from asthma.

Showing filling defects in sigmoid colon and splenic flexure due to gas cysts.

She was admitted to hospital, and, apart from some deep tenderness in the left iliac fossa and a minor degree of haemorrhoids, nothing abnormal was found on either abdominal or rectal examination. Her blood picture was normal. Sigmoidoscopy was performed and the bowel was normal to 23 cm. At this level several polypoid masses were seen filling the lumen of the colon; these were sessile, and measured from 0.5 to 1.5 cm. in diameter. The surface was translucent and of a bluish hue, the appearance being more like that of lymphangiomatosis than polyposis. There was some evidence of recent haemorrhage from the surface of the cysts.

Examination by a barium enema showed rounded translucent filling defects in the sigmoid colon and the splenic flexure (see Fig.). It was decided to perform laparotomy to elucidate further the diagnosis and the extent of the involvement of the bowel.

On opening the lower abdomen the diagnosis was at once evident. Masses of gas cysts were found, involving 6 in. (15 cm.) of a redundant sigmoid colon and 4 in. (10 cm.) of the splenic flexure and distal transverse colon with a normal descending colon between. These cysts presented a similar appearance to that seen at sigmoidoscopy and were aggregated around the entire circumference of the bowel but stopping short of the mesentery. No other abnormality was demonstrated in the abdominal cavity. In view of the symptoms, it was decided to excise the distal colon, and this was performed with end-to-end suture of the transverse colon stump to the pelvi-rectal junction.

Convalescence was uneventful and the patient was discharged from hospital 12 days later free from symptoms. When seen at the out-patient department two months later she had fully recovered from her operation, and her bowel action was normal and her pain and bleeding had gone.

Pathological Report.—"The specimen consists of distal transverse colon, splenic flexure, and descending and sigmoid colon, and shows the typical submucous and subserous gas-filled cysts. The phenomenon of 'skipping' is well illustrated. Microscopically the cysts bear evidence of an endothelial lining with commencing giant-cell formation. No portal of entry for the 'air' has been demonstrated in the colon."

Conclusions

Enteric pneumatosis is a condition in which the intestinal lymphatic channels become blocked and distended by gas, producing multiple gas cysts both subserous and submucous in position.

The condition occurs mainly in men between the ages of 30 and 50, is accompanied by vague digestive and abdominal symptoms, and would appear to be subject to spontaneous resolution. Intestinal obstruction has been pointed out as the most likely complication.

The case reported above is of interest apart from the rarity of the condition in that barium enema and sigmoidoscopic evidence of the disease was found and had not previously been reported in the literature.

The distribution of the cysts in this case seems to differ from that of cases previously noted, and the all-important symptom of haemorrhage on defaecation led the patient to seek medical advice.

I wish to thank Dr. W. MacCullagh Wilson, of the Coventry and Warwickshire Hospital, for his help with the pathological investigation of the specimen.

ULCERATIVE COLITIS AND CARCINOMA OF THE LARGE INTESTINE

BY

I. P. M. MacDOUGALL, M.D., M.R.C.P.
Temporary Senior Registrar, Follow-up Department,
St. Bartholomew's Hospital; Medical Registrar, the
Gordon Hospital

That ulcerative colitis apparently predisposes to cancer of the colon or rectum seems now to be widely accepted. Upon the correct assessment of this risk the whole therapeutic policy towards the disease might well depend. I have been unable to find any report in which such cancer risk has been estimated, although there are many papers which record the occurrence of this complication of colitis.

The purpose of this communication is to report a further five cases of malignant disease of the intestine arising in the course of colitis, and to consider these cases, in conjunction with reports by other authors, in an attempt to estimate the cancer risk.

Clinical Material

Between January 1, 1947, and December 31, 1951, 154 patients with the diagnosis of idiopathic ulcerative colitis were admitted to St. Bartholomew's Hospital under the care of the physicians and surgeons and to the Gordon Hospital under Dr. E. R. Cullinan's care.

Three of these have gone abroad; their fate is unknown, and they have not been included in the discussion which follows. A further 25 have been excluded from the series on the grounds of incomplete investigation and uncertainty of diagnosis. No case of proctitis without evidence of colonic involvement has been included.

Table I gives the age and sex distribution of the remaining 126. Table II shows the result of a combined postal and personal-attendance follow-up by January 1, 1953. Table III sets out the period for which each patient has been under surveillance since January 1, 1947, with additional information concerning the recognition of cancer of the bowel. In this Table the follow-up is recorded as finishing if colectomy is performed, as, of course, cancer of the large intestine can no longer occur. Table IV classifies the patients according to duration of the disease.

In addition to the five cancer cases recorded here, it should be stated that a further four cases have occurred in the period under review. These have been excluded from the current study because, the diagnosis of cancer having been made elsewhere, the patients were referred to us for treatment of the growth.

TABLE I.—Age (in 1952 or at death) and Sex Distribution. The Ages at Which Cancer of the Large Intestine Appeared are Shown

Case Reports

Case 1.—A 51-year-old housewife was referred to St. Bartholomew's Hospital in October, 1949, because she had had bloody diarrhoea for 20 years, with slight remissions. Medical in-patient treatment in other hospitals had helped her little. Physical examination revealed a mobile tender swelling in the left hypochondrium, and this was shown radiologically to be a colonic neoplasm, the rest of the colon showing the changes of ulcerative colitis. Total colectomy and ileostomy were performed. The operation specimen showed a carcinoma in the left half of the transverse colon, with the characteristic changes of chronic ulcerative colitis affecting the whole of the remainder of the colon. Histologically, the growth was described as "moderately anaplastic" and one out of 27 lymph nodes was infiltrated with carcinoma cells. In 1953 she was free from recurrence of growth, and plans for ileo-rectal anastomosis were being considered.

Case 2.—A 26-year-old unmarried carpenter was first seen at St. Bartholomew's Hospital in 1935, with a two-year history of bloody diarrhoea. Sigmoidoscopy showed the changes of ulcerative colitis, but the colon was not x-rayed. Appendicostomy was performed, with temporary improvement. This closed spontaneously two years later. Remissions and relapses continued until 1945, after which he became well for two and a half years. In August, 1949, he reported the appearance of alternating constipation and diarrhoea, with small stools. Barium enema revealed a carcinoma at the junction of the descending and pelvic colon, with chronic colitic changes above the growth. Exploration confirmed the presence of the growth, but numerous peritoneal metastases were seen, and no curative treatment was possible. No biopsy was taken. Palliative caecostomy was performed, and death occurred five months later. Necropsy was not permitted.

Case 3.—A married clerk aged 50 was referred to St. Bartholomew's Hospital by his doctor in February, 1949. He had had bloody diarrhoea from 1918 intermittently until 1922, when a caecostomy was performed. Thereafter there were a number of minor relapses of the colitis symptoms, and a very severe one. For several years a prolapsed caecum had been troublesome, and because of this he was sent to this hospital. Examination showed the rectum to be greatly stenosed; right hemicolectomy and ileostomy were carried out; the left colon was to have been removed later. The operation specimen showed the appearances of ulcerative colitis throughout its length, but not spreading to the ileum. He remained well until May, 1950, when left iliac pain and abdominal distension appeared. A mass could be felt in the abdomen, and laparotomy revealed a large carcinoma of the descending colon, with many peritoneal metastases. Biopsy showed a mucoid adenocarcinoma. He returned home and died in January, 1951. No necropsy was performed.

Case 4.—A married woman, aged 63, was referred to the Gordon Hospital by her doctor in April, 1951, with a history of bloody diarrhoea intermittently since 1925, more continuous since a severe relapse in 1935. In 1935 ulcerative colitis was diagnosed, and after eight months' hospital in-patient treatment she had to some extent improved. Symptoms remained troublesome, but six months before we saw her she became much worse, with 20 to 30 bowel actions a day and much blood and mucus. On examination she was found to have a carcinoma of the rectum, and laparotomy revealed peritoneal metastases. She died on the eighth post-operative day. **Necropsy report:** Carcinoma of rectum of mucoid type, peritoneal secondary deposits, severe generalized ulcerative colitis: confirmed histologically.

Case 5.—A married woman aged 25 first attended at the Gordon Hospital in August, 1949, with a six-year history of bloody diarrhoea for which she had had three previous periods of in-patient treatment at other hospitals. Barium enema and sigmoidoscopy showed the typical appearances of ulcerative colitis throughout the colon. After six weeks' in-patient medical treatment she was much improved. For two years she was fairly well, but in September,

1951, she reported a lump in the breast, an abdominal mass, and pain in the chest. Laparotomy revealed carcinomatous peritonei, and she died two weeks later. *Necropsy report*: primary colloid cancer of the transverse colon, with generalized metastases; the whole colon was affected by extensive and severe ulcerative colitis, without spread to the ileum. The diagnosis was confirmed histologically.

Discussion

During the period of observation of 126 patients with ulcerative colitis, five cases of carcinoma of the rectum or colon have been found. That this is not an unusually high proportion is suggested by other reports. Rice-Oxley and Truelove (1950) found 4 cases out of 129; Counsell and Dukes (1952) discovered 7 cases with this complication in a group of 63; Lyons and Garlock (1951) reported that 9 in their series of 226 showed malignant change; Dennis (1945) noted 2 certain cases and 1 probable case of bowel cancer in his series of 82 cases of colitis; Kirsner *et al.* (1948) reported 2 in a selected group of 100; Lahey (1949) found 17 in a series of 600; Brown *et al.* (1951) found 7 in 147; and Sloan *et al.* (1950) reported 109 cases of intestinal malignancy in a group of 2,000 cases of ulcerative colitis.

Earlier papers (Feder, 1938; Willard *et al.*, 1938; Hurst, 1935) do not record this complication. Up to 1945 Lynn, in his review of the literature on this subject, found that 98 cases had been reported, and he stated that by collecting the reported series together he found that 28 cases had arisen in 1,467 patients with colitis. In a more recent paper Felsen and Wolarsky (1949) reported that they had found no cases of intestinal malignant disease in a study of 855 patients with ulcerative colitis. It is difficult to reconcile the negative findings of the last-named with the recent reports from so many other centres. Nevertheless, even including this series, the average ratio of cancer to total cases in the post-war reports is about 3.7%.

Most clinicians would feel that this figure is so small as to have little weight in the decision whether a particular patient should have his colon removed. It is important to recognize, however, that this figure does not represent the chance of a patient eventually developing cancer of the diseased intestine, but only the cancer incidence over a particular time—in the majority of reports an unspecified time. If, for example, all the patients in the accumulated series had been observed for an average of 10 years each, 3.7% incidence represents 3.7 cases for every 100 of the population at risk, during a period of 10 years, or 3.7 per 1,000 living per year.

In England and Wales in 1950 (Registrar-General, 1952), 16,389 deaths were registered as being due to neoplasm of the colon and rectum. A guess that this represents an annual incidence of 20,000 new cases cannot be very wide of the mark. A negligible number of these occur below the age of 25, and the population over that age in 1950 was 28½ million. This gives an annual incidence in the population of England and Wales over the age of 25 of 0.7 per 1,000 living. The estimated annual incidence in the U.S.A. is 0.88 per 1,000 (Bargen, 1949).

So that, by our quite generous guess that every patient in all these reports has been followed up for an average period of 10 years, we derive the result that cancer of the rectum and colon in these cases is five times more common than among the population as a whole.

If we apply the same principle to the much smaller group formed by my own cases we obtain the figure of 366 patient-years (Table III) in which five carcinomas have occurred—an annual incidence of 14 per 1,000, or twenty times the national figure. This calculation is unsatisfactory because of the extremely small number of cases. It is worthy of note, however, that the small group here reported closely follows the pattern of other accounts. Thus the proportion of cancer cases to colitis cases is very close to the average figure of the other reports: the relatively youthful incidence of cancer in this site as compared with the com-

monest ages in the whole population is commented on by others (for example, Sauer and Bargen, 1949); that the growths appear especially in those who had had colitis for many years (Lahey, 1949; Counsell and Dukes, 1952) is borne out in our series, in which four out of the five cancer patients had had colitis for 15 years or longer.

This method of assessing the cancer morbidity in the present series as compared with the general population is, for lack of data, crude and involves a good deal of guess-work. It is not possible, with the information at my disposal from other publications, or with the small numbers in my series, to analyse these figures with greater refinement. It seems reasonable to deduce that in the reports I have quoted carcinoma of the rectum and colon has occurred at least five times as often as one would have expected if they had been a sample of the normal adult population.

Conclusions

The fallacy of reporting an "incidence" in the neighbourhood of 4% without reference to time has been illustrated. It would appear that such an incidence represents a cancer risk to these patients which is many times that for the "average" person. Cancer of the rectum and colon in the general population is by no means a rare disease (being responsible for 1 in 30 of all deaths), and a possible fivefold increase in our patients is therefore no mere academic observation. One feels that until long-term study has produced more cases and an opportunity for more exact examination of survival times and cancer incidence, the increased risk of malignant disease in the rectums and colons of these patients should be held to be an important factor when the question of surgical intervention is being considered.

Summary

Five cases of carcinoma of the large intestine occurred in 126 cases of ulcerative colitis. Case reports of the carcinoma cases are presented.

An attempt is made to assess the cancer risk for this site in ulcerative colitis, with reference to this and other reported series.

It is suggested that the cancer risk for this site in patients with ulcerative colitis is not less than five times that for the population as a whole.

ADDENDUM.—Since this paper was written, the workers at the Mayo Clinic have published an analysis of cancer mortality in a series of 1,500 cases of ulcerative colitis. They conclude that carcinoma of the rectum and colon is 20 to 30 times commoner as a cause of death in this disease than in the population as a whole (Bargen, J. A., Sauer, W. G., Sloan, W. P., and Gage, R. P., *Gastroenterology*, 1954, 26, 32).

I am greatly indebted to Mr. Basil Hume for permission to report Case 1; to Sir James Paterson Ross for Case 2; to Mr. J. P. Hosford for Case 3; and to Dr. E. R. Cullinan for Cases 4 and 5. The staff of the follow-up departments at St. Bartholomew's Hospital and the Gordon Hospital have been of tremendous help in tracing the patients. Dr. Cullinan has given me much valuable advice and encouragement, and Mr. M. P. Curwen, medical statistician at St. Bartholomew's Hospital, has been most helpful with his kindly criticism.

ASSOCIATION OF DIABETES MELLITUS WITH CEREBRAL TUMOUR

BY

A. PATON, M.B., M.R.C.P.

Late Medical Registrar, St. Helier Hospital, Carshalton

AND

C. P. PETCH, M.D., M.R.C.P.

Consultant Physician, St. Helier Hospital, Carshalton

Ashby and Tweedy (1953) stated that "no neurogenic lesion causing permanent diabetes has been described," and they added that numerous cerebral lesions are known to cause transient hyperglycaemia, but not permanent diabetes. In view of this we are prompted to record the following case.

Case Report

A 51-year-old lorry driver was sent to the out-patients department on April 6, 1951, with symptoms of polydipsia and polyuria which he had had for three months; he had lost a good deal of weight in spite of an excellent appetite. There was no family history of diabetes.

Examination showed a well-built man, not obese, who was thought to be rather slow mentally, though co-operative. He had a thickly furred, dry tongue, and was moderately arteriosclerotic, but all peripheral pulses were palpable. The blood pressure was normal. Fundi and media were clear and all reflexes were brisk and equal, with normal power and sensation in the limbs. The urine was acid, specific gravity 1028, and orange to Benedict's reagent; there was no acetone or albumin. A glucose-tolerance test showed a diabetic curve (see Chart), and the patient was admitted a week later for stabilization. The above findings were confirmed, but in addition the ankle-jerks were now absent and the right knee-jerk was weak. There was some subjective difficulty in using the left leg, and both calves were tender.

He was placed on a 200-g. carbohydrate diet and was finally allowed out of hospital on April 30 on two injections of 48 and 24 units of soluble insulin daily. During his stay in hospital his diabetes was difficult to stabilize and the urine contained acetone on occasion. His weight remained steady and he felt better, though he was still rather slow in cerebration. He was seen in the clinic two weeks later, before going to a diabetics' convalescent home, when he seemed well, though complaining of some weakness in the right leg. On return from convalescence at the beginning of June, however, he was not at all well, appeared increasingly slow mentally, and had difficulty in getting about.

He was readmitted the next day, when he was found to have weakness of both quadriceps and foot extensors, with absent tendon reflexes. The plantar responses were flexor. His feet felt numb, but there was no objective sensory loss, except to light touch in the left palm, where the grip was poor. The fundi were normal. There were crepitations at the bases of the lungs, but no evidence of congestive failure. A diagnosis of peripheral neuritis was made, and he was treated with injections of vitamin B₁ and physiotherapy. A chest radiograph was normal. The Wasser-

mann reaction and Kahn test were negative. A lumbar puncture revealed normal fluid under a pressure of 220 mm., with a protein content of 20 mg. per 100 ml. His condition deteriorated rapidly and he became increasingly comatose. Eleven days after admission he was found to have regained his tendon reflexes in the legs and the left plantar response had become extensor. There was no papilloedema. A left hemiparesis developed, and he died in coma with hyperpyrexia 10 weeks after first attending hospital. His urine during the last period of admission still contained moderate amounts of sugar and acetone, but the blood sugar the day before death was normal.

At necropsy (Dr. T. Goodier) a large glioblastoma multiforme, containing mainly spongioblast-like cells, was found in the left temporal region, spreading down into the hypothalamus, but not involving the pituitary. The pancreas showed degenerative changes compatible with diabetes mellitus. There were no other gross findings.

Discussion

Since Claud Bernard (1849) produced glycosuria by puncture (piqûre) of the floor of the fourth ventricle in animals, repeated attempts to define a cerebral centre concerned with carbohydrate metabolism have yielded conflicting results. The centres for piqure glycosuria are now thought to lie in the hypothalamic nuclei in the walls and floor of the third ventricle, but most authors agree that experimental damage to this region causes transient hyperglycaemia and glycosuria only, and that thereafter the blood sugar returns to normal or low normal figures (Long, 1940). Ranson *et al.* (1938) recorded the production of diabetes in only one of 50 monkeys and in none of 300 cats with hypothalamic lesions, and thought that the disturbance in carbohydrate metabolism in their one animal was related to obesity and overeating. No other worker has reported the production of permanent diabetes in the experimental animal.

Clinically, it is well known that cerebrovascular accidents, cerebral trauma, meningitis, and tumours may cause transient hyperglycaemia and glycosuria. Cushing (1930), however, stated that he had never seen even transient glycosuria after operations in the hypothalamic region. Joslin *et al.* (1952) also quite clearly subscribed to the view that there is no justification for assuming a cerebral role in the aetiology of diabetes mellitus, and that where the two are associated there is a coincident hereditary weakness of the pancreas. Nevertheless, van Bogaert (1928) mentioned two patients with tumours of the third ventricle, with hyperglycaemia and diabetic sugar-tolerance curves. The pancreas was normal in one case at necropsy. Byrom and Russell (1932) gave a detailed account of a woman with an insulin-resistant diabetes, who was found to have an ependymal cyst of the third ventricle. There was, however, a strong family history of diabetes, but they suggest that hypothalamic irritatory of diabetes, but they suggest that hypothalamic irritatory may lead to hyperglycaemia through overactivity of the sympathetic nervous system, and eventually to diabetes. Penfield (1934) also mentioned a patient with insulin-resistant diabetes of five years' duration in whom a cyst of the mid-brain was found at necropsy.

In the present case the association of diabetes mellitus with the cerebral tumour seems inescapable. The short history, the absence of any hereditary predisposition, and the insulin resistance are points in favour of this. The retarded mental state was a striking feature, though there were no other hypothalamic symptoms. The mechanism of production of the diabetes, however, is difficult to explain.

There seems little doubt that the hypothalamus is concerned in the emergency regulation of the blood sugar through its control of sympathetic-parasympathetic pathways. If this control is upset hyperglycaemia might result from sympathetic overactivity; the hyperglycaemia would act as a stimulus to increased insulin production and might lead to eventual exhaustion of the β -cells of the pancreas. Permanent diabetes has been produced in animals by long-continued hyperglycaemia (Dohan and Lukens, 1947). Alternatively, parasympathetic overactivity might increase insulin production through vagal stimulation of the pan-

creas, which again might lead to islet atrophy and permanent diabetes. The evidence for vagal control of insulin secretion, however, is not very clear-cut (Long, 1940). With either hypothesis, the finding of changes in the pancreas at necropsy does not necessarily implicate that organ as being primarily responsible for the diabetes.

In conclusion, experimental and clinical evidence suggests that the production of diabetes mellitus by hypothalamic damage is exceptional. Nevertheless, the hypothalamus seems to play some part in the regulation of carbohydrate metabolism, and its role is worthy of further study.

Summary

A case is described in which diabetes mellitus of recent onset was associated at necropsy with a neoplasm in the region of the hypothalamus.

It is suggested that the cerebral lesion was responsible for the onset of diabetes.

Experimental and clinical evidence gives some support to the view that the hypothalamus is concerned in the regulation of carbohydrate metabolism.

SYSTEMIC ANTIBIOTICS IN CERTAIN DERMATOSES

TRIAL CONDUCTED UNDER THE AUSPICES OF THE MEDICAL RESEARCH COUNCIL

Under the auspices of the Medical Research Council clinical trials were undertaken at St. John's Hospital for Diseases of the Skin* in order to evaluate the effect of the newer antibiotics when given systemically for certain chronic, recurrent, and resistant skin conditions. This trial was under the direction of Dr. J. O. Oliver (director of pathology) and was regarded as a "pilot" survey to indicate whether subsequent large-scale trials would be of value.

The trials were designed for use with out-patients, the antibiotics under scrutiny being aureomycin, chloramphenicol, and oxytetracycline ("terramycin"). For control purposes dummy capsules were prescribed to a second group of patients, and it was arranged that neither the doctor nor the patient knew which medication was being given. Dosage used for the antibiotic was 2 g. a day, taken in four divided doses, and the treatment was continued for three weeks unless the patient was forced to stop because of side-effects. A compound vitamin-B tablet was taken with each capsule. All cases which did not complete three weeks' treatment were regarded as failures. The observed results (see Table) were as follows.

1. *Herpes simplex recurrens* (31 cases, including 8 controls). No effect in preventing recurrence was observed as the result of the administration of aureomycin, chloramphenicol, or oxytetracycline. One case relapsed under active treatment.

2. *Plantar warts* (30 cases, including 9 controls). No indication of superiority of any of these antibiotics over the dummy capsules. In fact, in the control series six patients

*The medical registrars responsible for this trial were Drs. R. H. Seville, C. D. Calnan, R. H. Meara, and J. H. S. Pettit. Dr. P. D. Samman undertook the lichen planus series.

Disease and Drug Used in Trial	Total	Cured	Improved	Unchanged	Failed to Complete Course	Observed Effect
<i>Herpes simplex recurrens</i>	31					
Chloramphenicol	12	0	0	12	4	Nil
Aureomycin	6	0	0	4	2

Aureomycin	5	0	1	2	2	
Oxytetracycline	3	0	1	0	0	
Controls	4	0	3	1	0	
<i>Pityriasis rosea</i>	25					
Chloramphenicol	8	0	0	8	1	Nil
Aureomycin	8	0	0	8	1	
Oxytetracycline	3	0	0	3	1	
Controls	6	0	0	6	1	
<i>Dermatitis herpetiformis</i>	12					
Chloramphenicol	3	0	1	1	1	Nil
Aureomycin	4	0	0	2	2	
Oxytetracycline	3	0	0	0	3	
Controls	2	0	0	2	0	
<i>Discoid eczema</i>	16					
Chloramphenicol	6	0	0	4	2	Nil
Aureomycin	5	0	1	2	2	
Oxytetracycline	2	0	0	1	1	
Controls	3	0	1	2	0	
<i>Seborrhoeic infective eczema</i>						
Short duration	7					
Chloramphenicol	4	4	—	—	—	Marked benefit
Aureomycin	2	2	—	—	—	
Oxytetracycline	1	1	—	—	—	
Controls	0	0	—	—	—	
Long-standing	7					
Chloramphenicol	3	0	—	3	—	Possible benefit
Aureomycin	3	1	—	2	—	
Oxytetracycline	1	1	—	0	—	
Controls	0	0	—	0	—	

recovered out of the nine, substantiating the well-known observation that warts are unpredictable in their behaviour.

3. *Lichen planus* (19 cases, including 4 controls). No apparent effect was noticed.

4. *Pityriasis rosea* (25 cases, including 6 controls). There was no apparent reduction in the duration of the condition as a result of administration of any of the antibiotics.

5. *Dermatitis herpetiformis* (12 cases, including 2 controls). Although this series was small no indication was given that any of the antibiotics exerted a favourable effect.

6. *Discoid eczema* (16 cases, including 3 controls). No apparent effect was detected.

7. *Seborrhoeic infective eczema* (patients with red oozing scalp and faces with crusting, scaling, and fissuring of the ears). These were divided into two groups: (a) *Of short duration* (7 cases, with no controls). All seven patients made a rapid and uninterrupted recovery. (b) *Long-standing cases lasting for months or years* (7 cases, with no controls). Two apparently recovered but five were unaffected.

Summary

From the small number of patients treated it would appear that the use of aureomycin, chloramphenicol, and oxytetracycline, when given systemically, is not indicated for herpes simplex recurrens, plantar warts, lichen planus, pityriasis rosea, dermatitis herpetiformis, or discoid eczema. It would seem, however, that in infective seborrhoeic eczemas of recent origin, in which one must regard an infective process as being superimposed on a readily infectable soil, rapid results are often obtained by the use of these antibiotics. It also became apparent that the use of large doses of these antibiotics on ambulant patients may cause such unpleasant side-effects (nausea, vomiting, and gastro-intestinal upsets)—particularly so when aureomycin is being used—as to make such treatment impracticable.

Our thanks are due to Miss H. M. Tedham, pharmacist, for her assistance.

Medical Memorandum

Carcinoma of the Pancreas in a Girl of 16, Presenting as Carcinomatosis of Lungs

The following case is of interest owing to its unusual presenting symptoms and to the rarity of the disease at this age.

CASE REPORT

The patient was a girl aged 16 whose father and mother were in a mental hospital. Apart from pertussis at the age of 7 she had kept well, and recently had been working in a toy factory and at a laundry. For the past year she had complained of a dry cough. In July, 1951 (four months before her death), she had measles and had been off work since. Since August there had been increasing tiredness and loss of weight. She became more breathless on exertion and had occasional substernal pain. About November 10 her condition began to deteriorate rapidly. She had a slight evening temperature of 99° F. (37.2° C.) and began to cough up thick white sputum which was never blood-stained.

When examined at home on November 21 she was a pale, wasted, toxic girl obviously breathless, even in bed. The throat was injected, but the tonsils were small. There were no palpable lymph nodes. Tachycardia was pronounced, but the heart sounds were clear. In the chest there was impairment at the right base anteriorly and posteriorly, with harsh breath sounds at the right apex. No added sounds were heard at that time, although her doctor had previously noted scattered crepitations and rhonchi at both bases, particularly the right. The abdomen was soft and no enlarged viscus was felt. An x-ray film of the chest showed widespread scattered shadowing throughout both lungs, confluent at the right lower zone—an appearance suggestive of secondary carcinomatosis. The sputum was consistently negative for *M. tuberculosis*.

On admission to the Copthorne Branch of the Royal Salop Infirmary on November 30 it was obvious that she had deteriorated further. She remained pyrexial, with a temperature rising to 102° F. (38.9° C.), and was even more breathless, the respiration rate being 54. She was cyanosed, her cough and sputum had now increased somewhat, and she complained of frontal headaches. The chest expansion was fair, but coarse and fine crepitations were heard all over the chest except at the apices. In the abdomen the liver edge was soft and just palpable. The spleen was also just palpable. A further x-ray film of the chest showed the lung fields to be almost completely replaced by multiple opacities, many of which had coalesced. X-ray films of the hands, dorsal and lumbar spine, and pelvis were normal.

She became weaker, her cough prevented sleep, and even in an oxygen tent she was breathless and cyanosed. Finally, on December 6 she died from progressive asphyxia.

Clinically, although the case resembled an acute tuberculous bronchopneumonia, the persistently negative sputum and the typical radiological appearances made the diagnosis of secondary carcinomatosis very likely. The site of the primary growth, however, was undetermined.

Post-mortem Examination.—The lungs were found to be consolidated to the shape of the thoracic cage by white and cream-coloured nodules of growth varying in size up to 4 cm. in diameter, so numerous as almost entirely to replace the lung tissue, and so dense as to make the lungs about five times their usual weight. On opening the abdomen the tail and part of the body of the pancreas were found to be replaced by a mass of scirrhous growth about 5 cm. in diameter. Numerous lymph nodes enlarged by metastatic growth were found around the pancreas and aorta, in the mesentery, and in the mediastinum. Secondary growths were also found in the liver and on the lower surface of the diaphragm. The remaining organs showed no significant abnormality. Serial sections taken from near the edge of the growth in the pancreas showed microscopically every gradation from normal tissue with varying degrees of fibrosis to

well-differentiated adenocarcinoma and then to anaplastic growth. The lung tumours were found to consist of solid masses of spheroidal cells separated into groups by fibrous trabeculae, and also occasionally more differentiated areas of columnar-cell adenocarcinoma.

COMMENT

Although carcinoma of the pancreas is very rare under the age of 20, we have found in the literature reports of eight cases, which were confirmed at necropsy. Mielcarek (1935) reviewed five previous cases and added one of his own. Since then Smith (1935) reported a case of a boy aged 14½, and Corner (1943) described a case of a baby girl aged 7 months. A possible ninth case (Kaletchiff, 1939) in a girl of 14 is quoted by Schnedorf and Orr (1941).

Only three of these cases were found at necropsy to have pulmonary metastases. In Kühn's patient (1887), a girl aged 2, the primary growth was in the head of the pancreas; there was a single secondary nodule in the lungs, and the only respiratory symptoms were due to a terminal pneumonia in the left lower lobe around this nodule. Kaufmann (1927) described the post-mortem findings in a girl aged 19: the primary growth was situated in the tail of the pancreas, and there were secondary growths in the liver and lungs; unfortunately no clinical details are given. In Smith's case the whole pancreas was involved; multiple metastases were found in the lungs as well as in the liver, lymph nodes, stomach, and adrenals; and respiratory symptoms were recorded throughout the illness accompanied by weakness and signs of an abdominal tumour.

The formation of extensive secondary tumours, which can cause presenting clinical features, probably depends largely on the exact site of the primary growth in the pancreas. If in the tail, the tumour is more likely to remain clinically latent, until metastases develop elsewhere. Of the reported cases all arose from the head of the pancreas, with the exception of Kaufmann's and Smith's cases. In our case the primary growth was in the tail, and the symptoms and signs during life were exclusively respiratory in origin. The organs invaded by secondary growth—liver, lymph nodes and lungs—are those most commonly involved in all age groups (Arkin and Weisberg, 1949), but the extent of lung involvement was here so great as to dominate the clinical picture.

We should like to thank Dr. W. D. Wallace for his help and interest in this case.

The International Conference of Social Work, of which Dr. René Sand was the founder, for many years president, and since 1948 honorary president, has initiated a memorial in his name, and for this purpose has opened a memorial fund inviting all those organizations and individuals who wish to pay tribute to the personality and work of René Sand to make a contribution. The fund is to be used to provide a René Sand Prize, to be awarded every two years to some individual who has rendered outstanding service in social welfare or social medicine, and presented at the biennial meetings of the International Conference of Social Work. The amount contributed will determine the length of time during which the prize can be awarded, but it is hoped to raise a sum of 10,000 dollars (£3,570), to be expended over the next 10 years. Contributions may be sent to Captain J. E. Stone, honorary secretary and treasurer of the International Hospital Federation, King Edward's Hospital Fund, 10, Old Jewry, London, E.C.2.

Reviews

INTERNATIONAL DERMATOLOGY

The Tenth International Congress of Dermatology: Proceedings, London, 1952. Foreword by Sir Archibald Gray, C.B.E., T.D., M.D., F.R.C.P., F.R.C.S., President of the Congress. (Pp. 556; illustrated. £3 3s.) London: British Medical Association. 1953.

Following an account of the organization of the congress and the list of patrons, officers, and members, the meeting of national delegates, the social arrangements, and the opening and closing ceremonies, come the main discussions. The first is on the pathogenesis of eczema, the second on the effects on the skin and its diseases of cortisone and corticotropin (A.C.T.H.), and the third on the treatment of tuberculosis of the skin and allied conditions. Readers of the discussions will obtain up-to-date views on these important subjects. Then come abstracts of interesting short papers (pp. 289-415) and clinical case reports (pp. 419-542). Some of the latter (clinical cases actually demonstrated at the congress) are listed below. They have been selected because the reviewer believes that, taken together, they illustrate "the fighting line of dermatological diagnostic progress."

Porphyria cutanea tarda in siblings (W. R. Goldsmith). Congenital porphyria in a man aged 37 (S. Gold). Naevus comedonicus with partial Sturge-Weber syndrome and extensive vascular naevi with haemangiectatic hypertrophy of leg (A. J. Rook). Keratoma palmo-plantaris in a man aged 38 (F. Ray Bettley and C. D. Calnan). Lichen amyloidosis in a Chinaman aged 68 of six years' duration (G. B. Dowling and D. R. Tipping). Localized amyloidosis in a man aged 59 of 26 years' duration (A. D. Porter and L. A. Musso). Circumscribed myxoedema of the lower extremities in a man aged 57 with bilateral exophthalmos and right-sided ophthalmoplegia (E. Prosser Thomas and E. Waddington). Sarcoidosis in a man aged 35 in whom neurosyphilis had at first been suspected (R. M. B. MacKenna and I. S. Hodgson-Jones). Epidermolysis bullosa dystrophica in a boy aged 17 (I. B. Sneddon).

Rosacea acuminata in a man aged 39 in whom a diagnosis of rosacea tuberculoides, rosacea acuminata, or sarcoidosis was suggested in 1948 (the reviewer would suggest what he calls the rosaceous type of sarcoidosis) (W. J. O'Donovan and S. P. Hall-Smith). "Benign" chronic polyarteritis nodosa in a man aged 30 with recurrent, slightly painful subcutaneous nodules in the forearms and legs (F. Ray Bettley). Polyarteritis nodosa treated with A.C.T.H. and cortisone in a man aged 53 with apparent success (G. B. Mitchell-Heggs and J. G. Holmes). Gastric and jejunal polyposis associated with melanin spots of the oral region and digits in a girl aged 17 whose younger sister had pigment spots around the mouth (references to the literature of this rare but important syndrome) (M. Feiwel). Incontinentia pigmenti in a girl aged 4 years (a sister had the same condition) (R. T. Brain and C. D. Calnan). Epidermolysis bullosa dystrophica vegetans in a boy aged 12 years whose twin brother was similarly affected and died at the age of 6 months (R. T. Brain). Miliary lymphocytoma in a woman aged 59 (F. Ray Bettley). Acanthosis nigricans in a woman aged 63 with suggested gastric neoplasm (O. L. S. Scott).

Hyperkeratosis follicularis et parafollicularis in cutem penetrans (Kyrle) in a woman aged 62 (R. M. B. MacKenna and R. H. Seville). Atrophie blanche in a woman aged 36 (A. Monroe and R. H. Meara), and another case in a girl aged 18 (F. Ray Bettley and C. D. Calnan). Local panatropy in a boy aged 15 apparently beginning eight years ago, also in a girl aged 16 apparently beginning 12 years ago (F. Ray Bettley). Erosive gingivitis-lichen planus of mouth mucosa and vulval skin—in a woman aged 50 (L. Forman). Acanthosis nigricans with Cushing's syndrome in a man aged 28; parents were first cousins, and a paternal cousin was grossly obese (F. Ray Bettley).

Poikiloderma vasculare atrophicum of Jacobi in a man aged 30: Gougerot and Eliaschew papules seen in some of the more marked erythematous areas (J. L. Franklin and J. B. Lyon). Poikiloderma atrophicum vasculare (Lane type) with mycosis fungoides in a man aged 43 (G. B. Dowling and E. Waddington). Poikiloderma: a benign variant confined to the extremities in a man aged 63; the condition has also been described as "lichen planus erythematosus" (R. M. B. MacKenna and P. D. Samman). Calcinosis universalis beginning at 7 years in a man aged 23 whose paternal grandmother suffered from "chalk gout":

no evidence of scleroderma, dermatomyositis or other "collagen disease" (Stephen Gold).

Hand-Schüller-Christian disease (with eosinophilic granuloma of right femur, "honeycomb" lungs, diabetes insipidus, and Simmonds's disease) in a man aged 61 (Brian Russell). Congenital telangiectasia of face and legs in a girl aged 6 years with dysostosis of clavicles and minor abnormalities of bony development and coloboma of right eye (H. T. H. Wilson). "Disseminated nodules of skin and bone": this title is suggested for two cases described by C. D. Evans and R. P. Warin respectively, who refer to a remarkable case discussed by F. Parkes Weber and Freudenthal (for a summary of that case see Parkes Weber's article in *Modern Trends in Dermatology*, 1948, p. 309). Dermatomyositis in a woman aged 69 with neoplasm of the cervix uteri (L. Forman). Pemphigus erythematousus in a woman aged 46 (F. Ray Bettley). Lichen sclerosus et atrophicus with alopecia in a woman aged 40: early lesions resembled morphoeic scleroderma (J. Morgan). Lichen sclerosus et atrophicus in a woman aged 64 who had been formerly under treatment for colitis, pelvic abscess, and diverticulitis (H. T. Calvert). Bullous eruption (? acquired epidermolysis bullosa) in a woman aged 52 (Brian Russell). Bullous eruption, starting as lichen sclerosus et atrophicus, later resembling pemphigus vulgaris, in a woman aged 52 (Brian Russell). Chronic familial benign pemphigus (Hailey-Hailey) in a woman aged 45 (L. Forman and C. D. Calnan), and her brother aged 42 (L. Forman and J. Pettit): the father who died at the age of 75 had the same condition all his life. Ocular pemphigus in a woman aged 70 (L. Forman).

Poikiloderma congenitale (Thomson) in a girl aged 4 years (R. T. Brain). Another case in a woman aged 38 (G. B. Dowling and D. L. Rees). Another case in a girl aged 13 (P. D. Samman). Porokeratosis (Mibelli) in a boy aged 14 (G. Savage). Another case in a girl aged 14 whose elder sister had a similar lesion (A. D. Porter and R. H. Seville). Another case in a girl aged 14 (W. Tillman).

In the limited space at my disposal I find it impossible to give more detailed accounts. Suffice it to say that the volume, which must have taken very much time and trouble in its production, contains excellent illustrations, and constitutes a valuable memorial.

F. PARKES WEBER.

SURGERY OF AUTONOMIC NERVOUS SYSTEM

Sympathikus Chirurgie. By Professor Paul Sunder-Plassmann. (Pp. 162; 146 figures. M. 54.) Stuttgart: Georg Thieme Verlag. 1953.

The title of this volume conveys no idea of its scope and its importance. It is in fact a brilliant study based on years of research, and it deserves the most serious consideration of all who are interested in the autonomic nervous system—which is after all the background of our lives. For most of us the sympathetic nervous system is a remote and difficult field, and it is only in recent years that our attention has been drawn to its surgical importance and possibilities, largely by the work of Leriche.

The book opens with a detailed study of the anatomy of the autonomic system, both general and microscopic, superbly illustrated by drawings of special dissections and photomicrographs. This is followed by a description of the relation of the autonomic nerves to the blood vessels and lymphatics. The "neurohormonal system" is discussed in great detail, with particular reference to the thyroid and adrenal glands, and this section of the book concludes with a description of the great sympathetic ganglia. The surgical section follows, with full descriptions of sympathetic block, excision of ganglia, and other procedures. The illustrations are here again of a high order and of real practical value. To those who are working in this field we can only say that they cannot afford to dispense with the experience which is here placed at their disposal.

Both in its material content and in its production the volume is a great achievement, but the author has in his introduction expressed the spirit which has inspired his work in an allegory so perfect and so simple in its grandeur that I cannot refrain from quoting this one passage. In the little town of Mittenwald in the Bavarian Alps stands a bronze statue of Mathias Klotz, master-maker of violins in 1700. "With his knife in his hand he carves the precious violin from the wood which he himself has brought from the heights of the Karwendel. Quietly and easily he carves it from simple wood. But from

this his violin the hands of the master will draw forth immortal symphonies, which may bring even to the tired men of the twentieth century some glimpse of those things real and eternal with which their destiny still remains inseparably bound."

HENRY SOUTTAR.

TEXTBOOK OF OPHTHALMOLOGY

Ophthalmologie. By Louis Guillaumat, assisted by Suzanne Schiff-Wertheimer, Guy Offret, and André Dubois-Poulsen. (Pp. 1,263; 265 figures. 10,500 fr. or £11 11s. approx.) Paris: Editions Médicales Flammarion. London: H. K. Lewis. 1953.

This is a large and important book, part of a larger and more important project, for it forms one of thirty-four projected volumes designed for the general practitioner as well as the specialist, dealing with the whole gamut of the medical specialties, therapeutics, and allied sciences such as bacteriology. If the remainder of the volumes are on the scale of that devoted to ophthalmology, the project is indeed formidable, and if they are of the same degree of excellence it will be greatly to the credit of French medicine.

The ophthalmological volume is written by the staff of the Clinique Nationale des Quinze-Vingts, Paris, and bears the authority one would expect from that school. It is divided into seven parts. The first is on methods of examination, but is so short and inadequate that it is difficult to see what is its value: ordinary techniques such as the exploration of the visual fields and more recent methods such as gonioscopy and slit-lamp ophthalmoscopy are equally dismissed in a few lines. The second part deals adequately with refraction and its correction, and the third, which forms the main mass of the book, discusses fully and informatively the diseases of the eye and its adnexa on a regional basis, after preliminary paragraphs on the embryology, anatomy, physiology, and clinical investigation of the part concerned. Operative techniques are less fully described than are most other matters, and the accounts are inadequate to form a sole guide to the surgeon. The fourth part, on neuro-ophthalmology (which includes ocular motility), is full and excellent, while the remaining three sections—on injuries, therapeutics, and medico-legal matters—are short.

The book itself is based on a scheme rarely seen in Britain. It is in loose-leaf form—but very substantially bound, so that it should resist much rough use—and the intention of the publishers is that additional pages will be supplied annually supplementing the original text and adding new knowledge as it appears. If this can be adequately carried out, it is an excellent and economic suggestion.

STEWART DUKE-ELDER.

VECTOR CARDIOGRAPHY

Spatial Vectorcardiography. By George E. Burch, M.D., F.A.C.P., J. A. Abildskov, M.D., and James A. Cronin, M.S. (Pp. 173; 121 illustrations. 37s. 6d.) London: Henry Kimpton. 1953.

This is a book we can certainly recommend to anyone who wishes to learn something of the subject. The reader must not be dismayed by the formidable definition on p. 10: "The vectorcardiogram may be defined as a record of the time course of the mean instantaneous electric spatial vector forces from the heart." Most of the book is much simpler than this. The expression throughout is clear and free from jargon. The information is neatly summed up. The fairly varied type gives clarity and emphasis. The advantages and disadvantages are set out in a judicial way, so that the reader gets a fair discussion of the various topics without bias of view.

As the heart is a three-dimensional structure enclosed in a volume conductor, the electrical events occur in space. In order to obtain a spatial vectorcardiogram a three-dimensional reference frame is needed. The authors favour the equilateral tetrahedron, the triangle of Einthoven forming the base, or frontal plane, and the apex being a point on the back, just to the left of the seventh dorsal vertebra. In order to get a stereoscopic effect two projections are used, frontal and sagittal; the true stereoscopic record is

obtained by specially selected resistances. This part is difficult to follow. The authors claim that stereovector cardiography simplifies the subject, avoids the making of wire models, and may eliminate some of the electrocardiography. They think that vector cardiography may perhaps be helpful in detecting the presence of infarction in the left ventricle when the activation of that chamber is delayed, but admit that much more study, with post-mortem confirmation, is needed. They find that hypertrophy of the left ventricle, which may produce electrocardiographic patterns resembling those of bundle branch block, can perhaps be distinguished by vectorcardiograms, which appear to be different when bundle branch block is present without hypertrophy. The presence of right ventricular hypertrophy could also be detected when bundle branch block on that side was present.

The authors point out that this subject is still in its early stages and that standardization of methods and nomenclature is most important. They would not claim that it replaced the electrocardiogram: it is obvious that the important early alterations in the T-waves are difficult to pick up in the vectorcardiogram. Altogether, this is an interesting and stimulating little book, clearly written, with a balanced and judicious view of the subject so far as it has developed at the present day.

TERENCE EAST.

SLIPPED EPIPHYSIS

Slipped Capital Femoral Epiphysis. By Armin Klein, M.D., Robert J. Joplin, M.D., John A. Reidy, M.D., and Joseph Havelin, M.D. American Lecture Series. (Pp. 130; 77 figures. 49s.) Springfield, Illinois: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953.

This monograph composed by four surgeons from the Massachusetts General Hospital incorporates the knowledge gained from the study in diagnosis and treatment of 81 cases of slipped capital femoral epiphysis. Early radiological diagnosis is described in detail and thrown into relief by an excellent survey of the appearances of hips in both sexes from infancy until the closure of the upper femoral epiphyseal line. The authors have divided their cases into three clinically distinct groups: (1) sudden traumatic displacement of the epiphysis, (2) a gradual and minor degree of displacement, and (3) a gradual and major degree of displacement. In each group surgical treatment is recommended, though differing from one to the other.

It is perhaps regrettable that the authors have not given a more detailed description of the operation for subcapital osteotomy, a procedure that others have not so often found to give good results as these leaders in this particular field. It was disappointing that a survey of results of previous conservative treatment was not included to serve as a comparison to the excellent follow-up results of this review.

This work is a valuable guide in the modern management of adolescent coxa vara, and the reader can be left with little doubt that the results of surgical treatment are superior to the older method of traction and immobilization.

PHILIP NEWMAN.

The Medical Directory for 1954 (J. and A. Churchill Ltd., London, 72s.) is the 110th annual issue of a work which is indispensable in an editorial office, in libraries, and in clubs which maintain reference books for their members. Medical men who replace their old copies from time to time would be advised to make the change now, for the present two volumes are an improvement over the former in that there is no longer that invidious distinction between London, the provinces, and other parts of the British Isles. The 80,983 names in the 1954 edition are listed alphabetically without any topographical distinction. This makes for much easier reference. The "local lists" are grouped together in the second volume, which also includes the usual information about health departments, learned bodies, postgraduate institutions, and the hospitals of the various regions. The first volume gives helpful details about medical periodicals, medical trades, the General Medical Council, and so forth. Messrs. J. and A. Churchill are to be congratulated on maintaining a remarkably high standard of accuracy and on improving the usefulness of this work.

REMUNERATION OF CONSULTANTS AND
HOSPITAL MEDICAL STAFF

The report of the Spens Committee on the Remuneration of Consultants and Specialists was published in May, 1948, and in the House of Commons on June 3 of that year Mr. Aneurin Bevan, then Minister of Health, said, "I should like to add that the Government accept the recommendations in principle. The task of evolving from it the best scheme of remuneration, to suit all cases—and especially the bearing of the recommendations on remuneration for teaching duties—will be difficult and will require the help of the profession in discussion. I propose to begin this quickly. . . ." In this week's *Supplement* we publish details of the agreement between the Staff and Management Sides of Whitley Committee "B" on the increases in the rates of pay of consultants and hospital medical staff along with a statement on the situation by Sir Russell Brain, P.R.C.P., chairman of the Staff Side. The increases can be briefly summarized. House officers are to receive an annual increase of £50 (£75 minus £25 for residence); senior house officers, junior hospital medical officers, and registrars of £75; senior registrars of £100; senior hospital medical officers of £200. The basic scale for consultants is to be increased by £400 at the minimum, tapering to £350 at the maximum, giving a scale of £2,100 to £3,100; consultants with "C" awards will have the same increase, with resultant scale of £2,600 to £3,600; those with "B" awards will receive an increase of £150, with a resultant scale of £3,400 to £4,400; the consultants with "A" awards will receive an increase of £50, the scale becoming £4,300 to £5,300. All these represent the increases over the rates of pay of 1948, and will not be retrospective. There is protection against anyone's present remuneration being diminished (no-detriment protection), and the maximum weighting allowed to part-time consultants and S.H.M.O.s is to be reduced from one and three-quarter sessions to three-quarter sessions; otherwise weighting will be the same.

It is difficult to see on what basis these increases have been determined; and it appears that the negotiators were not armed with the facts and advice that an expert economist and statistician might have given them. Sir Russell Brain points out that in the draft terms accepted in 1948 by the hospital staffs the betterment factor was then the same as that given to general practitioners—namely, 20%—but that this betterment factor was not accepted by the profession as being a

realistic adjustment of the 1939 figures to post-war conditions. In January, 1949, a deputation from the Joint Consultants Committee and the General Medical Services Committee made representations to the Ministry on this, the Ministry then declining to make any upward adjustment. In July of that year the Ministry of Health assured the Joint Committee that changes would not be made in the terms and conditions of service without discussions through the Whitley machinery, that remuneration was looked upon as a subject suitable for arbitration, and that save in exceptional circumstances remuneration would become the subject for arbitration or inquiry. Accordingly the Joint Committee advised hospital staffs to accept permanent contracts on the basis of the terms and conditions of service then offered. Sir Russell then briefly reviews the general practitioners' negotiations, culminating in the Danckwerts award, and quotes the statement made by the Chancellor of the Exchequer in the House of Commons in July, 1952, to the effect that the Government did not adopt the view that similar adjustments in other fields would follow. Legal advice since then is to the effect that the Staff Side had no claim which was enforceable at law, and Mr. F. Grant, Q.C., "did not think that it could be argued that an undertaking by the Ministry to implement the terms of the Consultant Spens Report was a part of the contract on which consultants entered the Service." Sir Russell goes on to argue that there was little likelihood of the Government's applying the Danckwerts decision to the remuneration of consultants and hospital medical staffs. He concludes that "the Staff Side is satisfied that the settlement it has achieved does in fact restore the balance between consultant and general-practitioner remuneration which was upset by the Danckwerts award"; and that "the Staff Side is . . . satisfied that the agreement it has made with the Management Side in no way weakens the Spens Report as a basis of consultant remuneration."

As was pointed out in a recent leading article,¹ the Staff Side negotiators on behalf of consultants and hospital medical staff are chosen by the Joint Consultants Committee, which has on it representatives from the Royal Colleges and Corporations of England and Scotland, and from the Central Consultants and Specialists Committee of the B.M.A., the distinguished President of the Royal College of Physicians acting as chairman. The British Medical Association has not in fact conducted the negotiations (as it did for the general practitioners). The B.M.A. has a clear-cut policy on the remuneration of consultants and that is that they should be based upon the Spens recommendations, a policy, after all, which was the policy of the Government six years ago as stated by Mr. Bevan and which has not yet

¹ *British Medical Journal*, March 13, 1954, p. 634.

been repudiated. It is therefore necessary to look at the present proposals in the terms of the Spens Report and to see how far they may or may not fall short of them. The actual sum of new money—some three million pounds—is perhaps less important than any departure from the principles of the Spens Committee. The levels of remuneration in the Report were in the 1939 terms of money, and the Committee made it clear that these should be adjusted in relation both to the present value of money and to the increases "which have in fact taken place since 1939 in incomes both in the medical and other professions." The Spens Report went on to add this: "In our judgment it is only if corresponding changes are made in the incomes of consultants and specialists that the recruitment and status of various branches of specialist practice will be maintained." Further on the following point was also made: "We would emphasize that if the best possible recruits are to be attracted to specialist practice there must remain for a significant minority the opportunity to earn incomes comparable with the highest that can be earned in other professions. . . . We concluded that specialists of the highest eminence should be able, in the public Service, to aspire to a remuneration of the order of £5,000 for clinical work." This attitude afforded the strongest argument for the merit awards, about which some doubts were expressed at the time. There could, however, be little disagreement with the view that to attract men of the highest calibre into medicine there should be for the few at the top rewards which would enable medicine to compete effectively with other professions for those who would add lustre to it. It is rather difficult to relate the Spens maximum of £5,000, in terms of 1939 values of money, to the present agreement that consultants with "A" awards will go up to a maximum of £5,300. This represents a betterment factor of 6% on 1939 values (excluding the Government's contribution to superannuation). This is not to ignore the position of those in the other ranks of consultants or hospital medical staff, and they will not take it amiss if it is suggested that it is the example and excellence of the eminent in a profession which set a standard for their colleagues not only in professional worth but also in prestige. A further departure from the Spens recommendations is in the alterations of weighting for part-time specialists, and whole-time consultants and specialists may doubt whether this slight relative improvement of their position is so satisfactory as would have been agreement on the allowances for their expenses which the Spens Committee recommended; the Staff Side will continue to press for these.

Consultants and hospital medical staff, either individually or through their various representative bodies, will express their own views on the present

agreement, and in doing so will no doubt take into account the extremely difficult position with which their hard-working negotiators have been faced, made still more difficult by the fact that the profession still has no right to insist upon arbitration. The present is perhaps less important than the future, and consultants would want to feel assured that their representatives of three, five, or ten years hence will be able to negotiate on the basis of the Spens recommendations, for it was these more than anything else which persuaded consultants to go into the N.H.S. in 1948. Sir Russell Brain says that in the view of the Staff Side "Spens remains the yardstick of consultant remuneration, and either side of Committee 'B' is free to seek future adjustments in any grade if experience shows that the present settlement is working unfairly." But it is not easy to escape the conclusion that the Spens recommendations have been so far departed from as to weaken still more their influence on subsequent Ministers and Ministries. Unless the present Minister of Health makes in the House of Commons a similar statement to Sir Russell's and to that of Mr. Bevan in 1948, consultants and hospital medical staff and the profession as a whole will remain uneasy about the future.

DOMICILIARY OBSTETRICS

The designation of general-practitioner obstetricians under the National Health Service Acts aimed at encouraging interested practitioners to acquire post-graduate experience in obstetrics, but only an extremely low standard of supervision before, during, and after labour is required to qualify for payment. In a review of domiciliary midwifery on page 841 of the *Journal* this week Dr. Ivor Cookson, as others have done previously, points out that if the doctor does no more than fulfil these minimum requirements he cannot practise good obstetrics, for he will not recognize anaemia or toxæmia nor diagnose twins or breech presentation at a desirably early time in pregnancy, nor will he prevent unnecessary delay in the second stage of labour, nor bleeding in the third stage. But, if matters are to be remedied, the general practitioner needs something more than a good training and a conscientious attitude; he needs, as Claye has pointed out in a challenging paper,¹ a large enough practice in midwifery to enable him to maintain his skill and knowledge. The increasing popularity of hospital confinement therefore presents a serious problem. For, despite ministerial fiat and financial inducements, the extent of domiciliary obstetrics is gradually diminishing, chiefly because more and more women are preferring to be confined

¹ Claye, A. M., *Midwives Chronicle*, 1954, 67, 40.

² Sheehan, H. L., *British Medical Journal*, 1949, 1, 849.

³ Jameson, J. E., and Handfield-Jones, R. P. C., *Lancet*, 1954, 1, 665.

⁴ Jeffcoate, T. N. A., *British Medical Journal*, 1953, 2, 951.

in hospital. Nevertheless a sufficiency still remains to make it desirable for the scope of domiciliary midwifery in terms of pure obstetrics to be delineated. It is in this regard that Dr. Cookson's paper, which gained for him the Sir Charles Hastings Clinical Prize for 1953, is particularly pertinent.

One of the objects of his survey was to find out how to select cases for hospital delivery so that the remainder could be delivered at home in reasonable, if not absolute, safety. It is noteworthy that in addition to the well-recognized indications for hospital confinement such as high parity, bad obstetric history, antepartum haemorrhage, toxæmia other than of mild degree, and concomitant general disease, Dr. Cookson has found from experience that premature delivery, breech delivery, and multiple births involve too high a rate of foetal loss to be acceptable for delivery at home. On the other hand, he believes that normal primigravidae need not be booked for hospital confinement unless over 30 years of age, nor transferred there unless labour is prolonged beyond 24 hours. With such a careful selection of cases, abnormalities will be rarely encountered in women labouring at home; nevertheless they must then be recognized early and treated adequately, if only pending the arrival of an obstetric flying squad. In particular, complications of the third stage and postpartum haemorrhage require skilled handling. Dr. Cookson believes that the prophylactic intravenous injection of ergometrine towards the close of the second stage should be more widely administered in domiciliary practice, especially after forceps delivery and in women of high parity. This procedure is generally regarded as best reserved for hospital practice, but there is much to commend its use to prevent postpartum haemorrhage in the home where blood transfusion is not readily available. The objection, not universally admitted, that manual removal of the placenta is then more often required is not valid, for in any environment postpartum haemorrhage is more dangerous to the patient than the operation of manual removal. Even in the absence of bleeding it is wiser not to leave the placenta in the genital tract for more than one hour.² If it has separated it is easily expressed; otherwise 0.5 mg. of ergometrine may be given intravenously or intramuscularly, and if the placenta is not then delivered it should be removed manually. The modern view is to recommend that this operation should be carried out either by the general practitioner or by the flying squad in the home rather than transfer the woman to hospital with the placenta still retained, for severe shock or haemorrhage or both may occur on the journey.

Dr. Cookson is rightly concerned at the high proportion of women delivered at home in whom the second stage was prolonged beyond two hours, notably one in every four primigravidae. He argues with conviction that many of these long second stages can be eliminated by the midwife calling the doctor earlier and more often and by the doctor having more frequent recourse to episiotomy, a procedure which will also reduce the forceps rate. He found that episiotomy was performed in only 17 of 74 domiciliary forceps deliveries in his area. Yet in 32 of the remaining 57 women the perineum was torn, in 4 of them through to the rectum. This, he remarks, is too high a price to pay for trying to avoid suturing. Perhaps undergraduate teaching on the indications for episiotomy, and practical instruction in the ease with which these and lacerations can be repaired under adequate local analgesia, are not emphatic enough.

Dr. Cookson concludes from his survey that any family doctor who is interested in domiciliary obstetrics and has had adequate and pertinent instruction can, in any area in which consultant support is available, supervise maternity cases with reasonable freedom from risk to mother and baby. There is no doubt that this conclusion is valid in regard to antenatal supervision. But it is doubtful whether it holds good equally for intranatal care, especially at a time when less than one woman in four of those delivered at home sees a doctor during labour and then often only when he is summoned by the midwife. However carefully the potentially abnormal cases are sifted antenatally, unforeseen complications may arise suddenly in labour to prejudice the life of mother or baby, and all facilities are not readily available at home to deal with these. One possible solution to this problem, which might also satisfy the demand by patients to be delivered in hospital, is the provision of hospital beds for general-practitioner obstetricians on the lines reported last month by Jameson and Handfield-Jones³ in a paper which, in terms of obstetric practice for the family doctor, is in striking accord with that of Dr. Cookson. However, while such provision reduces the risk, especially for the baby, it cannot produce the best possible results unless arrangements are made whereby the general practitioner who engages in obstetrics has a large enough midwifery practice to develop and maintain a high degree of special knowledge and technical skill. Means must also be found by some rota system whereby one doctor is always immediately available in emergency. The factor chiefly responsible for the dramatic fall in maternal and foetal mortality and

morbidity in the large maternity hospitals was the introduction of highly qualified resident, as distinct from non-resident, obstetricians,⁴ for the hospital consultant, like the general practitioner, is not always immediately available for assistance or even advice. Indeed, a maternity hospital without skilled residents in obstetrics, paediatrics, and anaesthesia is not fully equipped to reduce risk to mother and baby to the minimum. But no matter how desirable this may be from the standpoint of statistics it is clearly an ideal not universally obtainable, and in any case it sometimes results in an impersonal type of efficiency. There will always be women who are happier having their babies in the familiar surroundings of their homes or in the friendly atmosphere of the small hospital staffed by attendants they know. These two reports from the same county by Dr. Cookson and by Drs. Jameson and Handfield-Jones indicate that the general-practitioner obstetrician can cater for these patients with a high degree of freedom from risk to mother and baby.

CONJOINED TWINS

In the opening pages of this issue we publish a paper by Professor Ian Aird entitled "The Conjoined Twins of Kano." These were the "Siamese" twins from Nigeria who hit the headlines with rather an alarming impact five months ago. Much of the information that appeared in the newspapers at the time was accurate, though of course incomplete, and much was wild surmise, and those whose appetite for further details was sharpened by the newspaper reports can now turn to Professor Aird's clear and dispassionate account of the investigations carried out on these twins and of the operation which separated them.

The great rarity of conjoined twins probably accounts for the fact that there is still doubt about the exact aetiology. It is thought that the origin of the malformation occurs very early in foetal development, either before the embryonic disk is differentiated, or by the initiation of two centres of axial growth instead of one in the embryonic plate. The position of the extra centre of axial development in relationship to the primitive streak may account for the type of conjoined twin produced.¹ It used to be held by some that many of the teratomatous malformations seen in the newborn were examples of twinning. This theory is not now generally accepted, and it is believed that such cases, and duplications of organs and parts of viscera, are due to other causes.

The classification of the varieties of conjoined twins is complicated. The position of the joined area is easily described in the symmetrical types—for example, xiphopagus (joined at the lower sternum), or craniopagus (joined by the heads). But the classification of the more bizarre forms becomes extremely complicated. Potter² has described and illustrated very well the almost surrealist range of monstrosities—mostly incompatible with life—which may occur. It has been generally accepted that conjoined twins are always uniovular in type. Professor Aird, however, casts some doubt on this theory. His reasons are that in the majority of the cases described the twins have not appeared identical, and he quotes several anatomical and pathological differences between them. While the proof that some conjoined twins are in fact polyovular is difficult, his views gain support from the fact that there is a family history of twinning in some of the cases described. Monoovular twinning is unrelated to a family history of twins and occurs in the same ratio in all pregnant women. Polyovular pregnancies are more frequent when there is a history of twins in either parent.

The separation of conjoined twins ranges in difficulty from the division of a small bridge of skin joining the umbilical region to what is often an impossible surgical problem. The number of cases in which both twins have survived operation is small: Professor Aird mentions that the first recorded successful separation was carried out at the Military Families Hospital at Portsmouth in 1912. It seems probable that when there is a large interchange of blood between the circulations of conjoined twins one twin becomes dominant to some degree. Stockard's³ notable work on this subject was carried out more than thirty years ago. Professor Aird stresses the importance of finding out how much one twin relies on the dominant partner not only for anatomical structures but for the production of hormones such as cortisone. His detailed description of the Kano twins is an important contribution to the sparse scientific literature on the subject, and the well-documented record of the complicated pre-operative tests carried out to determine the chances of a successful separation, and of the operation itself, will be of the greatest value to any surgeon faced with the same problem. Those who saw the film of the operation at the Royal Society of Medicine on Wednesday this week will, by reading Professor Aird's paper, be able to complete the picture of this brilliant example of teamwork at the Hammersmith Hospital.

THE ESTIMATES

The most noteworthy feature of the Health Service estimates for the financial year that has just opened is the apparent standstill in the cost of prescriptions. Ever since a tight hold was imposed on hospitals' spending, the pharmaceutical service has been the most uncontrollable part of Health Service financing. The charges for dentures and, in particular, for dental treatment and the charge for spectacles led to a sharp fall in the amount the taxpayer had to find for these two branches of the Health Service. But the shilling charge for prescriptions appeared to be an inefficient brake. The latest figures available for the number of prescriptions dispensed—for the calendar year 1953—show a higher total than ever.

The year 1952-3, the first year in which the charge was in existence, was an abnormal year in the amount of illness that occurred in the winter months. Nearly £5m. was added to the drugs bill for this reason alone. The year just ended has been more fortunate in this respect, and there may well have been some falling off in the number of prescriptions dispensed in the winter months of 1953-4 compared with the previous winter. But the Ministry of Health is perhaps counting on a greater saving in the cost of each prescription than in a fall in the total number. The detailed estimates show that payment to chemists in respect of dispensing fees are expected to be slightly higher in 1954-5 than in 1953-4. A small fall, on the other hand, is shown in the cost of ingredients. Perhaps Mr. Macleod is relying on achieving some savings by his appeal to doctors to prescribe from the *National Formulary* wherever possible. Figures given in Parliament a few weeks ago show that in the first half of last year the average cost of each prescription was 49.15d. This is over a shilling more than in 1949. Even when allowance has been made for the development of expensive antibiotics since then, there would appear to be room for economies without interfering with the doctor's freedom to prescribe what he thinks best for his patient.

The total net cost of the Health Service to the taxpayer is expected to rise by some £16m. in the new financial year. Most of this rise can be attributed to higher advances to hospital boards; the estimate for these advances allows for increases in wages and salaries. An extra £4m. is also to be allowed to these boards for capital expenditure. This increase is welcome in itself. Even so, much larger sums will have to be spent on improving the hospitals' accommodation—particularly that of the mental hospitals—before anyone can accuse them of extravagance in this respect.

In the other branches of the Health Service, it is worth noting that the initial check to dental treatment caused by the charges is evidently wearing away to some extent, and there is a rise of nearly £2m. in the estimate. A somewhat similar trend can be observed in the supplementary ophthalmic service. But the whole cost of the Health Service is so dominated by the hospitals, whose advances on capital and revenue account combined now exceed £300m. a year for the first time, that increases elsewhere seem small beer indeed.

To sum up, and apart from long-term factors such as the ageing of the population, the Health Service's finances appear to have achieved some sort of stability. But this has been secured only at the cost of deferring many worth-while schemes and in particular of postponing much hospital building which will have to be undertaken some time. The fixed limit of £400m. a year as the amount the taxpayer would have to find for the Health Service has been abandoned. Instead a sharp brake has been imposed, which is released only when the pressure on it is too heavy to be withstood. Unfortunately, the result precludes any form of planning—of expanding here and contracting there—which is essential for a wise administration of the hospitals. It is probable that, without any increase in the amount voted, the money could be spent to better advantage if there were less control at the centre and more independence elsewhere.

LOCAL HYDROCORTISONE

The recognition that cortisone, or hydrocortisone, which is the adrenal steroid occurring in the body, produces many of its effects through an anti-inflammatory mechanism^{1,2} rather than by any fundamental influence on underlying disease processes has led to some change of approach to the use of these drugs. Much attention has been directed to their value in chronic inflammatory joint disorders of the rheumatic type, partly no doubt as a result of the original discovery of their effects in rheumatoid arthritis. Further experience of their use in the management of this disease has shown that the prolonged systemic administration of cortisone is not always entirely satisfactory in controlling symptoms,^{3,4} and, although hydrocortisone may be more active^{5,6} when given systemically, there is little doubt that it is apt to be similarly unsatisfactory. There is evidence that the source of the pain of arthritis is in the joint capsule, and perhaps to a lesser extent in the synovium,⁷ and, since systemic administration of these hormones diminishes joint temperature and blood flow,^{8,9} it was logical to study the effect of local injection into the joint space. As expected, it was found that both reduced the amount of joint fluid, lowered the cell count, especially of polymorphonuclears, and increased the viscosity.^{10,11} These changes are accompanied by temporary clinical improvement which cannot be attributed to any general systemic effect, even though the rate of absorption from the joint is at much the same rate as from intramuscular injection. workers are agreed that cortisone has a less reliable and constant effect than hydrocortisone when given intra-articularly,^{11,12} although Fearnley¹³ believes that this is simply a reflection of different effective therapeutic doses, twice as much cortisone being required to produce a comparable effect.

Hollander and his colleagues¹⁴ have found that intra-articular injection is a relatively simple procedure and suitable as an ordinary out-patient manoeuvre; not only the knee but most other joints except those of the spine are accessible, the hip being the most difficult. They have now been able to report their clinical results after nearly 4,000 such injections in over 500 patients suffering from various types of rheumatic condition, using a dosage of 25 mg. of hydrocortisone for the larger joints (occasionally increased to 50 mg.) and of 5 mg. for the small joints.¹⁵ In rheumatoid arthritis they found that such treatment gave continued local palliation with repeated injections as often as symptoms returned—every one to four weeks—in 90% of the cases selected. The use of hydrocortisone in this way is, as they emphasize, only an adjunct to the general management of the patient. Selection of patients was restricted to those in whom one, or very few, joints were affected, or predominantly affected and resistant to other treatment. Although the effect of systemic cortisone has been almost uniformly disappointing in osteoarthritis, local injection may be more helpful, for 20% of their cases had no return of symptoms after a series of injections, some 6% having been followed for more than one year. This response is not necessarily so inexplicable as it may seem at first, for Trueta and his colleagues¹⁶ and Lloyd-Roberts¹⁷ have recently thrown light on the pathology of osteoarthritis. Both have shown that hyperaemia either in the juxta-chondral bone or in the synovium and capsule is an important feature of this type of arthritis, and the suggestion of Trueta that compression of cartilage by use is necessary for its healthy nutrition might give such therapy a theoretical basis and open the way to a new and more active therapeutic approach to the problem of degenerative joint disease.

As might be expected, the more transient, self-limiting articular and non-articular inflammatory conditions showed a good response. Thus acute gouty and traumatic arthritis often responded well to a single injection. The results of Hollander and his colleagues in non-articular conditions were similar to those which Cyriax reported recently in this *Journal*.¹⁸ Acute sub-deltoid or pre-patellar bursitis responded well; the results in tennis elbow and stenosing tenosynovitis were encouraging also, but in chronic sub-deltoid bursitis they were disappointing. Untoward effects were rare and were usually mild, occurring at the rate of 2.3% of injections. Most of them were temporary local flares, but acute staphylococcal joint infection occurred in one case. They also record that one case of tuberculous arthritis was injected as a result of faulty diagnosis. It is clear that the presence of infection is an absolute contraindication to this form of therapy. In view of these very encouraging reports it is unfortunate that supplies of hydrocortisone are so scarce in Britain, but it is to be hoped that sufficient will

be made available to allow for controlled therapeutic trials to investigate further its place in the local therapy of these various rheumatic conditions.

SYNTHETIC ATROPINE

In spite of the enormous output of synthetic drugs in recent years there are still many indispensable drugs of plant origin which cannot be produced synthetically at an economic price and for which no entirely satisfactory synthetic substitute has been found. Until recently atropine belonged to this group. No doubt in Britain we could cultivate *Atropa belladonna*, or other plants containing atropine, on a sufficient scale to supply our needs, but we have normally relied upon other countries, in which atropine-containing plants grow wild, for this essential alkaloid. During the last war a serious effort was made to find a synthetic substitute for atropine, because at the time it was thought, and probably quite rightly, that the synthesis of atropine itself was not a practical proposition. Atropine was first synthesized in 1896 by Willstätter, but his synthesis involved fourteen stages and was obviously not one which could be adapted to manufacturing processes. In 1917 Sir Robert Robinson¹ devised a new synthesis which reduced the number of chemical processes to three, but one of his starting materials (namely, succindialdehyde) was at the time economically inaccessible. It is therefore of great interest that T. and H. Smith, Ltd., of Edinburgh, have taken advantage of new methods of obtaining succindialdehyde from furan and have developed a process for manufacturing atropine based on the Robinson synthesis.

Whether synthetic atropine will be able to compete economically with the natural alkaloid is not for the scientist to say. Synthetic ephedrine has not entirely replaced the natural drug, probably because the plants containing this alkaloid grow wild and in great abundance in many parts of Asia and can be collected and extracted cheaply; but this situation will not last indefinitely. The probability is that synthetic drugs will ultimately replace drugs of plant origin.

Atropine is an ester of tropic acid and a bicyclic basic alcohol, tropine. Pyman and his colleagues^{2,3} investigated the mydriatic effects of numerous esters of tropine, applied locally to the eyes of cats, but no systematic pharmacological study of the esters of tropine has ever been made, probably because the only source of tropine was the expensive natural alkaloid, atropine. A commercial source of tropine will make possible a thorough reinvestigation of many new esters and other derivatives of this substance, which appears to have a peculiar affinity for many types of tissues in animals. Consequently the achievement of a manufacturing process for tropine and its derivatives is an important advance: it may make this country independent of foreign sources of an essential drug, and it may also lead to the development of new drugs of value in medicine.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

THE ASSESSMENT OF GONADAL FUNCTION

BY

G. I. M. SWYER, D.M., D.Phil., M.R.C.P.

Consultant Endocrinologist to the Obstetric Department, University College Hospital, London, W.C.1

In both sexes the gonads serve two functions: the secretion of the sex hormones and the production of germ cells. These two functions are not entirely independent. Assessment of endocrine function can be made by purely clinical means and by special investigation. The gametogenic function can be studied by special tests alone.

Normal Development

The endocrine activities of the gonads can be considered in four phases: pre-pubertal, at puberty, in the adult, and after the close of the reproductive period.

Before puberty the gonads are physiologically functionless, not apparently through any intrinsic incompetence but because they receive no gonadotrophic stimulation. It is obvious, therefore, that before puberty a diagnosis of hypogonadism is meaningless. At a variable age, usually falling within the range 10-16 years, and for reasons which are quite unknown, the anterior lobe of the pituitary gland begins to secrete effective amounts of gonadotrophic hormone, which stimulates the gonads. Under this influence they secrete their respective sex hormones, which, acting upon their various target organs, bring about the changes of puberty. In the male the interstitial cells of Leydig secrete testosterone; and at the same time the hitherto inert germinal epithelium of the seminiferous tubules begins to proliferate and to differentiate into spermatozoa. Thus, in the male, endocrine and gametogenic functions begin at the same time.

In the female events are rather different. It appears that oogenesis—the production of potential ova—is a wholly foetal phenomenon, so that the newborn female infant possesses preformed all her potential germ cells—perhaps some 400,000. A large proportion of these disappear through atresia before puberty is reached. Thereafter, again the majority are destined to undergo atresia and no more than some 400 are ever likely to become mature ova. At puberty in the female gonadotrophic stimulation leads to the development of Graafian follicles which secrete oestrogen. It is probable that during the first year or two of post-menarchal life no ovulation usually occurs. During this phase menstrual periods are the result simply of cyclically waning oestrogen levels. Eventually, however, one of the maturing follicles becomes predominant, outstrips the rest, and from it the ovum is extruded. Immediately following this event the corpus luteum is formed and secretes progesterone as well as oestrogen. If the ovum is not fertilized and does not become embedded within the endometrium, the corpus luteum begins to degenerate and the levels of ovarian hormones fall. Following this, menstruation takes place and the cyclic changes recommence.

In the male the reproductive phase usually has no clear ending. The testis may continue to produce its hormones and spermatozoa, though on a gradually waning scale, right into old age. For this reason the "male climacteric" does not usually exist or have any outward manifestation. Occasionally, however, testicular function may decrease more abruptly, with the production of climacteric symptoms—such as loss of energy, fatigability, impaired memory and powers of concentration, reduced libido and potency, hot flushes, and so on. These symptoms can be relieved by the administration of testosterone.

In the female the Graafian follicles are used up as described above. When no more remain the ovary ceases to

produce effective amounts of oestrogen. For some time before this final stage is reached the endocrine function of the ovary becomes inadequate to maintain regular menstruation. At the menopause all menstruation ceases. Because the pituitary is no longer subjected to the inhibiting influence of oestrogen, it produces excessive amounts of gonadotrophin, which may be detected in the urine. Other endocrine glands—thyroid and adrenal cortex—tend to become hyperfunctional and so to cause the climacteric symptoms, until a new balance is eventually re-established.

Hypogonadism

Hypogonadism in both sexes may be either *primary* or *secondary*. In the former the gonad itself is the defective organ, failing to respond to gonadotrophic stimulation. In the latter there is failure of gonadotrophin production by the pituitary. It may be possible to differentiate these two types clinically. A clear-cut syndrome—Turner's syndrome—of primary hypogonadism was first recognized in the case of the female, but male examples of the condition are now known to occur. In this there is an absence for all practical purposes of the gonad, and the individual remains stunted in growth, often with a typical squat appearance, and a number of congenital anomalies usually coexist. Outstanding among these are webbing of the neck and cubitus valgus; others include coarctation of the aorta of varying degrees, supernumerary digits, squints, etc. Some elevation of blood pressure is almost invariable. Complete failure of the secondary sex characters occurs.

The key laboratory finding is an increased excretion of gonadotrophic hormone in the urine. This is due to the fact that the sex hormones normally produced by the gonads exert an inhibiting action on the pituitary production of gonadotrophin so that in their absence the pituitary becomes hyperactive. In secondary hypogonadism the characteristic appearance noted above is not found. The individual remains more or less infantilistic and may be either tall or short. Examination of the urine fails to reveal the presence of pituitary gonadotrophin. In these individuals, therefore, the fault lies in the production of gonadotrophin by the pituitary, the gonads themselves being essentially normal, though remaining unstimulated.

Androgen Production

In the male the determination of androgen production by the testis would theoretically be the logical method of obtaining an objective assessment of gonadal function. Androgen assay, however, is not a practical procedure for clinical purposes. It can be done by preparing suitable urinary extracts and testing them for their ability to induce growth of the capon's comb when applied direct to it. A more practical method is to estimate the 17-ketosteroid excretion, which can be done by purely chemical means. The 17-ketosteroids—so-called because they possess a ketone group on the 17 carbon atom of the steroid nucleus—are among the metabolites of testosterone. The position is complicated, however, by the fact that the adrenal cortex also produces androgens, some of which are metabolized to form 17-ketosteroids. It is therefore clear that, even in the absence of testicular testosterone, 17-ketosteroids will be present in the urine. Indeed, they may be produced by normal women in amounts not very different from those produced by normal men.

The mean figures for children of both sexes rise from the order of 1 mg. per 24 hours to 5 mg. before puberty. From then on the mean increases more rapidly for males than for females, reaching 14 mg. for adult males and about 9.5 mg. for adult females. The ranges for adults show considerable overlap in the two sexes, being 8-32 mg. for males and 5-20 mg. for females. In old age the mean figure again falls off with increasing years. It is thus quite obvious that the interpretation of the significance of the 17-ketosteroid excretion is none too easy, and the test has only a limited value in the assessment of male gonadal function. Of distinct value in some instances is the study of testicular biopsies. These are not difficult to carry out as a purely out-patient procedure under local analgesia, cause no undue discomfort and no loss of time from work, and enable one to assess the status of the Leydig cells, which are the source of the male hormone.

Oestrogen Production

In the female the simplest and one of the most useful objective tests of gonadal endocrine function is the study of the vaginal smear. This is obtained by inserting a cotton-wool applicator into the vagina, twirling it round a few times, and then rubbing it on a clean microscope slide. To obtain the best results this should be fixed immediately by immersion in equal parts of absolute alcohol and ether, and then stained with haematoxylin and a suitable differentiating stain such as Shorr's. In the absence of oestrogenic stimulation, the vaginal smear consists almost exclusively of small rounded basal cells with relatively large vesicular nuclei, and frequently contains many leucocytes. The fully oestrogenized smear consists of large squames which may have curled-over edges and contain either small densely staining pyknotic nuclei or larger vesicular nuclei (late intermediate cells). Intermediate grades may contain varying proportions of these different types of cell (Fig. 1). One

FIG. 1.—The principal types of epithelial cell found in vaginal smears: (a) basal; (b) primitive; (c) late intermediate; (d) fully cornified, with pyknotic nucleus.

drawback to this method of oestrogen assessment is that the vaginal epithelium is very sensitive to oestrogens, so that a very significantly reduced level must exist before it becomes apparent from the vaginal smear.

Another wholly practical method of oestrogen assessment is by the histological study of the endometrial biopsy specimen. This is easily obtained without an anaesthetic in the adult woman, though in girls and young unmarried women the position is, of course, less simple. An atrophic endometrium denotes either deficient oestrogen production or failure of endometrial response. Which of these alternatives is correct can be decided by studying the response to oestrogenic treatment; if, after an adequate course, the endometrium is still atrophic, a failure of target organ response may be concluded. A hyperplastic proliferative endometrium suggests a high oestrogen level but does not prove it, since the same conditions can result from prolonged though moderate oestrogenic stimulation. Under the influence of progesterone the proliferative oestrogenic endometrium becomes converted into a secretory type. Inadequacy of secretory development in the endometrium obtained during the latter part of the menstrual cycle suggests deficient production of progesterone. Once again, however, this result can arise through failure of endometrial response and can be tested for in the same manner as described above.

The assessment of oestrogen production by the determination of oestrogen excretion or levels in the blood is not yet a procedure of clinical value. In the case of progesterone, however, the estimation of urinary pregnanediol excretion is a not too difficult laboratory procedure and sometimes has practical value. Nevertheless, in normal menstrual cycles the variability of pregnanediol excretion is considerable, so that it is necessary to make several determinations on 24-hour urine collections during the supposed luteal phase in order that useful information may be obtained. It should further be pointed out that accurate methods capable of dealing with small quantities of pregnanediol must be used, since the output may be very small. Less accurate methods, which may have their value during pregnancy, are useless in the non-pregnant state. It is generally believed that the level of pregnanediol excretion reflects the level of production of progesterone by the corpus luteum, but there is no certainty that the parallelism is at all exact.

Gonadotrophin Assay

Mention has already been made of gonadotrophin estimation in both sexes and its value in differentiating primary from secondary hypogonadism. A few words about this estimation may therefore be appropriate. The test is usually referred to as the assay of follicle-stimulating hormone (F.S.H.), since F.S.H. probably is the main gonadotrophin found in non-pregnant urine. There is no doubt, however, that in some circumstances the urinary gonadotrophins include luteinizing hormone (L.H.), so that the test is perhaps better referred to simply as "gonadotrophin assay." The test requires a 24-hour specimen of urine, which should be kept chilled (preferably on ice) during the collection and should be delivered to the laboratory as soon as collection is complete. The urine is subjected to one of a variety of extraction procedures which aims at recovering the total protein content.

The methods which are in use include alcohol precipitation, ultrafiltration, and kaolin adsorption; of these the last is perhaps the most satisfactory technique. The extract is made up into a small volume with saline or distilled water, and groups of immature female mice are injected with fractions at various dilutions. At the end of the injection period (usually four days) the mice are killed, the uteri are removed, dissected free from other tissues, blotted dry, and weighed. Different laboratories have their different "mouse units"; the most commonly used definition is that quantity of gonadotrophin which will cause an increase of 100% in the mean weight of the uterus as compared with that of the controls. It must be emphasized that this assay is a relatively crude affair and that only large differences in gonadotrophin content can be detected. Generally speaking, it is impossible to say that the gonadotrophin excretion is definitely less than normal; at most one can say that the excretion is within the normal range or definitely increased, but this information is usually all that is required.

Semen Analysis and Testicular Biopsy

In the assessment of gametogenic function in the male the key test is the seminal analysis. To be of value the seminal specimen for this purpose should be collected by masturbation after a period of abstinence of three to five days (which should be stated). The specimen jar should be clean, dry, and warmed to something approaching body temperature. The time of production of the seminal specimen should be known. For religious or moral reasons, some men may find themselves unable to comply with these instructions; for them there is no really satisfactory alternative. It cannot be too strongly emphasized that condom specimens are utterly valueless; the presence of various chemicals in the sheath leads to the rapid immobilization of spermatozoa and often to their clumping, so that when examined the spermatozoa are invariably all dead and sperm counts are usually grossly misleading. The production of

seminal fluid by coitus interruptus again usually leads to gross errors, since the ejaculate as produced is not homogeneous and variable losses always occur when this method is attempted. If masturbation cannot be found acceptable, the only reasonable alternative is examination of the wife's cervical mucus some time after intercourse—the test being arranged during the ovular phase of the cycle. Such a test will at least determine whether active spermatozoa are being produced in reasonable numbers or not, though more precise information cannot of course be obtained.

The report on the seminal fluid should note its volume and appearance, the sperm density in millions per millilitre, the proportion of morphologically abnormal spermatozoa, and should give an estimate of the activity and viability of the spermatozoa.

The mean volume of semen is about 3.5 ml.; a volume of less than 1.5 ml. may be of serious consequence, since the interface between semen and cervical mucus after ejaculation within the vagina may be so small as to permit few spermatozoa to penetrate the mucus. On the other hand, if the volume is very large, a normal total number of spermatozoa may be so diluted that again relatively few are able to reach the cervical mucus.

Opinions vary on the lower level of sperm density compatible with normal fertility. Recent accurate studies have tended to lower this figure as compared with former views. It is probable that, provided other features of the seminal fluid are adequate, a density of more than 20,000,000 per ml. is quite satisfactory.

Density aside, it seems that the activity and viability of the spermatozoa are the most important criteria for evaluating fertility. Unfortunately, methods for the accurate determination of these criteria still leave a good deal to be desired. They also vary in different laboratories, so that it is difficult to compare the reports from the various centres. It is fair to conclude that highly fertile seminal fluid contains more than 40% of actively motile spermatozoa which retain their motility for periods in excess of 12 hours *in vitro*.

Although a great deal of attention has been paid to morphological abnormalities, it is doubtful whether most of these studies are really justified. In general, provided the proportion of total abnormal forms does not exceed 40%, the morphology of the spermatozoa is of much less importance than their activity.

Testicular biopsy has already been mentioned. Its value in the assessment of gametogenic function is twofold. In the first place, in cases of azoospermia testicular biopsy enables one to decide whether this is the result of failure of sperm production or failure of sperm delivery through obstruction of the efferent ducts. In the former circumstance the biopsy would reveal absence of spermatogenesis and in the latter a normal testicular structure. In the second place, the biopsy is of prognostic value where the seminal fluid is grossly inadequate, since a study of the histology of the testis may enable one to decide whether treatment has a chance of effecting improvement or could not possibly be of value. It is a fact that in most cases of oligospermia the biopsy reveals severe disorganization of the germinal epithelium in most tubules, while the other tubules are unaffected; clearly in these cases the stimulus to the testis must be normal and its modification by treatment cannot hope to produce any tangible results.

Tests for Ovulation

The direct study of ova is unfortunately not a practical procedure; we are, for example, quite unable to say whether the ova are morphologically normal or not, even though ovulation appears to be taking place. Our assessment of the occurrence of ovulation or its failure has to be made on deductive grounds. The principal methods in use for the determination of the occurrence of ovulation are: basal body temperature records, endometrial biopsy studies, and vaginal smear examinations.

Basal Body Temperatures.—If the temperature is carefully taken every morning as soon as the patient wakes up, and before any activities are undertaken, characteristic changes are found in ovular cycles. It is of little consequence whether the temperature is taken orally or rectally; provided the thermometer is left in place for three to five minutes and the mouth is kept closed, oral temperatures are normally quite satisfactory. Generally speaking, the temperature runs at a mean value of about 97.4° F. (36.3° C.) during the first half of the cycle, then it rises and thereafter runs at a level of approximately 98.2° F. (36.8° C.) until shortly before the period begins. It then falls to its previous level and the changes are repeated in the following cycle. In this way a biphasic pattern is produced, and this pattern is characteristic of ovulation (Fig. 2). The temperature rise during the latter half of the cycle has been shown to be due to the action of progesterone. It follows therefore that such a pattern could occur even in the absence of ovulation, provided a corpus luteum were formed. Indeed, this happens occasionally.

FIG. 2.—Basal temperature records. The black shapes represent menstrual bleeding. (a) The biphasic record of regular ovular cycles. (b) An anovular cycle, with no rise of temperature (monophasic) and relatively scanty period, between two ovular cycles. (c) Irregular ovular cycles; the intervals from the start of the periods to the arrows marking the occurrences of ovulation are inconsistent, but the post-ovular intervals are of more uniform duration. (d) The temperature rises slowly in the post-ovular phase in this record. (e) The temperature falls slowly from the post-ovular plateau. (f) A combination of (d) and (e), so that little more than a mid-cycle depression remains to represent the biphasic pattern. (g) Here conception has occurred and the post-ovular plateau persists. (h) In this case delayed ovulation, not conception, accounts for the non-appearance of the period.

the ovum being trapped within the follicle instead of being extruded. Nevertheless, trapped ovum is probably so rare a phenomenon that it is safe to say that regular biphasic basal temperatures reflect regular ovulation. It cannot be too strongly emphasized that the temperature record merely indicates that ovulation has occurred. It does not indicate with any certainty when ovulation occurs and it certainly cannot predict when ovulation is going to occur. Consequently, the advice sometimes given to women wishing to conceive—to time intercourse in accordance with their temperature record—is likely merely to perpetuate their infertility, since, once ovulation has occurred, intercourse can no longer lead to the fertilization of that particular ovum. If ovulation is not taking place the biphasic pattern described above does not appear, the temperature running a more or less uniform course. When the cycles are irregular but nevertheless ovular, the temperature pattern reveals that it is the pre-ovular rather than the post-ovular phase of the cycle which is variable. If the period is overdue the basal temperature record may indicate whether the delay is due to conception or to delay in ovulation. In the former circumstance a normal pre-ovular phase followed by a prolonged post-ovular plateau will be found; if the plateau exceeds three weeks the existence of pregnancy is almost certain. In the latter case either the post-ovular rise will be missing or it will have followed a prolonged pre-ovular interval.

Endometrial Biopsy.—An endometrial biopsy taken shortly before a period is expected will reveal a secretory pattern in an ovular cycle. Such a result indicates the existence of a functional corpus luteum, from which the conclusion that ovulation has occurred is usually justifiable. If the periods are irregular it is best to take the biopsy on the first day of bleeding; if the bleeding is taking place from a proliferative type of endometrium an anovular cycle may be inferred.

Vaginal Smear.—If daily vaginal smears are followed characteristic changes occur at and after the time of ovulation, from which it is possible to infer that this event has occurred. It must be emphasized, however, that daily smears are necessary for such a study. The method is thus of limited value and can be applied only to patients in hospital, or to those who can be instructed to take and prepare their own vaginal smears.

The detection of pregnanediol in the urine during the latter half of the cycle has sometimes been advocated as a test for the occurrence of ovulation. Clearly, it is in general of less practical value than temperature records or endometrial biopsies.

Observations on changes in the cervical mucus have also been advocated for the detection of the occurrence of ovulation. Their limited usefulness does not warrant further elaboration.

Next article on Clinical Pathology.—"Liver-function Tests," by Professor N. F. MacLagan.

The Wellcome Foundation, Limited, has increased its authorized capital from £1m. to £3m. The issued capital has been increased to the same amount. At the time of his death in 1936 Sir Henry Wellcome owned all the shares in the Wellcome Foundation, Limited. By the terms of his will he established the Wellcome Trust, a public charity administered by five trustees to whom all the shares were bequeathed. The objects of the Trust are the furtherance of research work bearing upon medicine, surgery, and allied sciences, and the entire declared dividends of the company are at the disposal of the trustees. The Wellcome Foundation, Limited, trades under the name of Burroughs Wellcome and Co., and the capital increase will bring the issued capital more into line with the capital actually employed in the business. It foreshadows a large programme of expansion starting with a new £350,000 pharmaceutical manufacturing unit at the Wellcome Chemical Works, Dartford, on which work has already started.

Reports of Societies

THE CLINICAL ASPECTS OF IMMUNITY

A symposium on the "Clinical Aspects of Immunity" was held on March 23 at the Royal Society of Medicine, under the chairmanship of the president of the Section of Medicine, Sir HENRY COHEN. The opening speaker, Professor A. A. MILES (Lister Institute), emphasized that specific immunity usually meant antibody immunity. The two factors to be considered were the capacity of the host to produce protective antibody, and the ability of the bacterial antigens to induce antibody formation. Bacteria contained many antigens, only a few of which were capable of inducing protective antibodies. The body did not discriminate, and was as likely to make an irrelevant response to the antigens of an invading organism as it was to produce a protective antibody.

It was difficult to separate relevant from irrelevant antigens for the production of vaccines, and to assess the results of immunization. The ideal test of a vaccine was a controlled clinical trial in a susceptible community, but this had rarely been made. Vaccine had therefore to be devised largely on the basis of laboratory evidence, which was valuable but required careful interpretation.

In diseases like diphtheria, immunity was very largely antitoxic; but in invasive diseases such as cholera, enteric fever, and whooping-cough the role of toxins was less certain. Resistance to endotoxins did not always confer protection against infection by the living organism. Endotoxins were often also surface antigens; in cases where antitoxic antibodies had been shown to be protective the reason was probably that they were acting as opsonins, not as antitoxins.

The search for relevant immunizing antigens had been outstandingly successful in the pneumococci. When virulent pneumococci lost their capsule they lost virulence, became useless as vaccines and susceptible to phagocytosis. Anti-capsular antibody was protective against infection and was clearly an opsonin. Another example of a non-toxic surface antigen largely determining protective immunity was the M-protein of *S. pyogenes*. Although *H. pertussis* possessed several surface antigens, none had been conclusively proved by laboratory methods to be protective. The effective antigen had not yet been demonstrated by *in vitro* reactions.

In addition to toxins and surface antigens determining resistance to the host's defences, bacteria might possess antigenic substances that appear to be auxiliary pathogenic factors. These should not be accepted as important for artificial immunization unless there was evidence, not only that they were associated with the virulent form of the organism and had an observable effect on the host in conditions resembling those of natural infection, but that they were capable of inducing protective antibodies. For example, streptococcal hyaluronidase and fibrinolysin could not be implicated, because they did not immunize against streptococcal infection.

Antibody Formation in Virus Diseases

Professor A. W. DOWNIE (Liverpool University) spoke on the relation of antibody formation to the course of virus diseases. Not all viruses were good immunizing agents. Acute generalized diseases with viraemia such as measles and smallpox often gave lifelong immunity with high titres of circulating antibody. Localized surface infections such as influenza and the common cold gave poorly maintained immunity. Lymphogranuloma and psittacosis viruses were poor immunizing agents. Relapse was common, and the complement-fixing antibodies produced had little relation to protection.

The relation of antibody formation to the course of the virus infection could best be considered in the acute

generalized diseases. In smallpox infection in the unvaccinated, neutralizing antibodies appeared after the fifth day of illness, but most deaths occurred in the second week. This apparent paradox could be resolved by considering the course of the disease. Generalized spread of the virus occurred in the first few days. The virus quickly became intracellular and was then protected from the antibody which developed subsequently. The role of the antibody could only be to limit further spread. Necrosis of cells already parasitized could still go on. The patient's chance of recovery depended very largely on the original severity of the infection, which would not be influenced by antibody, if this appeared late. The duration and degree of viraemia were less in patients who subsequently recovered than in those who died.

After vaccination, antibody might be found for many years though individual variation was great. Exposure to infection was more likely to cause clinical disease in those whose antibody titre waned soonest, but even in these cases there remained an enhanced capacity to respond to the antigenic stimulus. Antibody was produced early and to higher titres than in the unvaccinated, and generalization of the disease was more rapidly checked. To prevent smallpox, antibody should be present in adequate amounts before the incubation period was over.

In poliomyelitis the virus was found in faeces and in the throat, and, in monkeys infected by feeding, could often be isolated from the central nervous system before paralysis appeared. Antibody, however, did not begin to appear until just before the paralytic phase. As in smallpox, efficient immunity required the presence of antibody in the serum before the end of the incubation period. This could be achieved by active immunization before exposure, or on occasion by passive immunization with immune sera in the first few days of the infection—that is, early in the incubation period.

Immunity to Protozoal Diseases

Professor B. G. MAEGRAITH (Liverpool School of Tropical Medicine) discussed immunity to protozoal disease with special reference to so-called "natural" resistance to infection. Protection in the absence of previous infection was not always as "natural" as it might appear, but often depended largely on a chance relationship of host and parasite. For example, infants in the first few months of life in endemic malarial districts often showed few signs of the clinical disease. This apparent resistance to the parasite was said to be associated with transferred maternal antibodies, but it had recently been demonstrated that it might be in fact related to their breast-milk diet.

Adventitious circumstances could also affect the acceptance or otherwise of *E. histolytica* by the host. For instance, the parasite readily established itself in the large intestine of the host, where the physico-chemical environment was suitable, but invasion could easily be restricted by changing this environment by varying the diet of the host. Invasion of the intestinal wall by *E. histolytica* depended on many things besides the establishment of the parasite in the gut lumen. The chance of contact with the epithelium and the length of that contact were important, for example. The presence of an inhibitor of the proteolytic enzymes of the parasite was sometimes decisive. Moreover, the host possessed a kind of negative resistance in that the conditions in its tissues were unfavourable for the parasite's development and the latter could apparently not easily adjust conditions to suit itself. Changes in the host tissues might lead to establishment and multiplication of the parasite. Induced hypersensitivity might be important in this respect, as shown in the development of amoebic liver abscesses after intraperitoneal injection of parasites in guinea-pigs with "chronic" gut infections or "sensitized" to amoebic antigen.

It was probable that when an animal was sensitized to amoebic products the presence of metastatic amoebae in the liver caused a reaction which led to profound local

circulatory changes resulting in the creation of conditions suitable for growth and multiplication of the parasite.

Acquired resistance was demonstrable in many parasitic infections, including vivax malaria. In this infection the resistance was specific for the species, and there was little overlap, even with other strains of the same parasite. It was reasonable clinical practice to separate patients with vivax malaria into those likely to have resistance and those unlikely to have any. Patients with previous exposure to infection, especially after repeated reinfection, developed a strong resistance to the clinical manifestations of the disease. A single dose of a good schizonticidal drug would in these patients usually abort an attack. In the case of a resident in an endemic malarial area this was all that was required. Eradication of the disease in such individuals might eventually lead to loss of valuable acquired resistance. In the case of an infected person taking up permanent residence in this country, however, eradication of the disease was desirable. Treatment comprised the use of a powerful schizonticide and of an 8-amino quinoline.

Antibiotic Therapy and Resistance

The discussion was opened by Professor R. CRICKSHANK, who stressed the effect of chemotherapy on immune responses. In scarlet fever administration of antibiotics limited the production of streptococcal antibodies, and while this increased the risk of recurrences it was also paradoxically associated with a decreased incidence of rheumatic fever following streptococcal infection. In long-continued fevers such as typhoid fever immunity developed relatively slowly. Interference with the natural course of the disease by antibiotics greatly reduced the degree of immunity attained, as was shown by the sharp rise in relapse rates in enteric fever following the introduction of antibiotic therapy. A solution to this problem might be to combine antibiotic therapy with immunization with an efficient vaccine. In enteric fever, however, vaccines gave relatively incomplete protection, and there was a need to define the antigenic fractions required for immunization.

Dr. D. McCLEAN emphasized the importance of early passive immunization in virus diseases after exposure to infection. He advocated the collection of blood after vaccination or from convalescents in order to prepare the appropriate immune globulins for use in those infections in which they were shown to be effective. These preparations should not be unduly expensive if fractionation was on a large scale, since the blood would be given free; immune globulin did not, apparently, transmit hepatitis. The most useful vaccines in infections caused by intracellular parasites, such as contagious abortion of cattle, tuberculosis, smallpox, and yellow fever, were living vaccines.

Dr. A. FELIX, F.R.S., confirmed the rising incidence of relapse and reinfection in enteric fever since the introduction of chloramphenicol. The rapid curtailment of the acute disease was achieved only at the expense of protection against future risk. The secondary infection was often due to a strain of a phage type different from that which caused the primary infection, and this had led workers in this country and abroad to draw the erroneous conclusion that these strains differed in their antigenic composition. However, there was no evidence of antigenic differences in the infecting strains when recurrences occurred.

Other points raised in the discussion were the complexity of immunological responses in helminth infections; the possibility that not all antibody may be equally efficient in neutralizing the effect of antigens, and that antibody produced years after immunization may be less potent than antibody produced earlier in protecting against disease. The age at which the antibody-forming mechanism became mature and capable of responding to antigenic stimuli in infants was also discussed.

Correspondence

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

The Sickle-cell Trait and Sickle-cell Anaemia

SIR,—Much of the literature on the sickle-cell trait and sickle-cell anaemia is contradictory and confusing. With reference to the recent letters published in your columns and the interesting paper by Dr. A. C. Allison (*Journal*, February 6, p. 290) suggesting that the possession of the trait endows the fortunate bearer with a positive survival value in a hyperendemic malarial area, may I be permitted to add to the literary confusion?

The theory of the positive survival value of the trait was evolved to explain the varying and often high incidence of the dominant sickling gene which in the heterozygous state is considered to be innocuous and in the homozygous state lethal. Allison has assumed that the homozygous theory of the inheritance of sickle-cell anaemia is correct in East Africa. I do not know if this assumption is justified. The majority of the literature from East Africa, apart from a rather neglected paper by Trowell¹ and a not entirely convincing paper by Foy *et al.*,² emphasizes the rarity of sickle-cell anaemia. Indeed it was stated in *Colonial Research*³ that the condition which has been described as sickle-cell anaemia could be recognized in Uganda as being malarial anaemia in persons with the sickle-cell trait. I have also been led to believe that cases of sickle-cell anaemia are rarely seen in necropsy material in this part of Africa. However, if it is accepted that the homozygous theory of the inheritance of sickle-cell anaemia is correct throughout Africa, the high incidence of the trait in certain parts of Africa is difficult to explain and Allison's conclusions may possibly have provided the answer. It is interesting to speculate that the expected malarial mortality in a population in a hyperendemic malarial area (in itself a controversial subject) might be calculated from the incidence of the sickle-cell trait in the population.

Malaria is considered to be hyperendemic in the Gold Coast; the incidence of the trait in the population of the Accra district is in the region of 18% and the homozygous theory of the inheritance of sickle-cell anaemia may well be correct.⁴ In 1949-50 in the Gold Coast I examined 527 children for the presence of the trait, and the blood was also examined for the presence of malarial parasites. Eighty-four exhibited the trait and malarial parasites were present in 30 (35.7%). Malarial parasites were present in 134 of the remaining 443 children (30.2%). Parasite densities were unfortunately not performed and only 200 children were of a strictly comparable group. In conjunction with Dr. M. J. Colbourne a further investigation was recently instituted and the results to date are shown in the following Table:

The Incidence of the Sickle-cell Trait and Malaria, Including Parasite Densities in 161 Children of Comparable Age Group and Social Class in Accra

	No.	Malarial Parasites	Average Parasite Density
Sickling positive	32	16 (50%)	500 c.mm.
" negative	129	77 (60%)	1,000 "

These results are as yet inconclusive and further work will require to be done. However, the general trend of the figures is in agreement with those of Allison, although it cannot be said as yet that the sickle-cell trait partially protects against malaria in the Gold Coast. There may of course be other explanations for the varying incidence of the trait and its persistence in various parts of the world. It must be remembered that sickle-cell anaemia may be a mild disease and improve with advancing years. One of my patients was a male African aged 40 years who had five children, all bearers of the trait, who were alive and well and showed no symptoms of sickle-cell anaemia. In addition, it is recognized that women suffering from sickle-cell

anaemia may still bear children although the mortality and morbidity in pregnancy may be high.⁵ The suggestion of Wells and Itano⁶ that there may be a quantitative as well as a qualitative inheritance of the trait is perhaps worthy of more consideration and further investigation.

One of the sickling children in the investigation discussed above, whose blood film was originally negative and was recorded as such, became ill while under observation and a peripheral blood film showed a density of 29,000 parasites per c.mm. This figure was not naturally recorded in those shown in the table and was the highest parasite density noted in the 161 children investigated. In addition, I have seen malarial pigment in the reticulo-endothelial system of children who have died from sickle-cell anaemia. Thus, although the bearer of the trait may possibly be partially protected against malaria, undoubtedly reasonably severe infestations occur. In addition it has been postulated that a malarial infection might precipitate a crisis in sickle-cell anaemia.⁴ This seems a reasonable hypothesis if the malarial parasite depends on oxygen for its survival, and is borne out by the history given by those suffering from sickle-cell anaemia. There is thus the possibility that malaria may be responsible for an increased death rate in sickle-cell anaemia. Lastly, to further complicate the picture, the "sickle-cell crisis" described by Reid⁷ and Edington⁸ is a common finding in our necropsy material, and may I say, albeit hesitantly, that I am not entirely convinced that this type of catastrophe may not occur in the heterozygous individual and that, in making this statement, I am not entirely unsupported in the literature?—I am, etc.,

Accra.

Neomycin in Pyogenic Skin Diseases

SIR,—The findings of Dr. R. E. Church (*Journal*, February 6, p. 314) have been further confirmed here in a recent series of 80 similar cases who have been investigated bacteriologically and treated by paired comparison—40 (series A) with 1% aureomycin in a P.M.F. base, and 40 (series N) with "nebacetin"—a preparation containing 5 mg. of neomycin and 250 units of bacitracin per g. of anhydrous ointment base. The numbers were limited by the amount of "nebacetin" available.

In the treatment of the superficial pyodermas, no significant difference was noted between the two groups. All of 30 cases of impetigo were cured within 18 days, the great majority in the first week. Twenty-six cases of infective eczematoid dermatitis were treated with only two unsatisfactory results in each series. One of these in series N showed sensitization, but whether to neomycin, bacitracin, or base could not be determined. In 14 cases of folliculitis barbae, only one failure was recorded in each group. In the treatment of sycosis barbae, however, a considerable difference in results was seen. Of 10 cases treated, the five in series N resulted in one cured, two temporarily improved, and two showing no response. Four of the five in series A were cured and remained so to a three-month follow-up—the other improved, relapsed, and later cleared with 3% terramycin ointment which recently has given comparable results in sycosis barbae to the aureomycin preparation.

The bacteriological results corresponded to Dr. Church's figures for the Sheffield area. *Staphylococci pyogenes* were isolated in all cases investigated and found to be resistant to penicillin in 49 cases (60%), to aureomycin and terramycin each in 8 (10%)—mainly the same patients—to chloramphenicol in 4 (5%), and to neomycin partially in one case only. This percentage of penicillin-resistant organisms has surprised colleagues not practising dermatology, but appears to be a general finding in other places.

The other figures correspond roughly to the proportionate use of these antibiotics to date, and it seems therefore not unreasonable to assume that penicillin resistance will slowly but surely be matched by resistance to the other antibiotics over the next decade and that patient-sensitization—so prevalent now with penicillin—may well follow a similar course.

If then the undoubted time-saving factor justifies the local use of these antibiotics at all, neomycin, which has no systemic use, should be the drug of first choice in the superficial pyoderms for as long as these other factors of low bacterial resistance and patient-sensitization remain. Preparations of aureomycin and terramycin which have wide systemic indications at present should now be discriminately restricted to stubborn cases and deeper seated lesions of the sycosis type. But impetigo and related conditions were not regarded with grave therapeutic alarm and despondency before antibiotics were added to our repertoire, and preparations such as lotio or pasta cupra-zincica and "lin. cal. with 2% ichthammol" still cure these conditions in reasonable time and will be both acceptable to the patients and to those concerned in pruning the nation's drug bill. The nebacetin was kindly supplied by Messrs. W. R. Warner and Co. Ltd., through Dr. D. D. H. Craig.—I am, etc.,

Aberdeen.

IAN W. CALDWELL.

Deep X-ray Therapy in Spondylitis

SIR,—The deep x-ray treatment for spondylitis, advocated by Drs. J. Sharp and E. C. Easson (*Journal*, March 13, p. 619), is very nicely shown by them to be effective and moderately safe, and the dosage of 150 r weekly for 10 weeks is, of course, less than that used in some other centres. I think, however, that no one should embark on such therapy without realizing the profound fall in the white cell count that results.

The diagram shows the lowest counts reached in a small sample of cases treated at 150 r weekly, and shows that a striking effect is still seen with a dose of 100 r weekly for 10 weeks. In a small uncontrolled series I have not found this fall in total white count, or the nausea and vomiting which also occurs, to be ameliorated by the injection intravenously of 200 mg. of mercaptamine immediately after treatment, but it is interesting that all of my subjects who were smokers were unable to smoke cigarettes for several days. If this suggestion is confirmed by further work it may be of use to would-be abstainers.—I am, etc.,

Manchester.

M. B. McVEDY.

SIR,—Drs. J. Sharp and E. C. Easson (*Journal*, March 13, p. 619) are to be congratulated upon their excellent results obtained with x-ray therapy in ankylosing spondylitis. We have learned to expect such good results well presented from the Christie Hospital and Holt Radium Institute.

Two points of practical importance referred to in their methods draw comment. The first is the praiseworthy use of dosage below that used in many clinics. I have used a dosage of 1,000 r (tissue) in one week to all the affected zones in sections from the sacro-iliac joints to the top of the cervical spine. The sacro-iliac regions are treated first in one week, next the lumbo-dorsal, 20 cm. in length, then the dorsal, again 20 cm., and lastly the cervical. The results are comparable with those of Dr. Easson. By thus dividing the tissue treated constitutional upset is avoided. The second is the treatment of sacro-iliac disease in the female. I believe I was one of the first to use glancing fields for this region and would like to give particulars of a case treated in 1945 with its effects on menstruation. The right and left sacro-iliac joints were treated with 1,000 r in one week. Ionization in the rectum showed that the patient had a maximum of 100 r from both treatments. Following this she had one excessive period followed by one month's amenorrhoea and then the periods were normal until 1950, when she complained of more pain in the midline of the back. She was given the same dosage again and, in addition, 500 r to a painful area in the midline through a field 6×4 cm. directed towards the head. Following this treatment she has had irregular periods, sometimes twice a month, sometimes five months' amenorrhoea.

The object of reporting this case is to show that x rays in small doses can affect menstruation and also that treatment can be repeated without producing permanent amenorrhoea. This patient's periods were perfectly normal and regular before radiotherapy, and commenced at the age of 16. I realize that this is only an isolated case and any conclusions are arguable, but it is very interesting.—I am, etc.,

London, W.1.

ANTHONY GREEN.

The Thyroid

SIR,—I have read your review (*Journal*, February 27, p. 503) of Mr. T. Levitt's *The Thyroid*; I have also made a careful study of the book itself. It seems to me that the reviewer did not fulfil his primary duty, which is to give a fair account of the general scope of the book. Though a reviewer's own interest may be limited, I think that he should always bear in mind the needs of the audience to which a book is addressed. Thus a surgeon would probably like to know that Mr. Levitt gives a detailed description of recommended operative procedures based on his own extensive experience. I found Mr. Levitt's account of the eye changes in exophthalmic goitre to be one of the fullest and most enlightening, and certainly the best illustrated, that I have ever come across and one which I am sure would interest many types of workers.

It seems to me regrettable that when a really important British monograph appears representing the fruit of much labour and reflection its scope should not be made abundantly clear and that the reviewer should instead take up your valuable space in discussing certain details on which his views are at variance with those of the author.—I am, etc.,

London, W.1.

SAMSON WRIGHT.

Rh Antibodies and Domiciliary Midwifery

SIR,—It is dangerous to draw conclusions from small numbers of cases of haemolytic disease of the newborn, for this disease can vary in severity from an infant so mildly affected as to require no treatment to one so severely affected as to be stillborn. We estimate that the infants of 100 Rh-negative women with antibodies fall into the following categories: Rh-negative and therefore not affected, 20; Rh-positive and therefore affected, 80 (stillborn 10, requiring treatment 42, not requiring treatment 28).

If simple transfusion is the treatment used, then as many as 13 deaths might be expected, whereas practically all could be avoided by the use of exchange transfusion. In our experience in the last two years, out of 52 affected babies born at home, 11 died; 8 were seen early enough

to be treated by exchange transfusion, but 3 of these died. We believe that 2 of these 3 infants would have survived had they been born in a hospital affording special facilities. During the same two years, out of 217 affected infants born in special hospitals, only 7 died, but in only 2 of these cases was death attributable solely to haemolytic disease of the newborn. Two were liveborn hydrops foetalis and therefore not viable, while the other 3 died from causes other than haemolytic disease.

The severity of this disease cannot be predicted accurately antenatally, and even a primipara may have a severely affected infant. It is probably true that only once in a lifetime will a family doctor be faced with a baby born *in extremis* and where exchange transfusion is urgently required. But to the family concerned that infant is supremely important, as witness this extract from a father's letter received by us in response to a postal follow-up of cases not delivered in special hospitals: "... I think the baby could have been saved and it was a great loss to my wife and I, after those months of planning and preparing. We would still like to have one, but we would rather wait until we have some guarantee that every effort would be made to keep the baby alive." It remains our conviction that hospital delivery should be offered to all immunized Rh-negative women.—We are, etc.,

SHEILAGH MURRAY.

WILLIAM WALKER.

Newcastle-upon-Tyne.

Primary B. coli Peritonitis

SIR,—I came across the following unusual case recently. It would be interesting to hear of any similar cases met with by your readers.

A girl aged 4½ years was admitted as an emergency at 11.15 p.m. with a history of abdominal pain since 4 p.m. The mother stated that she was perfectly well up to that time. There had been some nausea but no vomiting. On examination the child was toxic with circumoral pallor, cold extremities, axillary temperature 103° F. (39.4° C.), and pulse 120. The throat, ears, and chest were normal. The abdomen was distended with generalized tenderness. Rigidity was most marked below the umbilicus and maximum in the right iliac fossa. A provisional diagnosis of pneumococcal peritonitis was made, but laparotomy to exclude appendicitis was decided upon. An injection of 250,000 units of penicillin was given, and the child premedicated with "nepenthe"/atropine.

A right lower paramedian incision was made. There was a film of odourless, slimy yellow pus covering the viscera below the umbilicus. The peritoneum was congested, being most marked in the pelvis. The appendix was normal except for the congestion of the outer coat; so was the pelvic colon and ileum. No primary cause was found and a specimen of pus was taken for culture. The appendix was then removed and the incision closed. The penicillin was continued post-operatively for five days. Recovery was uneventful, the temperature falling to normal on the third day by lysis. The bacteriological report was as follows: pus cells +++, Gram-negative bacilli ++, culture: *B. coli* +++, sensitive to aureo-, chloro-, strepto-, and terramycin. The child was discharged perfectly fit on the 16th day.

As the swab was taken before removing the appendix the possibility of contamination could be excluded. I have seen many similar cases where culture of pus proved sterile, probably due to delay in plating and pneumococci being very short-lived on an ordinary swab, but the profuse growth of *B. coli* obtained here seems to justify regarding the case as one of genuine primary peritonitis due to that organism.—I am, etc.,

Bath.

C. P. DE FONSEKA.

Elastic Stump Socks

SIR,—It is well known that amputation stumps require careful early post-operative treatment so that a conical, well-healed, and durable stump can be measured and fitted with an artificial limb as quickly as possible.

I am finding elastic stump socks made from two-way stretch material, specially woven to give maximum pressure at the distal end of the stump, most useful in post-operative cases. The advantages of these elastic socks are: (1) they

exert an even pressure (reduces the oedema); (2) they do not produce folds and invaginate the skin, thus leaving furrows; (3) they shape the stump in a conical manner and produce an even contour, leaving a linear scar; (4) the patient can apply and adjust the socks himself; (5) they are not cumbersome, require no bandaging, and save the time of the physiotherapist; (6) the employment of these socks prevents any injury to the stump which may occur as a result of inexpert bandaging of a stump with vascular disease.

These stump socks are made in two types, one set for above and another set for below knee amputations in three graded sizes—small, medium, and large. The small below-knee socks are also suitable for arms. They are easily washable, are economical, and can be used by the patient at night as well as by day. They are said to last for at least 18 months.—I am, etc.,

London, S.W.15.

LEON GILLIS.

A.C.T.H. and Cortisone

SIR,—Regarding the future possibilities of A.C.T.H. and cortisone, Dr. Sulzberger writes: "It is not at all venturesome to predict that, in the future, these hormones may well prove even more useful in dermatologic research than in dermatological therapy." And Dr. J. T. Ingram, writing on "Stress as a Factor in Dermatology," says: "It may be that the results of treatment of skin disease by A.C.T.H. and cortisone will throw some light on the mechanism involved in skin reaction."

In 1950 an article entitled "Deficiency Patterns in Metallic Poisoning" appeared in the *B.M.J.* In this Dr. W. Hughes recorded his observations on a series of cases of poisoning with heavy metals and also a number of cases of avitaminosis in which the skin lesions were very similar in type and in distribution. He drew attention to the biochemical changes resulting in the case of metal poisoning, in which the enzyme system concerned in cellular oxidation was blocked by the metallic ion having attached itself to the protein moiety. Following the discoveries of Sir Rudolph Peters these cases were successfully treated by dimercaprol, which acted by competing for the metallic ion and freeing the enzyme system.

In the cases of avitaminosis, however produced, the same enzyme system was inactivated, this time by lack of the necessary factor in the form of the vitamin, the addition of which allowed the enzyme action to proceed normally and cured the condition. Following the appropriate treatment in the two types of case, the skin lesions were seen to heal.

It is suggested that there may possibly be other patterns of skin disorders having a dual or even a multiple type of causal origin, particularly those manifestations of rather an obscure origin and mechanism which have been cured by drugs having an equally obscure action on the physiological processes of the body. There are cases of dermatitis herpetiformis which respond to sulphapyridine, others to suramin, others to neither, or to calciferol. Lupus erythematosus of the acute type will respond to A.C.T.H. and the chronic variety be unaffected by it. A rash produced by a sensitivity to penicillin with a similar distribution and appearance to an acute L.E. may also respond dramatically to A.C.T.H. Other examples will probably occur to the reader.—I am, etc.,

Leeds.

DOROTHY C. MACLENNAN.

Anaesthetics in Out-patient Departments

SIR,—Despite the enormous number of articles and letters about anaesthesia which have appeared recently in the *Journal*, including the report of the meeting of the Section of Anaesthetics at the Royal Society of Medicine on February 5 (*Journal*, February 20, p. 452) in regard to dental anaesthetics, I am prompted to add my own experiences in

this connexion, as I feel they may be of interest. I have given, in the last six years, over 12,000 of these from all age groups; all of which have been given in school clinics, hospital out-patient departments, or in private practice. In no cases, except in private practice, have I ever used any premedication. It would seem to me that in the clinics and hospital out-patient departments doing 20 to 30 patients in a session, and with lack of staff or suitable accommodation for recovery, this is quite impossible.

All cases have been given nitrous oxide-oxygen mixtures with supplementary trichlorethylene or ethyl chloride as available, or if necessary. No ill effects that I know of have occurred in any case. I agree with Dr. J. G. Bourne's views on premedication, but they would seem to be impracticable, and surely the use of cyclopropane as he suggests would be prohibitive from the point of view of expense. I have used all the standard machines and feel that the McKesson-Nagraf machine with trichlorethylene attachment is the most satisfactory of all. I cannot see how the use of cyclopropane, with its risks of explosion, sickness, and salivation, can be considered safer in the hands of a novice than nitrous oxide.—I am, etc.,

London, N.W.6.

KENNETH W. LEON.

SIR,—Following the appearance of your leading article on this subject (*Journal*, February 27, p. 505), there has been some discussion centred mainly on the disadvantages of cyclopropane. All correspondents have failed to recognize the two main points of Dr. J. G. Bourne's thesis (*Journal*, March 13, p. 641): (1) the danger of anoxia in nitrous oxide and oxygen anaesthesia, and (2) the simplicity of Bourne's method.

My only comment on (1) is that it is well known that even a short period of anoxia during a major surgical operation contributes to shock, and yet anoxia (or hypoxia) is gaily used by all and sundry in out-patient departments, doctors' surgeries, and dental surgeries all over the country as an adjuvant to a known weak anaesthetic. Other anaesthetics have their disadvantages also. (2) The apparatus used by Bourne is simple and costs less than half the price of the standard nitrous oxide and oxygen apparatus. The method is simply learnt, and because cyclopropane is a powerful anaesthetic its dose can be regulated by the duration of the inhalation. The mask is removed, leaving the surgeon a quiet subject who is not cyanosed, and still giving him ample time to perform a short operation. I had the privilege of seeing Dr. Bourne's film at the Royal Society of Medicine in which he demonstrated (to me at any rate) the impossibility of maintaining anaesthesia with nitrous oxide and oxygen in the correct physiological admixture in a high proportion of cases.

With regard to Dr. H. Newton-Andrews's comment (*Journal*, March 13, p. 641) on the possibility of explosion by a spark from a difficult extraction, I would point out that a throat pack should always be used, which would minimize the risk of explosion. The time has now come for a reassessment of anaesthesia in all forms of minor surgery. In conclusion, I would recommend correspondents to re-read Dr. Bourne's original paper.—I am, etc.,

London, E.17.

FRANCIS J. GODDARD.

Ion-exchange Resins

SIR,—I would like to support Professor M. L. Rosenheim's contention (*Journal*, March 27, p. 758) that ion-exchange resins are a very promising form of treatment for nephrotic oedema. We have under observation a lady aged 35 suffering from nephrosis, who was completely resistant to all types of treatment, including cortisone. The use of ion-exchange resin ("kationium") produced most satisfactory results. She has been on continuous resin therapy for close on two years, and is able to lead what is virtually a normal life. I feel, like Professor Rosenheim, that there is a definite place for these compounds in the therapy of nephrosis.—I am, etc.,

Inverness.

JAMES RONALD.

Children's Nursing Unit

SIR,—I read with the greatest interest Dr. J. A. Gillet's account of the Rotherham experiment (*Journal*, March 20, p. 684). I am wondering if he has ever considered extending the benefits of such a scheme to the aged and chronic sick. Their care is becoming an increasingly grave problem and their needs bear many resemblances to those of sick children. Like them, they have a strong attachment to familiar surroundings and dependence on others for the ordinary necessities of life. If adequate care and some skilled nursing were available in the home, many patients now admitted to hospital could be discharged sooner and others would not require admission at all, thus relieving the present famine in hospital beds and the financial burden to the community which hospitalization entails. The disturbance caused by the cerebro-arteriosclerotic in a general ward need arise much less often.

The personnel of such a service would consist of homely women whose work would be supervised by the health visitor or district nurse. Such work might be made to attract old age pensioners if the present pension regulations were modified to allow women so employed to earn up to £3 per week without deduction of pension instead of the £2 at present permitted. I am aware that various schemes already exist for the help of the aged sick, but the success of the Rotherham experiment makes it an excellent model.—I am, etc.,

Tiverton.

G. NICHOLSON.

SIR,—The children's nursing unit described by Dr. Jos. A. Gillet (*Journal*, March 20, p. 684) shows what can be achieved by providing an adequate domiciliary nursing service for children. Such a service could help to reduce the infant mortality rate in a way not mentioned by Dr. Gillet or in your annotation.

It is apparent that an increasing proportion of the hospital deaths in infants are occurring in babies who are admitted in a moribund or practically moribund condition. In very many of these cases the baby has been under treatment by the family practitioner. The mother has often failed to recognize a deterioration in the baby's condition or has been unable to contact the doctor, who may be out on his rounds. In other instances she has hesitated to call him because he had already arranged to visit later or the next day. Dr. Gillet's scheme, by which such babies are visited two or three times daily by a trained children's nurse, who would also be readily available for urgent visits, would do much to prevent such tragedies. Furthermore, experienced practitioners realize that many young mothers may not appreciate a deterioration in their child's condition and naturally tend to send such cases into hospital early. The knowledge that they have at their disposal a children's nursing unit would encourage them to treat such children at home, thus saving hospital beds. It is hoped that more local authorities will follow Rotherham's enlightened example.—I am, etc.,

Huddersfield.

W. P. SWEETNAM.

Synopsis of Children's Diseases

SIR,—Professor Wilfrid Gaisford (*Journal*, March 27, p. 744) is undoubtedly able to distinguish a mongol from a cretin, but how many of his students are able to do so? Confusion between the two conditions is still quite common and is not confined to undergraduates. I recently saw a child of 4 years with very marked cretinism. The child had been diagnosed as a mongol in infancy by the family doctor, and this had been "confirmed" by a consultant paediatrician. No treatment had therefore been given. I think that Dr. John Rendle-Short was well justified in including a table of differential diagnosis of the two conditions in his book.—I am, etc.,

Liverpool, 12.

S. E. KEIDAN.

Injection into Artery

SIR,—I wish to correct what may be a wrong impression left in the minds of some of your readers after seeing the medico-legal report in the *Journal* of March 27 (p. 766) concerning intra-arterial injections. Reading this report may make me appear to be too dogmatic.

In my evidence I divided the act of intra-arterial injection into (a) intra-arterial puncture—which I said was a mishap which can befall anyone—and (b) injection of thiopentone after arterial puncture—which I said was not a careful or skilful act. I gave four means of ascertaining whether a needle was in an artery, and said that to continue further with an injection, having perceived one or more of these signs, was not the act of an experienced person. I also used the expression "person skilled in intravenous work," avoiding the word anaesthetist. I hasten to make myself clear, for it may happen that my turn for intra-arterial puncture instead of intravenous is just around the corner.—I am, etc.,

London, N.19.

O. H. BELAM.

Erythromycin

SIR,—It was with pleasure that I read your leading article (*Journal*, January 30, p. 261) saying that erythromycin had been released for use by general practitioners. It was therefore with surprise and concern that I read the letter from Dr. H. A. Evans (*Journal*, March 20, p. 702), in which he urges that erythromycin should be kept for hospital use only. An actual case history will illustrate my reason. I was called to see an active 75-year-old man, who had bilateral lobar pneumonia. He had been under observation at the local chest clinic as a tuberculosis contact. Specimens of sputum were sent for routine examination, but, as he was very ill, treatment with penicillin was started with "estopen" 500,000 units 12-hourly. Instead of the expected response, his condition deteriorated. The pathologist's reports were negative for tubercle bacilli; culture grew *N. catarrhalis* and *Streptococcus viridans*; Gram-positive cocci and Gram-negative bacilli were also present. On the fourth day I stopped the "estopen" and prescribed erythromycin—300 mg. 6-hourly. Within 24 hours there was an improvement, and by the time the chest physician saw him with me and confirmed the diagnosis he was steadily responding to treatment. After three days the dose was reduced to 300 mg. 8-hourly, and after two more days it was stopped. In all 60 tablets of erythromycin (6 g.) were given, and no side-effects were experienced by the patient. Two weeks later he attended the chest clinic, and it was reported: "This man seems to have made a remarkably good recovery. . . ."

I do not understand why Dr. Evans is prepared to give penicillin empirically, yet not other antibiotics. I agree entirely that laboratory tests for sensitivity are desirable before using any antibiotic, including penicillin, but in a case such as the one described here it is surely imperative to treat the patient by all available means. Otherwise the delay while awaiting sensitivity tests may lead to a very scientific report but a dead patient.

I firmly believe that a patient should be treated in his own home whenever possible, unless he requires a special treatment or technique that is available only in hospital. Apart from the near impossibility of getting a 75-year-old man into hospital, it is better for the patient and more economical to treat him in his own home. Sixty tablets of erythromycin are not so costly as three weeks' maintenance in a hospital bed. Finally—and it cannot be said often enough—the more we general practitioners treat our patients ourselves, the better will be our relationship with the public.—I am, etc.,

London, N.W.3.

PHILIP HOPKINS.

SIR,—It has been well established that erythromycin may be usefully employed in the treatment of certain infections where normally susceptible organisms have become resistant to penicillin. I must disagree strongly with Dr. H. A. Evans

(*Journal*, March 20, p. 702) when he says that this fact will never concern a general practitioner.

As Dr. Evans's experience would indicate, it is probable that penicillin is the best antibiotic for staphylococcal, streptococcal, and pneumococcal infections. Moreover, I agree with him that if a patient suffering from one of these infections does not respond to penicillin, then this is an indication for laboratory testing of sensitivities. If such tests reveal the presence of penicillin-resistant organisms, does Dr. Evans consider that it is outside his province to prescribe erythromycin? It is not my experience that these tests can only be done by a hospital laboratory. In this area I have always found the Public Health Laboratory Service to be most helpful. I welcome the introduction of erythromycin for the limited purpose of dealing with the troublesome problem of penicillin-resistant infections.—I am, etc.,

Sutton Coldfield.

T. A. W. PARKES.

The Nephrotic Syndrome

SIR,—We agree with Dr. F. C. Reubi (*Journal*, March 20, p. 705) that the method we adopt (*Journal*, December 26, 1953, p. 1389) for calculating tubular reabsorption of protein from the results of albumin infusions is complex, and that the graph he shows is simpler. Unfortunately the latter is fallacious, since "the different proteins [albumin and globulins] compete with each other for reabsorption." The evidence for this statement was not given fully (it will be published in detail elsewhere), but to illustrate the point the result of infusing albumin into one patient is shown on the accompanying graph. No significant changes in serum globulin concentrations followed infusion, yet the globulin clearances rose and fell in parallel with the rise and fall in albumin clearance and in serum albumin level.

The simple relationship shown in Dr. Reubi's letter is only valid where one substance of uniform molecular size and "permeability" is being reabsorbed by one tubular mechanism. When several substances of differing molecular size and permeability are being reabsorbed by the same mechanism in proportion to their concentration, and the tubular "load" of only one of them (albumin) is varied, then the increased tubular "load" of albumin will compete with the globulin for the available reabsorptive capacity and the globulin excretion will rise; hence the "clearance" (UV/P) of the globulin fractions will increase in constant proportion to the increase in albumin "clearance," as is seen in the graph. For example, the α_2 -globulin clearance in this case remained about 97% of the albumin clearance, while the latter ranged from 0.4 to 1.7 ml./minute. The method of calculation described thus estimates the total reabsorption, which the simpler method mentioned by Dr. Reubi must therefore underestimate, and, moreover, this simpler relationship between U_{VAIB} and $(P_{AIB} \times g.f.r.)$ will be non-linear. This proportional increase in globulin clearances has now been a constant finding after seven infusions on four patients, and we feel that the theory advanced constitutes the most rational explanation of the observed facts.—We are, etc.,

J. R. SQUIRE.

J. HARDWICKE.

Birmingham.

Fear of Litigation

SIR,—One statement in the medico-legal report (*Journal*, March 20, p. 709) where it is reported that Christine Bayliss was awarded £5,000 needs denial. It is the one made by Mr. R. C. Vaughan, appearing for the defendants, that: "Nurses and doctors will shut up like clams, and

you'll never get any information out of the hospital as to what is wrong with yourself, far less your child." The judge then stated: "If it were a child of mine, I would change my doctor," and Mr. Vaughan made a further statement that "one can't get facts from hospitals. They are grossly impertinent when you ask."

I am sure I am voicing the opinion of those who see after children when I say that those in charge of them in hospital try to give parents information about their children. Parents are given appointments for this purpose, told the truth, savoured albeit sometimes with hope which is scarcely justified, and encouraged to come again. This practice, which is rewarding in many ways, was in vogue before the National Health Service Act came into operation. Even then it was our duty to give "a dying pauper" as much attention as we give now to those who pay.—I am, etc.,

Rugby.

R. E. SMITH.

SIR,—When an employer of labour is held responsible for an injury to his workman he alone faces criticism, and employers in general are not forced to share in the disparagement. Why, then, is it possible, on the evidence advanced in a single case, for counsel to assert that "nurses and doctors will shut up like clams and you'll never get any information out of the hospital as to what is wrong with yourself, far less your child," or, again, "One can't get facts from hospitals, they are grossly impertinent when you ask." Remarks of this kind are pounced upon by the popular press, public dissatisfaction is intensified, and we are forced to focus our interest not on the patient but upon self-protection. Surely distinguished lawyers are sufficiently in touch with our problems and difficulties to avoid such expressions of personal opinion which can only serve to damage a sister-profession and to destroy, without cause, the confidence of twenty million people.—I am, etc.,

Swansea.

C. J. CELLAN-JONES.

Change of Sex

SIR,—Your annotation on "Change of Sex" (*Journal*, March 20, p. 694), coupled with the remarks of your medico-legal correspondent (p. 710), raises a serious problem. Intersexes are imperfect males or females, this imperfection being due to the disturbance of the sex-forming—or sex-differentiating—mechanism which occurs in the course of embryological development. In rarer cases the sex differentiation breaks down in the course of post-natal life following, for example, certain endocrine diseases. Although imperfect men and women, intersexes possess what has been called since the Roman jurist Ulpianus, of the third century of our era, the predominant sex.

The problem is, What is the predominant sex in an intersexual? As I pointed out in my Thomas Vicary lecture many years ago,¹ with our contemporary ideas the predominant sex is that manifested by the total personality and not that indicated by special features of nuclear genes, gonads, endocrines, or even by the balance of sexual characters. Total personality is shown by the behaviour and will of the individual. Thus, in principle, an intersexual individual has the right to demand of us to perfectate his sex according to his choice.

The application of this principle is accepted for that class of intersexes designated as hermaphrodites ("true" or "false" according to our ridiculous terminology)—that is, in individuals who show in their genital organs and sometimes in their gonads a mixture of male and female features. Since the work of Ambroise Paré in the sixteenth century we accept to use medical and surgical procedures to perfectate these unfortunate individuals towards the sex they will and to allow them to register accordingly. Legal complications such as marriage can be settled by the procedure of annulment. Sexual behaviour complications are not important, because, with the exception of certain cases of exhibitionism, hermaphrodites have a very weak libido. Fertility is non-existent.

The application of this principle of free choice for the other class of intersexes, the transvestites, is much more difficult. These are individuals whose genital organs and gonads are distinctly male or female but who feel they belong to the opposite

sex and want to live, dress, and work like members of the opposite sex. I have noted the curious fact, however, that this does not apply to their sexual behaviour, and genuine transvestites do not generally wish to act as individuals of the opposite sex. With this group, as with the hermaphrodites, it appears that the intersexualizing process inhibits the development of the libido. In my opinion, these transvestites are as much hermaphrodites as those designated with this term, and, in fact, we find definite endocrine, genital, and other physical stigmata pointing to a definite intersexuality. They are the most unfortunate beings, leading lives of misery often terminating in suicide. We have to help them—but how? In this country psychotherapy, guidance, and help towards registration are sufficient. In Denmark Dr. Hamburger and his co-workers² have had the courage to apply more drastic endocrinotherapeutic and surgical measures. Can we go as far as that?

One important point: We must distinguish between the real transvestites, who are in fact hermaphrodites, and certain homosexuals, as well as patients with special obsessional neuroses, but the life history, the physical stigmata of intersexuality and the maldevelopment of the gonads and genital organs, and the unimportance of the heterosexual libido will help us. Although there are intermediary forms such differentiation is necessary and usually possible.—I am, etc.,

London, W.1.

Elderly Psychiatric Patients

SIR,—I was impressed by the diagnostic accuracy recorded by Drs. Vera Norris and Felix Post (*Journal*, March 20, p. 675) in elderly psychiatric patients. I would have wished that the distinction between affective and arteriosclerotic illnesses had been more clearly defined. Of four patients over 65 recently discharged from this hospital suffering from mania and depression which had responded to E.C.T., all had been given a hopeless prognosis of which the patient had unfortunately become aware.

Depression in the elderly is often complicated by confusion, and mania always is, but this does not prejudice the response to E.C.T. The statement that "affective disturbance is commonly the leading symptom in cerebral arteriosclerotic dementia" may perpetuate errors. Again, the authors state: "Special inquiry was usually needed to elicit a history of fainting turns, transitory pareses, or speech disturbances; and this, even in the absence of neurological signs or patchy intellectual defects, was regarded as indicative of cerebral arteriosclerosis." This statement surely needs clarification. Fainting attacks are very common in the aged. Sheldon¹ records that 64.7% of women between 70 and 74 suffer from vertigo and 47.5% are liable to falls. Even patients who suffer from cardiovascular disease or have had strokes may also suffer from depression which can remit completely with E.C.T.

I feel the concept of arteriosclerotic dementia is based on shaky pathological and clinical criteria and the majority of cases so diagnosed are suffering from post-apoplectic dementia and mixtures of psychosis and dementia, but many recoverable illnesses are doomed by this diagnosis. Depression and mania can be fatal diseases, and early death does not necessarily mean a senile process. The points raised in this letter have been discussed at greater length by Gallinek,² so I will not trespass further on your space.—I am, etc.,

Sheffield.

"Antidotarie Chyrurgical"

SIR,—As Mr. L. Jolley truly remarks (*Journal*, February 20, p. 456), the Tweed appears to be an insuperable barrier to the bibliographer. In your note on "Some More Rare Books" (*Journal*, March 20, p. 699) you say that *Childbirth, or the Happy Delivery of Women*, London, 1635, is

very rare, and only one copy, that in the British Museum, is listed in the *Short Title Catalogue*. There are three copies in the West of Scotland, one in the Royal Faculty Library, one in the Hunterian Library of Glasgow University, and one in William Smellie's Library at Lanark. The latter is historic, as it is the copy which Professor Miles Phillips had restored to Lanark after many years' sojourn in the library of the Royal College of Surgeons in Ireland. It may also interest you to know that we in the Royal Faculty and the Hunterian Museum also have the 1612 edition. The other books mentioned are easily available in one or other of the medical libraries of Scotland.—I am, etc.,

ARCHD. L. GOODALL,

Hon. Librarian,

Royal Faculty of Physicians and Surgeons.

Glasgow, C.2.

Strangulated Hernia

SIR,—Dr. J. Rendle-Short and Mr. Cyril Havard (*Journal*, March 20, p. 680) have done a service in reminding us that, although nearly all herniae in infants can be reduced by conservative means, occasional cases of true strangulation and incarceration do occur. It would be interesting to know how many of their 45 cases required emergency operation, and whether they advocate early elective operation after successful reduction by conservative means. They remark that the age-incidence is remarkably constant, and that the greatest number of cases are found in the first year of life. Textbooks of surgery seldom mention the age-incidence of strangulation, and it may not be appreciated that this condition is virtually confined to infants and the middle-aged and elderly.

A year or so ago, after reflecting that I had never seen a case of strangulated inguino-femoral hernia in a young adult, I examined the case records of 100 patients admitted to Barnet General Hospital with strangulated hernia, and 100 similar cases admitted to Edgware General Hospital. The records of the latter group were obtained by the courtesy of the Medical Director, Mr. J. N. Deacon, whose remarkable records department produced the relevant data by return of post. The average age of the Barnet group was 65.8 years, and of the Edgware group 64.4 years. Even more striking is the fact that, although both hospitals serve large areas, only two patients under 40 years of age (excluding infants) were admitted to Barnet with strangulated hernia in six years, and only five such patients to Edgware in three years. No patient under 30 years of age was admitted to either hospital. Some rather obvious assumptions were confirmed by the study, among which may be mentioned the much greater risk of gangrene in a femoral hernia, and the predisposition to strangulation imposed by the wearing of a truss for inguinal hernia.

These figures are mainly of academic interest, but they may help to resolve an individual clinical problem. For example, if an inguinal hernia is first noticed during pregnancy in a young woman, the risk of disturbing the pregnancy by elective operation is probably more than the risk of strangulation during labour. In this connexion it may be of interest that no case of strangulation has complicated pregnancy or labour in the last 7,000 cases admitted to the maternity department of Barnet General Hospital.—I am, etc.,

Barnet, Herts.

V. J. DOWNIE.

Aetiology of Non-specific Urethritis

SIR,—Dr. R. R. Willcox in his article (*Journal*, January 2, p. 13) dealing with the aetiology of non-specific urethritis, sees the cause of this not uncommon disease in a presence of some "virus" which has not been isolated, and remains to be discovered. In my opinion the bacteria, and even some undefined virus, are just the secondary feature, the main basing on changes of tissue. Non-specific urethritis is a common disease even in my country in recent years, and, besides that, I am observing in practice quite a considerable number of polyurias, pollakisurias, nycturias and enureses in children as well as in adults, without any aetiological

grounds. In all these cases we find one constant symptom, and that is the pronounced alkalinity of urine, detectable with litmus paper, and reaching often points from pH 7.5–8. The alkalinity is not always present in all portions of urine, usually the morning urine being acid and the afternoon alkaline.

What may be the cause of this alkalinity, which years ago was not so often pronounced? I think there is a relative alkalinity of food due, first, to shortage of proteins owing to the second world war, and, secondly, to the over-emphasizing of vegetable foodstuffs by official medicine in both our countries, in respect to a vitamin fashion. However, if we consider the alkalinity of urine as the aetiological cause of non-specific urethritis, the illness should disappear when the kidney excretion is acidified. That is really the fact. After giving 1 g. of ammonium chloride daily the disease disappears within a week. Ammonium chloride forms urea in the body, and free chlorine ions remain acidifying urine finally. Aetiological treatment would be, of course, to enlarge the level of proteins in the food.

For illustration here is one case: a 52-year-old Army colonel, who for six years suffered from a purulent discharge from his urethra, bacteriologically non-specific flora, gonococci never present. During these six years he went through all kinds of treatment: antiseptics, antibiotics, sulfadiazole, abstinence from coitus, and kurort treatment with alkaline mineral water. Finally he shifted from cavalry to artillery, without effect either. After taking the above-quoted medicine he was within a week without any discharge, and remains in good state until now—that is, after a year. He takes ammonium chloride occasionally, when he feels itching in the urethra. The puzzle remains why his wife, vegetarian as him, and many other vegetarians remain without any ill symptoms from the urinary tract.

Please excuse, dear Sir, my bad English—it is now over 15 years since I was a short while in your country, and a year in the U.S.A. I am very indebted to the extraordinary high level of your *B.M.J.*, which is the best one from all Western papers dealing with general medicine.—I am, etc.,

Brno, Czechoslovakia.

JIRI STEFL.

Polio-myelitis

SIR,—In your annotation on immunization against polio-myelitis (*Journal*, March 13, p. 635) you speak of polio-myelitis as "a disease with so low an attack rate . . . and one of which the dissemination is so mysterious that we cannot know whether or when any given individual has been exposed to infection." Can you really say that the attack rate is low or the whether and when of infection mysterious when we have repeated examples of exactly the reverse? As many as 4 out of 13 babies infected in a maternity home,¹ 16 out of 120 inhabitants on a housing estate,² 3 cases in the infant class of a school of 22 pupils,³ 4 cases in a children's hospital ward,⁴ 12 cases in a school of 73 pupils,⁵ 6 cases (1 fatal) in a school of 65 boarders,⁶ numerous examples of multiple infection in a family;⁷ etc.

A great problem is often made of the odd sporadic cases although these form only a small minority of the annual notifications; the majority of cases occur in local outbreaks⁸ and so, far from being distributed over the total population of the affected area, are confined to those associated with an infected school, nursery, hospital, family, or other group, in which the individual's chance of developing the disease and/or transmitting the infection may be a hundred or more times that of the rest of the local population. Thus in the epidemic in Rye in 1952⁹ 17 of the 23 cases were either pupils or home contacts of pupils of the Rye Elementary School, and five of the remaining six cases were indirect contacts.

The tragedy is that the mumbo-jumbo of "mysterious dissemination" of the virus—more worthy of the pre-Pasteur days of "spontaneous generation" than of the present day—is preventing our using the only effective weapon we have against the disease; namely, prevention of transmission of the virus by the enforcement of quarantine restrictions. "Prevention," one is tempted to urge, "is better than cure." But in poliomyelitis we have no cure. Wrong treatment can certainly add to the disaster, but we must recognize that the results of even the best treatment are pathetically insignificant compared on the one hand with what we might do by prevention, and on the other with the

"hard core" of disablement and death which persists in spite of all our efforts. The final score of the 23 cases at Rye was three deaths (two deaths were extremely rapid and one occurred before treatment could even be summoned), two very severely paralysed, three severely paralysed, and four moderately paralysed, giving a combined death and disablement rate of 50%. In addition, two families (four young children) lost their mothers. This score is typical and we cannot afford to continue to ignore it.

It is my firm belief, based on careful study of the records of epidemics and the histories of individual patients, that routine isolation of contacts of poliomyelitis cases might very well prevent at least 50% of the cases notified annually in this country.¹¹ In addition, it would rid us of the danger of experiencing the severe epidemics which we have seen occurring in other countries. It is time that we recognized poliomyelitis as a dangerous infectious disease which can disrupt family and national life and that we took the necessary measures to prevent it.

In closing might I refer you back to your own leading article on the same subject.¹² In it you say "we must regard the family as an 'infected unit,' and 'it is clear that people inside the family infect people outside.'" Replace your "family" by "family and/or institution," and you have stated the problem and indicated its solution.—I am, etc.,

Oxford.

Accurate Equivalents

SIR,—May I make a plea for a greater sense of proportion, and less blind acceptance of arithmetic, both in assessing results of treatment and in conversion of figures from one system of units to another? This was prompted by the recent statement in your *Journal* that "Two pints (1.1 l.) were transfused..." and that out of 34 mothers in a certain group, 27 (79%) gave birth, etc.

Now I question whether the translation of pints into (I presume) litres, while desirable, would not gain in clarity more than it lost in accuracy by rendering as "Two pints (1 litre)"; and has the figure of 79% any significance? In fact 27 out of 34 is as near 80% as it is to 79%, and a result differing by one case (76.5% or 82.5%) would be surely not unlikely? Nor would it affect the author's argument. This is not in any way intended as a criticism of the letters quoted, for they are but representative of a host of authors who have less understanding than they have fear of inaccuracy—I once met a doctor who proposed quoting a figure of 50% in a paper, out of two cases.

Where lies the logic of stating, as is often written, that a baby's birth weight is "7½ lb. (3.4 kg.)"? To call it 3.5 or even 3½ kg. would still be right to the nearest quarter-pound. I am on thinner ice when I criticize equivalents in dosage, but I pick at random: "Galla B.P.C., dose 10 to 20 gr.—0.6 to 1.2 grammes" and "Acidum hydrochloricum dilutum B.P., dose 2 to 5 min.—0.12 to 0.3 ml." What harm (or measurable loss of effect) would come from a dose range for galls of 0.5 to 1.0 gramme, or for hydrocyanic acid of 0.1 to 0.3 ml.? And who ever measured 0.12 ml. anyway?—I am, etc.,

Acle, Norfolk.

J. F. FILBEE.

* The authors of papers are responsible for inserting percentages of the kind criticized by Dr. Filbee; we are responsible for the metric equivalents. These are not intended to guide the practice of the foreign reader but to serve as a close, though not a pedantic, translation for him of British weights and measures.—Ed., *B.M.J.*

Abbreviations

SIR,—I would like to express agreement with Dr. C. H. Morhouse of the U.S.A.F. Hospital, Arrington, Herts (*Journal*, March 20, p. 703). Abbreviations have become a necessity, but are sometimes difficult to interpret—e.g., A.P.T. can mean alum precipitated toxoid, artificial pneumothorax or, to the M.O.H. (medical officer of health or Ministry of Health), administrative, professional, and technical staff. Specialist reports often contain abbreviations with which their colleagues may not be familiar—e.g., O.A., osteoarthritis; A.F.B., acid-fast bacillus; C.S.O.M., chronic suppurative otitis media; and few would guess that O.B.E. may refer to oil, bath, and enema. Again, students from one hospital use P.R. to denote an examination by the rectum, whereas R.E. is used in another.

May I suggest that a list of recognized abbreviations be compiled by the B.M.A. (British Medical Association)—not the less well known Bald Men's Association), the M.O.H. (Ministry of Health), or even by the W.H.O. (World Health Organization).—I am, etc.,

Plymouth.

O. L. L. LANDER.

POINTS FROM LETTERS

Teach Bacteriology in Schools

DR. ARTHUR TURNBULL (Glasgow) writes: Is it not high time that bacteriology should be taught in British schools? A few microscopes in every school, with culture slides of various germs, would enable our boys and girls to see these interesting organisms for themselves, and once seen by them never forgotten. Our youth would become bacteriologically minded, and a great move forwards in the intelligent prevention, early recognition, and national cure of disease would accrue. For seeing is believing to cinema-minded children. In addition, the practical application of television to schoolchildren's education might well include direct teleray study of the different races of micro-organisms, those real enemies of mankind.

Prostatic Obstruction Due to Ephedrine

DR. H. J. WRIGHT (Nuneaton) writes: In the course of the past six years in general practice I have found the ephedrine given to elderly male asthmatics in therapeutic doses caused symptoms of prostatic obstruction in at least four cases. No previous history of dysuria was elicited, but rectal examination in each case showed moderate prostatic enlargement. Within a day or two of withdrawing the ephedrine the difficulty in micturition disappeared; in no case was catheterization or admission to hospital required. I find no reference in a standard textbook of pharmacology to any effect of ephedrine upon bladder function, and should be interested to know with what degree of frequency this phenomenon may have been observed by others.

Presternal Oedema in Mumps

DR. JOHANNA SPINNER (Mitcham, Surrey) writes: Referring to your recent reports on presteral oedema (*Journal*, January 30, p. 258, and February 27, p. 518), the mother of a little girl who was ill with mumps asked me to see her as "the swelling seemed to be on the top part of her chest as well." This child had a marked presteral oedema, which was slightly painful on palpation. I suppose this symptom is often overlooked and not as rare as one would think.

Second Attack of Chicken-pox

DR. J. I. LYONS (Heston, Middlesex) writes: During the present winter I have been called to a number of cases of a second attack of varicella, a substantial proportion occurring in adults. The illness is accompanied with pyrexia of up to 102° F. (38.9° C.) and subsides within 48 hours. Hitherto, one has regarded a recurrence of the condition as being very rare, sufficient to regard as questionable the diagnosis of the first attack. It would be of interest to know whether other practitioners are encountering similar cases, and any explanation of this phenomenon.

Smoking and Lung Cancer

MR. ANTHONY C. PEARSON (Great Baddow, Essex) writes: The quality of cigarette tobacco and cigarette paper in France differs from that in England, and it would be of interest to know if the increased incidence of lung cancer in France compares with that in this country.

Obituary

Sir FRANK COLYER, LL.D., F.R.C.S.

Sir Frank Colyer, who died on March 30 at the age of 87, was not only a dental surgeon of the highest reputation and an authority on human and comparative odontology, but a leading historian on the subject. For something like 50 years he was curator of the odontological museum of the Royal Dental Hospital, formerly housed in Hanover Square, but later at the Royal College of Surgeons in Lincoln's Inn Fields. His discourses on the specimens in this collection were always fascinating, and nothing delighted him more than to demonstrate them to appreciative visitors.

Born in 1866, James Frank Colyer was trained at Charing Cross Hospital and the Royal Dental Hospital, with both of which he remained associated for the rest of his life, in later years in a consultative capacity. He took the L.D.S. diploma of the Royal College of Surgeons in 1887, and after holding various house appointments at the Royal Dental Hospital he was appointed surgeon there and held for five years the office of Dean. In 1893 he was elected dental surgeon to Charing Cross Hospital. Other hospitals to which he gave his services included the Croydon War Hospital and Queen's Hospital, Sidcup. He served the Ministry of Pensions as honorary consulting dental surgeon. Colyer was the author of several authoritative books on his specialty. His textbook *Dental Surgery and Pathology*, which he wrote with Mr. Evelyn Sprawson, ran through eight editions. He also published in 1936 a work entitled *Variations and Diseases of Teeth in Animals*. A well-known historical book of his was on John Hunter's work in odontology. To him, as to all connected with the Royal College of Surgeons, the damage done to the museum by the air raid in 1941 came as a great blow. But, although he was already 75 years of age, he set himself to the task of salvage and repair and also continued his work on a catalogue of old instruments for dental extraction, on which he published a book as recently as 1952.

Among both the dental and the medical professions Sir Frank Colyer was a greatly liked figure. He was made F.R.C.S. in 1916 and F.D.S. in 1947; Bristol University made him Hon. LL.D. in 1933. He was knighted in 1920. He had been secretary and editor for the old Odontological Society of Great Britain, which in 1907 became the Odontological Section of the Royal Society of Medicine, and of that Section he was President in 1919. In 1932 he became the first President of the British Society of Dental Surgeons, and in the same year at the Centenary Meeting of the British Medical Association he was Vice-President of the Section of Comparative Medicine. He was elected an Honorary Member of the British Dental Association and he was a corresponding member of dental societies in Belgium and Italy.

He is survived by a son and a daughter. Lady Colyer died in 1950 after 55 years of marriage.

S. C. GUPTA, M.B., F.R.C.S.Ed.

Professor S. C. Gupta, professor of general surgery in the Medical College of Bengal, died on January 31 after a short illness. He was 50 years of age.

Subodh Chandra Gupta was born of poor parents on June 10, 1903. As a medical student he had a brilliant career at Calcutta University, and in 1927 was placed

first in order of merit among the successful candidates for the degree of M.B. Soon after graduation he entered the Bengal Medical Service and subsequently worked at a number of hospitals in the province. In 1945 he was appointed civil surgeon and came to the United Kingdom on study leave, obtaining the F.R.C.S.Ed. in the following year. After his return to India he was appointed professor of surgery at the Lake Medical College, Calcutta. He also became presidency surgeon and a member of the standing Medical Board of the West Bengal Government. It was only last year that he took up the appointment of professor of general surgery in the Medical College of Bengal, and by his death the University has lost a good teacher and Calcutta one of its finest surgeons.

Professor Gupta was greatly respected by all who knew him. Very generous to the poor, his hospitable nature had a touch of the Victorian age about it. He is survived by a widow, two sons, and three daughters.

E. H. M. MILLIGAN, M.D., D.P.H.

Dr. E. H. M. Milligan, formerly medical officer of health for the borough of Glossop, died on March 21 at the age of 75.

Ernest Henry Marcus Milligan was born at Belfast on October 13, 1878, the son of S. F. Milligan, M.R.I.A. He was educated at the Methodist and Campbell Colleges, Belfast, and pursued his medical studies at the old Queen's College, Belfast, and at Trinity College, Dublin. He obtained the Irish conjoint diplomas in 1906, graduating M.B., B.Ch. from the former Royal University of Ireland in the same year. Four years later he was granted the M.D. by the recently established Queen's University of Belfast; in 1911 he obtained the Dublin D.P.H. Dr. Milligan was resident medical officer at the Northern Ireland Fever Hospital, Purdysburn, Belfast, from 1906 to 1908. Three years after relinquishing that post he became medical officer of health for Long Eaton, in Derbyshire. In 1917 he moved to Bath as school medical officer, and after three years there he became the first whole-time medical officer and school medical officer for Glossop. On retiring from these offices in 1946 he became a medical officer under the Ministry of Health.

The people of Glossop have good reason to remember the name of Dr. Milligan. For 26 years he worked unceasingly to better the living conditions in the town and so to improve the health of the community. In 1920 the occupants of 2,864 houses were obliged to deposit their refuse in ashpits; 20 years later only 30 were without the more sanitary ash-bin; and over the same period he saw to it that 2,512 pail-closets were replaced by water-closets. From the one small child-welfare clinic of 1920 he developed a series of well-equipped and well-staffed clinics; the health of children became his chief concern. He also bent his energies to improving the water supply. At the request of the county medical officer of health he undertook a campaign against tuberculosis, the death rate from the disease in Glossop making the town a black spot in the county. A pioneer of immunization against diphtheria, he brought about a sharp fall in the number of deaths from this disease: in his last annual report (1945) as medical officer he was able to state that no child in Glossop had died from diphtheria in the previous eight years.

Dr. Milligan was more widely known for his work on nutrition, especially during the last war. During 1941-2 he assisted the Ministry of Health in a vitamin-

feeding test carried out in Ipswich, Glossop, and London. Between July, 1940, and July, 1942, with Dr. Lewis Fanning he investigated the rate of growth of children under one year, attributing the reasonably satisfactory result to the provision by the Government of milk and vitamins for expectant mothers and infants. Comparing the heights and weights of schoolchildren in 1934 and 1944, Dr. Milligan found an improvement in the latter year in the average mean weights of boys of 12 to 14 years of age. One of his last investigations was into the haemoglobin levels of pregnant women, and with Dr. H. E. Magee he published a paper on this in the *British Medical Journal* of December 1, 1951.

Dr. Milligan took an active part in B.M.A. affairs, being honorary secretary to the Glossop Division from 1929 to 1939 and president of the Derbyshire Branch from 1938 to 1939. After his retirement he was in 1946 elected as a Labour member to the Glossop Town Council, resigning from it on account of ill-health in 1949. Apart from his contributions to professional journals, he collaborated with his son-in-law in writing plays, a number of which were broadcast by the B.B.C. He leaves a wife and three daughters, to whom the sympathy of his colleagues is extended in their loss.

Dr. J. ARTHUR REES, who was one of the best-known medical practitioners in North Cardiganshire and the last of the older generation there, died at Aberystwyth on January 12 in his 84th year. John Arthur Rees was born on August 1, 1870, the son of a farmer, David Rees, J.P., and was educated at one of the local academies, the University College of Wales, Aberystwyth, and at Edinburgh University, where he graduated M.B., C.M. in 1896. After graduation, he worked as an assistant in London, and then at Pontycymmer, Glamorganshire, where he distinguished himself in the Llest colliery disaster; he bought a practice in his native village of Llanilar in 1900. Although he moved to the nearby town of Aberystwyth in 1916, he had substantially the same practice until he retired in 1952. He had thus practised in his native district for an unbroken period of 52 years, which fact and the changes he had seen in his working life were widely commented upon at the time of his retirement. Dr. Rees was a Welsh country practitioner of the old school, who knew and was known by everybody throughout a wide and scattered area. In all his 52 years of practice his entire holidays amounted to a month, of which one week was spent at a postgraduate school at Cardiff, and for 43 years he did not have a day's illness. His work was his hobby, and the practice of medicine, often in trying conditions, was truly his whole life. He was of the best type of family physician, not without his little eccentricities, and was to be seen for over half a century on either his bicycle or his Welsh cob, then on motor-cycles, and later in a series of cars which bore evidence of the difficulties of reaching his more inaccessible patients. In his younger days Dr. Rees was a great sportsman. He enjoyed walking, shooting, rowing, and swimming, and he had played football for the Aberystwyth college's first eleven and first fifteen, and for the first fifteen at Edinburgh. Up to the age of 70 his normal habit was to plunge into the sea about 8 a.m. daily from Easter to October each year. Increasing blindness made him retire in December, 1952, and he was totally blind for the last year of his life, which affliction emptied life of much of its savour for him. Dr. Rees had held many appointments in the district, including those of medical officer of health, medical officer to the old board of guardians, and medical officer to the Bronglais Hospital for 43 years. Members of the medical profession, officials of local bodies, clergy and ministers, and hundreds of patients attended the funeral service at Llanilar church. He leaves a widow, a daughter, and two sons.

Dr. JAMES T. MCGLOSSON, who died at Edinburgh on January 24, will be remembered as a conscientious and kindly general practitioner in the Canonbie area of Dumfriesshire. Dr. McGlasson was born at Eastriggs, Dumfriesshire, on June 14, 1901. He graduated M.B., Ch.B. at Edinburgh University in 1925, and, after six months at Stockton Infirmary and a year of assistantship at Pontefract, he spent two years as assistant to the late Dr. R. H. Watt, Langholm. He took up practice in Canonbie in 1929, where his warm-hearted humanity endeared him to his many friends and patients. In addition to running an extremely wide and busy practice Dr. McGlasson found time to take an interest in many of the social activities of the district. He was an ardent horticulturist and apiarist, and in these capacities he was chairman for many years of the Canonbie Horticultural and Crafts Society. He was actively associated with the Canonbie Drama Club and with the local branch of the British Red Cross Society. He also took a keen interest in the Langholm Rugby Club, and both of his sons are playing members. Dr. McGlasson was an extremely active member of the Dumfries and Galloway Division of the B.M.A. In the 1949-50 season he was Deputy Representative to the Annual Representative Meeting, and in the following year he was appointed Representative of the Dumfries and Galloway Division in 1952-3, and was secretary to the Border Counties Branch from 1949 until his death. He was also secretary of the Dumfries and Galloway Division of the British Medical Guild. Dr. McGlasson filled all these appointments with enthusiasm and efficiency. These many interests made him an extremely busy man, and yet he always found time for a cheerful word to a friend or patient and was untiring in his efforts on their behalf. The sympathy of us all goes to his widow, sons, and daughters. He will be greatly missed.—T. M. S. C.

Professor KLOTHILDE GOLLWITZER-MEIER, one of the leading medical research workers in Germany, died at Hamburg on March 2 at the age of 59. She was born at Wolnzach, Upper Bavaria, on October 29, 1894, and studied medicine at Munich, where she graduated in 1919. After holding assistant posts at Halle, Greifswald, and Frankfurt, she was senior physician, under Volhard, at the university clinic in Frankfurt. During 1929-32 she was chief physician of the in-patient department of Hildegarde Hospital, Berlin, and then became extra professor of pharmacology and pathological physiology at the Balneological Institute, University of Hamburg. From 1945 until her death she was director of the Institute for Experimental Pharmacology and Balneology at Hamburg. Professor Gollwitzer-Meier published important papers on the control of the circulation, acid-base balance, and mineral metabolism, and for her experimental work on veins she achieved an international reputation. She married Professor Dr. Christian Kroetz, director of the General Hospital, Hamburg-Bergedorf, and he survives her.

Dr. R. N. DEANE, who died suddenly on February 20, at the early age of 56, had been in practice in Croydon for 27 years. He was one of the best-known doctors in the borough, and his loss leaves a gap which it will be hard indeed to fill. Reginald Neville Deane was born on April 11, 1897, and received his medical education at Queen's University, Belfast, where he graduated M.B., B.Ch. in 1919, taking first place in surgery in his final examination. Electing to enter general practice, he was conspicuously successful, building up a large practice, so that at the time of his death he had two partners. In addition he was one of the first who availed himself of the trainee assistant scheme, with the happiest results. But his success was very much more than material. He stood in the direct line of the best general practitioners of the past, and so became dearly loved by his patients, to whom he was always as much a friend as a doctor. He was an extremely busy man, but though, apart from his practice, he found time for various hobbies,

he always had some to spare to give help to any who were in need of it. To his fellow practitioners he was best known for his interest in medical politics. During the war he was an assiduous member of the local medical war committee, where, as in all committees, his immediate grasp of the essential of any problem was of immense service. He was never afraid to take an unpopular line and was a staunch advocate of the National Health Service. He became an original member of the Croydon Executive Council, and was chairman of the Croydon Local Medical Committee at the time of his death, a position he had filled with conspicuous ability since 1949. But apart from these things he will be remembered with affection by his colleagues as a genial and kindly host, always friendly and optimistic and always full of plans and of energy to carry them into effect. He was widely read, an able mathematician, a country-lover, and no mean inventor. We shall not easily see his like again. We can only guess at the gap which will be left in the lives of his widow and stepson, and offer them our sympathy.—J. N. H.

Dr. JOHN CUMMING died at his home at Sutton-on-Hull, East Yorkshire, on March 3 at the age of 81. He had been in practice at Hull for just over fifty years and he had continued to visit his patients until eight months ago, when a painful illness compelled him to give up. John Cumming was born on October 25, 1872, and was educated at Glasgow High School and at Glasgow University, where he graduated M.B., C.M. in 1895. Before settling at Hull early in the present century, he served for a period as a ship surgeon. In 1911 he decided to remain outside panel practice, and throughout his medical life built up and retained an extensive and busy private practice. For many years he was chief surgeon to the Hull city police until he retired from the post in 1938. During the last war, however, he was recalled to serve again in that capacity and even after the war he retained his interest in medico-legal work. He was the medical examiner for superannuation for the Hull education authority, as well as medical referee for assurance companies.

R. R. S. writes: John Cumming was a well-known figure in the medical life of Hull. His sturdy, native independent spirit kept him outside both the panel and the National Health Service. He was the family doctor in the old tradition, and in that tradition he retained the trust and affection of his patients through almost four generations. Because of his many Glasgow associations, he was especially proud of his presidency of the Hull and District Glasgow University Graduates' Association.

Dr. W. F. UMNEY, consulting physician to the old South-Eastern Hospital for Children, died at his home at Beckenham on March 3 at the age of 87. William Francis Umney was born in London on August 17, 1866, and from the Merchant Taylors School entered St. Thomas's Hospital with a scholarship in 1885. He qualified M.R.C.S., L.R.C.P. in 1890, taking the London M.B. in the following year with honours in medicine and obstetric medicine, and proceeding to the M.D. in 1892. He held a number of house posts at St. Thomas's and then became resident clinical assistant at the Bethlem Royal Hospital; while there he obtained the certificate of the Royal Medico-Psychological Association in 1892. An enthusiastic cricketer in his younger days, he was a member of the Merchant Taylors cricket team from 1883 to 1885, being captain in his final year. He also played for St. Thomas's for four years and was captain in his last two years, in one of which, 1889, St. Thomas's won the inter-hospitals cup. The United Hospitals cricket team also called on his services and he frequently captained the side. In 1893 he settled in practice at Sydenham, and almost at once he was appointed physician to the South-Eastern Hospital for Children (now the Children's Hospital) and medical officer to one of the districts of the London County Council. He held these appointments until 1928, when he was obliged to retire through failing eyesight. He was then

made honorary consulting physician to the hospital. For a few years after starting practice he played a good deal of cricket for a local club and was top of the bowling averages in several seasons. When war broke out in 1914 he formed and trained a voluntary aid detachment of Sydenham ladies, which became V.A.D. 142, Kent, and of which he was medical officer for four years.

Mr. CHARLES MONTAGU POWER, who died on March 6 at the age of 64, became secretary of the Westminster Hospital in 1921, and from then on he was closely concerned with the planning of the new hospital, medical school, and nurses' home. The building committee, at which plans for the new buildings were discussed, soon discovered that in Mr. Power they had a secretary possessing not only a wide knowledge of hospital requirements but also one with the tact and ability to sort out the demands for space which were made by the various sections of the hospital. Years later he supervised the arrangements for the opening of, first, the new nurses' home by the late Queen Mary in March, 1938, then the new medical school by the Earl of Athlone in May, 1938, and, finally, the new hospital in April, 1939, when King George VI performed the ceremony. Mr. Power served in the first world war, was mentioned in dispatches, and in 1917 was awarded the Military Cross. In the last war he was inspector of hospitals and convalescent homes in the home counties, and his work for the Emergency Medical Service, the British Red Cross Society, and Lady Churchill's Aid-to-Russia Fund received official recognition in 1945, when he was appointed O.B.E. Earlier, his election to the presidency of the Institute of Hospital Administrators in 1937-8 was an indication of the admiration in which he was held by his colleagues in the same field of activities. He is survived by a widow and two daughters.

Mr. J. E. KILVERT, who died at his home at Derby on March 10 at the age of 78, was in practice there from the beginning of the century. John Ellis Kilvert was born on May 30, 1875, in India, where his father was a district commissioner. He received his medical education at St. Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1898. Among the hospital appointments he held were those of house-surgeon and ophthalmic house-surgeon at St. Thomas's, clinical assistant at the Evelina Hospital for Sick Children, and house-surgeon at the Derbyshire Royal Infirmary, where his abilities were soon appreciated. In 1903 he joined one of the honorary physicians as partner in general practice, thus following a tradition which was not without merit; at that time the visiting staffs of such hospitals were all in general practice. In 1906 he was appointed honorary assistant surgeon, and he continued as one of the visiting surgeons until 1940. In the first world war, when two of the honorary surgeons were abroad on active service, he dealt with an immense amount of work, including the surgical care of wounded soldiers, work which was accepted as part of the honorary duties of the staff. For his wartime services he was appointed O.B.E. in 1920. In his later years he gave much time to the administrative side of the Infirmary, to which his professional life was devoted, and he made many friends in all departments. In general practice throughout the whole of his active years, which continued until a year or two ago, he was renowned for his clinical acumen, and for the trouble he took in caring for his patients. To many of them he showed a generosity which was private and kindly, and a very wide circle remember him with gratitude. For many years he was the local secretary of Epsom College. Mr. Kilvert had few hobbies, but he had read widely and had a considerable knowledge, among other things, of criminal trials. When he started in practice the partnership relied on horse transport, but in 1906 he bought his first motor-car—of seven horse-power, with one cylinder. Mr. Kilvert is survived by his widow, who before their marriage nearly fifty years ago was a sister at the Derbyshire Royal Infirmary.—H. B.

DR. CHARLES VISGER, who was in practice at Clevedon, Somerset, for very many years, died at his daughter's home at Chippenham, Wiltshire, on March 21 after a short illness. Charles Visger was born on February 28, 1875, and qualified M.R.C.S., L.R.C.P. from University College Hospital, London, in 1901. After qualification he held house appointments at University College Hospital, the Beckett Hospital, Barnsley, and the Victoria Hospital for Children, Chelsea. He then joined the late Dr. Theodore Davis in partnership at Clevedon, where he succeeded to a large general practice, in which he continued until a few weeks of his death at the age of 79. During the first world war Dr. Visger played a prominent part in the organization of a military hospital at Clevedon, work for which he was appointed O.B.E. in 1920. In the last war he was actively associated with a local maternity hospital to which expectant mothers from the more thickly populated areas were admitted under the evacuation scheme. He was a trustee of the Stoke Park Colony and the Burden Neurological Institute, and medical officer to the local cottage hospital and certifying factory surgeon for the district. A member of the British Medical Association for nearly 50 years, he was chairman of the Bristol Division in 1926-7. From his early days at Clevedon Dr. Visger identified himself with many local interests, especially cricket, tennis, and golf. He was also a devout churchman and was a sidesman and a member of the council of the parish church of St. Andrew's at Clevedon, to which he was deeply attached. The large congregation at the funeral service at the parish church bore ample testimony to the esteem and affection in which he was held. His wife died in 1914, and he lost his son a year earlier. He is survived by his daughter, to whom the sympathy of his many friends and patients is extended.—G. M.

DR. MYLES PATRICK MORIARTY died at Blackburn, Lancashire, on March 25 at the age of 53. Born at Dublin on November 9, 1900, he was educated at Belvedere College and University College, Dublin, where he graduated M.B., Ch.B. in 1925, after a brilliant career as a student. In 1929 he took the D.P.H. and then came to England and practised first at Leeds and then at Luddenden Foot, Yorkshire, before settling at Blackburn in 1939.

F. C. R. and J. D. C. write: Myles Moriarty was a rare combination of high intelligence and natural charm, together with kindness and consideration. A true Irishman, he had a wit matched by few, and his touch of humour lightened many a heavy heart. He was as popular with his colleagues as he was with his patients. He took a keen interest in professional affairs and was a member of the British Medical Association and the Blackburn Local Medical Committee. He was a great reader and had an encyclopaedic knowledge of many subjects. Above all else, he was a true Christian and an example to all. Although he must have known the import of his symptoms for some time, he was careful to conceal them to avoid giving anxiety to those around him. It was not until he collapsed in harness in August of last year that the seriousness of his condition was realized. In spite of his long illness his spirit never flagged, and he retained his cheerfulness to the end. Myles Moriarty was a good doctor, a good man, and a good friend, and his loss will be felt by all who knew him. Our sympathy goes out to his widow and his seven children.

DR. ELIZABETH CASSON writes: May I be allowed to add a few words of appreciation to your obituary (*Journal*, March 27, p. 764) of Dr. G. H. GRILLS? His enthusiasm for modern treatment led him to visit mental hospitals in Germany and Holland, and he spent a few days at the Dorset House School of Occupational Therapy in its early days at Bristol. No detail of treatment went unnoticed, to the extent of his joining a Margaret Morris Movement class of patients and students going on at the time. On his return to Chester he incorporated three large and airy

occupational therapy rooms in his hospital improvements, which he named "Sandepoort," "Dorset House," etc. He gave many students opportunities for study of occupational therapy at Chester, and his work led to a rapid spread in other hospitals.

DR. R. E. S. GIBSON died suddenly at his home at Cleethorpes, Lincolnshire on February 18, the day after his 58th birthday. Robert Ernest Stewart Gibson was the son of the late Mr. Robert Gibson, of Hamilton, Lanarkshire. During the first world war he served in the Royal Flying Corps. On demobilization he entered Glasgow University as a medical student and graduated M.B., Ch.B. in 1923. He was in practice at Newcastle-upon-Tyne, Kidderminster, Cambridge, Bideford, and Westward Ho, before he finally settled at Cleethorpes early in 1935.

E. A. R. writes: Dr. R. E. S. Gibson will be remembered by many Glasgow graduates as president of the Students' Union in the vintage era of the Birkenhead Rectorial, and by others as one of the originals of the Royal Flying Corps. His was a ripe intelligence, fortified by wide reading and a detached, critical, and humorous survey of life. Although he had been in indifferent health for several years, his opinion was one which exercised a balancing view in local medical politics, and much of the harmony and co-operation of practitioners in the Grimsby and Cleethorpes area was due to his privately expressed views. His widow and son, who is also a graduate of Glasgow University, survive him.

We are indebted to Dr. W. PAGEL for the following appreciation of Dr. DOROTHY STOPFORD PRICE, whose obituary was printed in the *Journal* of March 6 (p. 589): Dr. Dorothy Stopford Price was outstanding as a personality and as a physician. She combined in her charming and dynamic personality vision, zeal, and the quest for a profound scientific foundation for her medical activities. Her vision led her at an early date to the recommendation and introduction, at a great financial and personal sacrifice, of B.C.G.; and her zeal made her organize and see through extensive tuberculin surveys for Ireland. Her quest for a scientific basis drove her on long and strenuous journeys in order to study the pathology of tuberculosis. She spent many hours in the post-mortem room selecting specimens for investigation. These specimens bespoke her rare gift for the detection of the essential behind the phenomena, and proved to be corner stones in our knowledge of, for example, epituberculosis, congenital tuberculosis, and the early histological changes in primary infection of the human lung (probably the earliest changes so far known). Her deep interest in her subject, associated with a rare sense of humour, made her visits to London special occasions. It was particularly inspiring, however, to see her at Dublin as the centre of a circle of distinguished medical men, young and old, highly enthusiastic for the promotion of medical knowledge and enlightenment. She will long be remembered in the organizations which she created, in her literary monuments, and above all in the memory of her grateful compatriots and her friends in all countries of the globe.

DR. SIMEON BURT WOLBACH, emeritus professor of pathology at Harvard University, died at Sudbury, Mass., on March 18, aged 73. He was born at Grand Island, Nebraska, on July 3, 1880, and graduated M.D. at Harvard in 1903. From 1905 he held various teaching posts at Harvard, becoming Shattuck Professor of Pathology in 1922. He retired in 1947. He was noted particularly for his investigation of rickettsial infections. In 1919 he described the causal agent of Rocky Mountain spotted fever, naming it *Dermacentor rickettsi*, and he was first to demonstrate its intranuclear multiplication in tick tissue. In 1920 Wolbach led an expedition to Poland to investigate epidemic typhus. His monograph on *The Etiology and Pathology of Typhus*, written with J. L. Todd and F. W. Palfrey in 1922, has become a standard work on the subject. Among other appointments held by Wolbach was that of pathologist-in-chief at the Peter Bent Brigham Hospital from 1917 to 1947.

In more recent years he was engaged in studies on vitamin deficiencies and on the effects of taking vitamin A in excess. After his retirement from his chair at Harvard he was officially connected in a consultative capacity with the U.S. Atomic Energy Commission and the Armed Forces Institute of Pathology.

Medico-Legal

E.C.T. INJURY CLAIM FAILS

A claim for damages for personal injuries, alleged to have been caused by the application of electric convulsion therapy, against the Horton Road and Coney Hill Hospitals Management Committee and the medical superintendent, Dr. F. C. Logan, made by Charles Davies, an insurance agent and cycle repairer, of Gorsley, Gloucestershire, was dismissed by Mr. Justice Hallett at Gloucester Assizes on February 17. Davies alleged that he had not been warned that the treatment might result in injury, and that the defendants had assaulted him by giving him the treatment without his consent.

Giving evidence, Davies said that in June, 1951, he suffered from insomnia and throat trouble. His doctor, Dr. K. M. Tomlinson, of Newent, sent him to see Dr. Logan at Gloucester Royal Hospital (Royal Infirmary). He saw him on August 24. He told Dr. Logan to what he attributed his throat trouble, and Dr. Logan said he thought he should have five lots of electrical treatment. Dr. Logan did not explain what the electrical treatment was. He (Davies) had no idea what sort of treatment he was going to have, but thought it was some sort of heat treatment. He had never then heard of the shock treatment. Had he been told that the treatment might result in a fracture and dislocation of bones or limbs, he would not have agreed without consulting his wife.

After describing a treatment, Davies said that one evening he saw Dr. Tomlinson, who sent him to see Dr. J. F. Bourdillon, consulting orthopaedic surgeon, Gloucester Royal Hospital. He was put into plaster on September 12. This was removed on November 9. He had been unable to work since the injury and claimed special damages of £541.

Dr. Bourdillon said that Davies had received a crush fracture of the eighth dorsal vertebra. In his opinion the injury occurred during E.C.T. When he saw Davies at a later date he thought he was making complaints which were more excessive than was justified by the nature of the injury.

Dr. Logan, in evidence, said he had been carrying out electric convulsion therapy for nearly 12 years. During that time he had carried out some 14,000 such treatments and had only experienced three cases of vertebral fractures, including this case, and six cases of jaw dislocation. He had advised five treatments of E.C.T. for Davies. He distinctly remembered telling Davies that under the treatment his muscles would go into spasms and produce violent contractions, and that there was a possible risk of fractures or of dislocation of the jaw. "At that time," said Dr. Logan, "I had had no previous cases of back injury, and there had been no case of jaw dislocation for several years." He distinctly remembered telling Davies that there was a risk, but it was a risk worth taking. He remembered saying to him that there was risk in everything, even crossing the road. Davies said he was quite prepared to undergo the treatment. In answer to the judge, Dr. Logan said relaxants had not then been introduced. He now used relaxants, but considered some small degree of muscular contraction was necessary, otherwise the treatment might as well not be given.

Fair Targets

Giving judgment, Mr. Justice Hallett said he was satisfied that Dr. Logan warned Davies of the risks of the treatment and that Davies accepted those risks. He also found that the treatment was administered carefully and efficiently in

the usual and proper way. He did not think Davies was a reliable witness. He thought that any disability he had suffered since November 9, 1951, had been psychological. Davies's claim would be dismissed with costs.

With regard to costs, Mr. R. C. Hutton, representing Davies, stated that Davies was a legally aided person and that his capacity to pay any part of the legal costs was nil. Mr. J. F. Bourke said that counsel for the defendants could do nothing but complain of the circumstances. The Judge said he made no criticism of the legal aid committee, but it was obvious that this was a case of "Heads I win, tails you lose." He supposed that doctors and hospitals must regard themselves as fair targets under the legal aid system.

The Medical Protection Society instructed Messrs. Le Brasseur and Oakley to act for Dr. Logan.

Medical Notes in Parliament

Tuberculosis Precautions in Navy

A personal case of a young seaman who contracted tuberculosis while serving abroad in a frigate, referred to by Mr. Albert Roberts (Lab.) on March 30, led Commander ALLAN NOBLE, Parliamentary Secretary to the Admiralty, to describe the precautions taken generally in the Royal Navy to avoid, detect, and control the disease.

He said that they attached the greatest importance to mass radiography, which was compulsory. It had been used since 1940, and the fact that the incidence had steadily fallen probably meant that they were reaping the results of what they had been doing over the past 15 years. Compulsory radiography was carried out on all new entries. The examination was repeated annually, and it was carried out on all men before they were sent abroad. When men were in the Far East the x-ray examinations were conducted at six-monthly intervals instead of yearly as at home. In the event of there being a tuberculous contact, all those concerned were x-rayed, and there was a routine follow-up within six months. The value of certain immunity measures such as B.C.G. was being investigated. Every opportunity was taken of giving the men lectures about medicine and health, and a point was made of encouraging men with coughs and colds to seek medical advice.

Appointments for Patients

DR. BARNET STROSS (Lab.) asked the Minister of Health on March 30 how many general practitioners saw their patients, using an appointment system; and, in view of the advantage to doctors and patients, whether he would consider circularizing all local executive committees, stating the advantages that would follow in the time that would be saved and the reduction of cross-infection. Mr. IAIN MACLEOD, Minister of Health, replied that the information was not available. It was in his view for doctors themselves, in the light of the particular circumstances of their practices, to decide how far they could use a system which seemed, when successfully organized, to have many advantages.

Disease Carriers

MR. GEORGE THOMAS (Lab.) asked the Minister of Health on April 1 what steps he took when a person was found to be a carrier of disease, and in how many cases he had taken such action during the past 12 months. Mr. IAIN MACLEOD stated that action was a matter for the local authorities, who could require carriers of certain diseases to cease work in any occupation connected with food and drink if there was a risk of spreading infection. There was no central record of the action taken.

Scottish Hospital Staffs

MRS. JEAN MANN (Lab.) asked the Secretary of State for Scotland on March 30 what representations he had received from hospital staffs, or from hospital boards, concerning the status and remuneration of registrars, junior and senior, and

senior hospital medical officers; and what action he proposed to prevent these staffs from leaving hospitals for general practice. Mr. JAMES STUART, Secretary of State for Scotland, said that he had received no recent representations about the status of these grades. He did not propose any action to prevent doctors from leaving hospitals for general practice or vice versa.

Colonial Service

Mr. JAMES JOHNSON (Lab.) asked the Secretary of State for the Colonies what steps he was contemplating regarding interchangeability of superannuation schemes for teachers, doctors, nurses, and similar public servants who took up service in the colonial territories. Mr. OLIVER LYTTLETON, replying on March 30, said that complete interchangeability of superannuation schemes was not possible, since nearly all colonial schemes were non-contributory and transfer values could not therefore be exchanged. Arrangements existed, however, for the preservation of the superannuation rights of Civil Servants, teachers, doctors, nurses, and local government officers who took up service in the colonial territories. Secondment from several of these home services was also possible.

Prescribed Diseases

Mr. O. PEAKE, Minister of Pensions and National Insurance, informed Dr. BARNET STROSS (Lab.) on March 29 that in 1950 about 36,000 men and 6,000 women were awarded benefit for a prescribed disease under the National Insurance (Industrial Injuries) Acts. The corresponding figures for 1951 were about 35,000 and 7,500. Dr. STROSS suggested that the figures seemed strangely small in relation to all scheduled diseases and the whole industrial population. Did it not mean that some cases, such as dermatitis, could not easily be accepted for full pensionable payments? Mr. PEAKE said that the whole question of the prescription of industrial diseases was before the Beney Committee. On the whole it was a matter for congratulation that the claims for industrial diseases were not of a large order.

£6m. for Salary Increases

Mr. IAIN MACLEOD stated in answer to Mr. A. BLENKINSOP (Lab.) on April 1 that nearly £6m. had been provided in the 1954-5 Health Service estimates for higher expenditure on wages and salaries due to advances already awarded or likely to be awarded.

School Dentists.—The Minister of Education informed Squadron Leader A. E. Cooper on March 31 that in December, 1953, there were the equivalent of 945 full-time dentists in the school dental service. The comparable number in 1952 was 850.

Vital Statistics

Scottish Returns

The preliminary return¹ for the year 1953 shows that the birth rate was 17.8 per 1,000 and was 0.4 below the average of the five preceding years. The infant mortality rate was 31 per 1,000 live births; this was the lowest ever recorded in Scotland, being 4 below the rate for 1952. The death rate was 11.5 per 1,000 and was 0.8 below the average of the five preceding years. 598 deaths were due to road transport accidents compared with 483 in 1952. Deaths from all forms of tuberculosis numbered 1,338, and 1,159 from respiratory tuberculosis. These deaths were, respectively, 274 and 250 fewer than in 1952. The number of deaths from the principal epidemic diseases was 386. These included 271 from influenza, 41 from whooping-cough, and 29 from measles. Only 2 deaths were attributed to diphtheria, the smallest number ever registered in Scotland. In 1940 and 1941 the deaths from diphtheria numbered 676 and 517 respectively. 13 deaths were attributed to acute poliomyelitis, an increase of 1 compared with 1952.

The birth rate for the December quarter of 1953 is shown in the *Quarterly Return* to have been 17.1 per 1,000 population; this was 0.1 above the rate for the preceding fourth quarter. The infant mortality rate was 32 per 1,000 registered live births and was the lowest rate recorded for any fourth quarter, being 7 below the rate for the December quarter of 1952. The general death rate, 11.3 per 1,000 population, was also the lowest recorded for any fourth quarter. 171 deaths were due to road transport accidents, an increase of 52 compared with the fourth quarter of 1952.

England and Wales in 1953

In England and Wales in 1953 the death rate from respiratory tuberculosis was 179 per million population as compared with 212 in 1952. The rate for males was 257 and for females 108 as compared with 304 and 128 in 1952. The death rate from cancer of the lung and bronchus was 343 per million population as compared with 323 in 1952. The death rate for males was 607 and for females 99 as compared with 568 and 98 in 1952. The death rate from other forms of cancer was 1,651 per million population in 1953 as compared with 1,711 in 1952. There were 522 maternal deaths, giving a death rate of 0.76 per 1,000 live and still births.

Infectious Diseases

The largest variations in the trends of infectious diseases in England and Wales during the week ending March 20 were increases in the number of notifications of 450 for whooping-cough, from 2,093 to 2,543, 123 for dysentery, from 1,001 to 1,124, and 112 for measles, from 2,325, and decreases of 194 for scarlet fever, from 1,476 to 1,282, and 51 for paratyphoid fever, from 96 to 45.

The number of notifications of paratyphoid fever in Wales declined from 89 to 44. The chief centres of infection were Glamorganshire 37 (Cardiff C.B. 21, the other 16 cases being returned from 8 areas), and Monmouthshire 7 (Newport C.B. 7). Durham with 1 case was the only other area with paratyphoid fever during the week.

19 cases of acute poliomyelitis were notified during the week. These were 2 fewer for paralytic and 1 fewer for non-paralytic than in the preceding week. The largest returns were 3 cases in Yorkshire West Riding and 2 cases in Devonshire, Surrey, Worcestershire, and Glamorganshire. No administrative area had more than one case.

For the third consecutive week the number of notifications of dysentery exceeded 1,000. The largest rise during the week was 67 in Leicester C.B., from 66 to 133. The chief centres of infection were Lancashire 213 (Bolton C.B. 42, Salford C.B. 33, Eccles M.B. 32, Liverpool C.B. 19, Preston C.B. 17, Manchester C.B. 16, Ormskirk U.D. 15), Leicestershire 141 (Leicester C.B. 133), London 125 (Islington 26, Lewisham 20, Shoreditch 14, Hackney 13, the remaining 52 cases were scattered through 18 boroughs), Yorkshire West Riding 111 (Dewsbury C.B. 40, Leeds C.B. 22, Bradford C.B. 17), Middlesex 92 (Southall M.B. 30, Edmonton M.B. 14, Hornsey M.B. 13, Willesden M.B. 11), Essex 86 (West Ham C.B. 28, the other 58 cases were spread over 13 administrative areas), Staffordshire 46 (Cannock U.D. 35), Norfolk 45 (Norwich C.B. 44), Warwickshire 37 (Birmingham C.B. 33), Kent 30 (Tonbridge R.D. 11), Devonshire 29 (Exeter C.B. 26), Gloucestershire 23 (Bristol C.B. 23), Nottinghamshire 23 (Nottingham C.B. 16), and Surrey 20.

The largest returns in Scotland were Glasgow 137, Edinburgh 35, and Lanark County 34.

Week Ending March 27

The notifications of infectious diseases in England and Wales during the week included pneumonia 661, scarlet fever 1,492, whooping-cough 2,553, diphtheria 14, measles 2,067, dysentery 1,315, acute poliomyelitis 24, paratyphoid fever 20, and typhoid fever 2.

¹Report of the Department of Health for Scotland for the Year 1953. H.M.S.O., 4s. 6d.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ————. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 20 (No. 11) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

‡ Includes puerperal pyrexia.

Medical News

Royal College of Obstetricians and Gynaecologists.—As part of the College's silver jubilee celebrations in July four honorary fellowships will be awarded. Their recipients will be: Lord Simonds, the Lord Chancellor, who as Mr. Gavin Simonds, K.C., gave invaluable help and advice during the foundation of the College; Sir Arthur Sims, who with his family endowed the Sims-Black Travelling Professorship (named after his wife and daughter) to enable a professor to visit the Commonwealth every second year; Dr. Doris Clifton Gordon, of New Zealand, who has rendered distinguished services to obstetrics and gynaecology in her own country, in particular being instrumental in obtaining funds for the endowment of a Chair at Dunedin; and Dr. Joe V. Meigs, clinical professor of gynaecology at Harvard University, and chief gynaecologist at the Massachusetts General Hospital.

Kingsbury Maternity Hospital.—On March 30 Princess Margaret opened a new antenatal clinic and an extension to the nurses' home at the Kingsbury Maternity Hospital, Middlesex, which is one of the Charing Cross Hospital group. The Princess was received by the Lord Lieutenant of the county and Lord Inman, chairman of the board of governors of the Charing Cross Hospital. After a service of dedication conducted by the Bishop of Willesden, Princess Margaret inspected the new buildings. In his speech Lord Inman referred to the new developments as the advance guard of the new Charing Cross Hospital which is to be situated at Northwick Park. The extensions are the first completed major capital project undertaken by the board of governors since the start of the Health Service.

3-D in a Medical Journal.—Not to be outdone by lay periodicals, the current issue of *Anaesthesia* provides its readers with two three-dimensional pictures and a pair of spectacles to view them with. The claim is made that, so far as the editor is aware, this is "the first time that this type of stereogram (Royer-Vala method) has been used in a medical journal." The pictures illustrate an article by Professor E. A. Pask on intravenous injection and the risk of injury to the median nerve. Seen through the glasses, the details of the pictures stand out sharply enough, but one is left wondering whether the slight gain in clarity is really worth the extra cost and trouble.

Middle East Medical Assembly.—The British Council has arranged for Sir Lionel Whitby (Regius Professor of Physics at Cambridge), Professor John McMichael, and Dr. P. M. F. Bishop (both of the Postgraduate Medical School of London) to lecture at the Fourth Middle East Medical Assembly at Beirut, Lebanon, from April 9 to 11. Sir Lionel Whitby will afterwards visit Turkey. Professor McMichael has recently been lecturing in Syria.

Central Midwives Board.—At the meeting of the Board on April 1, Mr. Arnold Walker was re-elected chairman and Professor A. A. Moncrieff vice-chairman for the ensuing year.

Sir Charles Dodds, F.R.S., Courtauld Professor of Biochemistry at the Middlesex Hospital Medical School, London, is to receive from Cambridge University the honorary degree of D.Sc.

COMING EVENTS

Edinburgh Course in Paediatrics.—A one-day course for general practitioners will be held on April 24 at the Royal Hospital for Sick Children, Edinburgh. Further information may be obtained from the Edinburgh Postgraduate Board for Medicine, Surgeons' Hall, Edinburgh, 8.

French Medical Week.—"Les Journées Médicales de France," organized by the Société Médicale des Praticiens, will be held in Paris from April 21 to 25 under the chairmanship of Professor Camille Lian. The "Journées" are open to doctors and medical students of all countries. Further information may be obtained from the Secrétariat des Journées Médicales de France et de l'Union Française, 12, rue Pierre Geoffroy, Colombes (Seine).

The Nutrition Society.—The Scottish group of the society will hold a symposium on "Nutrition and the Liver" in the Lecture Theatre, Departments of Biochemistry and Physiology, University of Glasgow, on May 8. Inquiries should be addressed to Dr. H. N. Munro, Biochemistry Department, The University, Glasgow, W.2.

First European Congress on Clinical Chemistry.—The congress will be held in Amsterdam from September 23 to 28. The main subjects for discussion will be "Isotopes in the Clinico-chemical Laboratory" and "The Physical Methods of Measurement in Connexion with Clinico-chemical Problems." Those wishing to attend should communicate with the secretary general, Ir O. Meulemans, Racineaan 17, Utrecht, Netherlands.

NEW ISSUES

British Journal of Ophthalmology.—The next issue (Vol. 38, No. 4) is now available. The contents include:

ARGEMONE OIL, SANGUINARINE, AND EPIDEMIC-DROPSY GLAUCOMA. *Sohrab A. E. Hakim.*
LATENT NYSTAGMUS AND ALTERNATING HYPERPHORIA. *J. Ringland Anderson.*
THE CORNEO-SCLERAL SUTURE: A TECHNICAL MODIFICATION. *H. B. Stallard.*
THE CORNEO-SCLERAL TRACK SUTURE: A NEW TECHNIQUE. *Mahmud Ali Shah.*

THE DARK-ROOM TEST. *A. C. Higgin.*
RETINAL IRRADIATION AND ANISEKONIA. *R. A. Weale.*

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.

Abstracts of World Medicine.—The April issue (Vol. 15, No. 4), which is now available, contains abstracts of important papers drawn from medical and other scientific journals published in some 20 different countries and in all five continents. The subjects covered range over the whole field of clinical medicine and include pathology, bacteriology, pharmacology, and chemotherapy; there are also sections dealing with medical genetics, public health, industrial medicine, forensic medicine and toxicology, anaesthetics, radiology, and the history of medicine.

Issued monthly; annual subscription £4 4s.; single copy 8s. 6d.; a specimen will be sent free on request.

These journals are obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London, W.C.1.

SOCIETIES AND LECTURES

A fee is charged on a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Monday, April 12

MEDICAL SOCIETY OF LONDON.—8.30 p.m., meeting of Fellows. Discussion to be introduced by Air Commodore T. C. MacDonald and Dr. I. J. Corbett: Medical Aspects of Air and Sea Travel.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. H. Osmond-Clarke: Fractures of the Upper End of the Femur; 6.30 p.m., Mr. R. C. Brock: Some Aspects of Surgery of the Heart.

Tuesday, April 13

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Mr. Charles Donald: Surgery of the Neck in Infancy and Childhood; 6.30 p.m., Mr. N. R. Barrett: Empyema.

WEST END HOSPITAL FOR NERVOUS DISEASES.—5.30 p.m., neurological demonstration by Dr. B. G. Parsons-Smith.

Wednesday, April 14

HARVEIAN SOCIETY OF LONDON.—8.15 p.m., discussion to be introduced by Dr. George Warren and Dr. Michael Ward: Health at High Altitudes.

NORTH-WESTERN TUBERCULOSIS SOCIETY.—At Aintree Hospital, Liverpool, 5.30 p.m., Mr. Dillwyn M. E. Thomas: Treatment of Tuberculous Mediastinal Lymph Glands and their Complications.

● ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5.15 p.m., Sir Reginald Watson-Jones: Injuries of Joints; 6.30 p.m., Mr. J. Cosbie Ross: Renal Tuberculosis.

ROYAL EYE HOSPITAL.—5.30 p.m., Mr. L. H. Savin: Ophthalmic Neurology (2).

SOUTHERN GENERAL HOSPITAL.—At Recreation Hall, General Hospital, Rochford, 8 p.m., First Sydney Body Lecture by Sir Francis Walshe, F.R.S.: The Changing and the Unchanging Face of Medicine.

APPOINTMENTS

GUNN, WILLIAM, M.B., Ch.B., D.I.H., Chief Medical Officer, North Thames Gas Board.
HART, DAVID MCKAY, M.B., Ch.B., F.R.F.P.S., F.R.C.O.G., Consultant Obstetrician and Gynaecologist, Stobhill Hospital, Glasgow.
HOSPITAL FOR SICK CHILDREN, Great Ormond Street, London, W.C.—J. N. Montgomery, M.D., M.R.C.P., D.C.H., Resident Assistant Physician; E. P. J. Silberstein, M.B., B.S., House-physician to Neurological and Neurosurgical Department; Daphne M. Kirkman, M.B., B.S., and T. J. Parkinson, M.B., Ch.B., M.R.C.P., D.C.H., House-physicians; B. J. Penry, M.R.C.S., L.R.C.P., House-surgeon; Mary F. Thomson, M.B., Ch.B., Resident Medical Officer, Tadworth Court.

MANCHESTER REGIONAL HOSPITAL BOARD.—H. Bolton, M.B., Ch.B., F.R.C.S., Consultant Orthopaedic and Accident Surgeon, Stockport and Macclesfield Hospitals; R. M. Fulton, M.D., M.R.C.P., Consultant Physician, Stockport and Buxton Hospitals; H. B. Andrews, M.B., Ch.B., Deputy Superintendent and Resident Medical Officer, Wrightington Hospital; K. Sen Gupta, M.B., D.A., Assistant Anaesthetist, Bury and Rosendale Hospitals; N. J. Roussak, M.B., Ch.B., M.R.C.P., Consulting Physician to Withington and Wythenshawe Hospitals, Manchester; Z. Golen, M.B., Ch.B., Assistant Psychiatrist, Whittingham Hospital, Preston.

NORTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—J. Littlejohn, M.B.E., M.R.C.S., L.R.C.P., D.L.O., Part-time Consultant Ear, Nose, and Throat Surgeon, Chelmsford and Essex Hospital and St. John's Hospital, Chelmsford; W. F. Dunham, B.M., B.Ch., D.Phys.Med., Part-time Consultant Physician in Physical Medicine, Vale Road School Spastic Unit, Tottenham; B. Fairburn, M.B., F.R.C.S., D.A., Maximum Part-time Consultant Neurosurgeon, Oldchurch Hospital, Romford; N. A. Thorne, M.D., M.R.C.P., Part-time Consultant Dermatologist, Mile End, St. George-in-the-East, and St. Andrew's, Bow, Hospitals; G. Grunberger, M.D., D.L.O., Part-time Consultant Ear, Nose, and Throat Surgeon, St. Margaret's, Epping, and Honey Lane, Waltham Abbey, Hospitals; R. W. Crockett, M.B., F.R.F.P.S., M.R.C.P.Ed., D.P.M., Part-time Consultant Psychiatrist, Oldchurch and St. George's, Hornchurch, Hospitals; J. J. F. O'Sullivan, M.B., B.Ch., M.R.C.O.G., Part-time Consultant Gynaecologist, Whipps Cross Hospital; G. C. Pritchard, M.B., F.R.C.S., D.O.M.S., Part-time Consultant Ophthalmic Surgeon, East Ham Memorial Hospital; D. V. Martin, M.R.C.S., L.R.C.P., D.P.M., Full-time Consultant Psychiatrist and Deputy Physician Superintendent, Claybury Hospital; Margaret M. Mason, M.B., F.R.C.S., Part-time Consultant Ear, Nose, and Throat Surgeon, Ilford and Barking Group of Hospitals and Clinics.

NORTH-WEST METROPOLITAN REGIONAL HOSPITAL BOARD.—Rosalind Child Guidance Clinic, Hilda C. Abraham, M.D., Consultant Psychiatrist, British Hospital for Functional Nervous Disorders, H. J. M. Stratton, Consultant Ear, Nose, and Throat Surgeon, Ashford Hospital, Ashford, F.R.C.S.Ed., D.L.O., Consultant Ear, Nose, and Throat Surgeon, Ashford Hospital, Ashford, Middlesex, H. S. A. Henry, M.B., B.Ch., F.R.C.S.I., D.P.H., D.L.C., Consultant Ear, Nose, and Throat Surgeon, Hornsey Central Hospital, E. F. G. Stewart, F.R.C.S.Ed., Consultant Ear, Nose and Throat Surgeon, Finchley Memorial Hospital; also at Northwood, Pinner and District Hospital, Northwood, Middlesex, C. P. C. Gore, M.D., M.R.C.P.I., D.P.M., Assistant Psychiatrist (S.H.M.O.), Child Guidance Training Centre, N.W.

ROBERTS, GRIFFITH WYN, M.B., B.Ch., D.P.H., County Medical Officer and School Medical Officer, Flintshire County Council.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Bihari.—On March 27, 1954, at University College Hospital, London, W.C., to Mac (formerly McMullan), wife of Julian Bihari, F.R.C.S., a brother for Katherine Anne—David Julian.
Cantor.—On March 27, 1954, at the Kent and Canterbury Hospital, to Kathleen, wife of Dr. Jack Cantor, D.Obst.R.C.O.G., of Kent Lodge, Faversham, Kent, a brother for Timothy.
Evans.—On March 19, 1954, at the Norfolk and Norwich Hospital, to Evelyn (formerly Smith), wife of Dr. Trevor Evans, a son—Andrew Leighton.
Gresham.—On March 28, 1954, at Mill Road Hospital, Cambridge, to Gweneth Margery (formerly Leigh), M.B., B.S., wife of Geoffrey Austin Gresham, M.B., B.Ch., a daughter—Diana.
Shrimman.—On March 28, 1954, at the Royal Buckinghamshire Hospital, Aylesbury, to Hazel (formerly Isaacs), wife of Irving Shrimman, M.B., B.Ch., D.P.M., of the Old Vicarage, Stone, Aylesbury, Bucks, a son.
White.—On March 20, 1954, at the Birmingham Maternity Hospital, to Frances Mary (formerly Cottam), M.B., Ch.B., wife of Dr. H. M. White, a son.

DEATHS

Cole.—On March 18, 1954, at 110, Cooden Drive, Bexhill-on-Sea, Sussex, Sydney John Cole, D.M., aged 83.
Colles.—On March 21, 1954, at The Limes Nursing Home, Jacob Post, Burgess Hill, Sussex, George Denbigh Collen, M.D., aged 86.
Freedlander.—On March 19, 1954, at Manchester Royal Infirmary, Isaac Harry Freedlander, M.B., Ch.B., of 618, Oldham Road, Failsworth, Manchester.
Gurney.—On March 18, 1954, at The White House, Grainger Park Road, Newcastle-upon-Tyne, Helen Mary Gurney, M.D., aged 79.
Halley.—On March 23, 1954, at Forester Hill, Aberdeen, Thomas Curr Halley, M.B., Ch.B., late of Bath, Somerset, aged 67.
Jacques.—On March 18, 1954, in a nursing home, Carlisle, Cumberland, Frederick Viel Jacques, V.R.D., M.B., Ch.B., D.P.H., D.T.M.&H., F.R.C.S., D.P.H.
Jones.—On March 23, 1954, at Aberdeen, Glam, Martin Llewellyn Jones, M.B., Ch.B., D.P.H.
Melville.—On March 25, 1954, Charles Melville, M.B., Ch.B., D.P.H., late of Grangemouth, Stirlingshire.
Milligan.—On March 21, 1954, in hospital, Ernest Henry Marcus Milligan, M.D., D.P.H., of Daisy Bank, Hadfield Road, Hadfield, Derbyshire, formerly of Glossop, Derbyshire.
Schwarzwald.—On March 18, 1954, Raimund Theodor Schwarzwald, M.D., of London, W.
Visger.—On March 21, 1954, at "The Paddocks," Chippenham, Wilts, Charles Visger, O.B.E., M.R.C.S., L.R.C.P., of Clevedon, Somerset, aged 79.
Walker.—On March 23, 1954, at the Old Manse, Tyndrum, Perthshire, Robert Alexander Walker, M.B., F.R.C.S., late of Peterborough, aged 79.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Drugs in Breast Milk

Q.—What drugs in common usage are excreted in the breast milk in amounts likely to have a harmful effect on the infant? In particular, I am interested in antihistamine drugs, sulphonamides, antibiotics, barbiturates, aspirin, and purgatives.

A.—Definite clinical evidence exists that breast-fed infants may suffer ill-effects if the mother is receiving bromide and iodide, ergot alkaloids, or thiouracil compounds. Excessive maternal consumption of alcohol or nicotine (cigarette smoking) has also been followed by symptoms in the suckling. Active constituents of purgatives of the anthracene group (cascara, senna, etc.) may be excreted in sufficient quantity to affect the baby, and it is wise to avoid their use in the nursing mother. Liquid paraffin is a suitable preparation to use. There is some evidence that sufficient amounts of the barbiturates and phenytoin may be excreted in breast milk to cause drowsiness in the baby. Caffeine, hyoscine, morphine, codeine, and atropine are either not excreted at all or only in insignificant quantities.

Other drugs which are excreted in breast milk, but in insufficient concentration to have a deleterious effect on the infant, include sulphonamides, antihistamines, salicylates, penicillin, streptomycin, chloramphenicol, terramycin (oxy-tetracycline), and aureomycin.

Ammoniacal Dermatitis in Infants

Q.—In view of the possible dangers of mercury absorption, particularly pink disease, is it unwise to continue prescribing conspersus hydrarg. subchlor. co. for ammoniacal dermatitis in infants? If so, what alternative treatment is recommended?

A.—The use of local applications containing mercury is contraindicated. Likewise rinsing of previously washed napkins in a saturated (or weaker) solution of boracic acid crystals is undesirable. Effective local treatment consists in the use of destructible napkins; bathing the affected parts in warm normal saline after each toileting; and applying pure lanoline if there is severe excoriation, the lanoline being replaced by dusting with a high-grade infant powder as the condition improves. If, as is frequently the case, the stools are abnormal in character, necessary feeding adjustments should be made.

Lipuria and Chyluria

Q.—A woman of 22 has visible lipuria. Diabetes, pregnancy, fracture, and phosphorus poisoning have been excluded as the cause. How should she be investigated now, and what possibilities must be considered?

A.—It is essential to determine whether the urine contains fat globules only (lipuria) or fat globules together with protein, fibrinogen, and a few red cells. In lipuria the fat globules can be recognized with a microscope, using the low power objective and ordinary lighting; in chyluria the fat globules are much smaller, but they can be seen with a high power objective, if dark ground illumination is used.¹

The only other condition, besides those mentioned, which may cause lipuria is said to be a severe chronic nephritis, which can easily be excluded. It is therefore unlikely that the patient has lipuria. Chyluria is due to blocking of a main branch of the receptaculum chyli. If the patient has been abroad the lymphatics may have been blocked by filarial parasites. A more likely cause in this country is

obstruction of the duct due to the after-effects of a tuberculous peritonitis, or pressure of a gland which is infiltrated with tuberculosis, lymphadenoma, or malignant disease. If the abdomen is opened for any cause the appearance is striking, as the lacteals are greatly distended and glistening white. The condition can be improved if the patient will tolerate a low fat diet.

Immunity after Tetanus Toxoid

Q.—How soon after inoculation with tetanus toxoid does reasonable protection develop?

A.—It is usually accepted that protection is significant ten days after the second of two injections of 1 ml. of tetanus toxoid at an interval of 6 weeks. A third dose should be given 9 to 12 months later to complete the primary course.

Tetanus Toxoid and Combined Prophylactics

Q.—If three doses of tetanus toxoid are given at appropriate intervals in childhood, will a useful amount of active immunity against tetanus persist into adult life? If so, can a combined vaccine against diphtheria, whooping-cough, and tetanus be recommended?

A.—In the Services the usual primary course of three well-spaced injections of tetanus toxoid gives a useful degree of active immunity, but it is reinforced in peacetime by boosting doses at intervals of five years. It is unlikely that a more durable immunity will develop in young children than in adults. As there is no maternally transferred passive immunity to tetanus in young babies, the first dose (0.5 ml.) of tetanus toxoid may be given in the early weeks of life without risk of any interference with the responses of the antibody-producing mechanism. After the full primary course in the first year we do not yet know how many five-yearly boosting doses may be necessary, but it seems likely that after two or three such doses further boosting need be very infrequent.

A combined prophylactic against diphtheria, tetanus, and whooping-cough is strongly recommended for primary immunization at the age of 3 to 4 months at the earliest. Three doses are given at intervals of four to six weeks for the primary course, followed by one reinforcing dose at the age of 12 to 15 months. Above the age of 5 years the pertussis constituent is no longer required, but further boosting is essential with either a combined diphtheria and tetanus preparation or the single prophylactics.

Episcope, Diascope, and Epidiascope

Q.—What is the difference between an episcope, a diascope, and an epidiascope? How do they work, and for what type of material is each best suited?

A.—An episcope is an apparatus for projecting images of opaque objects, such as illustrations, graphs, and diagrams, by reflection. A diascope projects transparent images and is made to use with either standard British lantern slides (3½ in. square—8.2 cm. square) or miniature slides (2 in. square—5.1 cm. square) and 35-mm. film strips.

To-day episcope are rarely constructed as a separate instrument, but are more usually combined with the diascope to make the composite instrument known as the epidiascope, which can be rapidly adapted to work with either an opaque image or a transparency.

In the case of a diascope or lantern-slide projector the light is concentrated on the transparency by means of a condenser lens, and a brilliant image is obtained. However, this cannot be done with an episcope, and the image of an opaque object is never very bright. Thus to obtain good quality results all illustrations should be photographed and transparencies prepared. Episcopic projection should be reserved for colour pictures which cannot readily be photographed and for other material required urgently.

Oestrogens in Mumps

Q.—The treatment of mumps orchitis by oestrogens seems to work in my very small experience of this condition. Can you tell me if androgens or oestrogens are of any use for mumps oophoritis?

A.—I am not aware of any reports on the treatment of mumps oophoritis with oestrogens or androgens. The incidence of the complication is extremely small as compared with orchitis, and such few cases as I have encountered resolved naturally so rapidly that it would be difficult to evaluate attempts at treatment or prophylaxis by these preparations. Incidentally, more recent reports on the use of diethylstilboestrol for the prevention of mumps orchitis have been discouraging, but a somewhat cautious acceptance of its use in treatment is allowed, with which I agree.

NOTES AND COMMENTS

Craving for Salt.—Dr. M. N. Ghosh (London, N.W.5) writes: In view of the recent revival of the fairly old concept that the dietary sodium might be a primary cause of arterial hypertension, I wonder whether one is justified in summarily dismissing the topic by concluding that craving for salt is a harmless oddity ("Any Questions?" February 27, p. 532). During recent years salt restriction (sodium ion) in diets has become too well-known a regime in management of cases of oedema and hypertension, and probably the question was put forward by the inquirer with this background in mind. If a salt restriction in diet produces a fall in raised blood pressure, it is quite logical to think of its corollary that hypertension might well be produced by an excessive intake of salt (sodium ion). It is true that one should not be led only by logic, and definite experimental evidence must be put forward either to support or to reject the theory. A glimpse into the available literature throws some light on this direction. By chronically feeding with diets rich in sodium chloride, a group of workers¹ has been able to produce a sustained arterial hypertension in albino rats. Moreover, a positive linear correlation was found between systolic blood pressure and concentration of sodium chloride in diets. They have also been able to produce a syndrome of oedema and renal failure associated with significant histological changes in kidneys and other organs in a certain percentage of their rats. These observations, although they do not bear any direct relationship to human hypertension, definitely point towards some possibilities that can be proved or disproved only by long-term experiments on humans.

OUR EXPERT writes: It is not logical to assume that because a low sodium diet lowers the blood pressure a high sodium diet will cause essential hypertension. It is known, of course, that a high sodium diet, particularly in conjunction with deoxycorticosterone, increases the blood volume and that this tends to raise the blood pressure a little if there is no compensatory vasodilatation. It is also known that the blood volume in essential hypertension is normal. I do not know of any careful research work proving that a high sodium intake over the years does not in fact produce essential hypertension, but the possibility is purely speculative, and has nothing to support it.

PSYCHIATRY AND GENERAL MEDICINE*

BY

Sir DAVID HENDERSON, M.D., F.R.C.P.

Professor of Psychiatry, Edinburgh University; Physician Superintendent of the Royal Edinburgh Hospital for Nervous and Mental Disorders

I regard it as a great honour to have been invited to deliver a lecture in the Birmingham Medical School, where so much is being done to effect a liaison between psychiatry and general medicine. This closer integration is greatly to be desired because of the further contribution which may be made to the science and art of medicine. We have worked far too long in considerable isolation, and in consequence we have been too localized, too one-sided, too much in the nature of special pleaders, when a more comprehensive outlook would have led to greater benefit both to our patients and to ourselves. The gap which exists between psychiatry and general medicine (which is inclusive of surgery, obstetrics, gynaecology, etc.) is still far too wide; it requires to be rebridged, and it is my purpose here to consider how that may be effected. The task is a formidable one, because prejudices and faults which are difficult to overcome have been developed on both sides. However, I shall try to examine the position as dispassionately and fairly as possible.

Aim of the Medical Profession

Our profession is vitally concerned not only with the treatment of persons who are ill and in need of help but also with the even greater responsibility of understanding the fundamental facts of human nature and of biology, which concerns itself equally with the health of the individual and the welfare of society. That wider concept of our aim is in process of being more generally recognized, so that it is customary in some universities to inform medical students at the very beginning of their career that medicine is not purely an objective mechanistic science but rather a sphere of work which embraces all the interactions of mind and body. Such a changed outlook constitutes a distinct advance, and prepares the mind of the student to think much more comprehensively of what is ahead of him. It indicates that we have departed a long way from the conception of illness as an organic disease, and it suggests that the multiple causative factors which may exist should be investigated at both a psychological and a physiological level. The result should lead to greater clinical acumen, more accuracy in prognosis and diagnosis, and more successful treatment. The fact that attention is being centred on the whole man will inspire greater confidence both in patient and in doctor, and healing will become more easily managed owing to the neutralization of fear, anxiety, and apprehension, which are so often at the root of all illness.

*A lecture given in the Faculty of Medicine of the University of Birmingham on January 8, 1954.

All who successfully practise the healing art recognize the above principle. The particular agent employed might have been a priest of experience at one or other of the Aesculapian temples; Mesmer or one of his disciples; a royal or other distinguished person who used the prerogative of "touch"; the Christian Science Church; or Lourdes; or Gheel; or any other person or place which inspired confidence. That that is not an antiquated theory is amply confirmed by a book recently published, *Stress and Disease*, by H. G. Wolff, whose work on psychosomatic disorders is so well known. A review of that book (*Lancet*, 1953, 2, 763) points out that "man's reaction to man may be at least as important as his reaction to a microbe." It is therefore not so surprising as it might seem that Wolff, as a result of his interesting and intensive study of 739 subjects, concluded that the main therapeutic aim to effect recovery was to produce tranquillity and freedom from sustained hostility and resentment. It was only then that satisfactory cures could be attained—surely a powerful argument in favour of the psychosomatic approach.

Attitude Towards Mental Illness

In earlier times, to which reference has already been made, it is probable that the main differentiation of illness was effected in terms of death, recovery, or apparent incurability. And it is a fair guess to suggest that the vast majority of psychotic and nervous patients belonged to the incurable class. No doubt it was their recalcitrancy, their inability to respond—either to kindness or to a beating—which led eventually to their exclusion from society. They were not understood; they were stigmatized as wicked and perverse rather than as suffering from an illness which, under proper conditions, might respond to treatment. I regret to say that I believe we may have helped to manufacture many of them by the harsh and arbitrary methods of treatment which were in vogue; padded rooms, excessive sedation, the too hasty employment of powerful physical remedies. In passing it is of some interest to comment on the fact that such conditions as multiple personalities and florid conversion hysterical states, often the results of ill-advised examinations, rarely occur to-day.

It seems to me that it is justifiable to state that our practice in relation to mental illness then was very similar to our attitude towards the delinquent classes to-day. Constructive rehabilitation measures—legal, medical, and social—for those who for one reason or another fail to make a satisfactory social adjustment because of mental illness or delinquency, are still sadly lacking.

Great advances have undoubtedly taken place; our therapeutic equipment is much more efficient and varied, but in the face of failure we are much too slow and unwilling to admit our incompetence and lack of knowledge. We behave much as our forebears did; we over-rationalize, we project our disappointments on the lack of co-operation of our patient, or question the genuineness of his complaints, or call him a wicked, immature person with a decided negative transference. This, of course, is the identical attitude adopted by those who criticize art, or poetry, or music, or anything else they neither understand nor like.

A Dangerous Trend

In the development of our special medical skills we have watched the progress of general medicine by way of biochemistry, biophysics, physiology, and therapeutics, while psychiatry has gained its particular stimulus through the study of biology, personality structure, psychogenesis, and psychotherapy. Such a parallel but divided course has constituted a dual misfortune, because general medicine became too organically minded, too mechanistic, almost too pathological, while psychiatry lost its objectivity and became dominated by the subjective, emotional, and hypothetical. The somewhat absurd stage has now been reached where, so far as the latter is concerned, a basic medical training is no longer regarded as a necessary prerequisite for the work of the clinical psychiatrist. Truly that is a most serious and disastrous state of affairs. It cuts across all medical tradition and practice. We must not be content with the thought that lay therapists are not accorded official recognition; that is not enough, because, irrespective of the lack of official recognition, certain institutes and clinics have drawn up comprehensive programmes of instruction (of which personal analysis is usually an integral part) to which many lay persons are attracted.

I regard such a development as dangerous and reprehensible; it tends to undermine the whole structure of medical education; it requires the critical attention of every faculty of medicine and of the General Medical Council. How has all this come about? Largely, I believe, because orthodox medicine has so often failed to give due consideration to the psychological factor which is so much part and parcel of all illness. There is truth, indeed, in the statement that the *malades imaginaires* are the reward of the quack and the despair of the honest physician. In consequence the advocates of the policy of training lay psychotherapists justify themselves by pointing to the large number of nervous invalids in need of help, and the scarcity of trained personnel to deal with them. For my part, I do not accept that statement as a valid argument. The management of the greater number of psychoneurotic states is not an essentially specialist problem, but one which should be brought within the scope of a well-trained general practitioner.

Some, at least, of the mistakes and difficulties I have mentioned would be avoided if we were more historically minded, and had more ability to correlate our clinical observations. It is so disappointing to find that so many of our colleagues seem to believe that psychiatry began to function only from the Freudian era, while others, even more modern, base their practice on the wonders of present-day physical therapy. This is evidenced by those candidates for senior appointments who, in support of their claims, proudly state that they have had a personal analysis, have introduced electric convulsion therapy into their out-patient departments or consulting-rooms, regard insulin coma as a specific for "early" schizophrenia, or have performed a transorbital leucotomy. It would be infinitely more encouraging if they expressed an interest in the broader aspects of psychiatry, in its history and its literature. It is more through good clinical observation and individual work with patients that we are likely to be successful in our search for so much which is still unknown. I do not want to flog that

issue too much, but, in order to keep a reasonable perspective before us, allow me to give you a glimpse of the thought and work of 100 years ago.

A View Held 100 Years Ago

In 1854 Forbes Winslow's first Lettsomian Lecture was entitled "The Psychological Vocation of the Physician," and what he said then is so apropos of my thought to-day that I venture to give a brief quotation. He wrote:

"I have undertaken in my first lecture to illustrate the special psychological attributes of the physician—to claim for the cultivators of medical science higher and more exalted functions than those usually assigned to them—to consider the physician in his spiritual character, as having at his command, and under his control, a *medicina mentis* as well as a *medicina corporis*—agents of great power and magnitude which have not been sufficiently recognized or appreciated. It will be my object to establish the close connexion between the Science of Mind and the Science and Practice of Medicine, and to illustrate the true philosophic character of the professors of the healing art.

"The physician is daily called upon, in the exercise of his profession, to witness the painful effect of mental emotion upon the material fabric. He recognizes the fact although he may be unable to explain its rationale. He perceives that moral causes induce disease, destroy life, retard recovery, and often interfere with the successful operation of the most potent remedial means exhibited for the alleviation and cure of bodily disease and suffering. Although such influences are admitted to play a part, either for good or evil, I do not conceive that, as physicians, we have sufficient appreciation of their great importance. . . . Many a disease is the *contre-coup*, so to speak, of a strong moral emotion; the mischief may not be apparent at the time, but its germ will be nevertheless inevitably laid."

That short extract indicates that many of the great physicians and psychiatrists of the past had an admirable knowledge of psychosomatic disorders, and it is surprising that the significance of the principles which they laid down is only now being fully recognized. Forbes Winslow and others like him, and some far greater than he, were broad-minded philosophical clinicians imbued with a wide outlook who, although they worked under great difficulties and against much prejudice, helped and cured their patients because of their interest and understanding of them, and because of the love of the work they were doing. To-day we are in a much stronger position than our forebears. Our technical resources have been greatly increased. We can readily enlist the help of chemists and physicists, psychologists, physiologists, brain surgeons, neurologists, all of whom can contribute their particular quota. But in our search for the new let us hold on to the experience, the wisdom, and the humanitarianism of the past.

Important Landmarks

We may now consider in more detail the biological concept which I have mentioned, and refer briefly to some of the more important landmarks which have contributed so much to an intensification of psychiatric thought and practice.

The descriptive and, may I add, the philosophical period of Kraepelin, Maudsley, Clouston, and their contemporaries was an era of brilliant achievement which has proved to be the foundation of many of the great advances which have occurred since. That is a categorical statement, no doubt, but yet I believe it will be substantiated by any fair-minded person who cares to examine the position for himself. It was the foundations and classifications of those men which inspired Adolf Meyer, in the first decade of this century, to describe his conception of psycho-biological principles, with particular emphasis on reaction types, and the study of the individual in his social setting. It is no exaggeration to say that his views and his teaching transformed the standard of psychiatric work not only in the United States but throughout most of the civilized world. His impact here in Britain was enormous. He was one of the great psychiatrists (clinical and neuro-pathological) whose penetrating, investigative mind made it imperative for him, in sizing up every case, to be in possession of all the facts derived from

whatsoever source, personal or environmental—a lesson and a discipline which it is essential for us to remember to-day.

During the same period Freud started from a much more specialized angle than Meyer, but it was not long before the ingenious technique of psycho-analysis for the treatment of certain psychoneurotic states broadened out into a system of philosophy and psychology which has received universal recognition. Whether Freud has done more for the advancement of an understanding of human nature than any other man since Aristotle might raise considerable argument, but he certainly infused an interest and a stimulus into psychiatry and philosophy which still persists. Our dreams, our words, our acts mean something, and even the weird and bizarre symptomatology of nervous and mental disorders which baffled our understanding for so long can be interpreted and understood. Freud brought us nearer the core of things.

Again, from a totally different and even wider angle, Clifford Beers, the young Yale undergraduate, promulgated the doctrine of mental hygiene as an educative force towards better, and healthier, and more understanding living. The small Connecticut Society for Mental Hygiene, which he founded in 1908, has grown into a mighty World Federation movement.

Each approach which I have mentioned has taken us a stage or two further. The work done has been complementary, and has been directed to the particular purpose of coming to a fuller understanding of nervous and mental illness so that it may be prevented and remedied.

Problem of the Nervous Invalid

We need help from all quarters in dealing with the tremendous problem presented by the nervous invalid—a problem which, whether in peace or whether in war, creates serious and numerous casualties, and one which, without wishing to be sensational, may be said to be eating into the life-blood and efficiency of every nation. At no time has it been more necessary to direct attention to the imperative need for a better appraisal of the interactions of mind on body, and body on mind—a study which can be successfully accomplished only by the friendly co-operation of psychiatry and general medicine.

A study of the epidemiology of psychoneurotic and psychosomatic disorders leaves us in no doubt of the upward trend which is occurring. Our out-patient departments are inundated with new cases, our in-patient accommodation is inadequate, and, furthermore, we have neither the quality nor the quantity of skilled medical personnel to deal adequately with those often so desperately in need of help. It may be that this present position merely reflects the disturbed social and economic conditions under which we are living, but it is more probable that the real cause lies a good deal deeper and is centred, to a certain extent, in the increase of the selfish, individualistic, irresponsible types in whom a sense of loyalty to family, friends, or organization is so greatly lacking. Wherever the fault lies it needs tackling, and one of the ways in which this may be done is to see to it that the doctors of the future are trained to investigate the psychological and social factors which may operate in any form of illness. It is partly a problem of medical education which will be referred to later.

But before I pass to another topic may I be allowed to comment on a group of psychosomatic disturbances which have always been of great interest to me. I refer to cases of pregnancy and child-bearing in which the interplay between the psychological and the physiological components must be very intense. In most cases, fortunately, the personality remains intact. Clouston was probably quite correct when he stated that nature seems to have a remarkable ability to look after the pregnant woman. But that is not always the case; many failures occur, and many difficult situations arise which lead to disturbances of thought and conduct that may be disastrous and tragic. Helene Deutsch

has explained all this very well in her book *Psychology of Women*, in which she points out "that there is hardly a woman in whom the normal psychic conflicts do not result in a pathological distortion, at some point, of the biologic process of Motherhood." I think, for instance, of those cases in which there is (1) a fear of transmitting nervous or mental disease; (2) an unwanted child; (3) marital disharmony; (4) infertility; or (5) repeated abortion. When such conflicts are present there may be a rich display of symptoms which operate like a conditioned reflex—for example, nausea, vomiting, miscarriage. This is indeed a field in which the closest possible co-operation should prevail between the obstetrical and psychiatric departments.

It is not a very far cry from the mother to the nervous child—to an understanding of its psychological as well as its physical needs. Kanner has always insisted that the problems presented by such children lie in the patients themselves rather than in their organs—for example, poor school progress, enuresis, food capriciousness, temper-tantrums, nail-biting, fear reactions, epileptic phenomena; others may exhibit tics, headache, sleep disturbance, sex problems, stealing. A fascinating and rewarding field for study if we believe, as we should do, that the sense of security and confidence attained in childhood passes on into adult life. It is both disappointing and surprising that, under these circumstances, there is still so little co-operative effort between psychiatrists and paediatricians.

Personality Disturbances

The above discussion has demonstrated many conditions involving body and mind which are not susceptible of care until we have understood and treated the psychological traumata which have created them. In contrast attention can now be directed to those personality disturbances involving emotional, ideational, or intellectual impairment which are due to or dependent on objective organic lesions. It is fairly certain that, here, no real betterment will occur until the organic cause has been successfully dealt with. We can think, for instance, of the anoxaemias which can produce quite devastating effects, as evidenced by the sensitive, suspicious, irritable, aggressive, and even murderous reactions of explorers, mountaineers, and others who may find themselves in dangerous straits due to exposure, hunger, or other circumstances leading to deoxygenation. In toxic exhaustive conditions such as alcoholism, malarial infection, and so on, intense fear reactions are in the ascendant, and often are accompanied by delirium with its dangerous sequelae. And then there are the great variety of inflammatory and/or destructive lesions of the brain structure due to primary tissue change or dependent on vascular disturbance. Nor should one forget to mention the personality changes which not infrequently may be the aftermath of leucotomy operations.

Some day, perhaps, we will gain a little more knowledge of the epileptic mechanisms, what determines their particular form, whether there is a particular epileptic temperament or character, to what extent the psychic epilepsies, the post-epileptic and fugue states, are linked up with emotional factors—for example, the aggressive behaviour of the psychopath. The pre-senile groups are still inadequately understood, and often not recognized, and we know practically nothing of how they arise or can be prevented. Brain tumours masquerade far too frequently as dyspepsias or neurasthenic states, when a careful neurological examination would often allow a correct diagnosis to be made at a remedial level. Great and quite unnecessary difficulty seems to circle round the correlation of the mental and physical symptoms in cerebral vascular disease, especially in relation to the vessels supplying the basal nuclei. The labile emotional state, the personality change, the lack of concentration, and puzzlement with insight all form a characteristic picture that should never be confused with hysterical or melancholic phenomena, which, unfortunately, is often the case. I have not mentioned the above matters from any critical angle, but merely to emphasize again the

importance of clinical observation and the ability to correlate one's findings. Furthermore, a warning may be incorporated to the effect that the use of electric convulsion therapy to remove what is called a depressive or emotional overlay is very questionable practice.

Finally, from the clinical standpoint attention may be directed to the large group of constitutionally predisposed persons who form the bulk of our mental hospital population. The origin and development of schizophrenic, affective, paranoid, and psychopathic states is as much a mystery to-day as it ever was, and little progress has been made in the prevention and control of the various forms of amentia. We may take a certain amount of encouragement from the genetic understanding of the transmission of Huntington's chorea, and from the interesting work of Penrose and Munro in this country and of Jarvis in the United States on the body-mind relationship which occurs in phenylketonuria. But a tremendous lot more requires to be done. The numbers of all such patients are increasing, hospital accommodation is inadequate, and our medical and nursing establishments are so curtailed that many of our patients are failing to get anything like the individual attention they need and deserve.

The above clinical situations which I have little more than mentioned show in no uncertain manner the vast territories which must be explored much more thoroughly. It is not a purely psychiatric matter, but one which calls for co-operative effort so as "to advance that knowledge which secures the development of the race, and establishes man's dominion over nature" (Laycock). My experience has taught me that the best psychiatrists are those who have acquired a sound, thorough training in general psychiatry and neurology before specializing in psychotherapy, psychoanalysis, child psychiatry, or forensic psychiatry. The great Charcot (his joints seem to have almost reached vanishing point) was an accomplished neurologist before he studied the manifestations of hysteria, and it has always impressed me that men like Freud, Meyer, White, Jelliffe, Ernest Jones, Putnam, Bleuler, and many others had had wide experience and training before embarking on their more specialized studies.

In any case, in this rich storehouse of the organic psychoses the diligent student, drawn from whatsoever sphere, will find infinite scope for his investigative spirit.

Medical Education

This takes me at once into the field of general medical education, which recently formed the subject of a World Conference. More specifically the relationship of psychiatry to medical education was discussed very fully at a conference organized in 1951 by the American Psychiatric Association and the Association of American Medical Colleges. The results of that conference are now available in book form under the able editorship of Whitehorn. The general formulation laid down is that the aim of all medical education—and especially of psychiatry—is "to prepare the medical student to deal intelligently and skilfully with patients as persons, and to provide him with the basic knowledge of psychological and social problems and resources in relation to health and disease."

In Edinburgh we have been able to put such a course into being. In the preclinical years an integrated course of instruction in psychology and psychiatry is given, dealing with such topics as the psychology of development and the life history of the individual; heredity and environment; temperament and character; personality structure; emotion and its role in symptom production. In the clinical years systematic and clinical lectures are given, and throughout the course emphasis is placed on out-patient work in the Royal Infirmary, Edinburgh. Psychiatry is one of the professional subjects which are obligatory in the final examination for the degree of M.B., Ch.B. During my teaching experience, both in Glasgow and in Edinburgh, large classes varying from 160 to 200 students annually have been the rule. While the students have not, therefore, had the close personal supervision which would be desirable, yet they have

developed a keenness and an interest which have not made the professional examination an additional unwieldy burden. For my part I am convinced that the system in being has been of immense benefit both to the student and to his teachers. Furthermore, the establishment of professional or degree examinations in psychiatry puts the subject on an equality with other major subjects and ensures that the professor has his rightful place in the faculty of medicine.

While I am on this topic I might mention that universities as well as big industrial concerns are vitally concerned with wastage turnover, which in this instance centres in the unsatisfactory student. It is too often forgotten that when students come to their universities they are at a most vulnerable period of their development, so that the promise of their earlier years may, tragically often, not be fulfilled. We have a duty surely in our universities to promote mental hygiene, and to have the facility through our various departments to make the thorough personal and environmental inquiries which may preserve health and promote efficiency. This could be facilitated if it were more generally accepted that psychiatric units should be established as an integral part of every large general hospital. A fair suggestion is that from 5 to 10% of general hospital beds should be provided for psychiatric cases. It is lamentable to reflect how in this Welfare State we lag so far behind what has been accomplished so successfully in the United States, Scandinavia, and Germany.

The same suggestion or argument applies even more cogently to the affiliation of departments of child psychiatry to paediatric hospitals. Here again one can take a lesson from our American and Scandinavian colleagues, and can do more than pay lip-service to the slogan that childhood is the golden period for mental hygiene. We can and should provide accommodation for such children—not in mental hospitals, but in specially appointed clinics where they can have the benefit of all that present-day medicine can provide.

Much of what I have said in regard to undergraduate training and the affiliation of psychiatric clinics with paediatric and general hospitals holds good in relation to post-graduate and general-practitioner training. My experience is that both groups desire much more instruction and training in the principles of psychological medicine. Their success in practice depends on it. There are, of course, some doctors who state, blatantly enough, that they have no use for psychiatry, that psychiatrists should be avoided like the plague, that the subject is too mystical, theoretical, and dangerous, that it puts far more wrong ideas into the patient's mind than it removes. But in contrast to those cynics and sceptics there are an increasing number who are genuinely interested and who appreciate its significance in the medical hierarchy both as a specialty and as part of the working equipment of the general practitioner. Elaborate courses of instruction are by no means necessary, but familiarity with the ordinary methods of psychiatric examination are necessary, and an elasticity of mind which will allow him to switch to the possibility of a psychological explanation instead of seeking, long and vainly, for that pathological focus which is going to solve all the mystery.

The Art of Case-taking

What are those ordinary methods of psychiatric examination which have been referred to? The answer is quite simple—the art of case-taking. It may sound very unspectacular, but it is really fundamental for the whole of medicine, and I believe that it is in this field that psychiatry has made one of its greatest contributions. To do justice to any case it is essential to have a comprehensive life-study embracing hereditary structure plus environmental circumstances of a personal, social, or economic nature which may have influenced bodily or psychological development. It is dangerous practice to base our diagnosis and treatment on the symptoms alone, because the really important thing is the way the patient feels about them, and the setting or background in which they occur. It is diathesis and constitution we need more knowledge about, and how the

particular individual reacts to and compensates for the various bodily and psychological disabilities from which he may suffer. Selye applies the same concept to organic bodily states. That is why personality studies are so important, as in the differentiation of types as described in the first place by Hoch and Amsden, and, later, notably by Bleuler, Kretschmer, and Sheldon.

Such chronological studies, in terms of life history, are infinitely more illuminating than the cross-section method of the general physician. The latter uses the presenting symptom as his starting-point, and, while skilfully tracing out its ramifications, far too often fails to pay attention to the background, personal or environmental, in which the symptom is occurring. Cabot has given many examples of the fallacy of that method. It is a fault of training, a relic of a too concentrated, mechanistic objective approach, a vain seeking for a specific cause. How seldom we find it, and how much better it is to deal with all the multiple causative factors which may be playing a part. Then we will become much more accurate in our diagnosis, prognosis, and treatment. Very modestly it is suggested that our psychiatric case-taking methods may be of considerable value to our general medical colleagues. They will help them to remember that physical symptoms are often purely a face-saving device to maintain the *amour propre* of the patient. If this is forgotten, then examinations and treatment are introduced which often obscure the clinical picture. This, as I have said already, can be obviated by good history-taking and careful clinical evaluation. If the procedure I advocate was adopted we would hear much less of the failure of orthodox medicine and of the success of the medically untrained.

Our understanding of illness would be greatly increased if the relationship between the doctor and the social worker was drawn a bit closer. The social worker is not used intelligently enough. Social work is not a matter of almsgiving, of arranging loans, of giving financial or other material assistance. But it is the social worker's ability to size up a situation, to sense the atmosphere of the case, and to establish a good liaison between patient and employer, which is one of the most potent factors in successful rehabilitation and preventive medicine. We medical people do not appreciate how much we could gain, and how much more our patients would benefit, if we worked directly with the social workers rather than through the intermediation of the ward sister.

While, therefore, I have been striving to indicate the fields in which all medically trained people may learn to work more co-operatively, yet my main theme has been to show how psychiatry can be more greatly developed in relation to general practice. It is the psychologically oriented general practitioner who can become a much more important force in dealing with the great majority of nervous and mental ailments. The College of General Practitioners, which has just been founded, may be willing to consider how such a development can be most successfully pursued.

Conclusion

To conclude, I might make the following general suggestions:

1. A wider concept of medical education, so that all universities and medical schools recognize that the understanding and treatment of nervous and mental disorders is a matter of paramount national importance and should constitute a major subject in the medical curriculum.
2. Psychiatric clinics for in-patients and out-patients should form an integral part of all large general and paediatric hospitals.
3. Far greater reciprocity and co-ordination should be effected between all groups of medical men and social workers, in the hope that psychiatry will become less of a specialty and more part and parcel of general medicine.

TREATMENT OF RENAL OEDEMA WITH DEXTRAN

BY

ARTHUR W. MOLLISON, M.B., Ch.B., B.Sc., F.P.S.

AND

J. BASIL RENNIE, M.D., F.R.C.P., F.R.F.P.S.

(From the Departments of Biochemistry and Medicine,
Stobhill General Hospital, Glasgow)

The obstinate oedema characteristic of type II nephritis (nephrosis, nephrotic syndrome, or chronic parenchymatous nephritis) is often difficult to treat. Limitation of salt and fluids seldom does more than mitigate the condition, and often not even that; the attempt to raise the level of albumin in the plasma with a diet rich in protein is equally unsatisfactory. Among the diuretics, only mersalyl is likely to be outstandingly successful. Even when circumstances appear favourable for administration of mercury—that is, absence of haematuria, normal renal-function tests, and normal blood pressure—many physicians are reluctant to use it in the presence of Bright's disease. More recently, ion exchange resins, A.C.T.H., and cortisone have been used. From the literature the response to these substances appears to be inconstant and the resins are difficult to stomach. The last resort is the removal of oedema by acupuncture or by the insertion of Southey's tubes at the ankles. With the introduction of antibiotics this procedure carries less risk of infection than formerly, but remains an unpleasant one.

Attempts to increase the colloid osmotic pressure of the plasma other than by high protein diet are not new. One of the earliest was by the intravenous injection of 6% gum acacia in normal saline, which was successfully used in the treatment of wound shock in the first world war. As a diuretic, this substance administered in 5% glucose achieved a measure of success, but became unpopular when experiments on animals showed that it remained in the tissues for years, deposited particularly in the liver, where it was said to depress the formation of plasma albumin. Later, blood and plasma were used, usually with little or no diuretic effect. With concentrated plasma, preferably with concentrated human plasma albumin, some diuresis is obtained. These latter blood products are expensive (concentrated plasma albumin is not obtainable in this country), and there is some risk of hepatitis in their use.

More recently the search for a substitute for plasma capable of restoring blood volume in patients suffering from shock has led to the use of gelatin, polyvinylpyrrolidone, and dextran. The last-named has been used as a diuretic in the treatment of renal oedema, and it is this aspect of its use with which this paper deals.

Dextran is a polysaccharide formed by the condensation of the glucose moiety of sucrose by the action of the organism *Leuconostoc mesenteroides*. Commercial dextran is prepared by the controlled hydrolysis and fractional precipitation of this crude dextran. It is thus theoretically possible to produce a dextran of any desired molecular weight, but, in practice, a fairly wide scatter in molecular size results, and it is so far practicable only to make preparations in which a large proportion of the molecules are within the chosen range of molecular size. Not only does the dextran made by

different drug firms vary in molecular distribution, but it is probable that different batches made by the same firm are not identical.

Dextran was introduced in Sweden by Grönwall and Ingelman (1944), who tested its properties in animals, and later in man (1945). They pointed out that an ideal substitute for plasma should be non-toxic, non-antigenic, and either completely excreted or completely metabolized—that is, it should not be stored in the tissues. They considered dextran to have these properties. Bohmanson, Rosenkvist, Thorsén, and Wilander (1946) confirmed the work with large-scale trials in which each batch of dextran was tried first on patients in the last stages of carcinoma. For some years dextran has been used extensively in Sweden for the treatment of shock, and Thorsén (1950) estimated the incidence of reactions to be as low as 0.1%. Bloom (1951) did not find any reactions in 51 patients suffering from shock, or in 50 others who were not suffering from shock.

On the other hand, Turner, Butler, Smith, and Scudder (1949), in America, observed reactions in 10 out of 30 patients. These reactions took the form of fever, headache, and tachycardia, with urticaria in six instances, cyanosis three times, and dyspnoea once. None of their patients was suffering from shock, but 500 ml. of 6% dextran was given in the short time of 30 minutes. More recently, in this country, Maycock (1952) noted reactions in only 1.51% of 1,647 patients who had received dextran at various medical centres, mostly to combat shock. There was one death, in a moribund patient, and the relationship to dextran was uncertain. Pyrexia, headache, urticaria, and pain in the loins and other abnormalities were noted. A severe reaction developed in one patient but none at all in 46 others who received infusions of the same batch of dextran. Accordingly, Maycock thought reactions possibly occurred as a result of sensitization to *L. mesenteroides* or antigenically related organisms such as pneumococcus type 2 or 20. As Maycock states, it should never be forgotten that large numbers of infusions have been given in the treatment of shock without any reaction whatever.

The fate of injected dextran is still being intensively studied. Thorsén (1949), after infusion into animals of an amount equivalent to one-third of the body weight, found by examination of watery extracts no dextran in the liver, spleen, bone marrow, brain, lungs, heart muscle, or kidney, and observed no morphological changes. On the other hand, Turner and his co-workers (1949) found minimal but in their view irreversible changes in the liver, spleen, kidney, and reticulo-endothelial system. These took the form of giant-cell formation and proliferation. Goldenberg, Crane, and Popper (1947) and Hartman (1951) also noted histological changes in the kidney, the liver, and the reticulo-endothelial system, but considered them to be probably reversible. Using rabbits, to which the equivalent of 1.5 litres of 6% dextran was given daily for seven days, Bull and his colleagues (1949) detected dextran by chemical methods in spleen and lymph nodes up to 21 days later. With a serological method, dextran was found to be still present up to 56 days afterwards.

The amount of dextran excreted in the urine varies considerably with the molecular distribution of the product used. Recent experimental work has shown that up to 40%, presumably of small molecular size, is excreted in the urine—mostly in the first 24 hours and the rest in four to six days. Dextran has also been

found in the faeces. Some of the remainder is metabolized, as shown by Gray, Siiteri, and Pulaski (1951), who found the D:N ratio arose when dextran was given to phloridzinized dogs. Work with dextran containing radioactive carbon indicates that some dextran is taken up by the reticulo-endothelial system. It therefore seems highly probable that this fraction also is eventually broken down and metabolized. Some tagged carbon is lost in expired air (Pulaski, 1952).

It is noteworthy that dextran has been approved by the Federal Food and Drug Administration, and that doctors of the American Forces have been authorized to use it wherever they believe it may be suitably employed in place of plasma (Government Services, 1953).

The objects of our investigation were (1) to confirm that dextran is a safe and efficient diuretic for relief of renal oedema; (2) to attempt to determine the influence of the size of the dextran molecule upon diuresis; and (3) to study some of the biochemical changes.

Clinical Material and Plan of Treatment

Dextran was given on 81 occasions to eight patients, all of whom showed oedema of long duration, heavy albuminuria, and marked hypo-albuminaemia. Full clinical data are given in the case histories. Throughout the period of treatment the patients were kept in bed and received a constant diet containing less than 2 g. NaCl and a fluid intake of 1,200 or 1,800 ml. in 24 hours. The protein intake in one patient was 60 g. daily, in the others either 100 or 120 g. No other treatment was given. Collections of urine were made over periods of 24 hours, and the patients were weighed daily as a further check on fluctuation in oedema. Dextran was not given until it was reasonably certain that diuresis from the effects of diet or rest in bed was not taking place.

During the period before administration of dextran, observations were made on the protein and cholesterol of the serum, on the blood urea and urea clearance, and on the haemoglobin and packed cell volume. Where possible these observations were repeated at regular intervals.

Salt-free dextran was used, much of which was presented to us by Benger Laboratories Ltd. 540 ml. was given by

FIG. 1.—Molecular weight distributions of the preparations of dextran used.

Four categories of dextran were used; the standard commercial salt-free preparation in 6% strength and three preparations of differing molecular distribution (Fig. 1). These

were designated for convenience large, medium, and small molecule, according to the predominant molecular size in each. All were salt-free and were of 10% strength.

Results

Diuresis.—Increase of urinary output was produced by every course of dextran. Outstandingly good results were obtained in Cases 1–3, which became at least temporarily free of oedema, losing 12.3, 13.6, and 18.2 kg. body weight respectively within 7–14 days. On recurrence of oedema, a further course of dextran was again followed by diuresis. In Case 4 a moderate diuresis was produced on five occasions although the patient was never free of pitting oedema. Results in Cases 5 and 6 were less striking, but it is fair to say that in neither was the degree of oedema at all comparable with that present in the other four (Table I). In

TABLE I.—Effect of Dextran on Oedema

Case No.	Preparation of Dextran	Weight Loss (kg.)	Weight before Start of Treatment (kg.)	Duration of Diuresis (Days)
1	Standard 6%	12.3	64.5	9
2	" "	3.2	60.9	8
3	" "	13.6	92.3	7
4	Large molecule 10%	6.4	83.6	6
5	Medium " "	18.2	65.9	14
6	Small " "	10.9	65.9	5
7	Standard 6%	6.4	70.5	9
8	Large molecule 10%	7.7	64.5	19
9	Medium " "	8.2	69.1	11
10	Large " "	6.4	69.5	22
11	Small " "	5.9	70.9	6*
12	Large " "	2.7	59.5	13
13	Medium " "	4.1	65.6	6
14	Medium " "	2.7		5

* Four infusions only.

Case 7 the administration of a course of small-molecule dextran was begun the day after an apparently spontaneous increase in the output of urine, and the data are therefore excluded from the assessment of dextran as a diuretic.

Effect of Molecular Size of Dextran on Diuresis.—Diuresis occurred with every preparation of dextran irrespective of whether the concentration was 6 or 10%, or whether large or small molecules predominated in the preparation used. With the method of administration employed and the number of observations made, it was not possible to say that one preparation produced a greater loss of oedema

FIG. 2.—The diuretic effect of two preparations of dextran on Case 4.

than another (Table I). It is clear, however, that the diuretic effect of large-molecule dextran is of longer duration than any of the others (Table I). The duration of diuresis with large- and small-molecule dextran in the same patient is shown in Fig. 2. The biochemical findings are in harmony with these clinical observations, which suggest that the larger molecules remain longer in the blood stream.

Effect of Dextran on the Course of Nephritis.—Dextran is an effective agent for dispelling oedema, but its effect is

temporary, and there is no evidence that it favourably affects the course of the disease in any other way. On the other hand, three patients (Cases 1, 3, and 6) have died of uraemia 54, 24, and 24 weeks respectively after the last infusion of dextran. In two of these patients the urea clearance was subnormal before the start of treatment. Two were suffering from amyloidosis of the kidneys, a progressive fatal lesion. Periodic observations on renal function for some months after dextran showed nothing to suggest that deterioration was due to its administration, and in our view death occurred in the natural course of the disease and was not accelerated by dextran.

Toxic Effects

Some form of side-effect was shown after most of the infusions, but seldom were there symptoms which gave rise to concern. In Case 4, on the conclusion of the fourth infusion of small-molecule dextran, shivering, marked dyspnoea, and cough developed. The patient complained of nausea and had a temperature of 100.4° F. (38° C.). On examination there were only scanty rales at the lung bases and no wheezing was heard. He was not cyanosed. The blood pressure remained unchanged. The pulse was poor in quality and the rate was 124 per minute. Within four hours these manifestations passed off. This patient had received four courses of dextran (Table I) over 11 months, but there had been an interval of four months since the last course. Accordingly, a skin test was carried out with dextran before the infusion. It was negative. A similar but less severe side-effect occurred in Case 7 during the infusion of small-molecule dextran, which was stopped after 340 ml. had been given.

After the earlier infusions, severe headache lasting for six or more hours was noted. Nausea and vomiting were less common. In one patient a subconjunctival haemorrhage developed and in another bleeding from the gums and nose occurred. Rashes were not seen. These side-effects were less frequent and less severe when the infusion was given more slowly—that is, not faster than four hours for 540 ml. It was not possible to correlate their occurrence with the molecular size of the product used; but it is worth mentioning that the sharpest fall in packed cell volume and in haemoglobin, indicating the greatest increase in blood volume (61%), was seen in association with the severe reaction in Case 4 after administration of small-molecule dextran. Blood-pressure readings before, during, and after infusion showed no change in our cases, but we have not given dextran to anyone with appreciable hypertension.

In two patients hepatic enlargement of two to three fingerbreadths below the costal margin was detected immediately after a course of dextran. This disappeared in two to three weeks, and at necropsy in Case 3 (dying of uraemia six months after administration of dextran) histological observations showed no evidence of damage and, with the method used, no evidence of dextran. We were at this time unaware of the special method required for the detection of dextran advocated by Mowry, Longley, and Millican (1952). This observation would seem to be in agreement with reports of the temporary deposition of dextran in various organs. The absence of other signs of cardiac failure make it unlikely to have been due to engorgement.

Biochemistry

Changes in Blood Volume as Reflected by Changes in Haemoglobin and Haematocrit

Since it was impracticable to make frequent estimations of the blood volume, observations on haemoglobin and haematocrit were made before and at intervals after the administration of dextran. It was thought unlikely that alterations in the total circulating haemoglobin as a result of marrow influence would occur over short periods, and consequently that changes in the haematocrit and haemoglobin level would provide an index of change in the blood volume.

TABLE II.—Behaviour of Haematocrit and Haemoglobin Levels after Infusion of Dextran

Preparation of Dextran	No. and Volume of Infusions	Case No.	Haematocrit %				Haemoglobin, g. per 100 ml.			
			Before Dextran	1 Hour After First Infusion	20 Hours After First Infusion	20 Hours After Last Infusion	Before Dextran	1 Hour After First Infusion	20 Hours After First Infusion	20 Hours After Last Infusion

	1 x 540 "	8	32.5	26.5	31.0	—	9.8	7.4	9.6	—

A considerable increase in blood volume was apparent immediately after the first infusion of 540 ml. of dextran, the degree of this increase varying from 13 to 46%. By the following morning a considerable reduction had taken place (Table II). With repeated daily infusions further increases tended to occur and the maximum fall in haemoglobin and haematocrit was usually noted after the final infusion. In general, the rise in plasma dextran was proportional to the fall in haemoglobin and haematocrit. No exact correlation could be determined between them and the preparation of dextran used. However, to Case 4, courses of all four were given and the fall produced by the small-molecule preparation was much the greatest (Table II). It was calculated that the blood volume increased by 61% in this instance, the highest value in the series. The first three cases received 6% commercial dextran. Observations were not made on the haemoglobin and haematocrit; but it is clear that a sharp increase in blood volume also took place as shown by the fall in serum protein. On two occasions restoration of the haemoglobin and haematocrit to the pre-dextran levels lagged behind the rise in serum protein. This was particularly noticeable in Case 4.

Serum Protein.—The serum protein levels showed a sharp drop within half an hour after an infusion of dextran, with gradual return to normal over seven or more days.

Serum Cholesterol.—A striking fall in serum cholesterol was observed within half an hour after the injection of dextran. When considered in relation to the fall in serum protein (Table III) it would seem reasonable to accept this

TABLE III.—Behaviour of Serum Cholesterol After Infusion of Dextran

Case No.	Serum Cholesterol mg./100 ml.	Serum Protein g./100 ml.	Serum Cholesterol mg./100 ml.	Serum Protein g./100 ml.	Serum Cholesterol mg./100 ml.	Serum Protein g./100 ml.

* Only 4 infusions. † Only 340 ml.

as further evidence of dilution due to increase of plasma volume. However, even a week or more after the infusion of dextran, when the serum protein had returned to pre-infusion level, the serum cholesterol was usually still well below its original value.

Plasma Dextran.—Values noted 20 hours after the infusion of 540 ml. of 10% dextran ranged from 0.7 to 1.2 g./100 ml. Too few observations were made, however, to determine whether differences could be correlated with the preparations of dextran employed. On subsequent days the values fell more rapidly in those patients who had received small-molecule dextran. When a course of five daily infusions of large-molecule dextran was administered the plasma levels after the final infusion ranged from 2.4 to 3.7 g./100 ml. Fourteen days afterwards plasma levels of 1.2 and 1.3 g./100 ml. were found in Case 3 on two occasions. Only one patient received a course of small-molecule dextran and this was stopped after four infusions of 540 ml. because of a severe reaction. The level of dextran in the plasma was then 1.7 g./100 ml.

Urinary Dextran.—Table IV shows the difference in the amount of dextran excreted in the urine when single infusions of large- and small-molecule dextran were given.

TABLE IV.—Excretion of Large- and Small-molecule Dextran in the Urine (g. per day)

Days after Infusion of 540 ml.	Large Molecule		Small Molecule	
	Case 7	Case 8	Case 7	Case 8
1	4.6	1.3	14.8	9.6
2	—	0.8	8.1	1.9
3	2.2	0.7	1.6	1.8
4	1.5	0.5	0.9	0.7
5	1.1	0.5	0.9	0.8
Cumulative	—	3.8	26.3	14.8

While there is no point in comparing these results with the theoretical loss in patients with intact kidneys, it is clear that excretion of dextran is much greater when a preparation containing a high proportion of small molecules is used. The fact that Case 7 excreted 26.3 g. in five days and Case 8 only 14.8 g. in the same period, although both had received small-molecule dextran, may possibly be explained by a difference in the nature of the lesion, the former being an example of type II nephritis and the latter of amyloid nephrosis. The greater excretion of small-molecule dextran was also demonstrated in Case 4, who, in the week following four daily infusions of the small-molecule preparation, excreted 112 g. (52%), whereas only 33 g. (12%) was excreted in a similar period after five pints (2.8 litres) of the large-molecule product.

Case Histories

Case 1.—A woman aged 21 developed oedema of her legs two years before admission to Stobhill Hospital on November 6, 1951. There was no history of preceding infection. On examination oedema was found to be general and the urine contained much albumin; but only scanty casts and red blood corpuscles were found. Serum protein was 4 g./100 ml., serum albumin 1.8 g./100 ml., and serum chole-

sterol 552 mg./100 ml. Blood urea was normal (22 mg./100 ml.), but urea clearance was 35% of average normal. Blood pressure was 120/80 mm. Hg. Fundi were normal. The heart, lungs, and nervous system showed no abnormality. Some ascites was present. On a diet rich in protein and poor in salt there was no improvement; but after a course of dextran massive diuresis took place. Oedema gradually reaccumulated and a second course of dextran was again successful. She was discharged improved on December 21. Her urea clearance three months later was 36%. About six months after dismissal renal function began to fail sharply, and she died in her own home on November 29, 1952, of uraemia.

Case 2.—A man aged 34 developed a sore throat in October, 1950, followed a week later by swelling of his feet. When admitted to Stobhill Hospital on January 10, 1951, there was marked general oedema. Blood pressure was 160/112 mm. Hg. The fundi were normal. The urine contained much albumin and numerous hyaline and granular casts. Red blood corpuscles were present, but in numbers too few to give a positive guaiac reaction. The heart, lungs, abdomen, and central nervous system showed no abnormality. Ascites was present. Serum protein was 4.5 g./100 ml., serum albumin 1.6 g./100 ml., and serum cholesterol 384 mg./100 ml. The blood urea was 42 mg./100 ml. and the urea clearance 57%. His condition remained substantially unchanged for 14 months in spite of diet, mercury, urea in large doses, A.C.T.H., cortisone, ion-exchange resin, and insertion of Southey's tubes in the legs. Profuse diuresis followed each of two courses of dextran, and he was discharged from hospital much improved in February, 1952; his blood urea being then 35 mg./100 ml. and the urea clearance 72%. Renal function since then has remained good (urea clearance 70% on January 10, 1954) and the blood pressure unchanged.

Case 3.—A woman aged 43 developed oedema insidiously 11 months before admission to Stobhill Hospital on May 2, 1952. For six months ascites had been present. Six years previously she had had pre-eclamptic toxæmia and labour had to be induced at seven and a half months. Eighteen months later there was a normal delivery, and during this pregnancy the urine remained free of albumin and the blood pressure did not rise above 160/110 mm. Hg. On examination in May, 1952, she showed generalized oedema and ascites. In the urine there was much albumin; casts were numerous; but there were no erythrocytes. Serum protein was 4 g./100 ml., serum albumin 1.2 g./100 ml., serum cholesterol 860 mg./100 ml., blood urea 32 mg./100 ml., urea clearance 45%. Blood pressure was 105/85 mm. Hg. The fundi were normal. The heart, lungs, and nervous system showed no abnormality. No improvement followed a protein-rich salt-poor diet. After a course of dextran 18.2 kg. of body weight was lost in 14 days and she was discharged on May 21. On July 5 she was readmitted because of massive oedema. Her serum protein level was 3.5 g./100 ml., albumin 0.8 g./100 ml., blood urea 47 mg./100 ml., and urea clearance 47%. Diuresis again followed a course of dextran. On the day after the fifth injection the liver was noted to be three fingerbreadths below the costal margin and very firm. The serum bilirubin and prothrombin time were within the normal range: the thymol turbidity was two units and the thymol flocculation test negative. When discharged, at her own request, 14 days later the liver was then only just palpable. Renal function was unchanged. She died of uraemia on January 27, 1953. The findings at necropsy were unexpected. There was marked amyloid disease of the kidneys and a large area of necrosis in the cortex of one. No gross or histological evidence of damage due to dextran was made out in the liver, spleen, or kidneys, nor could any focus of sepsis be found except a degree of sinusitis.

Case 4.—A man aged 44 noticed oedema of the legs a month before admission to hospital in December, 1951. There was no history of preceding infection. On examination there was widespread oedema. The urine contained much albumin but only a few red blood corpuscles and

casts. Blood pressure was 120/90 mm. Hg. The fundi were normal. Serum protein was 4.8 g./100 ml., serum albumin 1.5 g./100 ml., serum cholesterol 235 mg./100 ml., serum urea 45 mg./100 ml., and urea clearance 33%. The heart, lungs, abdomen, and nervous system showed no abnormality. This patient received no relief from diet. Five courses of dextran were given, each of which produced considerable diuresis, but never enough to make him free of oedema. Renal function was unchanged during the six months he was receiving the first four courses, but is gradually deteriorating: blood pressure 170/110 mm. Hg and blood urea 134 mg./100 ml. on September 15, 1953.

Case 5.—A man aged 49 had suffered from pulmonary tuberculosis for at least five years. In January, 1952, he was admitted to hospital with erysipelas, and a month later swelling of the legs was noted. When admitted to Stobhill Hospital in April there was oedema of the legs only. The urine contained much albumin and many granular casts, but no red blood corpuscles. The blood pressure was 110/60 mm. Hg. The fundi were normal. Serum protein was 5.5 g./100 ml., serum albumin 1.6 g./100 ml., serum cholesterol 350 mg./100 ml., blood urea 47 mg./100 ml., and urea clearance 54%. The heart, abdomen, and nervous system showed no abnormality. There was dullness over the left lung, with deficient respiratory murmur. No adventitious sounds were heard. The trachea was deviated to the left. A skiagram showed collapse of the left lung and a small effusion. At this time no tubercle bacilli were found in the sputum. The fingers showed marked clubbing. A diagnosis of amyloid nephrosis complicating pulmonary tuberculosis was made. With dextran a moderate diuresis which caused reduction in oedema was induced on two occasions. On September 15, 1953, the serum protein was 5.5 g./100 ml., serum urea 37 mg./100 ml., and urea clearance 71%. His condition remains stationary.

Case 6.—A man aged 50 was proved to have pulmonary tuberculosis in 1944. For three months before admission in April, 1952, swelling of the legs had been noted. On examination oedema was found to be moderate only, and confined to the legs. Albuminuria was profuse and casts and erythrocytes were scanty. The blood pressure was 140/85 mm. Hg. The fundi were normal. The heart, abdomen, and nervous system showed no abnormality. There was marked clubbing of the fingers. Over the right upper chest there was extensive dullness, with areas of bronchial respiratory murmur and rales. A skiagram showed cavitation and fibrosis. No tubercle bacilli were found in the sputum at this time. Serum protein was 6 g./100 ml., serum albumin 2 g./100 ml., serum cholesterol 335 mg./100 ml., blood urea 30 mg./100 ml., and urea clearance 90%. A diagnosis of amyloid nephrosis complicating pulmonary tuberculosis was made. Dextran produced slight diuresis. Five months after his discharge from hospital on May 16, 1952, renal function rather suddenly deteriorated and death occurred from uraemia. The clinical diagnosis was confirmed at necropsy.

Case 7.—A boy aged 14 developed generalized oedema in January, 1953, without preceding infection other than boils on the face. When seen on February 20, 1953, he had moderate oedema of the legs and sacrum. The fundi were normal; blood pressure was 130/75 mm. Hg. The heart, lungs, and nervous system showed no abnormality. In the urine there was much albumin; a few granular casts and erythrocytes were found. Serum protein was 3.5 g./100 ml., serum albumin 2 g./100 ml., serum cholesterol 462 mg./100 ml., blood urea 34 mg./100 ml., and urea clearance 56%. When he was last seen his condition was unchanged.

Case 8.—A man aged 62 was admitted to hospital on April 14, 1953, complaining of swelling of the legs and abdomen for two weeks. For many years previously he had had a productive cough which had become worse in the past year and was associated with loss of weight. On examination he was emaciated, but showed gross generalized oedema and also ascites. There was very marked clubbing of the fingers.

In the sputum tubercle bacilli were numerous. The upper zone of the right lung was dull and the breathing bronchial. Rales were numerous and a skiagram confirmed the presence of cavitation. The heart and nervous system showed no abnormality. Blood pressure was 140/80 mm. Hg; the fundi were normal. After withdrawal of 2,700 ml. of fluid from the peritoneal cavity, the liver and spleen were not felt. In the urine there was a large amount of albumin but no casts and no erythrocytes. Serum protein was 5.5 g./100 ml., albumin 1.2 g./100 ml., serum cholesterol 168 mg./100 ml., serum urea 37 mg./100 ml., and urea clearance 37%. A diagnosis of pulmonary tuberculosis complicated by amyloidosis was made. There has been little change in his condition.

Discussion

An earlier publication by Wallenius (1950) indicated that dextran was a diuretic for nephrotic oedema. While Olive, Mills, and Lundy (1953) achieved good results in 7 out of 12 children, Bedford and Broughton (1951) had no success in three attempts on one patient. Both Wallenius (1950) and Olive and co-workers (1953) suggested that single injections are of little or no value.

When we gave five infusions of 540 ml. of 10% dextran on consecutive days, three out of six patients were rendered free of oedema and three were improved. In one instance dextran was successful after a wide variety of measures, including ion-exchange resin, A.C.T.H., cortisone, and even Southey's tubes, had made little impression. The good result was temporary in every instance, but a further course of dextran was again satisfactory on all of 11 occasions. We have found dextran to be consistently effective, and consider it to be a powerful diuretic which is valuable when other measures fail. It is perhaps particularly useful when it is decided not to use mersalyl.

Concerning the mechanism of this diuresis we have little to say. In the treatment of shock the object of administering dextran is to restore the blood volume by infusion of a substance which will remain in the vascular system for a long period. In patients suffering from type II nephritis with hypoproteinaemic oedema, the increase of osmotic pressure of the plasma due to the circulating dextran draws oedema fluid from the tissues into the blood stream. Similar changes followed the intravenous injection of acacia, a plasma volume expander of the first world war, which had a short vogue as a diuretic in nephrotic oedema (Lepore, 1937). Peters (1935) linked increase in blood volume after acacia with the production of diuresis, and, while the mechanism of this is still not understood, more recently MacArthur (1946) found that increase of blood volume was associated with the onset of spontaneous diuresis in nephrotic children. Marked haemodilution without diuresis was observed in the case reported by Bedford and Broughton (1951), who attributed this to the poor state of renal function. None of our cases is comparable with their case in that respect.

When the dextran is excreted or leaves the blood stream the blood volume returns to normal, as shown by the return of the haematocrit, haemoglobin, and total plasma protein to pre-infusion levels. The diuretic effect is therefore of limited duration.

Boyd, Fletcher, and Ratcliffe (1953) showed that dextran containing a high percentage of small molecules left the blood stream more rapidly than a product with a high percentage of larger molecules. The loss occurred into the urine and also, it was stated, into the interstitial fluids. There is not yet general agreement concerning the optimum molecular size to promote diuresis. Wallenius postulated that a preparation of small molecules might prove to be more effective, as they are osmotically more active, and, since they pass freely into the urine, they might also promote diuresis by hindering tubular reabsorption of water. Yet he held that they might pass more freely into the tissue spaces and there exert osmotic pressure against the plasma protein and circulating dextran. This we have not confirmed, in so far as no dextran was detected on examination

of oedema fluid. Bedford and Broughton (1951) also failed to find dextran in oedema fluid, and made the point that it may be present in too great dilution to be detected.

A preparation of larger and consequently less osmotically active molecules would, on the other hand, remain longer in the blood stream and so might produce a greater total diuresis. With the preparations used we were, however, unable to detect any material difference in the amount of oedema lost even when the three preparations were given to the same patient with a comparable degree of oedema as judged by body weight.

The findings of this paper cannot easily be compared with those of Wallenius (1950) or of Olive and his co-workers (1953), since both used dextran prepared by Pharmacia, of Sweden, differing in molecular distribution from the dextrans used by us. There is no support from our results for the suggestion made by Wallenius that diuresis might be due to diminished reabsorption of water from the tubules in the presence of a large number of small molecules of dextran, since the diuretic effect was just as good with large-molecule dextran as with the small-molecule preparation.

Hazards of Dextran

The hazards may be considered under two heads. In the first place, those that develop during the period of infusion or very shortly afterwards. Reactions of this type, usually of mild degree, were seen in most of our patients. They included headache and nausea; vomiting and dyspnoea were less common. These, along with rashes and backache, have usually been attributed to sensitivity or to the large molecules of dextran. We are inclined to think, however, that most if not all of these side-effects occurring in patients with oedema are due to overloading of the circulation. We have also seen subconjunctival haemorrhage and bleeding from the gums and nose. Headache, at least, is certainly minimized if the dextran is given slowly. Severe reactions, causing concern, occurred twice, on both occasions when small-molecule dextran was given. The high incidence of reactions in our patients may be explained on the basis that a normal blood volume is suddenly much increased by the attraction of oedema fluid into the blood stream when the plasma osmotic pressure is raised by dextran. Consequently very slow administration is clearly advisable to minimize reactions, and the use of small-molecule dextran is best avoided.

The second potential hazard of dextran administration is the possibility of its retention in the tissues. For a time at least it appears to lodge in the reticulo-endothelial system, particularly of the liver and spleen, and we have twice observed that the haematocrit and haemoglobin values have not returned to the pre-infusion level along with the serum protein. In one patient there was a drop in haemoglobin of over 2 g./100 ml. which was not made good until two months after the dextran was stopped. We can only tentatively interpret this as an indication that marrow function may be temporarily impaired by dextran in some individuals. The evidence gradually accumulating is strongly in favour of the view that all dextran injected is eventually excreted or metabolized. In our work there was no evidence that renal function was adversely affected by its use.

Appendix: Analytical Methods

Haemoglobin, haematocrit, and plasma dextran levels were determined on heparinized blood.

Haemoglobin was estimated as oxyhaemoglobin by photoelectric colorimetry.

Plasma dextran was estimated in the first cases by the method of Hint and Thorsén (1947), but later samples were estimated by a method using anthrone and based on the work of Morris (1948). This method, which was found to give comparable results, was preferred because of its greater rapidity and simplicity. Urinary dextran was also estimated by this procedure.

Serum total protein was estimated by the biuret method. It has been widely reported that the biuret reaction gives falsely high results in the presence of dextran, since dextran combines

with copper in alkaline solution (Jacobsson and Hansen, 1953), but these same authors have pointed out that this occurs only when a method such as that of Lehmann (1944) is used in which there is no initial precipitation of the proteins.

As they have shown, and we have confirmed, the disturbing influence of dextran is, for practical purposes, eliminated by precipitating the protein with trichloroacetic acid.

Serum cholesterol was estimated by the modification (King, 1951) of the method of Sackett (1925).

Summary

The diuretic action of dextran in renal oedema has been investigated and confirmed.

Attention is drawn to the large increases in blood volume produced in these patients by intravenous infusions of dextran.

Headache and nausea, usually of slight degree, occurred in most of our patients, and it is postulated that these symptoms were due to overloading of the circulation. Vomiting and dyspnoea were less frequent.

In an attempt to find the optimal molecular size of dextran to promote diuresis four preparations with differing molecular distribution were used. There was little difference in the amount of diuresis produced, but the most severe side-effects, accompanied by the greatest increases in blood volume, occurred after infusion of the preparation containing the greatest proportion of small molecules. The most prolonged diuresis was effected by the large-molecule dextran.

Attention is drawn to the fact that the presence of dextran does not interfere with the estimation of plasma proteins by the biuret reaction provided the proteins are first precipitated by trichloroacetic acid.

We wish to express our thanks to Dr. Frank Fletcher, medical director of Benger Laboratories Ltd., who obtained for us three preparations of dextran and gave us the data in Fig. 1, and to Benger Laboratories Ltd., who provided the dextran gratis. We also thank Dr. J. W. Chambers, clinical biochemist to Stobhill General Hospital, in whose department much of the work was done, for his valuable help and encouragement.

Lecturer in Rheumatic Diseases, University of Edinburgh

Various authors, reporting on the incidence of toxic reactions to gold salts, record percentages varying from 20 to 77. Severe reactions occur in approximately 6%. Amongst the most serious are thrombocytopenic purpura, agranulocytosis, and aplastic anaemia. Hartfall *et al.* (1937), in a series of 750 cases of rheumatoid arthritis given gold, noted toxic reactions of greater or lesser severity in 40% of patients, which included nine cases of thrombocytopenic purpura. Three of these patients died. Wintrobe *et al.* (1939), in a review of the literature, reported seven cases of purpura, four of which were fatal. Cecil *et al.* (1942) recorded three cases of purpura, one fatal, in a series of 245 cases given gold. Price and Leichtentritt (1943), in a series of 101 patients, noted three with purpura, one of whom died. Short *et al.* (1946) reported one fatal case of purpura in a series of 47 patients. Nyström (1950) encountered one fatal case of purpura among 572 patients given gold. Mettler *et al.* (1948), on the other hand, recorded four cases of purpura among 160 patients, none of which were fatal. Various other workers have reported isolated cases, but the incidence of this complication of gold therapy has declined in recent years, presumably owing to a better appreciation of the dangers of gold administration.

The introduction of 2,3-dimercaptopropanol (dimer-caprol, "B.A.L.") by Peters *et al.* (1947) as a therapeutic agent in the treatment of poisoning by arsenic and other heavy metals quickly led to its use in the treatment of toxic reactions due to gold. Many of the less serious reactions, such as dermatitis, rapidly improved following the use of dimercaprol (Ragan and Boots, 1947; Cohen *et al.*, 1947; Macleod, 1948; Montgomery, 1950; Edström, 1950; Kirsch, 1951). Good results have been recorded in cases of thrombocytopenic purpura, but only a few have been reported in detail. Lockie *et al.* (1947) describe a case of thrombocytopenic purpura due to gold which had shown no response to various methods of treatment over a period of three months and ultimately developed a subarachnoid haemorrhage. Dimercaprol was administered in doses of 180 mg. four-hourly for two days, then twice daily for ten days (total 5.7 g.), and the patient made a good recovery. The platelet level rose from 36,000 to 120,000 in three weeks, and was at approximately the same level three months later. Kroese (1949) described two cases of purpura following gold administration. In one case the response to dimercaprol was excellent. The drug was given immediately the symptoms appeared. The

second case was of five months' duration and showed no response to dimercaprol. Brodthagen (1950) reported one case in which 2 ml. of 5% dimercaprol was given daily for three days, but the patient died on the third day.

Initially dimercaprol was used mainly by intramuscular injection in the doses recommended by Peters *et al.* (1947). A course consisted of four injections, each of 2 ml. of 5% dimercaprol, at four-hourly intervals on the first day (400 mg.), followed on the second, third, and fourth days by 2 ml. twice daily. On the fifth and sixth days a single injection of 2 ml. was given (total dose 1.2 g.). In severely ill patients nearly double these doses were given, but "with considerable trepidation" (Lóngcope and Luetscher, 1946).

Only a small number of cases of thrombocytopenic purpura due to gold administration and subsequently treated with dimercaprol have been described in detail. In view of this it was considered important to report in full two further cases, in one of which the total amount of dimercaprol far exceeded the recommended dose, without ill effect.

Case 1

This patient, a man aged 49, was first seen as an out-patient in October, 1948. He had suffered from rheumatoid arthritis since 1946. He was treated conservatively until 1949, when a course of gold was recommended. Three days after the fifteenth injection (total 0.22 g.) a purpuric eruption appeared. He was admitted to hospital two days later.

On admission there was evidence of a recent epistaxis with haemorrhagic bullae present on the tongue and mucous membrane of the mouth, and a widespread purpuric eruption on the hands, feet, shoulders, neck, and face. He complained of a feeling of weakness, but was not distressed. His blood pressure was 170/110. Nothing abnormal was found in the cardiovascular, respiratory, nervous, and renal systems. The spleen was palpable, and enlarged lymph nodes were present in both axillae. There was typical spindling of the proximal interphalangeal joints of the fingers. Pain, swelling, and limitation of movement were also present in the wrists, elbows, ankles, and feet. At this time his haemoglobin was 90%, white blood cells 10,000 per c.mm. E.S.R. 46 mm. per hour, and platelets 163,000 per c.mm. Examination of a sternal marrow smear showed some hyaline degeneration of the megakaryocytes.

A transfusion of 2 pints (1,140 ml.) of whole blood was given and the bleeding stopped for three days. Epistaxis then recurred, and the patient complained of abdominal pain, nausea, headache, and diplopia. Haematuria developed and a subconjunctival haemorrhage appeared in the right eye. Ptosis became apparent and the power of accommodation was lost. Some weakness of the left leg was noted and the knee-jerk could not be elicited. There was no evidence of sensory loss. Paralysis of the third cranial nerve on the right side became complete. A further 2 pints of whole blood was transfused, but this did not control the bleeding. At this stage the platelet count had fallen to 20,000 per c.mm. The white-cell count was within the range of 5,600 to 8,200 per c.mm. The haemoglobin was 102%.

In view of the failure of transfusions to control bleeding, and the presence of a persistently low platelet count, dimercaprol was given in doses of 150 mg. six-hourly. After the second injection the patient complained of a feeling of constriction in the chest, with flushing. The individual dose was reduced to 100 mg. and no further reactions occurred. A total of 1.3 g. was given over six days. The bleeding diminished, and ceased during the course of treatment with dimercaprol. After withdrawal of the drug no further haemorrhage occurred. The platelet count remained low during dimercaprol treatment, values between 30,000 and

50,000 per c.mm. being recorded. A further transfusion of 1½ pints (850 ml.) of fresh whole blood was given without appreciable effect on the platelet count. Power in the left leg gradually improved, but the knee-jerk did not return for about eighteen months. Paralysis of the right third cranial nerve slowly improved and recovery was complete in seven months.

Comment.—Although the administration of dimercaprol coincided with the cessation of haemorrhage there was no appreciable rise in the platelet count for a further 25 days, and it is doubtful if dimercaprol, in the doses given, materially influenced the course of the disease. The most remarkable feature in this case was the localized lesions of the nervous system. Damage to the central nervous system can undoubtedly complicate the administration of gold. Mollard (1935) reported a case which developed bulbar palsy and paralysis of the right facial nerve. Hinault and Mollard (1934) described a patient in whom facial neuralgia, impairment of accommodation, and transitory blindness arose during the administration of gold. Sundelin (1941) collected 107 cases in which some evidence of neurological damage had occurred as a result of gold therapy. Hartfall *et al.* (1937), Cohen *et al.* (1947), and Doyle and Cannon (1950) reported cases of severe peripheral neuritis, in all of which recovery was eventually complete. In the present case it is difficult to be certain whether the neurological symptoms were due to the direct effect of the gold on the central nervous system or to small haemorrhages into the brain stem and cord. In view of the widespread purpura, the latter is considered to be the more likely explanation.

Case 2

This patient, a woman aged 44, was admitted to hospital with a history of profuse vaginal bleeding and widespread purpura for 12 days. She had suffered from rheumatoid arthritis of a very mild type for three years. Six months before admission her symptoms became much more acute and a course of gold was recommended. Injections were given at weekly intervals. A substantial clinical improvement was noted when a total of 0.85 g. had been given. After an interval of three weeks she received three further injections, each of 0.05 g. She noticed a metallic taste in her mouth and complained of general malaise. Menstruation began at the normal time, but bleeding became profuse and continuous. A generalized purpuric eruption appeared. She was admitted to another hospital and found to be severely anaemic. She received 4 pints (2,280 ml.) of blood before transfer to the rheumatic unit.

On admission her haemoglobin was 35%, red blood cells, 2,000,000 per c.mm.; white blood cells, 2,050 per c.mm.; and platelets, 20,100 per c.mm. The bleeding-time was raised to 20 minutes. Purpura and ecchymoses were present on the hands, thighs, and buttocks. Physical examination revealed only minimal evidence of rheumatoid arthritis in the small peripheral joints. The spleen was not palpable and no other abnormality was discovered. Vaginal haemorrhage continued. Her condition improved somewhat with repeated transfusions, 5 pints (2,840 ml.) of packed cells being given initially. The haemoglobin rose to 53% and the red cells to 3,270,000. In view of the value of A.C.T.H. and cortisone in idiopathic thrombocytopenic purpura (Bethell *et al.*, 1951; Wilson and Eisemann, 1952; Faloona *et al.*, 1952) and in other varieties of toxic reaction to drugs (Steinberg and Roodenburg, 1951), it was decided to explore their value in this condition. A total of 100 mg. of A.C.T.H. was given by the intravenous route, in the course of three days, combined with 40 mg. of "acthar gel" twice daily. Little evidence of haematological response appeared. The platelet count remained less than 40,000 per c.mm. and the bleeding-time remained over 10 minutes. The red-cell count and haemoglobin level fell from their post-transfusion levels to 2,780,000 per c.mm. and 47% respectively.

The dose of acthar gel was therefore increased to 60 mg. twice daily from the fourth day of treatment and, in addition, 100 mg. of cortisone was given daily by mouth. Apart

from a transitory fall in the bleeding-time, there was no evidence of any improvement. The dose of cortisone was increased to 125 mg. and subsequently to 150 mg. daily, while the dose of A.C.T.H. was reduced to 40 mg. daily. Signs of fluid retention appeared, in the form of ankle and sacral oedema, basal pulmonary crepitations, and a rise in systolic blood pressure. The bleeding-time remained over 10 minutes. Vaginal bleeding continued. The haemoglobin had fallen to 42%, red-cell count to 2,410,000, and platelets to 18,000 by the fourteenth day of treatment. The white-cell count was reduced to 2,500 per c.mm. A further 3 pints (1,700 ml.) of blood was given.

In view of the complete absence of any signs of improvement in the haematological condition, it was not considered justifiable to continue with cortisone or A.C.T.H. When the hormones were finally withdrawn, a total of 1.41 g. of A.C.T.H. and 1.75 g. of cortisone had been given. It would appear, therefore, that these hormones may be of little value in the treatment of severe cases of thrombocytopenic purpura following the administration of gold. It is of interest to note that the E.S.R. fell from initially high levels of 120 and 130 mm. in one hour to within normal limits during the period of hormone therapy and rose rapidly after withdrawal. The capillary resistance, measured by the method described by Robson and Duthie (1950), also rose during the period of hormonal treatment and fell after withdrawal. A similar effect on the blood pressure was noted. Eosinophils were absent from the peripheral blood during the period of hormonal therapy.

Dimercaprol was then given in doses of 150 mg. eight-hourly for 10 days. There was an immediate and dramatic response (see Chart). Haemorrhage ceased, the bleeding-

time fell rapidly, while the platelet count rose from 20,000 to 200,000 per c.mm. and the haemoglobin level rose from 52% to 60%. On the abrupt withdrawal of dimercaprol this improvement was quickly reversed. The platelet count and haemoglobin level fell, the bleeding-time rose again, and there were further episodes of haemorrhage, this time from the rectum and nose.

After an interval of six days dimercaprol was again given in doses of 450 mg. daily and the haematological response was unequivocal (see Chart). Five days later the dose was reduced to 300 mg., but some deterioration again took place. The dose was restored to the former level of 450 mg. daily and continued for a further 12 days. During this time normal menstruation occurred, and it was thought to be safe to begin withdrawal of the drug. This was done during the course of 10 days, without any sign of relapse. The patient's condition improved rapidly and there has been no relapse for one year. A feature of interest that occurred during administration of the second course of dimercaprol was a marked eosinophilia. The eosinophil count rose abruptly to 1,200 per c.mm. from its previous level of 50. This marked eosinophilia persisted during the second course of dimercaprol and subsided slowly as the drug was withdrawn.

No flare-up in the joints occurred after the withdrawal of cortisone, A.C.T.H., or dimercaprol.

Discussion

Several points of interest emerge from a study of the response to treatment of these two patients. In Case 1 purpura and thrombocytopenia appeared after the administration of a relatively small amount of gold (0.22 g.).

Dimercaprol given in the recommended doses (total 1.2 g.) appeared to have little immediate effect on the course of the condition. The platelet count remained at a very low level for 25 days after its administration was stopped. The fact that the cessation of haemorrhage coincided fairly closely with the administration of dimercaprol may be of little significance, as bleeding was not a prominent feature and anaemia did not develop. The neurological complications in this patient have already been discussed.

In Case 2 1 g. of gold had been given before purpura appeared. Haemorrhage was severe and continuous. A marked degree of anaemia rapidly developed. Repeated transfusions were necessary as a life-saving measure, but were of very temporary benefit. Large doses of A.C.T.H. and cortisone had no significant effect on the platelet count or the anaemia. The bleeding-time did show some improvement, and the capillary resistance, as measured by the negative-pressure method (Robson and Duthie, 1950), rose sharply from an initially subnormal level. This is an observation of some interest, as it would suggest that the reduction in the strength of the capillary wall found in thrombocytopenia of both the idiopathic and the toxic type may be of little importance as a cause of haemorrhage. The findings in this patient would suggest that there is a closer inter-relationship with the platelet count, but other as yet unknown factors must be concerned, as low counts are not infrequently found in the absence of bleeding (see Case 1). The failure of these hormones is in marked contrast to their effects in the idiopathic variety of thrombocytopenic purpura, in which a response occurs in most cases, although it may be incomplete and temporary.

Davidson *et al.* (1952) have also reported the failure of A.C.T.H. to influence the haematological condition in one case of thrombocytopenic purpura following the administration of gold. Virkkunen (1952), however, describes the effect of A.C.T.H. and cortisone in two cases with severe thrombocytopenic purpura after gold therapy. In one case a short course of cortisone produced a substantial rise in the platelet level, with an immediate fall on withdrawal. A subsequent more prolonged course produced a permanent return of the platelet level to normal. In the other case a total of 2 g. of A.C.T.H. was administered over one month, without any improvement in the extremely low platelet count. Clinically the patient improved without further haemorrhagic phenomena, but the thrombocytopenia persisted until four months after treatment, when a spontaneous remission occurred.

In Case 2 the response to dimercaprol was prompt and unequivocal. Cessation of treatment was followed by deterioration. Resumption of dimercaprol restored the position, but reduction of the daily dose to 300 mg. was again followed by relapse. The critical dose at this time lay between 300 and 450 mg. daily. The occurrence of normal menstruation was thought to indicate that dimercaprol might safely be withdrawn, and this proved to be the case. This patient received a total of 15.575 g. of the drug without any evidence of toxic effects. An interesting finding was the marked eosinophilia during the second course of dimercaprol. This is difficult to explain, as the patient had no clinical signs of hypersensitivity such as rash or fever. The presence of a persistent leucopenia would suggest a depression of all the cellular elements of the bone marrow. It may be that the adequate removal of the gold in the tissues by dimercaprol prevented further damage of the marrow and thereby avoided the possible onset of agranulocytosis or aplastic anaemia.

The pharmacological properties and therapeutic uses of dimercaprol have been reviewed by Weatherall (1948). Its action depends on its ability to form stable complexes with the heavy metals. By so doing it transfers the toxic element from the cells to the tissue fluids, from which it is excreted in the urine. In doses above 5 mg. per kg. body weight it may cause lacrimation, salivation, vomiting, and a rise in blood pressure, but permanent damage to organs has not been reported. It is not known why certain individuals develop toxic reactions to gold, but in such individuals it

would appear necessary to protect any susceptible tissues from the damaging action of gold until it is no longer being absorbed from tissue depots in significant quantities. This point is well illustrated in Case 2. It would seem that in the past some of the poor results reported in the treatment of thrombocytopenic purpura with dimercaprol may have been due to failure to give the drug in large enough doses for long enough periods. Results are likely to be more satisfactory if dimercaprol is given immediately toxic effects appear, as in these circumstances it may be possible to clear gold both from the damaged tissues and from the tissue depots, thus protecting susceptible cells from further injury. In recent years the successful use of much higher doses has been reported. Montgomery (1950), in two cases of gold dermatitis, gave a total of 9.6 g. in one case and 11.9 g. to the other over periods of 12 and 8 weeks respectively. One patient developed skin sensitivity to dimercaprol, but suffered no other ill effects.

Summary

Two cases of thrombocytopenic purpura following gold administration are described.

Unusual neurological signs occurred in one case, probably due to small haemorrhages into the cord and brain stem.

One case appeared to show no response to dimercaprol, but it is now considered that the total dosage given was inadequate.

One case showed no response to large doses of A.C.T.H. and cortisone, but responded promptly to dimercaprol.

The need for a higher daily dose and more prolonged courses of dimercaprol are discussed.

During the period when these cases were studied, the Rheumatic Unit, Northern General Hospital, was in receipt of grants from the Medical Research Council and the Nuffield Foundation. The cortisone and A.C.T.H. were supplied by the Medical Research Council, to whom we are indebted.

HYPOPARATHYROIDISM AND PSEUDO-HYPOPARATHYROIDISM

BY

R. R. de MOWBRAY, D.M., M.R.C.P.
Registrar, Endocrine Department, Guy's Hospital

S. H. LLEWELLYN SMITH, B.M., M.R.C.P.
Physician, Lewisham General Hospital

AND

W. J. C. SYMONDS, B.M., B.Ch.
Medical Registrar, Guy's Hospital

Hypoparathyroidism is well recognized as a complication of thyroidectomy. In most series of cases reported in the literature the incidence has been less than 1% after operations for hyperthyroidism, the figures ranging from 0.2% (Cattel, 1934) to 3.5% (Lachmann, 1941); in about half the cases the tetany is only transient. Idiopathic hypoparathyroidism is generally regarded as a rarity. Only 60 to 70 proved cases have been recorded in the literature, and only three of these have been reported from this country (Humphreys, 1939; Hims-worth and Maizels, 1940; Jordan and Kelsall, 1951). Still rarer, perhaps, is the condition of pseudo-hypoparathyroidism, described by Albright *et al.* (1942), which results from abnormal resistance to parathyroid hormone rather than from deficient secretion. Only 18 cases have so far been reported.

We have been impressed by the variety of ways in which this group of disorders may present, and by the ease with which they may escape recognition. We believe that they may not be as rare as is commonly supposed. We therefore record three cases of idiopathic hypoparathyroidism, together with three illustrative cases of the post-operative condition and one case of pseudo-hypoparathyroidism. This last case has already been reported elsewhere (Bishop and de Mowbray, 1951), and is, so far as we are aware, the first to be recorded in this country.

Case 1. Idiopathic Hypoparathyroidism

This patient, a man aged 44, first noticed stiffness of his leg muscles after mild exercise when aged about 12. At 22 he began to develop progressive failure of vision, at 40 a cataract was removed from his left eye. At the age of 32 he began to have carpal spasm, and between the attacks he had difficulty in moving his joints, owing to a feeling of "hardness" in the muscles. A few years later he developed sudden involuntary "flinging" movements of his limbs, occasionally causing him to fall to the ground. For four years he had difficulty in initiating sudden leg movements, on account of spasm of the

muscles. For about 20 years his wife had noticed a gradual loss of his critical and introspective faculties, and, more recently, he himself had been aware of an impairment of his powers of concentration and emotional control. He had never had an operation on the thyroid gland. He had been treated for some years as a hysteric and later as an epileptic (one of his sisters had suffered from epilepsy in the past).

On examination he was facile and emotionally unstable, and liable to attacks of uncontrolled and sometimes inappropriate laughter. His powers of concentration were limited and variable, and intelligence tests showed deterioration (Wechsler Bellevue, 61; progressive matrix, Grade V). Chvostek's and Trousseau's signs were positive. A mature cataract was present in his right eye, and one had already been removed from his left eye. His skin and nails were normal, but his teeth were poor in quality.

Investigations.—The serum calcium was 6.5 mg., the phosphate 4.3 mg., and the alkaline phosphatase 18 units per 100 ml. The Sulkowitch test showed no calcium in the urine. The Ellsworth-Howard test gave a normal response to parathyroid hormone (Fig. 1). The faeces contained no excess of fat. X-ray films (Figs. 2 and 3) showed radiating striae of calcification in the caudate nucleus areas of the brain and possibly calcification in the cerebellum. Two of the last molar teeth were unerupted (Fig. 2). The pelvic bones showed increased density, with some calcification of the tendon insertions. The electroencephalogram

Fig. 1.—Ellsworth-Howard test. Administration of parathyroid hormone to subjects with true hypoparathyroidism (and to normal subjects) leads to a marked increase in urinary phosphate excretion and a water diuresis. There is no significant response in the case of pseudo-hypoparathyroidism. The patients were under basal conditions, except in Case 2. — Urinary phosphate level. Urinary volume.

showed abnormally slow dominant frequency at 6 to 7 cycles a second in the post-central areas. These waves were bilaterally symmetrical, and were inhibited by visual attention; hyperventilation led to a slight increase in dominant

FIG. 2.—Case 1. Idiopathic hypoparathyroidism. Bilateral calcification in the basal ganglia, arranged in radiating striations. One of the unerupted molars is also shown.

frequency. The electrocardiogram showed low voltage in all leads, especially in the T waves, and the Q-T interval was prolonged.

Treatment.—Dihydratichysterol, 1 ml. (1.25 mg.), was given three times daily, and the dose was gradually reduced

FIG. 3.—Outline drawing of radiating striae of calcification shown in Fig. 2. The electroencephalogram improved, now showing a dominant alpha rhythm at 8 cycles a second, and the electrocardiogram returned to normal.

Case 2. Idiopathic Hypoparathyroidism

A man aged 41 was seen by an ophthalmic surgeon in February, 1951, on account of failing vision of three years' duration. He was found to have extensive bilateral posterior lamellar cataracts, and a reducing substance was present in the urine. He was therefore referred for a physician's opinion. On further questioning it was revealed that 12 years previously the hair of his head had fallen out rapidly in a patchy manner, and that it had never completely grown again. The eyebrows had also fallen out, and several of his nails had been shed and had only partially regrown. He had never had any symptoms of tetany, except for some paraesthesiae in the hands and a tendency to paraesthesiae and cramps in the legs. His wife said that for two or three years he had been becoming more morose, irritable, and forgetful, and had been losing interest in his appearance and cleanliness. He had never had an operation on the thyroid gland, and there was no relevant family history.

On examination the vertex of the scalp was almost completely bald, and at the sides of the head were patches of thinning, where the hairs were small, white, and brittle. Several of his nails had only partially grown again and

were ridged, broken, and brittle (Fig. 4); scrapings from them failed to show any fungus. Chvostek's sign was positive, but Trousseau's sign was negative. The blood pressure was 130/70 and the urine normal.

FIG. 4.—Case 2. Trophic changes in the finger-nails.

Investigations.—The serum calcium was 5.8 mg. and the phosphate 6.2 mg. per 100 ml. The Ellsworth-Howard test showed a normal response to parathyroid hormone (Fig. 1). X-ray films showed no calcification in the brain and the bone density was normal.

Treatment.—Dihydratichysterol and calcium lactate were given, as shown in Fig. 5, the maintenance dose being 1 ml. and 75 gr. (5 g.) daily, respectively. The mental symptoms resolved soon after treatment was begun and the paraesthesiae disappeared. The nails have completely regrown (Fig. 6) and there is some evidence of regrowth of hair. There is no apparent change in his cataracts, and it has not so far been necessary to operate on them.

FIG. 5.—Case 2. Response of blood calcium and phosphate levels dihydratichysterol dosage. (50,000 units of calciferol = 1 ml. of dihydratichysterol.)

FIG. 6.—Finger-nails of Case 2 after six months' treatment with dihydratichysterol.

Case 3. Idiopathic Hypoparathyroidism

This patient, a man aged 50, had been seized with severe cramps in the hands after an attack of "influenza" when aged 31. The cramps continued intermittently, being brought on particularly by his work as a boot-repairer. In March, 1933, two months after the onset of symptoms, he had an exceptionally severe attack, which involved the muscles of the face and throat, causing dyspnoea, and he was admitted to hospital. On admission Chvostek's and Trousseau's signs were strongly positive, and the serum calcium level was 5.4 mg. and the serum phosphate level 8 mg. per 100 ml. Within six hours after injections of calcium chloride and "para-thor-mone" the symptoms

disappeared. He was discharged from hospital, free of symptoms, with a serum calcium level of 8.1 mg. per 100 ml. and taking calcium gluconate, 2 dr. (8 g.) thrice daily, and "ostelin," 3 minims (0.18 ml.) thrice daily, and 2 pints (1.1 litres) of milk daily. On return to work, however, he continued to have cramps. These became more severe again and he was readmitted to hospital in December, 1933. At that time x-ray films showed normal bone density and there was no excess of fats in the faeces. He was treated with para-thor-mone 10 units weekly. Eight years after the onset of the tetany his vision began to fail. A cataract was removed from the left eye seven years later (in 1949), and another was removed from the right eye in December, 1951.

When first seen by us, on February 14, 1952, he was still having intermittent attacks of tetany, mainly after any infection or anxiety, or during the winter and spring. The spasms were painful and were accompanied by sweating. He had never had any epileptiform convulsions. He was not receiving any regular treatment, but was given injections of para-thor-mone during attacks of tetany, with complete relief. He had never had an operation on the thyroid gland.

On examination Chvostek's and Trousseau's signs were positive. There were no trophic changes in the skin, hair, or nails. The blood pressure was 130/80 and the urine normal.

Investigations.—The serum calcium was 6 mg. and the serum phosphate 4 mg. per 100 ml. He had, however, received an injection of para-thor-mone a fortnight previously, and after a further 10 days without treatment the calcium fell to 5.5 mg. and the phosphate rose to 5.4 mg. per 100 ml. The serum alkaline phosphatase was 7.5 units per 100 ml. The Ellsworth-Howard test gave a normal response to parathyroid hormone (Fig. 1). X-ray films showed normal bone density and no evidence of calcification in the brain.

Treatment.—The serum calcium level has been raised to 8.8 mg. per 100 ml. by treatment with dihydratichysterol, and the serum phosphate figure is now 3.6 mg. per 100 ml.

Case 4. Pseudohypoparathyroidism

This patient, a girl aged 18, developed tetany after operation for an acute mastoid infection at the age of 6. The symptoms were alleviated by "ostocalcium," but she continued to have mild tetany from time to time and the serum calcium level remained below normal. She had always been undersized and mentally retarded. The menarche was at the age of 13, since when she had menstruated normally. There was no relevant family history.

On examination she was dwarfed, thick-set, and somewhat obese. Her height was 55 in. (140 cm.), span 53½ in. (136 cm.), floor to pubis measurement 26½ in. (67 cm.), and pubis to vertex 28½ in. (72 cm.). Thus the limbs were a little short in comparison with the trunk. The hands and fingers were short and there was a characteristic roundness of the face (Fig. 7). X-ray films showed disproportionate shortening of the fourth and fifth metacarpals. The tibiae were slightly bowed, especially the left one. Secondary sexual development was normal, except for a slight degree of hirsutism. There were no defects in the skin, hair, and nails, and no lens opacities, but the teeth were poorly formed. Chvostek's and Trousseau's signs were positive. The blood pressure was 110/65 and the urine normal.

Investigations.—The serum calcium was 6 mg., phosphate 6.8 mg., and alkaline phosphatase 2.7 units per 100 ml. The Sulkowitch test showed no calcium in the urine and quantitative estimation showed only 12 mg. per 24 hours. The Ellsworth-Howard test showed almost complete resistance to parathyroid hormone (Fig. 1). X-ray films showed patches of calcification in the basal ganglia of the brain. The bone density was normal. Epiphyseal closure was well advanced for her age. Small patches of calcification were seen in the soft tissues of the limbs, some of them being deposited along the course of the blood vessels. The first

premolars of the lower jaw and the first molars of both jaws were unerupted and none of the second molars showed proper root formation. Renal function was impaired; the urine could be diluted to 1002 and concentrated to 1020, but the maximal urea concentration was only 1.08%. Intravenous pyelography was normal.

Treatment.—Dihydratichysterol, 1 ml. (1.25 mg.), was given three times daily. Calcium was detectable in the urine after one week, and within three weeks the serum calcium level had risen to 11.6 mg. per 100 ml. The symptoms and signs of tetany disappeared, and the patient has remained well, with normal serum calcium and phosphate levels, on a maintenance dose of 0.5 ml. of dihydratichysterol daily.

FIG. 7.—Case 4. Pseudo-hypoparathyroidism. Rounding of the face.

Case 5. Post-operative Hypoparathyroidism

A woman aged 37 had had two operations for hyperthyroidism at the ages of 31 and 35. On the second occasion a total thyroidectomy was performed, as the surgeon was suspicious that the goitre might be malignant. After operation she lost her voice, and in the course of five months became myxoedematous. She responded to treatment with thyroid, but then began to have epileptiform convulsions with asphyxial symptoms. She developed a marked laryngeal stridor, due to abductor paralysis of both vocal cords, presumably from injury to the recurrent laryngeal nerves. A tracheotomy was performed, but this failed to relieve the asphyxial attacks. The epileptiform convulsions were not relieved by phenytoin sodium, 1½ gr. (0.1 g.) twice daily, and one year after the second operation she also began to have paraesthesiae in the neck and in the right arm and leg. At this time, while her blood pressure was being recorded, it was noticed that she showed a positive Trousseau's sign, and the serum calcium level was found to be 7.2 mg. (phosphate 4.2 mg.) per 100 ml.

Calcium lactate, 75 gr. (5 g.) and calciferol, 6,000 units daily, failed to alter the serum calcium level, and after a week she was given 9 ml. (11.25 mg.) of dihydratichysterol daily. The serum calcium level rose to 10 mg. per 100 ml. after nine days and the fits ceased to occur. For the past four years she has been maintained on a dose of 6,000 units of calciferol daily, together with 75 gr. (5 g.) of calcium lactate. It has not been possible to dispense with the tracheotomy, and it is therefore clear that the laryngeal palsy was not a result of the hypocalcaemia. It is of interest that both she and her siblings had convulsions in infancy, which suggests that her threshold for convulsions is low.

Case 6. Post-operative Hypoparathyroidism

A married woman aged 46 underwent three operations for a non-toxic goitre between the ages of 15 and 17. She apparently had no symptoms until five years later, when she began to have generalized convulsions. These were thought to be epileptic and were treated as such for a number of years. Some 14 years later it was recognized that she was suffering from chronic tetany. At that time she showed bilateral cataracts, and the serum calcium level was 6.5 mg. per 100 ml.; the serum phosphate level was

not estimated. She was treated with a high calcium intake, hydrochloric acid, and ammonium chloride, with only partial relief. Two years later she was given calciferol, 100,000 units daily, with remarkable improvement. The cataract in the right eye was removed at the age of 44. A year later she began to develop menopausal symptoms, accompanied by emotional instability and a tendency to overbreathe, thus precipitating further symptoms of tetany.

When first seen by us she had been taking vitamin D, 100,000 units daily, for eight years, but was still having tetany. Chvostek's sign was weakly positive, and Trousseau's sign was strongly positive, being accompanied by emotional disturbance and overbreathing. The hair of her head was generally sparse. The blood pressure was 170/110 and the urine normal. The serum calcium was 7.1 mg., phosphate 4.5 mg., and alkaline phosphatase 9.5 units per 100 ml. The electrocardiogram showed left axis deviation with low voltage T_1 , inverted T_2 and T_3 , and depression of the ST segment. The Q-T interval was prolonged. X-ray films showed marked calcification in the basal ganglia and in the region of the cerebellum. The bone density was normal. The Ellsworth-Howard test showed a poor response to the injection of 40 units of para-thor-mone (Fig. 1).

Dihydrotachysterol was substituted for calciferol, and the symptoms and the serum calcium level were controlled by a maintenance dose of 0.66 to 1 ml. daily. Three months later the cataract in the left eye was successfully removed, but a month later still, after a respiratory infection, the symptoms of tetany and epilepsy relapsed to their original state. Neither the symptoms nor the serum calcium level could be controlled by as much as 4 ml. of dihydrotachysterol daily, and treatment with calciferol was resumed instead. The symptoms were well controlled by a dose of 200,000 units daily, and four successive normal serum calcium figures were obtained within a fortnight under inpatient conditions. Five days after discharge from the ward she developed anorexia, followed by thirst, polyuria, an unpleasant taste in the mouth, weakness of the limbs, dyspnoea, and vomiting, and she was readmitted five days later in a confused state, with muscular atony and a serum calcium level of 15.9 mg. per 100 ml. The calciferol was discontinued, but she became maniacal and deluded, and had to be transferred to a mental ward. She subsequently developed a hemiparesis, and the blood urea rose to 72 mg. per 100 ml. Both the mental symptoms and the hemiparesis cleared up within 10 days, and the serum calcium level fell to normal after a further four weeks.

Case 7. Post-operative Hypoparathyroidism

A married woman aged 23 underwent thyroidectomy for hyperthyroidism at the age of 21. Four days after operation she developed tetany, which was relieved by injections of calcium gluconate and dihydrotachysterol. Treatment with dihydrotachysterol was continued only intermittently, in view of difficulty in obtaining supplies. Fifteen months later she became pregnant, and continued to term in spite of the fact that she received no calcium or dihydrotachysterol during pregnancy. There was, however, a return of the attacks of tetany during labour. Lactation was terminated after two months on account of a breast abscess. When inadequately treated she was inclined to emotional instability and hyperventilation, with exacerbation of her tetany. She was investigated when not under the influence of treatment, and showed positive Chvostek's and Trousseau's signs, a serum calcium level of 6.1 mg. and a phosphate level of 4.9 mg. per 100 ml., and only a trace of calcium in the urine. The Ellsworth-Howard test showed a normal response to parathyroid hormone (Fig. 1). There were no defects in the skin, hair, or nails, and no opacities in the lenses on examination with a slit-lamp.

Her symptoms were controlled, and a normal serum calcium level was maintained, on a dose of 1 ml. of dihydrotachysterol daily.

Mode of Presentation

Tetany.—Three of our cases presented with this symptom (Cases 3, 4, and 7). Carpopedal spasms also occurred in Cases 1, 5, and 6, but they were overshadowed by other manifestations. In Case 2 the only symptoms of tetany which could be elicited were mild paraesthesiae and cramps. The symptoms may indeed vary from trivial paraesthesiae to severe generalized spasms. Sometimes these involve the respiratory muscles, and, rarely, the diaphragm is affected, with fatal results. Shelling (1935) describes other occasional manifestations of tetany, such as strabismus, nystagmus, abnormalities of the pupils, dysphagia, dysarthria, symptoms of pyloric or intestinal obstruction, bronchial spasm, retention or incontinence of urine, peripheral oedema, Raynaud's phenomenon, tachycardia, cardiac irregularities, or even sudden cardiac arrest. Boothby *et al.* (1931) describe weakness and fatigability of the muscles, and Lachmann (1941) describes intermittent pareses in the limbs in one case. Infantile convulsions may occasionally be due to hypoparathyroidism, which may be physiological in the neonatal period or may represent the onset of idiopathic hypoparathyroidism (Bakwin, 1939).

Epilepsy.—Cases 5 and 6 presented with typical major seizures, and were treated for some time as cases of idiopathic epilepsy. In Case 6 the fits did not begin until five years after thyroidectomy, which made the diagnosis more elusive. Approximately 40% of the cases of idiopathic hypoparathyroidism recorded in the literature have presented with epilepsy, and many cases have escaped recognition as a result of this. Either major or minor seizures may occur. They are not necessarily associated with frank symptoms of tetany, and, when they are, their onset is often independent, but they usually cease when the serum calcium level is restored to normal. The electroencephalogram may show typical epileptic changes, and the abnormal waves tend to disappear with correction of the serum calcium level, but the record does not necessarily become normal, suggesting either that these patients are latent epileptics or that irreversible cerebral changes have occurred (Kowallis, 1941; Taubenhau and Engle, 1945; Mortell, 1946; Gotta and Odoriz, 1948). In Case 1 there were no true epileptic manifestations, but there was a history of seizures of a myoclonic pattern.

Ectodermal Lesions.—Case 2 showed patchy loss of hair, loss of the eyebrows and eyelashes, and deformity of the nails. More commonly, the hair of the head is generally sparse, and rarely there is complete alopecia. There may also be loss of pubic and axillary hair. In some cases the skin becomes dry, rough, and scaly. The nails and the mouth may become infected with moniliasis in idiopathic hypoparathyroidism (Thorpe and Handley, 1929; Sevringhaus, 1942; Sutphin *et al.*, 1943; Talbot *et al.*, 1943). Impetigo herpetiformis has also been described as an association with chronic tetany (Lachmann, 1941).

Cataracts.—Case 2 attended an eye hospital with cataracts in the first instance and was referred to a physician only because of the finding of a trace of reducing substance in the urine. Cataracts were also present in Cases 1, 3, and 6, and had to be extracted. They may occur in chronic hypocalcaemia from any cause (Albright and Reifenstein, 1948). Although some authors have claimed that those occurring in hypoparathyroidism have a distinct pattern and that they tend to develop in the subcapsular layer, O'Brien (1932) came to the conclusion that there was no characteristic morphology. Cataracts may develop in the absence of frank symptoms of tetany or when the symptoms have become much milder, either with or without treatment. They may develop rapidly, leading to blindness within a few months (Emerson *et al.*, 1941).

It is clear that cases of hypoparathyroidism may present in various ways and that they may be referred in the first instance to various special departments. Thus Case 1 first came to a neurological clinic, and Case 2 to an eye hospital, and it is likely that other cases might be found in skin clinics. Though classical carpopedal spasms may easily be

recognized, mild tetany may be mistaken for acroparaesthesiae, "neuritis," "fibrositis," "cramps," or "hysteria." More cases of hypoparathyroidism might come to light if the diagnosis were borne in mind in such cases, and in cases of epilepsy, in cases of cataract occurring in young persons, and in patients with trophic lesions in the skin, hair, and nails.

Other Manifestations

Changes in Teeth.—When parathyroid deficiency arises in childhood the enamel is often deficient and shows transverse ridges, and changes occur in the dentine. Sometimes there may be delay or failure of eruption. These changes do not occur when the disease arises in adult life, and decalcification never occurs (Albright and Strock, 1933).

Mental Changes.—Anxiety symptoms were prominent in Cases 6 and 7, and there was a resulting tendency to hyperventilation, precipitating further attacks of tetany. Case 1 showed intellectual deterioration and emotional instability and incongruity, and Case 2 showed moroseness, irritability, impairment of memory, and loss of interest in his appearance. Frank psychoses of manic-depressive and delusional types have been described (Barr *et al.*, 1938; Eaton and Haines, 1939; Greene and Swanson, 1941; Scarlett and Houghtling, 1944). These mental changes usually resolve within a few weeks after the serum calcium is restored to normal, which suggests that they are the direct result of hypocalcaemia. Mental retardation has also been recorded in a number of cases of idiopathic hypoparathyroidism arising in childhood.

Papilloedema occurs occasionally. It subsides when the serum calcium level is restored to normal (Albrecht, 1923; Shelling and Goodman, 1934; Barr *et al.*, 1938; Hurxthal, 1942; Sutphin *et al.*, 1943; Mortell, 1946; Berezin and Stein, 1948). The combination of papilloedema and epilepsy may suggest a cerebral tumour.

Physical Development.—In a number of cases arising in childhood the patients have been undersized. The height has been recorded in the literature in 10 cases in which the patient has reached the age of 18. The heights ranged from 57 to 67 in. (145 to 170 cm.), average 61½ in. (156 cm.). In some cases puberty has been delayed and secondary sexual characters have been underdeveloped.

Other Endocrine Disorders.—These are seldom found. Hypothyroidism occasionally occurs in post-operative cases (as in Case 4); it has also been described in two idiopathic cases (Himsworth and Maizels, 1940; Lachmann, 1941). Addison's disease has been associated with idiopathic hypoparathyroidism in three cases (Sutphin *et al.*, 1943; Talbot *et al.*, 1943; Leonard, 1946). In Leonard's case necropsy showed atrophy of the adrenal glands as well as absence of the parathyroids; in the case of Sutphin *et al.* there was tuberculous infection.

Hypoparathyroidism has not been recorded in panhypopituitarism, and there is no good evidence that a pituitary parathyrotrophic factor exists. This subject is reviewed by Collip (1940), Törnblom (1949), and Engfeldt (1950).

Diagnosis

Blood Chemistry.—The serum calcium figure is reduced and the serum inorganic phosphorus level is raised. The normal range for the serum phosphate level is given by Albright and Reifenstein (1948) as 3.2 mg. per 100 ml. $\pm$ 0.5 but in our laboratories it is from 2.5 to 5 mg. per 100 ml. Drake, Albright, *et al.* (1939) regard a raised serum phosphate level as an essential diagnostic criterion. This distinguishes hypoparathyroidism from other low-calcium disorders, such as rickets, osteomalacia, and steatorrhoea, in which the blood is unsaturated with calcium and phosphorus and both levels tend to be low. The only other condition in which a low serum calcium level and a high serum phosphorus level are found is chronic renal disease; this should therefore be excluded. In Case 1 the serum phosphorus level was never higher than 4.5 mg. per 100 ml.;

this figure is raised by Albright and Reifenstein's standards, though it falls within our normal range.

Radiological Findings.—Calcification was present in the basal ganglia in three of our cases (Cases 1, 4, and 6). In Cases 4 and 6 it was punctate, but in Case 1 it was arranged in radiating striations (see Fig. 2). The radiological aspects of Cases 1 and 3 have already been reported (Medill, 1951), and the subject is reviewed by Camp (1947), Siglin, Eaton, Camp, and Haines (1947), and Foley (1951). The bone density is normal or increased. It was increased in Case 1, but was normal in the others. Rarefaction does not occur as a primary feature of hypoparathyroidism; it was reported in one of Emerson, Walsh, and Howard's cases (1941) and in one of Lachmann's cases (1941), but in both of these it was probably due to post-menopausal osteoporosis. The metabolic and radiological changes can best be explained on the basis of the theory of Albright and his colleagues that the primary action of parathyroid hormone is to increase the excretion of phosphorus in the urine, leading to a fall in the serum phosphate level and a compensatory rise in the serum calcium level. It follows that in hypoparathyroidism the initial change will be a rise in the serum phosphate level, followed by a compensatory fall in the serum calcium level. Since the blood is fully saturated with calcium phosphate, a rise in the phosphate concentration, together with continued absorption from the intestine, will lead to a tendency to supersaturation of the blood, with an increase in deposition of bone salt and an increase in bone density (Albright and Reifenstein, 1948). The cerebral calcification may be due to the same mechanism, but it is not clear why the brain is affected and other soft tissues are not.

Electrocardiographic Changes.—The characteristic change of hypocalcaemia is seen—namely, prolongation of the Q-T interval.

Electroencephalographic Changes.—There may be: (a) slow waves of 2 to 5 cycles a second (as in Case 1), usually in series of three or four waves, but sometimes in stretches of up to 10 seconds; (b) typical epileptic changes, with groups of slow waves and spikes; (c) a continuous generalized disturbance of rhythm; or (d) a normal record (Gotta and Odoriz, 1948).

Pseudo-hypoparathyroidism

This consists of three independent genetic defects. (1) There is a disturbance of the peripheral action of parathyroid hormone, producing effects exactly similar to those of true hypoparathyroidism, except that the injection of parathyroid hormone usually fails to increase the excretion of phosphate in the urine (see Fig. 1). The parathyroid glands are shown to be normal or hyperplastic on biopsy. (2) There is a dyschondroplasia, resulting in a short stature and in shortening of various bones, particularly the metacarpals and metatarsals. (3) There is a tendency for the subcutaneous tissues to become calcified and to form bone. The appearance of these patients is characteristic. They are short and thick-set; the face is rounded (see Fig. 6) and they are often mentally retarded. All these features are well shown by Case 4. The suggestion that the condition is due to a genetic disturbance is confirmed by its occurrence on two occasions in a pair of twins, and in another case in a mother and child (Elrick *et al.*, 1950).

The distinction from true hypoparathyroidism is to a large extent academic, as the treatment is the same, but it is of considerable general interest, since it shows that an endocrine disorder may result not only from failure of secretion of a hormone but also from an abnormal peripheral response to it.

Treatment

Para-thor-mone is of very limited value, since acute cases following operation are more rapidly controlled by administration of calcium salts, and in chronic cases the hormone has four disadvantages: (1) it is expensive, (2) it has to be given by injection, (3) it is apt to give rise to local

reactions, and (4) it leads to antibody-formation and therefore begins to lose its effect after a few weeks (Albright and Ellsworth, 1929).

Either calciferol (vitamin D₂) or dihydrotachysterol should be used. These substances differ in chemical structure only in the saturation of a double bond. Whereas parathyroid hormone increases the excretion of phosphate in the urine but has no effect upon calcium absorption, calciferol acts principally upon calcium absorption, and only to a less extent upon phosphate excretion. Dihydrotachysterol, on the other hand, more closely resembles parathyroid hormone in its action, in that it acts primarily upon excretion of phosphate and only to a less extent upon absorption of calcium (Albright *et al.*, 1938). There is also evidence that both calciferol and dihydrotachysterol have a direct action upon bone, leading to resorption and mobilization of calcium (Selye, 1932).

Dihydrotachysterol is usually given in doses of 3 ml. (3.75 mg.) daily initially, the dose being reduced to 0.5 or 1 ml. (0.625 to 1.25 mg.) daily for maintenance treatment. Calciferol usually has to be given in doses of 100,000 to 400,000 units daily (Sevringhaus and St. John, 1943) or occasionally 500,000 units (Himsworth and Maizels, 1940).

McLean (1941) states that the toxic effects of vitamin D have been overemphasized, and that many of the effects reported by earlier workers were due to the high toxicol content of the original preparations. The dangers are by no means negligible, however, as Anning *et al.* (1948) and Howard and Meyer (1948) have pointed out. Anning *et al.* found toxic symptoms in 19% of 200 patients who were receiving 100,000 to 150,000 units of calciferol daily for treatment of various skin diseases. Howard and Meyer describe toxic effects in 11 cases but only one of these was suffering from hypoparathyroidism. The symptoms of intoxication consist of thirst, anorexia, vomiting, tiredness, malaise, nausea, headache, constipation, abdominal pain, polyuria, intolerance of noise, loss of weight, excitability, photophobia, rhinorrhoea, generalized pruritus, and, occasionally, drowsiness and coma, psychic disturbances, impaired memory, paraesthesiae, muscular pains and atony, and amblyopia. Howard and Meyer report calcium deposits beneath the conjunctival basement membranes, as seen with the slit-lamp, in 9 of 11 cases, and albuminuria in seven cases. All their cases showed impairment of renal function, with blood non-protein-nitrogen levels of 46 to 106 mg. per 100 ml. Psychotic changes as severe as those occurring in Case 6 do not appear to have been reported previously. It seems that the risk of toxic effects is smaller in cases of hypoparathyroidism, and in fact few such cases have been reported. But Howard and Meyer's case and our Case 6 show that the risk exists and that the consequences may be serious.

It is probable that toxic symptoms are due to an individual idiosyncrasy or to impaired renal function. In Case 6 they resulted from a dose of 200,000 units daily, and in Howard and Meyer's case of hypoparathyroidism on a dose of 300,000 units daily, whereas many other patients have received much higher doses without untoward effects. Both in Case 6 and in Howard and Meyer's case the symptoms occurred within three weeks of starting calciferol treatment, though our Case 6 had previously received a prolonged course of 100,000 units daily, and had been thought to have developed mild intoxication some years previously.

If toxic symptoms appear the drug must be discontinued immediately, fluids must be given copiously, and the calcium intake must be reduced to a minimum. Howard and Meyer found that the serum calcium level remained raised for two to four months, and in one case for as long as 20 months, during which time the blood urea level remained slightly raised and renal function remained impaired. Under such conditions there is, of course, a risk of widespread soft-tissue calcification. In our Case 5 the serum calcium level returned to normal within four weeks.

Similar toxic effects have been observed by some workers with dihydrotachysterol, but these have not been of serious

import; no fatal case has been reported so far as we are aware, and no evidence has been obtained of chronic damage, even when the serum calcium level has been raised temporarily as high as 15 mg. per 100 ml. (McLean, 1941). Dihydrotachysterol is probably less likely to give rise to hypercalcaemia than is calciferol, since it does not predominantly influence calcium absorption.

Summarizing, dihydrotachysterol is preferable to calciferol on theoretical grounds, in that it more closely resembles parathyroid hormone in its action. In practice there seems to be little difference between them so far as their effect upon the clinical and biochemical picture is concerned. But, assuming that an average maintenance dose of dihydrotachysterol is 0.5 ml. daily, and that this is equivalent to 100,000 units of calciferol daily, the expense of treatment amounts to approximately £1 a month in the case of dihydrotachysterol, as against approximately 1s. a month in the case of calciferol. On the other hand, calciferol is probably more likely to produce hypercalcaemia, since it acts primarily upon calcium absorption. Occasional cases show resistance to dihydrotachysterol (Holtz, 1933), and cases of pseudo-hypoparathyroidism may be relatively resistant to dihydrotachysterol as well as to parathyroid hormone (Albright *et al.*, 1942).

We have not found it necessary to give calcium salts as well, and, as dosage has to be readjusted repeatedly, it would appear to be easier to deal with only one variable than with two. Nor have we paid any attention to the diet, as no patient is likely to maintain a strict intake of calcium and phosphorus, and it does not seem to be necessary to control it. Milk should, however, not be taken in excess, for its phosphorus content is high (Albright and Reifenstein, 1948).

Albright and Reifenstein state that treatment can be controlled adequately by testing the urine for calcium, with Sulkowitch reagent. We have not found the Sulkowitch test to be reliable in practice. In Case 6 only a moderate reaction was obtained, even though the patient was in a state of acute hypercalcaemia, and on other occasions we have found subnormal calcium levels when the Sulkowitch reaction was optimal. Sevringhaus and St. John (1943) and Jordan and Kelsall (1951) have also found the test to be not completely reliable. In our experience, it is necessary to control treatment by means of repeated estimations of the serum calcium level. The chief value of the Sulkowitch test is that it can be performed regularly by the patient himself, and that a strongly positive or negative reaction should warn him that his treatment requires immediate readjustment. It is important that the test-tubes should be cleaned with distilled water, as tap-water usually contains considerable amounts of calcium.

Dosage may have to be increased during pregnancy, but a few cases improve at this time, as in Case 7 and in Scarlett and Houghtling's case (1944), and some cases quoted by Lachmann (1941). The dose may also have to be increased during periods of physical and mental strain, during infections, and after operations.

In practice we have found that stabilization is not nearly as easy as might appear at first sight, and that the dosage repeatedly needs to be adjusted. The principles of treatment are in fact very similar to those involved in the treatment of diabetes mellitus.

The aim should be not only to control symptoms but to maintain a persistently normal level of serum calcium, in the attempt to avoid such serious complications as cataracts, mental changes, and calcification in the brain.

Summary

Three cases of idiopathic hypoparathyroidism, three post-operative cases, and one case of pseudo-hypoparathyroidism are described.

The cases usually present with tetany, the symptoms of which are very variable. Epilepsy is also a common presenting symptom. Some cases may present with

cataracts or with ectodermal defects. Other manifestations include defects in the teeth, psychoneurotic or psychotic disturbances, papilloedema, and physical and mental retardation.

The serum calcium level is reduced and the serum phosphate level is raised.

X-ray films often show calcification in the brain, especially in the basal ganglia, and normal or increased density of the bones.

The electrocardiogram shows a prolonged Q-T interval and the electroencephalogram shows abnormal slow waves or epileptic changes.

Pseudo-hypoparathyroidism is due to abnormal resistance to parathyroid hormone and presents exactly similar features, together with a dyschondroplasia, resulting in a short stature and shortening of the metacarpal and metatarsal bones, and a tendency to metaplastic bone formation in the soft tissues.

Treatment is by means of dihydrotachysterol or calciferol. Theoretically, the former is preferable, in so far as it more closely resembles parathyroid hormone in its action; but in practice there is little to choose between them. Dihydrotachysterol has the disadvantage that it is considerably more expensive, while calciferol is probably more apt to give rise to hypercalcaemia.

Though idiopathic hypoparathyroidism and pseudo-hypoparathyroidism are generally regarded as rare disorders, it is likely that more cases would come to light if the diagnosis were borne in mind in cases with obscure paraesthesiae and pains and cramps in the limbs, and in cases of epilepsy, of cataract in young persons, and of defects in the ectodermal tissues.

We are grateful to Dr. P. M. F. Bishop, Dr. M. J. McArdle, and Dr. W. N. Mann for permission to publish their cases and for their help and advice. Professor R. H. S. Thompson advised and encouraged us from the start, and the biochemical investigations were carried out in his and in Dr. W. H. H. Merivale's laboratories at Guy's Hospital and in Dr. E. N. Allott's laboratory at Lewisham General Hospital. We are also indebted to Dr. W. A. Oliver, who referred the case of pseudo-hypoparathyroidism, to Dr. A. Bookless and Dr. D. Gullick, who referred two of the post-operative cases, and to the medical illustration and photographic departments of Guy's Hospital, Lewisham General Hospital, and the Institute of Ophthalmology.

Addendum. Since this article was submitted for publication we have found it necessary to increase the doses of dihydrotachysterol (A.T.10) considerably above the amounts indicated in the text. Thus Case 4 now requires 6 ml. daily, and Case 7 4 ml. daily, of the material at present available in this country, in order to maintain a normal serum calcium level. Case 3 has required 3 ml. throughout. We are in close consultation with the manufacturers, who are investigating this discrepancy.

THE RECENT TRENDS OF INFECTIOUS DISEASES IN CHILDHOOD

BY

W. J. MARTIN, D.Sc., Ph.D.

(From the Medical Research Council's Statistical Research Unit, London School of Hygiene and Tropical Medicine)

Since the inception of the National Health Service Act in 1948 the level of the notifications of three common infectious diseases of childhood—scarlet fever, whooping-cough, and measles—has been above that of the immediately preceding years. During the first quarter of 1951 the weekly notifications of both measles and whooping-cough reached the highest point since these diseases were made notifiable, and an even larger incidence of measles has been recorded in the first quarter of 1953. Diphtheria, on the other hand, has declined consistently and rapidly, and the average weekly notifications during the first quarter of 1953 were only 20, compared with 900 for the first quarters of 1940 and 1941. The number of notifications and the deaths per 1,000 notifications for these four diseases, for the years 1940 to 1952, are shown in Table I. The incidence of measles, scarlet fever, and whooping-cough rose in 1948, and it may well be thought that the recent high level of these diseases is due only to the operation of the National Health Service, because medical advice is more often sought regarding mild cases. It is to be noted, however, that the incidence of all three was unusually large for the first six months of 1949—that is, preceding the operation of the Service—as can be seen from Figs. 1, 2, and 3.

Table I shows that the fall in the fatality rates, which had been apparent since 1942, was accentuated in 1948 for measles and whooping-cough. The fatality rates for these diseases were about half of those in the preceding year. The obvious explanation for the large drop in fatality is that more mild cases were being notified. Scarlet fever did not show a large fall in the fatality rate, and the decrease was no larger than would have

TABLE I.—*Infectious Diseases: Notifications and Death Rates. England and Wales*

Year	No. of Notifications				Deaths per 1,000 Notifications			
	Measles	Whooping-cough	Scarlet Fever	Diphtheria	Measles	Whooping-cough	Scarlet Fever	Diphtheria
1940	407,468	53,545	63,778	45,445	2.1	12.7	2.4	54
1941	407,949	173,249	58,051	49,432	2.8	13.8	2.3	53
1942	285,446	65,986	83,830	40,042	1.6	12.1	1.2	45
1943	373,788	96,105	113,917	33,277	2.1	11.6	1.1	41
1944	157,125	93,944	90,581	22,085	1.5	11.2	1.2	40
1945	445,412	62,663	72,174	17,580	1.6	11.0	1.1	39
1946	159,553	92,892	56,099	11,601	1.3	8.7	0.7	39
1947	393,116	92,657	57,246	5,492	1.6	9.8	0.7	44
1948	399,185	146,372	73,940	3,531	0.8	5.1	0.5	44
1949	385,753	102,801	70,186	1,874	0.8	5.1	0.4	45
1950	367,598	157,752	65,878	959	0.6	2.5	0.5	51
1951	616,093	169,347	48,735	658	0.5	2.7	0.8	50
1952	389,505	114,868	67,251	375	0.4	1.6	0.3	85

been expected from a continuation of the existing trend. It would appear that clinically recognizable attacks of scarlet fever were fairly completely notified prior to 1948. The trend of diphtheria appears to be unaffected by the events of 1948, although the fall in the number of notifications was not proportionately so large as in the preceding year. The percentage rates of decline for 1945 to 1948 were 21, 33, 53, and 36 respectively. The case fatality of diphtheria in 1948 was the same as in 1947. There is no evidence, therefore, from the notifications or deaths that the trend of diphtheria was disturbed in 1948.

It seems of interest to examine the trends of whooping-cough, scarlet fever, and measles in an attempt to decide whether more complete reporting can wholly or partially explain their increase in incidence or whether there has been a real increase in prevalence.

Scarlet Fever

The number of notifications of scarlet fever has been generally accepted as a good index of the actual incidence for the 20 years prior to 1948. On the basis of notifications it has been estimated that about 10% of the child population suffered from a notifiable attack of scarlet fever before the age of 15. This value was in close agreement with the

FIG. 1.—Number of notifications of scarlet fever by quarters, England and Wales.

FIG. 2.—Number of notifications of whooping-cough by quarters, England and Wales.

proportion found in field surveys—for example, Stocks's (1930) investigation in St. Pancras. The records of over 10,000 children in 26 English public boarding schools examined during 1930–4 (Epidemics in Schools, 1938) showed that a history of an attack of scarlet fever before entry into school was given by 8.3% of the boys and 7.2% of the girls.

It follows that it was not to be expected that the operation of the National Health Act would materially affect the reported incidence of scarlet fever, since there was no evidence that any appreciable number of cases escaped notification. The rhythm of the seasonal trend was altered just before the operation of the Health Service, when instead of the expected fall in incidence in the first quarter of 1948 the number of notifications slightly exceeded those in the preceding fourth quarter (Fig. 1). This phenomenon of the postponement of the seasonal peak to the first quarter occurred again in 1951–2. The difference between the expected and the actual number of notifications is so large that it seems extremely unlikely that the exceptional trend in the first quarter of 1948 can be explained by the inclusion of mild cases which in preceding years would have escaped notification. The deaths per 1,000 notifications given in Table I also show that no large abrupt change occurred in 1948. It would appear, therefore, that there was a real increase in the prevalence of scarlet fever just before the introduction of the Health Service.

The age of attack of scarlet fever differs from that of measles or whooping-cough. The school-child has a greater

TABLE II.—*Notifications of Scarlet Fever per 100,000 Living. England and Wales*

Year	Ages 0–4	Ages 5–14	Ratio (5–14/0–4)
1944	652	1,056	1.62
1945	531	836	1.57
1946	410	647	1.58
1947	362	658	1.82
1948	338	839	1.56
1949	380	770	1.33
1950	565	679	1.20
1951	403	504	1.25
1952	522	724	1.38

rate of attack from scarlet fever than the pre-school child, while the reverse is the case for the other two diseases. The attack rate for recent years is shown in Table II.

There is a suggestion that the attack rate for the pre-school child compared with that of the school-child has become relatively larger in the last four years of the period. This may have been due to young children receiving medical attention who prior to 1948 would not have been seen and notified by a medical practitioner. Just as likely an explanation is that there has been a real shift in the age of attack.

Whooping-cough

The numbers of notifications of whooping-cough prior to 1948 were known to be defective, and from them the estimated proportion of children who had an attack of whooping-cough before the age of 15 was 15%. This value was much below that of about 70% found in field surveys or in the inquiry into the 26 English public schools (Epidemics in Schools, 1938), when 70% of the boys and 67% of the girls had a history of whooping-cough before entry. The available evidence leads to the conclusion that only about one-quarter of the children with whooping-cough were notified in the years immediately preceding 1948. Probably in many

cases medical attention was not sought. In discussing this deficit, Stocks (1949) stated: "Whether or not the National Health Service, coupled with the increased notification fee for whooping-cough, will result in an increase in the proportion of children and adults notified remains to be seen, but there is room for a large increase."

A large rise in incidence began before the start of the Health Service in 1948, and the number of notifications in that year was larger than in any of the six preceding years—though less than in 1941 (Fig. 2). A further large rise occurred in 1950–1, when the outbreak lasted two years. Table I shows that the recorded fatality rate, which had been falling slowly since 1941, fell abruptly in 1948 to almost half the level of 1947. The large outbreak in 1950–1 was accompanied by a further halving of the recorded fatality rate. The trend of this rate suggests that since 1948 the increase in the numbers of notifications of whooping-cough is due to more cases coming to the notice of the medical practitioners than formerly.

If the evidence of the field inquiries is accepted that 60 to 70% of the child population suffer an attack of whooping-cough before the age of 15, then even the higher incidence of whooping-cough since 1948 would imply that less than half of the cases of whooping-cough were notified during 1948–52. It seems, therefore, that most of the increase in the number of notifications in the past five years could be accounted for by increased case-finding, but the rather erratic decline in the recorded fatality rate makes an estimation of the amount of real increase in prevalence rather uncertain. This uncertainty is increased by immunization against whooping-cough, which has been practised during this period. If immunity has been conferred on any appreciable proportion of the child population then a part of the increase in the number of notifications was due to an increased prevalence of the disease.

Whooping-cough is a disease of the pre-school child, and the attack rate for children aged 0 to 4 is slightly more than three times that of children aged 5 to 14. The ratio of the attack rate of the pre-school children to that of the schoolchildren has been practically constant during recent years.

Measles

The estimated proportion of children notified as suffering from measles between 1940, when measles was first made notifiable, and 1947 was slightly less than 50%. This compares with 72.5% for boys and 63.1% for girls with a history of measles before entry into English public schools in 1930–4 (Epidemics in Schools, 1938). Many children suffering from a mild attack of measles were not seen by a medical practitioner, and Stocks (1949) estimated that the notification rate represented only about two-thirds of the true incidence. He stated: "The National Health Services and raising of the notification fee in 1948 may result in some increase in the proportion who are notified." Prior to 1948 measles had a well-marked biennial distribution with alternating years of high and low incidence (Fig. 3). In years of low incidence the maximum occurred in the second quarter, while in years of high incidence the peak was in the first quarter, except for 1945, when the number of notifications in the second quarter slightly exceeded the number in the first.

According to this pattern 1948 should have been a year of low incidence, but in fact the number of notifications slightly exceeded those in 1947. The outbreak in 1948, with a large rise in the second quarter, differed from preceding major outbreaks in seasonal distribution. The distinctive peak in the alternate first quarters reappeared in 1949, 1951, and 1953, but the incidence in the inter-epidemic years did not fall to the low level recorded prior to 1948.

and the notifications in 1950 and 1952 were twice the number recorded in 1944 and 1946. A large fall in the fatality rate supports the hypothesis that many more mild cases than usual were notified. The fatality rate had been falling since 1941, with a large fall in the years of low incidence and a small rise in the years of high incidence. From the trend of the fatality rates a value of 1.1 instead of 0.8 would have been expected in 1948.

If we assume that the difference between the observed and the expected fatality rate was due to an increase in case-finding then the number of notifications necessary for 326 deaths to give a rate of 1.1 per 1,000 would be 296,000, and the difference between this value and the actual notifications gives 100,000 as the estimated increase due to better case-finding and reporting. Reducing the number of notifications in 1948 by 100,000 still leaves a total which is almost twice that of 1946 or 1944, the preceding non-epidemic years. On this basis it appears that the increase in incidence in 1948 was contributed in equal parts by a real increase in prevalence and by more complete notification, and the disease was almost twice as prevalent in 1948 as in 1946 or 1944.

It was expected that the operation of the National Health Service would appreciably raise the number of persons seeking medical attention and the number of consultations, especially among the previously non-insured section of the population, mainly women and children, in the lower-income groups. How far this group contributed to the increase in the number of notifications of infectious diseases is a matter of speculation. A comparison between the experience of different types of areas selected according to their degree of industrialization presents some difficulties.

TABLE III.—*Number of Notifications of Measles*

Year	Group 1	Group 2	Ratio
1947	4,081	2,588	1.6
1948	7,264	4,893	1.5
1949	7,101	4,134	1.7
1950	5,551	2,473	2.2
1951	11,671	7,966	1.5
1952	7,203	4,543	1.6

The two chief are: (a) the dispersal of the child population during the war years, which invalidates any comparison before 1946, and (b) the only information at present available regarding occupations and industries is that of the 1931 census. Despite these difficulties, it was thought it would be of interest to compare two contrasting groups of London boroughs. These groups were chosen on the basis of the social classes of the occupied males.

Group 1 consisted of six boroughs—Hampstead, Holborn, Kensington, Lewisham, Wandsworth, Westminster—with the largest proportion of occupied males in social classes I and II and a low proportion in classes IV and V. Group 2 comprised six boroughs—Bermondsey, Bethnal Green, Finsbury, Poplar, Shoreditch, Southwark—which had the largest proportions of the male population in social classes IV and V. Although the classification of these boroughs depends

FIG. 3.—Number of notifications of measles by quarters, England and Wales.

on outdated material it is not likely that any borough has moved from one extreme to the other in social grading. The trend of the incidence of measles in both these groups of boroughs was very similar, and there was no difference of any importance between them. A summary of their positions is given in Table III. It appears from these values that the relative incidence of measles was constant during the period, although Group 1 had relatively a larger outbreak than Group 2 in 1950 owing to a summer rise in incidence. The introduction of the National Health Service in 1948 did not have any differential effect on the incidence.

In recent years the measles attack rate has been twice as large among pre-school children as among school-children, and the ratio of these attack rates has been practically constant during the past nine years.

Summary

The number of notifications of scarlet fever, whooping-cough, and measles rose in the six months preceding the operation of the National Health Service in 1948 and has remained above the level prevailing in 1946-7.

Scarlet Fever.—Although the incidence in the first quarter of 1948 was unusually high the subsequent level of the notifications does not suggest that the prevalence of scarlet fever has undergone much change in recent years. There is, however, a suggestion that since 1948 the disease has tended to be more concentrated on the pre-school child.

Whooping-cough.—A large increase in the numbers of notifications has occurred since 1948. If the pre-war estimate that 70% of the child population have an attack of whooping-cough before age 15 is still valid, then only about one-half of the cases are being notified. But if immunization against whooping-cough has been carried out on large enough numbers it is possible that the higher level of notifications since 1948 is due to a real increase in prevalence.

Measles.—The level of notifications of measles has increased in recent years. The whole of the rise in 1948 cannot be explained by increased case-finding and reporting, and it seems that there was a real rise in prevalence just before the operation of the National Health Service. The proportion of children under 15 who suffer a notifiable attack of measles has risen from about one-half in the early 1940's to about two-thirds in the last five years. It seems probable that there has been a real increase in prevalence during these years.

The Pakistan Minister for Health, Dr. A. M. Malik, in his country's parliament last month, gave details of steps taken in co-operation with the World Health Organization to improve public health and provide facilities for medical treatment. He said that the United Nations International Children's Emergency Fund had offered a 700 tons annual capacity plant for making Pakistan self-sufficient in her requirements of D.D.T. Work on the construction of the buildings and installations of the plant at Naushera in the Frontier Province had progressed considerably, and the plant should go into production in July. A B.C.G. vaccination campaign had been started in 1949, and so far more than 2,200,000 persons had been vaccinated. In East Pakistan a three-year programme for improving teaching and practice facilities at a nursing school in Dacca had been launched.

CLINICAL AND CHEMICAL STUDIES IN HUMAN LACTATION*

VI. THE FUNCTIONAL CAPACITY OF THE BREAST

BY

F. E. HYTTEN, M.B., B.S.

Midwifery Department, University of Aberdeen

There is little published evidence about the relationship of the size of the breast to its functional efficiency, but it is generally held by clinicians that no strong relationship exists. On the other hand, there is a well-recognized relationship between the size and function of the cow's udder: Gowen and Tobey (1927) computed that 1 lb. (450 g.) of udder would produce 1 lb. (450 ml.) of milk in three hours. It is reasonable to expect that, if there were any clear relationship in women, then this knowledge would have been incorporated into the general folklore of lactation; but the only idea occurring sporadically in the old literature, and still commonly held to-day, is that the very large breast is likely to have a poor performance. Nevertheless, Lussky (1951), in a hospital study, found that successful lactation occurred in 50.2%, 36.6%, and 19.0% of women with "large," "medium," and "small" breasts respectively.

The capacity of the breast to secrete milk probably depends on the amount of functional tissue it contains, and this is not necessarily related to the size of the breast: not only is there a layer of subcutaneous fat of variable thickness, but the gland itself, as has been demonstrated in post-mortem material by Engel (1941), shows an enormous variation in the ratio of parenchyma to fibrous tissue, ranging from almost 100% secretory tissue to almost none.

It would nevertheless be surprising if there were no relationship whatever between the size of the breast and its functional ability, and it is of some clinical interest to determine accurately what that relationship is.

For comparative studies, an estimate of the amount of functional tissue might be made in the living subject by measuring changes in breast size occurring in response to the menstrual cycle or to pregnancy. Engel (1947) believes that subjective impressions of breast enlargement during the premenstruum are a good index of the breast's functional equipment, presumably on the basis that the enlargement is due to proliferation of glandular tissue. This may be so, but breast changes during the cycle are due only partly to such proliferation, and, in any case, mostly to non-secretory tissue; much of the enlargement may be caused by oedema in the stroma (Geschickter, 1945), perhaps as part of a more general mechanism of water retention, and not directly related to the amount of gland present. The enlargement which occurs in pregnancy is likely to be a more reliable index of the amount of functional tissue, since it is due mostly to the proliferation of the gland. No study of these changes has been reported.

Previous Technique of Breast Measurement

Ingleby (1949) measured wax impressions taken from serial plaster casts of the breasts of 17 women during the menstrual cycle, and appeared able to measure differences of the order of 30 ml. Geschickter (1945) estimated the menstrual enlargements of the breasts in two women by measuring the

differences in the amount of water required to fill a glass vessel, applied to the chest and enclosing the breast. He describes a difference in one subject of only 15 ml., but this difference is likely to be less than the experimental error of such a method. Reimann and Seabold (1933), incidental to a study of breast lesions during the menstrual cycle, calculated areas of the x-ray shadows of breasts in profile, but this method is clearly subject to a good deal of inaccuracy and is, in any case, not comparable with three-dimensional estimations.

The fundamental difficulty in the determination of breast volume by any method *in vivo* is to define the posterior surface; that is, the chest wall underlying the breast. If a plaster cast of the breast is taken, then it is not difficult to curve the posterior wall to an arbitrary approximation of the chest contour, but, if a series from the same subject are to be made, then an artificial "chest wall" must be made first and all subsequent models fitted to it, so that the posterior surface, if not true to life, is at least constant for all the models. The method of making plaster casts takes time and requires a considerable degree of co-operation from the subject. It is also unsatisfactory for the large pendulous breast.

Several indirect methods which might be used to assess the functional tissue of the breast have been suggested. Pickles (1953) has described two rather complex techniques which will indicate the amount of blood flow through the breast, but there is no evidence of a fixed relationship between blood flow and breast function, and there are many circumstances which will confuse such estimations. An even less direct method of estimating blood flow is by infra-red photography (Bowes, 1950), but the amount of incident light is difficult to control and quantitative interpretation of the photographs would not be simple.

Method

In this investigation a method of water displacement has been used to study breast size.

The apparatus is illustrated in Fig. 1. It consists of a "perspex" container,* shaped to fit closely to the average

FIG. 1.—The method of estimating breast size. 1, Tube for filling apparatus. 2, Tube for emptying apparatus. 3, Tube for inflating the sealing ring.

chest wall round the breast, the seal being ensured by an inflatable rubber ring at the periphery. This ring is inflated by mouth and forms a cushion with a section of about $\frac{1}{4}$ in. (6 mm.) diameter. This arrangement proved to be leak-proof in all but two cases examined, the exceptions being small women with thin narrow chests.

With the subject seated upright, the apparatus is held firmly against the chest and filled with water at body tem-

*The apparatus may be obtained from Arnoplast Ltd., South Hillingdon Farm, Kelhead Avenue, Glasgow, S.W.2.

perature through an opening at the highest point, air escaping from a small hole alongside. When it is completely filled the water is drained off through another tube into a measuring cylinder. This volume of water is subtracted from the volume of the container, which has been previously determined using a perspex sheet curved to represent an approximately average chest wall. All measurements were made by one observer to ensure, so far as possible, that the rubber ring was inflated to a similar pressure for each observation, and that the apparatus was held against the chest wall with similar force. Results were reproducible to within 20-30 ml., an error of about 5%. Only the left breast was measured in all subjects except one, in whom the breasts were obviously asymmetrical, and in this woman both breasts were measured and the mean was taken.

Measurements were made on the seventh post-partum day, immediately following complete emptying by the "humalactor," in 86 primiparae and 23 multiparae. In nine of the primiparae and two of the multiparae measurements were also made during the course of pregnancy, beginning at the third month.

A detailed history of breast reactions during the menstrual cycle was obtained from 50 of the subjects whose breasts were measured.

The method of collection of milk samples has been previously described (Hyttén, 1954a); the volume and composition of the seventh-day milk for all these subjects is included in Table II of an earlier paper of this series (Hyttén, 1954c).

Results

For the 86 primiparae, the mean size of the empty breast on the seventh day of lactation was 787.0 ± 219.6 ml., and for the 23 multiparae 756.9 ± 314.0 . The difference is not statistically significant.

Fig. 2 shows the relationship between breast size and the milk output on the seventh day of lactation. The calculated

FIG. 2.—The relationship of milk yield on the seventh post-partum day to the size of the left breast. The regression lines calculated from these data are superimposed, the continuous line representing primiparae, the broken line multiparae.

regression lines for the primiparae and multiparae are superimposed. There was a correlation in the primiparous series ($r = +0.31$) significant at the 1% level, and a correlation of about the same magnitude for the multiparae ($r = +0.35$), although this was not statistically significant, probably because of the small numbers. The precision with which the seventh-day milk output could be predicted from breast size was not significantly different in the two groups, although this again may be due to the small sample.*

There was no correlation between the size of the breast and the fat, protein, or lactose content of the seventh-day milk.

*The regression equation combining both sets of data is: Seventh-day milk output = 0.23 (breast size in ml.) + 260 ml. ± 0.07 .

In an attempt to reduce the effect of "fatness" on the size of the breast, an index was calculated by dividing the measured breast size by the weight-to-height ratio of the subject. In this way a breast of the same actual size would have a higher index in a thin woman than in a fat woman. The correlation between this index and the seventh-day milk output was no better than the correlation of the measured breast size and the seventh-day milk output.

Of the 50 women questioned about breast symptoms in the premenstrual period, only 10 (20%) had noticed any reaction at all. The mean seventh-day milk output of these 10 women was 573 ml., and for the remaining 40, 430 ml., the difference being statistically significant ($P < 0.01$). The difference between the mean breast sizes of these two groups (838 ml. and 746 ml.) was also statistically significant ($P < 0.01$).

The serial breast measurements taken throughout pregnancy on 11 subjects do not permit an accurate interpretation of the pattern of breast enlargement, since in this pilot experiment measurements were made during routine antenatal visits and were too widely spaced. Moreover, the estimation of small increases with an apparatus liable to an error of 20-30 ml. is not close enough. Nevertheless, in five cases there was almost no further increase after about the twenty-fourth week of pregnancy, the remainder continuing to enlarge, but at a slower rate than during the first half of pregnancy.

The Table shows the breast sizes at the third month of pregnancy, together with the post-partum breast sizes, milk output on the seventh post-partum day, and the ages of the 11 subjects.

Serial Breast Measurements in 11 Subjects

Case No.	Age	Left Breast [Volume (ml.)]			Seventh-day Milk Volume (ml.)
		3rd Month	Post-partum	Enlargement	
113	19	295	775	480	800
129	25	295	490	195	455
184	28	860	960	100	390

246	25	410	760	350	805
248	21	990	1,050	60	250
263†	41	785	1,050	265	565
265	22	1,800	1,920	120	600
		600	580	-20	180

* Second pregnancy. † Fifth pregnancy.

Results from the nine primiparae only were subjected to statistical analysis. There was a high correlation between the pregnancy enlargement of the breast and its milk output on the seventh post-partum day ($r = +0.87$), significant at 1%, and this can be clearly seen in the scatter diagram (Fig. 3). The regression line for primiparae has been drawn, and data for the two multiparae are also shown. There was no relationship between the initial size of the breast and its subsequent enlargement.

FIG. 3.—The relationship of milk yield on the seventh post-partum day to the enlargement of the breast which occurred during pregnancy.

There are clearly not enough results to test statistically the effect of age, but it can be seen from the Table that, apart from subject No. 265, who showed no enlargement at all, the four subjects aged 22 or under all had an enlargement of more than 200 ml., and the four older than this all enlarged by less than 200 ml. This confirms the clinical impression that while the very young primiparae are usually first seen at the antenatal clinic with tender swollen breasts and uncomfortably tight clothes, the older primiparae tend to show little reaction at the same stage of pregnancy.

Multiparae present an entirely different picture, since the glandular enlargement occurs into the loose stroma which has been left by involution from the previous lactation. There is therefore no tension, and the enlargement which occurs is not readily appreciated by either patient or examiner.

Discussion

Although there is an undoubted correlation between the size of the lactating breast and its milk production in hospital, the scatter is wide and the predictive value for an individual breast is obviously low. Fig. 2 does suggest, however, that the smallest breasts have a ceiling of performance on the seventh day.

In view of the differences in the actual shape of the chest wall which must occur between subjects, the results of measurement of breast size are not strictly comparable, but the error involved is probably slight in relation to the large range of values for breast size. Again, the milk output on any given day is not necessarily equivalent to the breast's potential yield, since it may have a considerable reserve which it does not exhibit in the absence of an appropriate demand. An artificial demand, such as the stripping of breasts by manual expression, may or may not provide this, although Waller (1950) claimed that the breast could be brought to maximum productivity during the first week of lactation by this means. However, Sydow (1952) has shown a close correlation between the milk output on the sixth day and the subsequent success of lactation, so that milk output in hospital can be accepted as of at least some value in indicating the true capacity of the breast.

It is difficult to interpret the striking relationship between breast size and breast-feeding in Lusk's series, since only half of the best group, those with "large" breasts, left hospital breast-feeding, in contrast to the overall hospital breast-feeding rate in this country of between 80 and 90% (Ministry of Health, 1951). It is unlikely that breast size was the only or even the major factor involved.

Two aspects of breast size must be kept in mind: one is the ability to produce milk, and the other the ability to store it. The small breast will suffer a double disability, and below a certain size this lack of storage capacity may become critical. Such an effect has been demonstrated in a previous paper (Hyttén, 1954b). Subject No. 74, with a breast size of only 530 ml., produced about 120 ml. of milk at each feeding; that is, the amount of milk in the breast at, say, 2 p.m., after four hours' secretion, was 120 ml., and at 6 a.m., after eight hours' secretion, the amount was no more, clearly indicating an upper limit to storage capacity.

The range of breast capacity may, in part, explain the gradual falling off in breast-feeding which occurs during the course of the first two months, since lactation will become unsatisfactory when an infant has outgrown the supply which the breast can secrete or store.

The degree of breast enlargement occurring during pregnancy, which is probably due to changes in the functional tissues alone, would be expected to show a high correlation with lactation performance, although it must be stressed again that the results from so few subjects can only be tentative. Data for increase in size are of comparative value only, and in no sense absolute measurements of the gland itself; much of the increase must be due to other changes, such as increased vascularity, but these are likely to parallel closely the growth of the glandular tissue.

The measurement of the enlargement of the breast during the whole course of pregnancy is in practice extremely difficult, since women are not usually seen until the third month, by which time some enlargement of the breast has already occurred; in fact, it is usually claimed that the most rapid enlargement occurs during the first three or four months. The amount of enlargement which is missed, however, should be proportional to the total breast enlargement, provided that the measurements are made at approximately the same stage of pregnancy, so that for a comparative study it is probably no serious disadvantage to have missed the first two months. A large-scale investigation of measurements during the entire pregnancy will be required to establish the precise pattern of enlargement. The suggestion that the most rapid enlargement occurs at the beginning of pregnancy is probably fallacious, since it is based on subjective impressions of discomfort which are greatest at this stage, probably because of vascular engorgement. The unreliability of such subjective impressions as an index of enlargement is supported by the finding that there is seldom any difference in size between the breast on the seventh post-partum day and the same breast at the end of pregnancy, although it is also claimed that the first few days of the puerperium are a period of rapid enlargement.

For the same reason a history of change of size of clothes required during the pregnancy can be misleading. Subject No. 113, for example, whose left breast increased in volume by 480 ml. (160%) said she noticed almost no change in the size of the breasts and had worn the same brassière throughout pregnancy.

It has been suggested that a simpler investigation could be undertaken by serial circumferential chest measurements, but these are unlikely to provide anything but the crudest information, because the breast may change in shape without becoming any more protuberant. In fact, Engel's (1941) finding that breasts with little glandular tissue have it disposed round the periphery suggests that a "spreading out" rather than a forward enlargement may be commonly found.

The few cases so far investigated suggest that breast enlargement during pregnancy in primigravidae is greatly influenced by age, and additional evidence, to be given in a later paper, shows that failure to establish lactation owing to an inadequate milk supply increases rapidly with age in primiparae. It is possible that the long delay, sometimes of over twenty years, from the time of puberty may lead to disuse atrophy, or it may be that small breasts are among a number of physical characteristics which make early marriage and child-bearing less likely.

Although the reason for breast symptoms during the menstrual cycle is not altogether clear, their occurrence seems to be a rough indication that the breast is well equipped, although the converse is by no means necessarily true. The small proportion of women who report the phenomenon (20%) is perhaps surprising, but it agrees well with Engel's (1947) findings that only in 20-30% of breasts is the structure predominantly glandular.

The different reaction to pregnancy shown by multiparae may be due to their having already laid down much of their glandular tissue during a previous pregnancy. The primipara reacts by encroaching on and replacing the fatty stroma of the breast with growing gland, but when the lactation is over only a small part of this stroma is reformed (Geschickter, 1945), and the characteristic flabby breast, which again becomes firm only during another lactation, results. Although only two multiparae had their breasts measured during pregnancy in this series, it can be seen from Fig. 3 that they have a higher milk production for the same degree of enlargement in pregnancy than primigravidae. Similarly, although the difference between the correlations of breast size with milk output in primiparae and multiparae is not statistically significant, nevertheless the regression lines (Fig. 2) confirm this parity difference, the multiparae having a better milk yield for the same size of breast. This is in accord with the histological findings of

Langer (1851), who found an increased amount of active breast tissue in women who had had repeated pregnancies.

Much of the variation in breast size and quantity of glandular tissue between individual women can probably be explained on the same basis as the difference in milk composition (Hyttén, 1954d)—that is, the absence of selective breeding for lactational ability in human society. In other mammals the lactating gland is "characterized by the absolute predominance of glandular tissue" (Engel, 1947), but this is true of only 20-30% of human lactating breasts.

No relationship has been found between the size of a breast and the composition of the milk it secretes. It is probable, then, that women who are unable to provide milk of adequate composition are not necessarily the same persons who are unable to provide sufficient milk because of inadequate mammary glands. There are therefore two groups whose lactation will be unsatisfactory, and it is not surprising that so many mothers resort to artificial feeding because of a dissatisfied baby.

Summary

The size of the lactating breast was measured, after emptying in 86 primiparae and 23 multiparae, by a method of water displacement.

There was a significant correlation between breast size and the output of milk on the seventh day of lactation, but not with any of the major constituents of milk.

In nine of the primiparae and two of the multiparae the amount of breast enlargement during pregnancy was also measured; the first measurement was made during the third month of pregnancy. Wide variations in the amount of enlargement occurred, and this was closely related to milk output.

I am grateful to Professor Dugald Baird and to the staffs of the Midwifery Department and the Aberdeen Maternity Hospital for invaluable help; to Dr. I. Leitch, of the Commonwealth Bureau of Animal Nutrition, Bucksburn, for criticism and advice; to Dr. F. H. C. Marriott and Mr. I. MacDonald for statistical assistance; and to Mr. T. C. G. McKay, of the Aberdeen Royal Infirmary, for technical assistance with the apparatus.

Because full particulars are not always given on prescriptions, the dispensing and pricing of prescriptions ordering certain Schedule IV poisons are proving unnecessarily difficult. This is stated in a recent notice from executive councils to practitioners (ECN/140). The difficulty particularly arises with drugs which are put up in several strengths, as unless the strength is stated prompt dispensing becomes impossible. Common examples of such drugs are "amylal" tablets (amyllobarbitone), "amylal sodium" capsules (amyllobarbitone sodium), "anthisan" tablets (mepyrmine maleate), "benadryl" capsules (diphenylhydramine hydrochloride), "butazolidin" tablets (phenylbutazone), "nembutal" capsules (pentobarbitone sodium), "phenegan" tablets (promethazine hydrochloride), phenobarbitone tablets, "seconal sodium" capsules (quinabarbitone sodium), quinalbarbitone tablets, and various sulphonamide preparations. In addition to the name, quantity, and dose of these drugs, the strength must also be given.

SPONTANEOUS REGRESSION OF THE GLANDS IN HODGKIN'S DISEASE

BY

A. W. JOHNSTON, M.B., M.R.C.P.

Late Senior House Officer, Royal Victoria Infirmary,
Newcastle-upon-Tyne

In view of the recent emphasis on the treatment of Hodgkin's disease, it is timely to remember that the enlarged glands may regress spontaneously. The purpose of this paper is to report three cases (Cases 1-3) in which this occurred and to refer to others collected from a survey of the hospital records.

In the first patient the regression was so striking and the restoration to apparently normal health so remarkable that the diagnosis was doubted even though supported by a gland biopsy. Only after a recurrence was it accepted. Shortly afterwards the second patient was admitted with a similar story. Meanwhile the diagnosis in the third patient had passed through a similar cycle to that of the first.

A review of the records of the Royal Victoria Infirmary from 1948 to 1952, inclusive, revealed 29 acceptable cases in which to study the occurrence of this phenomenon. All underwent biopsy or necropsy. Five showed it clearly and six less definitely.

Case Reports

Case 1.—A farmer aged 46 attended first on October 2, 1952. One month previously he had developed glands in his neck associated with sweating bouts and persistent itching. Apart from the enlarged glands there and in his groins and axillae, nothing abnormal was found on clinical or laboratory examination. On October 18 he was pyrexial, with further involvement. On gland biopsy the case was reported as being more like Hodgkin's disease than anything else. One month later he said that he was better and that the glands had disappeared. They were, however, just palpable. The diagnosis was doubted and the question of the histology raised, but the pathologist maintained his position. A fortnight later the patient was readmitted with stridor, the glands having enlarged again. All the superficial groups were affected, but particularly the cervical. A final diagnosis of Hodgkin's disease was made and radiotherapy given. On February 17, 1953, he was readmitted with symptoms and signs of bone involvement and marrow replacement. He died three days later. **Necropsy:**—Lymph glands: abdominal mainly involved, pink or mottled red. The liver and spleen were large, the latter being soft, with an early infarct but no Malpighian bodies. **Histology:**—The spleen showed a pleomorphic mixture of lymphocytes, plasma cells, large mononuclears, occasional polymorphs and eosinophils, scanty Dorothy Reed cells, and primitive reticular cells. The lymph nodes were similar, with some haemorrhages. The marrow showed no haemopoietic tissue but small collections of cells resembling those in the spleen. The liver showed a non-specific picture. **Comment:**—The appearances are like those of Hodgkin's disease, but are not absolutely classical.

Case 2.—A schoolboy aged 14 was admitted as an emergency case on January 2, 1952, complaining of swellings in his right groin for two weeks. His temperature was 103.8° F. (39.9° C.). He was ill and drowsy. He had marked tender enlargement of all the right inguinal glands. There was a small uninfected scratch on the right calf and no lymphangitis. Blood cultures were sterile and his white-cell count was 4,600 per c.mm. He was treated with antibiotics, but his temperature seemed to settle fortuitously. The glands decreased to about half their original size, but

in August others appeared elsewhere. Section showed Hodgkin's disease. He was readmitted on November 26 with visceral as well as glandular involvement. He responded to nitrogen mustard therapy, but subsequently died at home.

Case 3.—A farm labourer aged 36 was admitted on June 7, 1952, as a case of Hodgkin's disease for a gland biopsy. His story was of malaise, night sweats, and a cough of recent onset. His temperature was 99.4° F. (37.4° C.). Most groups of glands were enlarged, and his spleen was palpable two fingerbreadths down. He had signs of collapse at the right base. Chest x-ray examination showed enlargement of the right hilar and paratracheal glands. After pyrexia for five days the swelling of the spleen and glands subsided along with the temperature. He was discharged with a tentative diagnosis of glandular fever in spite of a negative Paul-Bunnell test and differential white count. His general condition improved. He was readmitted with a recurrence and a remittent temperature up to 102° F. (38.9° C.). The glands had enlarged, as were the spleen and liver to four fingerbreadths. The chest x-ray report stated that there was "marked decrease in the glandular shadows but not complete resolution." Biopsy showed Hodgkin's disease.

Case 4.—A miner aged 50 was admitted on March 5, 1952. Eighteen months previously he had noticed lumps first on the right and then on the left side of his neck. They subsided without treatment. Four months before admission they enlarged again. With the glandular enlargement went general symptoms. He was pyrexial, with discrete enlargement of all groups of glands except the posterior cervical and the axillary. Section of a gland showed appearances more like Hodgkin's disease than anything else.

Case 5.—A housewife aged 29 was admitted on February 4, 1952. Her main complaint was of pain subternally after meals and night sweats. She was pyrexial, with epigastric tenderness but no significant glandular enlargement. Chest x-ray examination showed hilar lymphadenopathy. A Mantoux test was positive at 1:1,000, but her sputum was negative for *Mycobacterium tuberculosis*. Tuberculosis or reticulosis was the provisional diagnosis. Following readmission for haemoptysis on February 26, she had a large tender gland above the left clavicle. Biopsy was postponed because she developed a cold and then because the gland disappeared. Subsequent biopsy of a recurrence showed appearances more like Hodgkin's disease than anything else.

In the remaining six cases the decrease in size was not so dramatic, and in two there was a possible focus of infection.

Discussion

There is no reference to this phenomenon in most recent textbooks. Horder and McNee (1950) describe Hodgkin's disease as "characterized by painless, progressive enlargement of the lymph nodes." Cecil and Loeb (1951) make a similar statement, and say that the onset may be associated with oropharyngeal infections, but there is no proof of their connexion. Longcope (1927) states that "the correct conclusion may not be arrived at until the subsidence of the swellings (glands) with complete recovery excludes Hodgkin's disease." It was such statements as these which made our original diagnoses suspect.

Again there are few papers in which it is mentioned. Wallhauser (1933), in a review mainly concerned with pathology, merely says that he has known regression to occur. Symmers (1948), in a paper of similar nature, does not hint at it; nor does Gilbert (1939), although many varied presentations are discussed. Slaughter and Craver (1942) mention a case in which it probably occurred.

Among clinical reports, Baker and Mann (1939) and Goldman (1940) also ignore it. Middleton (1937) briefly mentions it, but without histories. This emphasis upon the progressive enlargement of the glands in Hodgkin's disease seems to be derived from Dorothy Reed's classical paper

in 1902. She, however, was faced with the problem of definition of the disease and therefore had to choose strict criteria for the cases for her studies.

As early as 1911 MacNalty recognized that there was a definite form of Hodgkin's disease associated with a relapsing fever. He noted that sometimes when the temperature became normal the spleen and glands decreased in size. This seems to have been widely forgotten in recent years, although Rolleston (1925) quotes MacNalty.

Hodgkin (1832) himself recorded a case in which the spleen and right glandulae concatenatae (cervical glands) were considerably enlarged, but "under the treatment employed these tumours, as well as that in the situation of the spleen, were at times very considerably reduced in size." This patient, Ellenborough King, was accepted by Fox (1936) as being a true example of the disease on histological grounds. The variations were probably spontaneous. Murchison (1870), who recorded the recurrent febrile episodes now erroneously accorded the eponym of Pel-Ebstein, comments on it clearly. Gowers (1879) stated that "a remarkable diminution in size of the glands may occur," and he refers to the "alternating pyrexia," thus avoiding inaccurate eponymy. Barron (1926) records a case in which the glands subsided, followed by a relapsing fever without a local recurrence.

Variation in the size of the spleen with the temperature is perhaps better appreciated. Whittington (1915) and Baldrige and Awe (1930) each recorded such a case. Jackson and Parker (1947) note that "it is not so well known that an enlarged spleen may diminish in size without any treatment whatsoever." However, they attribute diminution in size of the lymph nodes to the elimination of secondary infection, and add that their virtual disappearance should not be taken as proof that they merely represent chronic inflammation. In support, they give a history, and comment on whether the glands which decreased in size were actually involved with Hodgkin's disease at the time or not. Elsewhere they quote histories, and four more of these contain definite statements of variation in size without treatment, although the diagnosis had not yet been confirmed. Horder and Dratman (1948) in a comprehensive review, do not refer to it in the clinical section, although elsewhere they quote it in favour of the inflammatory nature of the disease.

Whenever regression of the glands or spleen is recorded and explained, either secondary infection is invoked to account for it or it is implied that the disease may not have been present in these glands. I submit that regression of the glands may occur as part of the natural history of one form of the disease. In Case 1 the diagnosis was thought to be Hodgkin's disease from the biopsy before the decrease in size occurred. Nor was there evidence of infection. It is unlikely that several groups of glands should regress as in Cases 1 and 3 if a local septic focus is the cause. Indeed, where only one group of glands has been involved there is not always a convincing source (Case 2).

The commonest group of glands affected appears to be the posterior cervical and not the tonsillar and superior cervical. It would be reasonable to expect the latter if secondary infection played an important part (Baker and Mann, 1939). Jackson and Parker (1947, p. 67) contrast the rarity of involvement of the tonsils by Hodgkin's disease with its frequent infections. They therefore deny a direct relationship, and suggest that they serve only to light up dormant disease or to draw attention to already enlarged glands. Case 5 shows how this may occur. There was no suggestion of an infection in Cases 1, 3, or 4, while in Case 2 both groups of inguinal glands were enlarged, which would be unusual for such a local lesion.

The reason for the decrease in size is unlikely to be necrosis, as it coincides with restoration to apparently normal health, whereas patients with necrotic neoplasms are usually ill. The enlargement of the glands in Case 1 prevented a proposed further biopsy. So far as our knowledge extends, such behaviour is seen only in some of the leukaemias apart from infections.

The reason for the high incidence of this phenomenon in the series under survey is uncertain. There is nothing to suggest sex, abnormal selection, geography, or inadequate records as a reason. Whatever it is, this phenomenon, which clearly has received insufficient attention in the past, is an important feature of one form of the disease. Such an occurrence is no reason for doubting the diagnosis.

Summary

The glands in a patient with Hodgkin's disease were observed to undergo almost complete regression without treatment.

Out of 29 cases, 5 showed the phenomenon clearly and a further 6 less well.

The cursory attention that this occurrence receives in the literature is noted; there is no evidence that elimination of secondary infection, adduced as a possible explanation, is responsible.

It is submitted that regression of the glands in Hodgkin's disease; often associated with an alternating fever, is an occasional but important variant of its natural history.

I am grateful to the various consultants under whom these patients were admitted for permission to publish, especially to Dr. T. H. Boon, and to Drs. L. W. Carstairs and J. N. Walton for their advice and criticism.

The fifth annual report of the medical officer in charge of the student health service at the Queen's University of Belfast contains an account of some student health services in the United States. The University of Minnesota, for instance, has one of the most advanced student health services in the world. It has been in existence for 32 years and is responsible for the medical care of 17,000 students. The staff consists of a director, an assistant director, 13 whole-time physicians (three of whom are psychiatrists), and 50 part-time physicians and consultants. The staff also includes a sanitary engineer and four sanitary inspectors responsible for the public health of the university campus. The service maintains its own laboratory, x-ray and ophthalmic departments, dental clinic, and a separate 50-bed hospital. The present hospital building was built four years ago and is magnificently equipped. The student health service is self-supporting and receives no funds from the general university budget. Each student pays a fee of five dollars a quarter, which entitles him or her to the initial medical and x-ray examination and four days in hospital. Fees are charged for special examinations, drugs, dental treatment, and any stay in hospital above the allotted four days. The main aim of the service is the care and treatment of the individual student during illness, and the service is used by about 80% of the student population. It is less expensive to the student than private or other hospital services.

SYMPTOMS AS A GUIDE TO ANAEMIA

BY

W. T. C. BERRY, M.D.

Medical Officer, Ministry of Health

AND

F. A. NASH, M.R.C.S., L.R.C.P.

Director, South-west London Mass X-ray Service

With the assistance of VIVIEN BURN, M.B., B.S.,
SHIRLEY F. DAUNCEY, M.B., B.S., JEAN FAIRHURST,
M.B., B.S., PATRICIA E. MORTIMER, M.B., B.S.,
and AUDREY MILLAR, M.R.C.S.

It is well known that persons with anaemia vary greatly in the degree to which they complain of symptoms. The study described below approaches the problem from the opposite angle—namely, the extent to which symptoms capable of being interpreted as due to anaemia, such as lassitude or feeling "below par," are in fact an indication of the prevalence of anaemia.

Method and Material

A total of 360 housewives, attending for miniature x-ray examination and found free from tuberculosis, accepted the offer of a haemoglobin test. They were asked to answer the following questions:

- Do you feel fit?
Average?
Below par?
Do you suffer from:
Breathlessness?
Poor appetite?
Always feel tired; lack of energy?
Swelling of ankles?
Do you need to take a laxative once a week or more?

It was realized that the questions were of a leading nature, but they were asked before the subject knew the result of the test, and were applied to all subjects without bias. The questions were not intended to include all the symptoms of which anaemic subjects are said to complain. The question on laxatives was posed so as to provide an objective index of the constipation which may accompany anaemia.

Haemoglobins were tested by the doctors, to whom acknowledgment is made above, using oxyhaemoglobin in Grey-Wedge photometers. Finger-prick blood was used. Each operator calibrated herself on an average once per ten

Haemoglobin Levels in Housewives who Complained, or Did Not Complain, of Certain Symptoms

	No.	Mean Hb (% Haldane: 100% = 14.8 g./ 100 ml.)	% Below	
			83%	73%
Below par	49	91.10	12.2	10.0
Average	172	89.70	16.3	5.8
Fit	127	89.95	12.6	4.7
Swelling ankles ..	73	89.80	20.5	4.1
Not	277	90.08	13.0	6.1
Breathless	134	90.24	16.4	9.0
Not	225	89.82	13.3	4.0
Always tired	153	90.04	15.7	7.8
Not	202	90.00	13.9	4.5
Poor appetite	43	90.21	9.3	7.0
Not	313	90.00	15.0	5.4
Constipated	104	89.31	19.2	5.8
Not	248	90.42	12.5	5.6
Fit, not always tired, not breathless ..	94	90.20	13.8	4.3
Below par, always tired, breathless ..	31	90.58	12.9	12.9

Where a reply was equivocal no entry has been made. Hence the difference in total numbers in each division. The level 83% was selected because at this level prospective blood donors are refused by the Ministry of Health Transfusion Service.

determinations by means of the invaluable samples provided by the M.R.C. haemoglobin standards scheme (Dr. I. D. P. Wootton).

Results

The Table shows that there was no difference in mean haemoglobin level between those that did and those that did not complain of these symptoms. Those whose haemoglobin level was below 73% were present in rather larger proportion in the group which complained of symptoms; but the differences were not greater than could occur by chance.

Discussion

The symptoms that we are dealing with are common to-day, as indeed the number of positive replies to our questionnaire suggests. Whether this has always been the case it is impossible to say; and, in any event, this is less important than to know the cause. Anaemia, to us, seemed to be one of the possible causes in practice, but it is clear from the analysis of our data that this is in fact not so.

Medical Memoranda

An Important Anomaly of the Long Saphenous Vein

Ligation of the superficial or deep veins of the lower limb is so commonly practised that the following anomaly of the long saphenous vein discovered in the course of routine laboratory dissection merits description.

Ascending through the femoral triangle the long saphenous vein crossed in front of the femoral artery to reach its lateral side 4 in. (10 cm.) below the mid-inguinal point. It then passed backwards and medially behind the artery to end in the femoral vein 2½ in. (7 cm.) below the mid-inguinal point—that is, about 1 in. (2.5 cm.) lower than usual. Where the long saphenous vein crossed in front of the artery the two vessels were firmly bound together by fibrous tissue. Thereafter the vein was intimately related to the artery below the origin of the profunda femoris branch, and thus it described a spiral course round the lateral side of the femoral artery (see Fig.). The level at which the vein pierced the deep fascia could not be determined, as the dissectors had removed the fascia in an attempt to elucidate the abnormal relationship. However, since the femoral artery is always beneath the deep fascia, it is likely that the long saphenous vein perforated that fascia at or before the point where it crossed in front of the artery. The femoral vein lay on a more posterior plane than the femoral artery immediately below the inguinal ligament, and the superficial circumflex iliac and the superficial epigastric veins ended in it.

The practical importance of this anomaly is clear. A point 1½ in. (3.8 cm.) below and lateral to the pubic tubercle, the standard guide to the middle of the saphenous opening (fossa ovalis), was found in this case to be opposite the

The long saphenous vein passing spirally round the lateral side of the femoral artery.

femoral vein just as it appeared on the medial side of the femoral artery. Using this surface marking, the surgeon intending to resect the terminal part of the long saphenous vein would not come upon that structure in this case. Instead, on tracing the superficial circumflex iliac and superficial epigastric veins to their termination, he would pass imperceptibly beneath the deep fascia, cribriform in this region, into the plane of the femoral vessels. If the vessel which then presented itself was the femoral vein, this might be ligated in error. On the other hand, if the dissection were carried low enough to encounter the long saphenous vein, the close relationship of this vessel to the femoral artery might result in the inclusion of both artery and vein in the ligature. That the femoral artery has been injured in the course of Trendelenburg's operation, occasionally with subsequent loss of the limb or death, is beyond doubt.

Luke and Miller (1948) cited three certain cases and one probable case of ligation of the femoral artery. McPheeters (1945) described two cases of ligation of the femoral artery, and in one of these the femoral vein was also tied. At least three cases have come to my notice in this country in which either injury or ligation of the femoral artery occurred during this operation. For obvious reasons it is difficult to get details of the operative findings, but it is possible that the anomaly described above may have been present in some of these cases.

A somewhat similar course of the long saphenous vein was described and illustrated by von Lanz and Wachsmuth (1938). It was also depicted in Fig. 5 of an article by Anson and McVay (1938), so that it cannot be exceptionally rare. No mention was made of its significance in either of these texts.

Whatever the explanation of the surgical errors associated with Trendelenburg's operation it is obvious that the surgeon should be aware of the deceptive variation described in this report. The technical difficulties which it presents are slight. The real danger lies in not knowing that such a condition may exist.

My thanks are due to Professor D. R. Dow for assistance in writing this report.

Two Cases of "Novalgin" Agranulocytosis

Numerous reports of the occurrence of agranulocytosis following the administration of "novalgin" and other drugs containing amidopyrine have been published (Kracke, 1931; Plum, 1934; Stenbeck, 1935; Benjamin and Biederman, 1936; Moloney and Vidoli, 1943; Kneeder, 1946). Now that these drugs have been put on the Fourth Schedule of the Poisons List, and the danger of their use is more widely appreciated, cases such as those recorded below should become rare.

CASE 1

A female domestic worker aged 70 was admitted as a suspected case of diphtheria in July, 1950. For three weeks previously she had been taking novalgin tablets (which she obtained direct from the chemist) for rheumatic pains, the exact dose being unknown. Two days before admission she had chilly sensations with malaise, and the next day a sore throat and difficulty in swallowing.

On admission she was found to be well nourished but not fat, and was obviously very ill, with stertorous breathing and a hoarse nasal-sounding voice. Both tonsils, uvula, and soft palate were covered with patchy exudate, greenish yellow in colour, and on the left tonsil it was becoming black, indicating early gangrene; fetor was pronounced and an icteric tinge was visible on the conjunctivae. The tonsillar lymph nodes were moderately enlarged. The blood pressure was 135/70. Blood count: Hb. 80%; red cells, 3,800,000;

white cells, 750 (lymphocytes 100%, no granulocytes). From the throat swab *Streptococcus viridans* only was grown. Penicillin, 500,000 units, and penicillinate, 10 ml., were given intramuscularly immediately on admission, but the patient died three hours afterwards, before arrangements for a transfusion of fresh compatible blood could be made. Necropsy revealed a superficial pharyngeal necrosis extending from tonsils to epiglottis and haemorrhagic congestion and oedema of the lungs with subpleural and subpericardial haemorrhages.

CASE 2

A female domestic worker aged 68 was admitted to hospital with tonsillitis and pneumonia in May, 1952. In the previous month she saw her doctor on account of painful stiff joints, when novalgin was prescribed in doses of 2 tablets, each containing 5 gr. (0.32 g.), three times a day; over a period of three weeks she had taken a total of 90 tablets, when she became febrile and weak with sore throat, dysphagia, and hoarseness. Novalgin was discontinued at once, and two days later she was given sulphamerazine, a total of 30 g. in five days, without apparent response, and was admitted to hospital.

She was obese, pale, and obviously ill, with hurried noisy breathing; her temperature was 101° F. (38.3° C.), pulse 120, and respirations 30. Exudate covered most of the tonsillar surfaces and spread to the uvula and soft palate without underlying ulceration. The associated lymph nodes were enlarged and tender, and moist sounds were heard at both lung bases without evidence of heart failure. Blood count: Hb. 78%; white cells, 2,000 (neutrophils 3%, lymphocytes 90%, monocytes 7%). Some of the lymphocytes were atypical early forms. A heavy growth of *Str. viridans* was obtained from the throat swabs, but haemolytic forms were not present. Crystalline penicillin, 1,000,000 units daily, was given for seven days, with amelioration of the symptoms and rapid disappearance of the exudate. Immediately thereafter she received 9.5 g. of chloramphenicol over four days on account of persisting bronchitis, to which she was known to be prone. Two days after penicillin was started the white cells numbered 3,100 (neutrophils 10%, lymphocytes 78%, monocytes 12%), and two days later the count was almost normal, subsequent recovery being uneventful.

COMMENT

Despite the similarity of the two patients in respect of age, occupation, and physical state, and probably also of the amount and duration of ingestion of novalgin, the clinical differences in the character of the disease—in the one brief and rapidly fatal, and in the other, over a week and mild with prompt resolution—are impressive, suggesting that idiosyncrasy may be the most important aetiological factor. There was no history of previous ingestion of the drug, although this could not be eliminated completely, especially in Case 1.

The absence of recognized respiratory pathogens, such as haemolytic streptococci, suggests that the faucial angina is a degenerative or allergic rather than an inflammatory condition, and therefore unlikely to respond to penicillin. Alternatively, *Str. viridans* may, under particular conditions, become pathogenic to the respiratory mucosa, as has been long suspected in association with virus infections. Aureomycin therefore seems to be the antibiotic of choice, as chloramphenicol has been shown capable of causing both agranulocytosis and aplastic anaemia. Sensitivity tests are probably essential in severe cases to find the correct antibiotic.

Reviews

SIGMUND FREUD

Sigmund Freud—Life and Work. Volume 1—The Young Freud, 1856–1900. By Ernest Jones. (Pp. 454, illustrated. 27s. 6d.) London: The Hogarth Press. 1953.

The author is the oldest colleague of Freud still alive. It was due to him that Freud spent his last months peacefully in this country following his rescue from Nazi-invaded Vienna. In this first volume of three Freud's life to the age of 44 is described. By 1900 Freud had established his basic concepts—the importance of unconscious mental life, the beginnings of sexuality in infancy, the value of "free association" and dream life, both for the therapy of neuroses and as a method of investigating psychic development.

Not only psychiatrists but all those who enjoy the story of the trials and triumphs of physicians will be fascinated by this book and the promise of the two further volumes to come. Dr. Jones has added to his laurels as a clear expositor. Rarely has a physician been so lucky in his biographer or a medical biographer in his subject. It is difficult to make comparisons, but one thinks of Cushing's much-read life of Osler and Pearson's unfortunately little-read life of Galton. Galton, Osler, and Freud were all clear and voluminous writers. Unfortunately, at one time Freud destroyed much of his previous writings, but Ernest Jones has had access to many family letters, perhaps the most significant being the 1,500 love letters sent by Freud to his future wife during their four years' engagement previous to marriage when he was 30. Freud's letters to his friend Fliess during the 'nineties, when he was gradually leaving neurology for psychology, have been preserved (they will soon be published in an English translation) and give a vivid picture of the doubts and mental anguish of a pioneer. Gradually his independence emerged, and he sought collaborators as critics rather than the opinions of those who did not seek confirmatory access to the facts he had discovered.

The author's stated aim is the hope of elucidating something of the processes in Freud's mind and the experiences in his life which led to his discoveries. The scanty details about Freud's childhood and adolescence which are available are partly compensated for by the greater knowledge of his medical studies until graduation at 25 and his career as a neurologist. Apart from his interest in cocaine as a treatment for depression—which nearly led to his discovering its use as an analgesic—his early years as a physician were typically those of one who wished to become a consultant neurologist. This period ended with his most important neurological publication "Aphasia" in 1891, which did not attract the attention in this country it deserved. In it he strongly supported Hughlings Jackson's genetic views. His numerous neurological publications established his reputation in this field as a hard worker and a close thinker, but only in his work "Aphasia" was there a hint of the genius which was to appear.

During the 'nineties the work that established psychoanalysis was done almost alone. His early contact with Breuer was, of course, important. But he soon had to test his developing hypotheses without the help of others. In 1889, replying to Meynert's criticism of his interest in hypnosis, he wrote: "Respect for greatness, especially intellectual greatness, belongs to the best qualities of human nature. But it should take second place to respect for facts. One need not be ashamed to admit when one sets aside reliance on authority in favour of one's judgment gained by a study of the facts."

The publication in 1893 of his and Breuer's experiences of transference phenomena in hysteria led to the first note of his work in this country, F. W. H. Myers giving a good account of it in the *Proceedings of the Society for Psychical Research* in June, 1893. His 1895 "Studies in Hysteria" were favourably reviewed by Mitchell Clark in *Brain* in

1896. During the period 1892–6 the method of free association gradually developed, and was freed from hypnosis, suggestion, urging, and questioning. In 1898 he began to realize the importance of the connexion between infantile and pubertal sexuality. From 1897 his own self-analysis continued.

In the 'nineties the beginning of the resistance and reaction to his views began—not so much to his view of unconscious mental life, which was generally accepted, but to the content he discovered. To Freud the unconscious gradually became an inner reality deep to consciousness just as real as the outer reality beyond that which our senses give access to. From the beginning of his interest in psychology he manifested his wish to understand normality. In 1882 he had written of his uncanny feeling when he could not understand someone in terms of his own experience. The passage from physiology to psychology meant much more to Freud than a change in intellectual outlook. It betokened a need to reach towards the depths of his own being, which for many years had been covered over. His long self-analysis was the first of many that have followed in physicians who are unsatisfied unless they can attempt to understand the sufferings and delights of others in terms of their own.

Freud emerges from this book as the complex man he was: with his scientific industry, his love of family, his love of travel and pursuits outside medicine, and his neurosis. The reader will be left baffled but thrilled. This is the lot of those who try to comprehend genius.

W. CLIFFORD M. SCOTT.

ARTERIOSCLEROSIS

Arteriosclerosis. By Dr. José Froimovich. (Pp. 218; illustrated. No price given.) Valparaíso, Chile.

This book, which is described as a clinical and experimental study of arteriosclerosis, comes in Spanish from Valparaíso. The term "hardening of the arteries," which is the exact translation, is in many ways unsatisfactory. It may refer to one or more of several distinctly different diseases. In this book the discussion of the pathogenesis refers to atherosclerosis or atheroma. It ranges over a wide field, rather too wide perhaps. At times other forms of arterial disease come into the discussion, so that the text becomes rather confusing. Many authors are quoted, but there is no summary or synthesis of views. In the account of morbid anatomy the reader is again confronted with a great many references from various authors. The experimental work is shown in a number of photomicrographs, but these are far from clear and do not show much detail. There are descriptions of the results of keeping rabbits on diets containing much cholesterol; the author claims that this leads to the development of atheroma; but he thinks that iodide of potassium checked the formation of the deposits. Then comes a chapter on the symptomatology of common disease. He gives some description of cardiograms, but no tracings are shown; his approach to this important subject is hardly up to date. He advocates propyl thiouracil in treating angina pectoris.

Although this book contains a large amount of work cited from many writers, the author does not discuss it well; there is a lack of correlation, sifting, and criticism. He leaves the reader without any clear idea of what he really thinks, and in some confusion about the whole subject.

TERENCE EAST.

MANUAL OF PSYCHIATRY

A Manual of Psychiatry. By K. R. Stallworthy, M.B., Ch.B. Second edition. (Pp. 314. £1 10s.) Christchurch, New Zealand: N. M. Peryer. 1953.

The writer of the foreword to this volume commends it to all who seek a soundly based, common-sense knowledge of modern psychiatry. The author achieves this objective only in part. The book will not interest the experienced psychiatrist, and the psychiatrist in training may find it rather fragmentary. But the psychiatric nurse will profit by reading the chapters on physical methods of treatment and special

nursing procedures. The chapter on the neuroses contains some recommendations which could scarcely be described as soundly based. We read that it is relatively uncommon for an anxiety state to require expert psychiatric treatment. Where it does, an effort should be made "to unmask the underlying complexes," and, should this fail, leucotomy may be advised. Psychotherapy is not much in favour. The doctor who has neither time nor patience to listen to the involved story of his patient should "refer the person to some colleague who has." The superficial references to the work of Freud and Jung suggest that the analysis of the unconscious occupies a lowly place in the treatment of psychiatric illness. Physical methods of treatment, on the other hand, receive considerable attention and, by implication, are the main concern of the psychiatrist. Psychiatry is a complicated subject, and it is probably impossible, without oversimplification, to summarize its essentials in a manual designed as "a practical guide for practitioners and students of psychiatry."

E. A. BENNET.

SCIENTIFIC LANGUAGE

The Language of Science: Its Growth, Character, and Usage. By Theodore H. Savory. (Pp. 184. 10s. 6d.) London: André Deutsch. 1953.

The object of scientific prose is to convey information as clearly as possible; for this reason, ordinary words used for scientific purposes have to be specially defined, and many words have to be coined to denote things and relationships outside ordinary experience. To this extent one can say that there is such a thing as scientific language, though it is possible to exaggerate its importance; and scientific authors probably think of themselves as writers of English or other languages also used by non-scientists. It would perhaps be better to speak of a scientific vocabulary, since grammar is the same for all users of a language. This book is a collection of essays on various aspects of scientific language. The author writes on such topics as technical terms and their derivation and date of appearance, the object of scientific writing, the translation of scientific literature; and the value of foreign languages to the scientific worker. He has been a schoolmaster for over 30 years, which no doubt explains his heavily expository style and tendency to labour the obvious; much of what he has to say is in fact common knowledge, in universities at any rate. The different problems of translators of poetry and scientific prose are well discussed, but scientific translation is more difficult than the author allows; the scientific translator needs as strong a grasp of idiom as the translator of verse. The author thinks that the university student of science has no time for interests outside his work, and we can only hope his sample was not representative.

The book is addressed to philologists and scientists, but its strongest appeal will probably be to schoolmasters and general readers with an interest in science.

RAYMOND WHITEHEAD.

DICTIONARY OF MIDWIFERY

A Dictionary of Midwifery and Public Health. By G. B. Carter, B.Sc., S.R.N., S.C.M., and G. H. Dodds, M.D., F.R.C.S., F.R.C.O.G. (Pp. 686; illustrated. 25s.) London: Faber and Faber Ltd. 1953.

This is more than a dictionary—it is an encyclopaedia. The greater part of the book is devoted to the definition of obstetric and other medical terms and concise and accurate descriptions of a wide variety of well-chosen topics. The other part is on public health and administration.

The book is intended for midwives both for reference and for study, but the dictionary part will be welcomed also by medical students and hospital administrators, and even a reviewer may be forgiven, I hope, for forgetting the task in hand and losing himself in the neat and instructive articles in this comprehensive dictionary. The many excellent line drawings have been executed by Miss P. Forman with artistic skill and baptismal patience. I recommend unreservedly the dictionary part to all associated with obstetrics.

The smaller part on public health and administration is constructed on somewhat similar lines. Here, too, are many interesting and informative articles, but unfortunately this part is marred by a number of errors and misleading statements. For example, the Ministry of Housing and Local Government receives its correct title under that heading, but elsewhere it becomes the Ministry of Local Government and Housing, and, again, the Ministry of Local Government and Planning. And the statement that "It is usually agreed in Great Britain that the trained hospital almoner is the medico-social worker in clinic and hospital and the health visitor in the home" will not commend itself as either fact or opinion to the thousands of health visitors working in hundreds of local authority clinics in addition to their work in the home.

The whole volume would be improved by eliminating the section on public health and administration altogether, or, better still, by careful revision raising it to the standard of the main part consisting of the excellent dictionary of midwifery.

C. METCALFE BROWN.

THE DERMATOPHYTES

Dermatophytes. By Dr. Jean Obtel. (Pp. 44; 196 coloured plates and 59 photographs. No price.) Prague: Editions Médicales.

This book presents a wide selection of beautifully executed coloured plates of dermatophyte cultures grown on standard Sabouraud media at room temperatures and an equally wide selection of good clinical photographs of the lesions caused by dermatophytes. But its practical value to the clinician and medical mycologist is vitiated by the author's adherence to the outdated classification instituted by Sabouraud. This classification is based chiefly on host-parasite relationships and on gross cultural features and does not represent the natural affinities between the various members of the dermatophyte group. The lesions caused by dermatophytes are well known to vary considerably, and similarly their gross cultural features, as is indeed so well demonstrated in this book. A classification based on such variable criteria is of doubtful value for purposes of identification and therefore defeats its own object. The classifications of dermatophytes most widely used in France, Belgium, Great Britain, and America are all based on microscopic morphological criteria presented by these organisms in culture, thus bringing them into line with the taxonomic treatment of other groups of fungi.

Some surprising mycological statements appear in the text—for example, "Le groupe Microdon comprend les dermatophytes du type ectothrix caractérisés par de grandes spores" (italics mine); and further on the same page, in reference to Sabouraud, "Il différencie dans le cinquième groupe les mucorinées dites Mégasporon en deux autres groupes indépendants" (italics mine). These are probably due to insufficient proof-reading and are such obvious errors that they are not likely to mislead at any rate the medical mycologist.

Some notes on distribution, epidemiology, clinical features, and therapy are included. While this information is in some cases based on insufficient data, it provides for workers west of the Iron Curtain an interesting documentary of local conditions as regards the dermatomycoses. The book is elegantly and sumptuously produced, but it is to be regretted that its artistic merit outweighs its scientific value. There are numerous typographical errors in the references to articles in the English language.

C. J. P. LA TOUCHE.

From the fact that the 7th edition (1953) of R. W. Fairbrother's *Textbook of Bacteriology* (Pp. 492; 20s. London: William Heinemann Medical Books) is, including reprints, its 18th issue in 16 years, it may be gathered that this work has found favour. The principal changes in this edition are in the chapters on chemotherapy and virus diseases.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY APRIL 17 1954

KIDNEY TRANSPLANTATION

The transplantation of kidneys is perhaps the most ambitious enterprise that has yet been undertaken in the surgery of tissue and organ replacement. Although the kidney is a firm and compact organ, with a single chief arterial input and venous outflow, and is an organ which seems not to need a nerve supply for its continued working, the obstacles to its successful transplantation are by no means merely technical. With rare exceptions—one of them described by Michon and his colleagues¹—grafts of kidney that are to be clinically useful must be homografts—that is, they must be grafts transplanted from one human being to another or between animals of the same species. In addition, therefore, to all the technical and physiological difficulties of transplantation are all the immunological impediments arising from the fact that the tissues of one individual provoke a highly efficient, if teleologically uncalled-for, defence mechanism after transplantation to the body of another.

The experimental work of Dempster^{2,3} and of Simonsen⁴ and their respective colleagues on dogs has given ground for believing that these immunological difficulties are of two kinds. First, there is the reaction of the host upon the graft, which both writers believe to be similar in all essentials to that provoked by homografts of skin—that is, a kind of immunological reaction. If that were the whole story the outlook would be grave but not desperate, for the problem of abolishing reactions of this kind has already been solved for laboratory animals,⁵ although by methods which, in their existing form, have no clinical application. But both Dempster and Simonsen have described certain histological appearances (confirmed, in Dempster's work, by irradiation experiments) which suggest, unfortunately, that a second factor is at work—the reaction of the kidney homograft against its host. This possibility, although it

still requires a formal experimental proof, is entirely plausible, and its recognition is one of the most important contributions to the theory of tissue transplantation immunity that has been made in recent years. There is no reason at all why a graft, if it contains antibody-forming cells, should not respond to the antigenic matter entering it from its host. When two animals are in parabiotic union, each is graft and each host, and Simonsen believes that the kidney homograft is best thought of as a parabiosis of unequal partnership. With homografts of many types—for example, of skin or cancerous tissue—a reaction of graft against host is either absent or of little importance; skin homografts, for instance, will survive indefinitely after transplantation from members of an inbred line of mice to the progeny of a cross between that inbred line and another. As every geneticist knows, such a situation is one in which the host does not react against the graft, for the graft contains no antigens not also present in the host; but there is nothing to stop the graft reacting against the host if it is immunologically qualified to do so. Neither Dempster nor Simonsen have had the good fortune to work with highly inbred dogs, perhaps because no dogs of sufficient genetic uniformity exist. It is not therefore possible to weigh up the relative importance of host-against-graft and graft-against-host reactions in homografts of kidneys. The former type are indeed entirely competent to account for the failure of kidney homografts as such, but the question is: if the reactions of the host can be subdued or abolished—it can surely be only a matter of time before they are—will the converse reaction, of graft against host, be in itself sufficiently severe to cause kidney homografts to fail?

So much for the immunological hazards of kidney transplantation. Superimposed on them are the technical and physiological disabilities of the transplantation itself. Autografts of whole kidneys are, in general, of two kinds: these are the isotopic (or orthotopic), in which the graft is transplanted into the position formerly occupied by a kidney, and the heterotopic, in which it is caused to derive its external blood supply from, perhaps, the iliac or carotid arteries. The orthotopic graft enjoys certain neighbourly relationships that are denied it elsewhere. For instance, it has long been known that removal of one of the adrenals increases the outflow of urine from the kidney of the same side. Dempster and Graber⁶ are satisfied that this alteration of function is not to be attributed to splanchnic denervation, and they think it possible (as Cow did some forty years ago) that the adrenal exerts a direct hormonal influence via the lymphatics upon the kidney of the same side. How-

ever that may be, a dog's kidney transplanted to the neck works, and may work permanently, but it does not work quite normally. Dempster and his colleagues^{7,8} have consistently recorded, among other shortcomings, a rapid and permanent deterioration of the graft's power to concentrate urine, the specific gravity of which falls to a fairly constant level of about 1012 (the normal range in dogs is 1035–1050). This deterioration was not corrected by the removal of the dog's remaining normal kidney. But removal of the normal kidney did restore to its original value a total urinary output which had fallen to a half or less in the period beginning from about a month after transplantation. A toxic syndrome which sometimes develops after a period of useful working in kidney autografts⁹ is probably due to infection consequent upon a vascular accident, since it usually yields to the administration of terramycin; but Dempster finds no ground for believing that the administration of any antibiotic can prolong the life of a kidney homograft as such.

Dempster gave an account of his interpretation of the behaviour of kidney homografts at a symposium on immunological problems of tissue grafting held at the Royal Society of Medicine on April 6, paying special attention to the histopathological evidence of the reaction of graft against host. It is against the background of these systematic physiological and immunological researches that we must appraise the occasional attempt to make use of kidney homografts in clinical practice.^{10,11} For reasons that are not yet clear the human being is, in a purely quantitative sense, more tolerant of homografts of all kinds than are most domesticated animals, and kidney homografts in human beings may therefore sometimes last long enough to raise hopes which later suffer a tragic disappointment. Kidney homotransplantation cannot at present be carried out in human beings with any theoretical expectation of success. The problems of tissue-transplantation immunity are not likely to yield to anything but prolonged, systematic, and fundamental research, and it should be a cause for some satisfaction that the homografting of kidneys has in recent years been made the subject of research of the concentration and skill required.

THE PROMOTION OF WORLD HEALTH

World Health Day, April 7, was celebrated in London at a meeting, addressed by Dr. M. G. Candau, Director-General of the World Health Organization, and by Mr. Walter Elliot, M.P., a former Minister of Health. The theme of the meeting was the vital part played by the nursing services, and a letter was

read from the present Minister of Health expressing appreciation of the importance of nurses in all branches of the National Health Service. On the following day Dr. Candau spoke at the Royal Society of Medicine and showed a film illustrating the work of W.H.O. His visit to London coincided with the publication of his annual report¹ to the World Health Assembly, which meets in Geneva in May. The report mentions that there were about 350 W.H.O. projects in 74 countries last year. The greatest number of these were proceeding in south-east Asia, and the next largest groups were in Europe, the Americas, and the Eastern Mediterranean, with 60 or 70 enterprises in each region. W.H.O.'s activities in Africa were relatively few in 1953, but they extended from public health education in Liberia to the supply of medical school equipment in Kenya and malaria control on the Congo. India received help in nearly 30 separate undertakings, from assistance for a school of nursing in Calcutta to a paediatric unit in Madras General Hospital, and from a campaign for B.C.G. vaccination in Delhi State to the establishment of a school of physiotherapy in Bombay. In the Eastern Mediterranean the projects ranged from a public health laboratory in Jerusalem to an eye diseases seminar in Cairo; and in Europe, from the setting up of a child guidance clinic in Dublin to venereal diseases control in Istanbul. Another feature of the European work of the Organization last year was inter-country programmes—for example, France and the United Kingdom continued a three-year pilot study to determine the kind of health visitor best suited to meet health and welfare needs, and they collaborated also in a study of the effects of separating the child from its mother in the early years of life. Many European countries also joined together in conferences and training courses.

As these projects are developed they seem to have a sharper definition than in earlier years. W.H.O. is not a rich uncle distributing largesse among impoverished nephews. Its purpose is to stimulate regional and local effort so that eventually there may be in every country and territory a band of trained and competent workers to man the health services. In the distant future when that is accomplished W.H.O. will have a different role to play. Meanwhile, as Dr. Candau rather sadly remarked at the World Health Day meeting in London, the funds available from technical assistance sources are liable to fluctuate. In order that the work of the Organization will not suffer, the World Health Assembly at its gathering in Geneva next month is to be asked to increase the effective working budget from the

previous year's figure of 8,500,000 dollars to 10,300,000 dollars. This amount, Dr. Candau said, was needed to enable them to carry out, without interruption, their planned health activities in 117 countries and territories in 1955. He added that the United Kingdom was the second largest contributor, after the United States, to the funds of W.H.O.: at the present moment the United Kingdom contribution to W.H.O. amounted to 1½d. per head of the population per year. If the budget was increased by the desired amount the cost to every person in the United Kingdom would be one halfpenny a year more. It is unfortunate that a number of countries are in arrear with their contributions, and that there is a phalanx of inactive members behind the Iron Curtain, but even with these disabilities W.H.O. achieved much to be proud of in 1953 and will undoubtedly continue to play a central part in the work of improving environmental conditions throughout the world.

THE PROPHYLACTIC EGG

With the coming of Easter and springtime we welcome both the chocolate eggs in the shops and the renewed determination of hens to start laying real ones. Unlike the chocolate variety or the somewhat rarer cardboard type enclosing a string of pearls, real eggs contain choline, and, if Wallis's theory about egg lack in rheumatic fever turns out to be correct, the sudden decrease of rheumatic fever after the peak maximum incidence of April¹ and its low incidence during summer might be due to Easter and its effect on the domestic fowl. Though this particular fancy is not included in the chain of possibilities elaborated by Wallis, he postulates that a deficiency of eggs during childhood (among other factors) leads to rheumatic fever. His argument is that low egg intake means low choline intake, and, since choline is necessary for serum phospholipid synthesis and cannot itself be synthesized, this may in turn lead to low phospholipid serum levels. Since serum phospholipid is one of the normal serum factors which inhibits the streptococcal exotoxin streptolysin S,² and since rheumatic fever is associated with streptococcal infection, the possibility exists that rheumatic fever might be conditioned partly by egg intake. This is a long and tenuous chain of reasoning, but it can be tested at various points, and Wallis provides some information at two. First, by retrospective inquiry among a group of 184 adult or adolescent patients with rheumatic heart disease and a group of normal subjects of similar economic status, he establishes³ that 41% of the former believe they ate few eggs in childhood as against 16% of the latter. Ten per cent. of the cardiac group dis-

liked eggs as against 5% of the controls. How significant this is we do not know. Such retrospective inquiries are difficult to conduct free from bias (although attempts were made to eliminate this) and even more difficult to interpret. His second contribution is a study of serum phospholipid levels at various ages in 146 normal subjects and in 178 patients with inactive rheumatic heart disease.⁴ This substance rises from a normal mean level of 8.2 mg. per 100 ml. in children aged 3-12 to 9.7 mg. per 100 ml. in adults aged 20-39, but with a great deal of scatter in the readings. In the cardiac group no mean values are given, but it is stated that the serum level was below normal average in two-thirds, tending to be lower in those with multiple attacks or of a severity great enough to need digitalis. Although Wallis found that 10.2% of 184 rheumatic heart disease patients and 4.6% of 1,380 normals disliked eggs, no information is given of the serum phospholipid level of the egg lovers and the egg haters.

Previously Coburn and Moore⁵ had reported a poverty of eggs and other materials in the diet of rheumatic children and had supplemented the diet of thirty convalescent rheumatic children with the equivalent of four egg-yolks a day. Recurrences occurred in 7% of this group, compared with 38% of thirty children whose diet was not supplemented. No further studies have been described in detail, though Coburn has reported⁶ briefly that 8-10 yolks daily prevented rheumatic relapses after group-A streptococcal infection in children who had previously had rheumatic fever.

The best hypotheses are the simplest. All current theories about the aetiology of rheumatic fever are complicated, and none more so than that recently suggested by Long⁷ on a basis of cabbage, thyroid, ascorbic acid, and tuberculin allergy in the guinea-pig. So long as a clear distinction is made between observation and speculation we should welcome theories if they are founded on fact and lead to the discovery of more facts. The egg theory might be described as "good in parts." Although support for it is meagre, we cannot afford to neglect any clue to the nature of the streptococcal role in initiating rheumatic fever. But the enthusiastic clinician might pause before loading his patients with eggs to prevent rheumatic fever lest he speed them on the way to atherosclerosis and coronary disease.

DEXTRAN AND NEPHROTIC OEDEMA

Recently two new therapeutic agents have been used in the treatment of nephrotic oedema. They are cation-exchange resins and dextran. So far, more of the clinical trials have been with cation-exchangers, but now the first studies on the effect of dextran have been published,^{1 2} and it is beginning to be possible to assess its usefulness in this syndrome. The essential principles by which resins and dextran work are quite different. Cation-exchangers increase the loss of sodium from the body, while dextran increases the osmotic pressure of the plasma and so attracts idle water from the oedematous parts, and possibly hinders tubular reabsorption of water in the kidneys.¹

Elsewhere in this issue of the *Journal* Drs. A. W. Mollison and J. B. Rennie report their experience of treating nephrotic oedema with intravenous infusions of dextran. Dextran was given on 81 occasions to eight patients. All were at rest in bed, on restricted salt intake, and a moderately restricted fluid intake. Seven patients received a high and one a normal protein intake. The dextran was used in a standard commercial 6% salt-free preparation, and three 10% salt-free preparations of large, medium, and small molecular size. Diuresis and delivery of the oedema occurred with all these preparations, regardless of molecular size or concentration, but the effect lasted longest with the large molecular preparation. In all cases the oedema re-accumulated. Dextran had no adverse influence on renal function. Toxic reactions to infusion were noted in all cases, and consisted of severe headaches, occasional nausea and vomiting, and fever; two patients developed transient hepatic enlargement; one patient developed fever, dyspnoea, cough, and scanty rales at the lung bases after the fourth infusion of small-molecule dextran, and another developed the same symptoms though less severely with a similar preparation. The more severe reactor of these two also showed signs of the greatest increase in blood volume of any of the patients in response to the infusion, and this occurred at the time of his reaction; skin tests for sensitivity to dextran were negative. The authors thought that the reactions they encountered were not allergic so much as due to overloading of the circulation, and they found that slowing the rate of infusion reduced the severity of the reaction.

It is interesting that subsequent courses of dextran after the first were effective in producing diuresis in this series of cases. Olive *et al.*² found that in two of the twelve children with nephrotic oedema whom they treated the second course of dextran failed to cause diuresis even though the first had been quite effective. On the other hand they noted toxic reactions in only three of their cases, the reactions being correlated with the use of a preparation of high molecular weight and with frequent molecular branching. Kabat and Berg³ noted that dextran given to healthy humans was antigenic, and Kabat, Turino, and Tarrow⁴ have shown that cutaneous sensitivity to dextran was statistically correlated with the occurrence of systemic reactions to subsequent intravenous infusions. Apart from the reactions of an antigenic or haemodynamic type Mollison and Rennie draw attention to a hitherto unremarked complication to its therapeutic use. Two of their patients suffered impairment of haemopoiesis, which in the more severely affected case persisted for two months after the last infusion of dextran. The authors thought this was due to the fact that the dextran is taken up by the reticuloendothelial system and therefore of the bone marrow and only slowly released and excreted or

metabolized. The hepatic enlargement which occurred in two of their cases was presumably from this cause, although histochemical examination of the liver from one case at necropsy failed to reveal the presence of any dextran. Dextran is also deposited in the renal tubules.⁵ Michie and Ragni⁶ noted that the repeated intravenous administration of it significantly decreased the maximal tubular excretory capacity for para-aminohippurate in two out of five subjects with normal kidneys and in three out of four patients with pre-existing renal disease. The significance of this finding in such a small series of patients is doubtful, particularly in view of other evidence of the innocuousness of dextran where the kidneys are concerned.^{1 7 8}

Most reports indicate that single infusions of dextran are not very effective in delivering nephrotic oedema,^{1 2} and Mollison and Rennie's experience is no exception to this. There is little doubt that dextran is a powerful diuretic and may succeed when all other measures fail, but by the very nature of its route of administration and the transience of its effects it is unsuitable for use in domiciliary practice.

PHOTIC CONVULSIONS

Cases have been reported from time to time of epileptic seizures apparently induced by flashing lights, such as sunlight through rows of trees. But it was Grey-Walter and his associates¹ who first showed systematically that rhythmic visual stimulation produced widespread physiological effects, leading in some cases to clinical epileptic attacks. Since then several modifications of the original technique have been made, such as triggering the stimulus frequency by a "feed-back" circuit from frequencies present in the stimulated brain.² Gastaut^{3 4} introduced the combination of injected metrazol with photic stimulation. Many studies of the effects of these methods of examination in various neurological and psychiatric conditions have now appeared. Recently Bickford, Daly, and Keith⁵ have reported on 27 epileptic children who all showed, on photic stimulation, epileptic discharges in their electroencephalogram, often with clinical attacks as well. As found by other workers, the effective flash frequencies were usually between ten and twenty flashes per second, and myoclonic jerks were the commonest clinical manifestation. Arrest of speech and clinical petit mal sometimes occurred. In several cases there was a clinical history of minor attacks precipitated by light stimuli. One child sometimes induced attacks at will by waving his fingers in front of his eyes, apparently getting a pleasurable sensation thereby. The authors do not specifically discuss the aetiology of their patients' epilepsy, but several obviously have diffuse degenerative cerebral disorders, and others have so-called idiopathic epilepsy.

A rational treatment of this abnormal light sensitivity would seem to be to cut down the intensity of visual stimulation by dark glasses. Bickford and his colleagues noted that this was an effective adjuvant to drug therapy in some cases. Ulett⁶ has used dark glasses to prevent laboratory staff exposed to experimental stimulation from suffering ill effects. Trimethadione and amylo-barbital are the most effective drugs in diminishing photosensitivity, especially when given intravenously. No one seems to have followed up the odd fact that the former drug, the most effective of all, has the unpleasant side-effect of producing glare and other visual disturbances, contrary to what might have been expected.

Abnormal photosensitivity, leading to the production of epileptic discharges in the E.E.G. and even myoclonic jerks, occasionally occurs in subjects who have never had any spontaneous epileptic attacks of any sort. Some hysterics, schizophrenics, and children with behaviour problems, for example, will give myoclonic jerks with photic stimulation (and no metrazol). Anticonvulsants are usually beneficial only to patients with spontaneous epileptic attacks: rarely, for example, will a pure behaviour disorder occurring in a photosensitive child respond to anticonvulsants. As these authors remark, neither their clinical studies nor current neurophysiological research gave unequivocal evidence of the pathways responsible for the abnormal spread of impulses from the visual to the motor systems. Gastaut and Hunter's experiments³ pointed to a sub-cortical, possibly thalamic "leak" (a view supported by Williams's observations⁷ on thalamic activity in spontaneous petit mal), but recent studies⁸ have indicated the pre-tectal region. The mechanism certainly appears different in pathway and function from the normal non-specific arousal responses obtainable from the reticular substance of the central grey matter. The solution of this problem may shed light on many neuropsychiatric disorders apparently far beyond the borderlands of epilepsy.

DANGERS OF EFOCAINE

Last year Iason and Shaftel¹ described the use of a solution known as "efocaine" for producing long-lasting local analgesia in the neighbourhood of operation wounds. They obtained favourable results in 100 cases. Efocaine contains procaine as base 1%, procaine hydrochloride 0.25%, butyl-*p*-aminobenzoate 5%, in a solvent composed of 2% polyethylene glycol, 78% propylene glycol, and water. When injected near the incision they found that efocaine produced analgesia for a period which varied from six to eighteen days as determined by the response to pricking the skin. Iason and Shaftel state that "when efocaine is injected into the tissue, the contact with the body fluid causes a deposition of the active ingredients producing anaesthetic depot." To obtain by this means more or less complete absence of pain around the incision is a notable achievement, and there have been several papers from surgeons giving favourable accounts of the use of efocaine. It has been used to relieve the

pain of fissure- and fistula-in-ano, to control the pain after removal of haemorrhoids, and to relieve pruritus ani; for caesarean section, episiotomy, and hysterectomy; for hernia, cholecystectomy, and gastrectomy. When it has been used it is stated that much less morphine, codeine, and pethidine have been required, but in many places these drugs are given as a post-operative routine, sometimes perhaps when not required. In this country Roualle² obtained a good result in eight and a fair result in three out of fourteen patients. He pointed out that to be effective the efocaine should be deposited close to the nerves supplying the area, and therefore he recommended a nerve block in preference to local infiltration.

More recently there have been accounts^{3, 4, 5} of some disadvantages of efocaine. After its use there have been perirectal sloughs, unilateral anhidrosis, severe neuralgia persisting for weeks, neuritis, prolonged motor paralysis of the legs, and atonic bladders. Finally, Angerer, Su, and Head⁶ have described a death which was clearly due to efocaine, when it was used to produce an intercostal nerve block. During the injection, when 1.5 ml. of efocaine had been given, the patient complained of severe pain in his back and radiating down both legs. He collapsed and died forty-four hours later. At necropsy there was acute thrombophlebitis of the 8th intercostal vein, and focal necrosis and acute inflammation of the spinal cord. The spinal fluid gave a positive test for procaine. The authors conclude that efocaine, "since it may produce myelitis and even death, should not be used for local anaesthesia, especially in a region near a vital organ such as the spinal cord."

The substances present in efocaine taken separately are not toxic, though butyl-*p*-aminobenzoate is a substance with a structure not wholly unlike that of butyn, which is a toxic anaesthetic. However, when present together in efocaine they may clearly damage both vascular and nervous tissue, with serious consequences in some patients, the changes being probably due to one or other of the solvents. Mannheimer and his colleagues⁷ have recently reported that perineural injections of efocaine in animals caused coagulation necrosis of the nerve fibres, and that the propyleneglycol and polyethylene glycol mixture (solvent for efocaine) alone and mixed with 5% butyl-*p*-aminobenzoate caused muscle and nerve changes identical to the changes caused by efocaine. This evidence also prompts the inquiry how far it is good physiological practice to seek to produce prolonged local analgesia in the neighbourhood of a healing wound. Are there grounds for supposing that the impulses arising in the sensory nerves carry out no useful or important function? Certainly the deposition of a large amount of foreign matter cannot evoke the normal tissue reaction in an anaesthetized area, and it is not surprising to learn of untoward results following this practice.

CLINICAL PATHOLOGY IN GENERAL PRACTICE

LIVER-FUNCTION TESTS

BY

N. F. MACLAGAN, M.D., D.Sc., F.R.C.P., F.R.I.C.

Professor of Chemical Pathology in the University of London at Westminster Medical School; Chemical Pathologist, Westminster Hospital

In view of the very large number of liver-function tests which have been elaborated, the present discussion is limited to a few tests of established value. These tests can be divided into two groups according to the nature of the material required. Tests in the first group can be performed on material collected by the practitioner, whereas those in the second group require the attendance of the patient at a laboratory or hospital centre or, alternatively, a personal visit by the pathologist. Tests performed on material submitted by the practitioner include serum bilirubin, serum alkaline phosphatase, flocculation tests, serum albumin and globulin estimations, and qualitative urine tests for bile pigments. More elaborate tests are the quantitative estimation of urine bile pigments, bromsulphthalein retention, and prothrombin response to vitamin K.

The blood tests in the first group require the collection of approximately 10 ml. of clotted blood reasonably free from haemolysis. To achieve this it is necessary to use a dry sterilized syringe and to remove the needle before squirting the blood gently into the dry collection tube. Urine can be naturally voided and should preferably be an afternoon specimen, since the amount of urobilinogen, for example, is small in morning specimens. It is, in general, inadvisable to rely upon any one test of liver function, and a "battery" of tests is usually employed. This need not necessarily include all the tests mentioned, and some guidance on the choice of tests is given below.

The various tests are considered individually in relation to their usefulness in the diagnosis of liver diseases.

Serum Bilirubin

It is difficult to avoid discussion of technique in this test, as so many different methods have been used since the pioneer work of van den Bergh. I prefer a separate estimation of "direct" and "indirect" serum bilirubin by a photoelectric method based on that of Malloy and Evelyn. With this technique direct pigment refers to colour developed in aqueous solution after 15 minutes, while the total pigment is read in alcoholic solution at 30 minutes. The indirect pigment represents the difference between the two values. Terms such as direct, indirect, and biphasic reaction are also used, but they are difficult to define quantitatively.

The normal total serum bilirubin is from 0 to 1 mg. per 100 ml. of serum, and a zone of latent jaundice not clinically detectable exists between 1 to 3 mg. per 100 ml., patients with values over 3 mg. being usually clinically jaundiced. The demonstration of latent jaundice is an important aid to diagnosis in conditions such as infective hepatitis, hepatic cirrhosis, and the haemolytic anaemias. In jaundiced patients both the direct and the indirect bilirubin will increase, but if more than half the total is indirect the jaundice is probably haemolytic in nature. Jaundice due mainly to increase in direct pigment is usually either obstructive or toxic and infective.

The serum bilirubin estimation is an important basic procedure as it provides an accurate record of the intensity

of any jaundice which may be present. It may nevertheless give normal results in certain cases of chronic liver disease such as cirrhosis, carcinomatosis, etc.

Serum Alkaline Phosphatase

The serum alkaline phosphatase is an enzyme produced mainly in the bones by the osteoblasts but also by the liver cells. It can therefore only be used as a liver-function test in cases in which the bones can be assumed to be normal. Its level in the blood (normal 3 to 13 King-Armstrong units) is elevated in a variety of liver conditions such as obstructive jaundice, hepatitis, carcinomatosis, abscess, amyloidosis, and cirrhosis. It is, however, on the whole much higher in obstructive jaundice than in the other conditions named, and values over 35 units, for example, are particularly suggestive of obstruction as opposed to hepatitis in a jaundiced patient. In the differential diagnosis of jaundice it is particularly valuable to combine this test with one or more of the flocculation tests.

Flocculation Tests

Under this heading are included a rather large number of empirical procedures which have been used to demonstrate hepatic dysfunction, ranging from the earlier formol-gel and Takata-Ara reactions to more recent tests such as the serum colloidal gold reaction and the thymol turbidity and flocculation tests. There are, however, considerable individual differences in these various tests, and the following remarks apply mainly to the thymol and gold tests.

These tests are positive, particularly in acute infective hepatitis (about 90%) and in cirrhosis (about 50%), and have a special tendency to be negative in obstructive jaundice. They are therefore of value in the detection of hepatitis and in the differential diagnosis of jaundice. It should always be remembered that they are not specific tests of liver damage, as they depend upon a particular type of serum protein disturbance which may also occur in various acute and chronic infections such as glandular fever, malaria, infective endocarditis, etc. The necessity of interpreting all laboratory procedures with due regard to the whole clinical picture applies particularly to these tests.

Serum Albumin and Globulin Estimations

These tests are of most value in the more chronic types of liver disease such as cirrhosis. In cirrhosis the albumin (normal 4 to 5.5 g. per 100 ml.) tends to fall and the globulin (normal 1.5 to 3 g. per 100 ml.) to rise. Alternatively, one may say that the albumin/globulin ratio (A/G ratio) (normally about 2:1) tends to fall in liver disease, but as changes in the two fractions are largely independent of one another it is preferable to consider the values individually. Neither change is an entirely specific indication of liver damage, but if both alterations are present hepatic disease is the most likely explanation.

These tests are of value in confirming a diagnosis of cirrhosis. From the prognostic point of view the albumin is the more important estimation, values below 2 g. per 100 ml. indicating a poor prognosis, and usually being associated with an obstinate oedema. High globulin values, on the other hand, are compatible with good health and do not usually produce symptoms. These estimations, based on

salting-out procedures, are to some extent becoming replaced by electrophoretic analysis of the serum proteins. However, this procedure is not available in all laboratory centres and rules for the interpretation of results are not yet so firmly established.

Qualitative Urine Tests for Bile

The ordinary clinical tests for bile such as the foam and iodine tests are, of course, very insensitive. The following remarks refer to tests such as the Harrison-Fouchet test for bilirubin and the Ehrlich-Watson test for urobilinogen. These tests reach their maximum usefulness in patients who are not clinically jaundiced. In such cases the occurrence of bilirubinuria suggests a latent jaundice usually due to hepatitis or to biliary obstruction, and this test may be positive some days before a rise in the serum bilirubin can be demonstrated. The test is therefore particularly valuable in the pre-icteric phase of infective hepatitis and in hepatic cirrhosis.

An increase in urine urobilinogen may accompany bilirubinuria but may also occur without any latent jaundice in chronic liver damage such as hepatic cirrhosis. It is a less specific indication of liver pathology than bilirubinuria and may occur as a temporary event in febrile states. Urobilinuria may also occur in jaundiced patients but is of limited diagnostic value in this group; on the whole, increased values are suggestive of toxic and infective jaundice, but there are many exceptions to this rule.

Quantitative Estimation of Urine Bile Pigments

As noted above, the urinary excretion of urobilinogen is increased as a result of liver damage, and this increase is best demonstrated by a quantitative estimation. Urobilinogen is formed mainly by the bacterial decomposition of bilirubin in the intestinal tract. It is partially reabsorbed from there into the blood stream and is partly re-excreted by the liver in the bile. It follows from this that urine for this test should not be collected in the morning, when the effects of bile flow will be minimal, and also that the investigation is of greatest value in patients not clinically jaundiced. In the absence of jaundice it can be assumed that bile is reaching the intestine, whereas in the presence of jaundice this may not be the case.

Although this examination can be carried out on 24-hour urine specimens it is more convenient to collect a timed specimen of urine in the afternoon and to estimate the amount of pigment in a one- or two-hour specimen by the methods of Watson. Normal values for urobilinogen are from 0 to 1 Ehrlich unit per 2 hours or up to 3 mg. per 24 hours.

The interpretation of this estimation is very similar to that given for the qualitative urobilinogen test above, but the procedure is more accurate and reliable. The test is of particular value in non-jaundiced cases of hepatitis and cirrhosis.

Bromsulphthalein Retention

Bromsulphthalein (phenoltetrabromphthalein disodium sulphonate) is a harmless dye which is injected intravenously and is excreted mainly in the bile. The recommended dosage is 5 mg. per kg. body weight and blood is collected exactly 45 minutes after injection. The amount of bromsulphthalein remaining in the serum is estimated. Normal subjects will show no significant bromsulphthalein retention at 45 minutes, and in pathological states the amount remaining in the circulation at this time is expressed as a percentage of the injected dose to give a figure of percentage bromsulphthalein retention.

Like the preceding test this is of little value in jaundiced subjects and is mainly used in non-jaundiced subjects and in cases of hepatitis and cirrhosis. It is a sensitive and convenient test in cases of this type, although even this test is not invariably positive in cirrhosis. It will also indicate the existence of liver dysfunction in other conditions, such as malaria, diabetes mellitus, glandular fever, etc.

Prothrombin Response to Vitamin K

This test has been used mainly in cases of obstructive jaundice but is also of value in the differentiation between surgical and non-surgical jaundice. It is, of course, applicable only to those patients who have low prothrombin values when first seen. This may happen either because the exclusion of the bile from the intestine interferes with the absorption of vitamin K (obstructive jaundice) or because the liver is too severely damaged to manufacture vitamin K from its plasma precursors (hepatitis or cirrhosis). About a quarter of all jaundiced subjects may be expected to exhibit an initial deficiency in prothrombin and therefore become eligible for this test.

After the initial estimation vitamin K is administered, usually as 50-100 mg. of a water-soluble preparation, and the prothrombin is again estimated after 24 to 48 hours. A rapid return towards normal indicates good liver function and confirms the diagnosis of biliary obstruction. An absence of response indicates gross liver damage and suggests a hepatogenous origin for the jaundice. In practice the first part of this test is often omitted; a low prothrombin value after adequate vitamin-K therapy is, of course, significant even in the absence of the preliminary observation.

Quite apart from its value in diagnosis the test is of great importance if operation is contemplated, as a low plasma prothrombin value indicates a greatly increased risk of haemorrhage.

Combination of Tests

Certain tests are particularly suitable for use in combination, and this applies especially to the serum alkaline phosphatase estimation and the thymol flocculation test in relation to the differential diagnosis of jaundice. The individual variations in these two tests have already been discussed, but the accuracy of diagnosis is improved when they are undertaken simultaneously. Thus cases of jaundice with negative thymol tests and serum alkaline phosphatase values above 35 units are almost invariably obstructive in nature, whereas those with strongly positive flocculation tests and/or with normal serum alkaline phosphatase levels are usually non-obstructive. In some 20% of cases the findings fall between these two extremes and are of no diagnostic value.

Indications for Liver-function Tests

Laboratory procedures in general can only be used to answer certain restricted types of question, and it is important to have a clear idea of exactly what the provisional diagnosis is before any help can be expected from tests of this type. Most of the indications for the tests will fall under one or more of the following heads:

In suspected primary liver disease the condition may be either acute or chronic in nature—for example, infective hepatitis or hepatic cirrhosis. Any of the tests described may assist in making the diagnosis, their relative importance varying, however, with the type of case. In pre-icteric hepatitis the first tests to become positive are those for urine bile pigments, particularly bilirubin. At a later stage all the pigmentary tests will be positive and usually the flocculation tests in addition. In hepatic cirrhosis, on the other hand, the pigmentary tests and many of the others may be at times completely negative and more reliance is placed upon the serum protein estimations and the bromsulphthalein retention.

The liver may be secondarily involved in a variety of diseases. In heart failure, for example, the turbidity and flocculation tests are often positive and urobilinuria may occur. In malaria and glandular fever the positive flocculation tests constitute the most frequent abnormality, while in thyrotoxicosis the disturbance is of a different type and may require the use of tests such as a galactose-tolerance test and a hippuric-acid test, which are not especially valuable for general diagnostic purposes.

The differential diagnosis of hepatic enlargement tends to be concerned mainly with the problem of distinguishing hepatic cirrhosis from carcinomatosis. The biochemical changes are usually distinctly different in the two groups, the serum protein and flocculation tests being mainly altered in cirrhosis while the raised serum alkaline phosphatase is the main change in carcinomatosis.

In the differential diagnosis of jaundice we are usually trying to distinguish jaundice due to a mechanical obstruction of the bile passages from that due to hepatitis or cirrhosis. As noted above, the thymol flocculation test and serum alkaline phosphatase used in combination give the best results in cases of this type, making the distinction satisfactorily in about 80% of such cases, the results being equivocal in the remaining 20%. Some assistance can also be given in the detection of haemolytic jaundice in which the indirect serum bilirubin is more raised than the direct pigment, and the serum alkaline phosphatase tends to be normal.

The tests principally used in the prognosis of liver diseases are the serum albumin estimation and the prothrombin response to vitamin K. In cirrhosis values for the serum albumin below 2 g. per 100 ml. indicate an irrecoverable liver damage with a poor prognosis. In obstructive jaundice failure of a low prothrombin level to respond to vitamin-K therapy suggests grave liver damage and a poor operative risk.

The investigation of anaemias is, of course, the province of the haematologist, but the differential serum bilirubin estimation may assist in the detection of haemolysis, in which the indirect pigment is mainly increased. This finding has been found valuable in the diagnosis not only of the various haemolytic anaemias but also in cases of pernicious anaemia.

Choice of Test

As mentioned above, it is usually desirable to combine several different tests, and the following scheme may be taken as a guide.

Tests for Routine Application.—Serum bilirubin, serum alkaline phosphatase, flocculation tests, qualitative urine tests for bilirubin and urobilinogen: this small battery of tests will often give all the information required, at all events from a diagnostic standpoint. They will establish the absence or presence of jaundice, and if jaundice is present they will provide a record of its intensity and will also give a good indication of its probable cause. In the non-jaundiced patient, on the other hand, one or more of the tests may be positive and provide enough evidence to confirm a suggested diagnosis of hepatic disease.

Further Tests.—If the above tests are negative or if their indications are in any way equivocal the remaining tests mentioned may be undertaken in the following order of preference: serum albumin and globulin estimations, quantitative estimation of urine bile pigments, bromsulphthalein retention, prothrombin response to vitamin K. It will usually be unnecessary to do more than one or two of these additional tests in order to support, for example, a diagnosis of liver cirrhosis, but the vitamin-K test is specifically indicated in surgical jaundice.

Conclusion

In conclusion it may be emphasized that modern liver-function tests reach a high degree of sensitivity and will rarely fail to demonstrate any significant liver damage which may be present. This implies that the disturbances of function occurring in various non-hepatic diseases may complicate interpretation, which should always be undertaken with due regard to the whole clinical picture.

Reports of Societies

CONVULSIONS IN CHILDHOOD

The Section of Paediatrics of the Royal Society of Medicine met under the chairmanship of Dr. C. T. Potter on March 26 to discuss "The Significance of Convulsions in Infancy and Childhood."

Dr. PETER TIZARD (Paediatric Unit, St. Mary's Hospital, Paddington) opened with a general review of the aetiology of convulsions. Most textbooks divided fits into the symptomatic—those caused by fever, cerebral tumour, brain injury, etc.—and the idiopathic, which included infantile convulsions, pyknolepsy, and true epilepsy. Was this sort of division justifiable? With regard to symptomatic convulsions, we did not know the effective cause, in the Aristotelian sense, of any fit. Clearly fever, for example, in itself could not be regarded as a cause. Were it so any individual would have a fit whenever his temperature reached a certain critical height, whereas in fact that happened only with an extremely small minority of children. Similarly, a focal lesion, such as a cerebral tumour or brain injury, could not in itself be the cause of a fit; if it were, the patient would convulse continuously and not intermittently.

Probably, in the production of any one fit there were several causative factors. This view led to the concept of a "convulsive threshold," to the idea that there was no fundamental difference between the epileptic and the non-epileptic, and that any person given an adequate stimulus would have a fit. The nature and degree of stimulus would vary widely, of course; at one end of the scale were those who would convulse only in response to a severe electric shock or an injection of insulin, while at the other end the threshold was so low that fits seemed to occur spontaneously. Between these two extremes were those who developed fits in response to such precipitating factors as fever or brain injury.

This view, that we are all potential epileptics but have varying degrees of natural resistance, provided a useful method of approach to the parent of a child who had fits. It took away much of the sting that goes with a diagnosis of epilepsy. Useful though it was, however, it represented an over-simplification of the problem. There was no evidence of hereditary predisposition in some forms of symptomatic epilepsy. In conclusion, Dr. Tizard discussed the possibility that included in what we now call idiopathic epilepsy there were several different diseases of unknown aetiology and pathology, of which the main symptom was the occurrence of fits.

The First Fit

Dr. CHRISTOPHER OUNSTED (Research Assistant to the Oxford Regional Hospital Board) spoke about the "First Fit." Its significance in a young child depended on the setting in which it occurred. In severe infections multiple fits were common and were of grave prognostic significance. Prolonged fits and status epilepticus were fatal *per se*. Dr. Ounsted gave figures showing that a sharp reduction in the mortality of purulent meningitis, and a parallel reduction in the incidence of fits, could be achieved by giving prophylactic anticonvulsants to affected children. Established convulsions should be aborted as rapidly as possible; phenobarbitone and chloral were valueless once a fit had begun, but sodium amyllobarbitone given intramuscularly in doses from 0.125 to 0.25 g. controlled convulsions rapidly and safely.

After a single fit the regular use of anticonvulsants was not necessary, but the child should be given prophylactic phenobarbitone during any future febrile illness up to the age of 4 years. This measure seemed to be effective in preventing fits, and the mothers were comforted by having some practical steps offered to them.

The relationship between infantile convulsions and adult epilepsy was not known, and studies made by different workers had given conflicting results. The paediatrician's problem was to give a prognosis at the time of the first fit. Various prognostic criteria had been proposed; in particular much weight had been given to electro-encephalographic abnormalities and to a family history of epilepsy. Neither of these criteria was a reliable guide. Study of 800 family trees of children with convulsive disorders had shown that benign convulsions and intractable epilepsies were often found in the same family. The E.E.G. was not a prognostic instrument in childhood. Records made on young children were often inscrutable.

E.E.G. Studies

Dr. W. A. COBB (Department of Applied Electrophysiology, National Hospital, Queen Square) gave an account of the contribution of electro-encephalography to the study of fits. The characteristic 3-cycle per second spike-and-wave tracing of petit mal remained a problem. Though it was always present, he thought, in petit mal, it might also occur in subjects with other types of fit, or rarely in subjects who were not suffering from any form of fit. Several tracings were shown in which, in addition to the usual spike-and-wave episodes, there was an occipital delta rhythm with bilateral foci in the occipito-temporal regions. Evidence was accumulating to suggest that this combination might provide a means of recognizing a certain type of epilepsy in children, a type hard to treat successfully but with nevertheless an excellent ultimate prognosis. The existence of such a group of cases with electro-encephalographic diagnostic criteria might perhaps justify a revival of the old term of pyknopsia.

Post-mortem Appearances

Dr. L. CROME (Fountain Hospital) gave an account (illustrated by slides) of the morbid anatomical findings in a series of 61 epileptics from an institution devoted to low-grade defectives. Gross structural abnormalities, affecting chiefly the cerebral cortex, were found in all these cases, and his material afforded no support for the existence of idiopathic epilepsy.

It was difficult to be sure to what extent comparison was justifiable with normally intelligent patients with fits, but it seemed possible that processes in the group with severely deranged brains were often greatly magnified reproductions of similar events occurring in more normal individuals.

Discussion

Dr. T. STAPLETON wondered whether there might not be some danger of adding to anoxia if phenobarbitone were given as a routine in cases of bronchopneumonia in small children. Dr. OUNSTED replied that he felt sure that there was no danger of this in the small dosage used.

Dr. R. M. MAYON-WHITE asked to what extent intrathecal therapy was related to the incidence of fits in purulent meningitis, and Dr. OUNSTED said that no correlation had been observed at Oxford.

Dr. E. S. STERN mentioned that Dr. Gillman had shown that barbiturate poisoning could be successfully treated with picrotoxin even in advanced cases, and that 1 g. of sodium hexobarbitone intramuscularly was an effective treatment for status epilepticus in adults.

Dr. HUGH ELLIS and others, including the CHAIRMAN and Dr. OUNSTED, commented on a pamphlet* recently issued by the Ministry of Health in which it was suggested that cases of fits should be notified to the school medical officer as soon as possible after the age of 2 years. It was generally agreed that this would be most inadvisable, as one or more convulsions at this age might have no prognostic significance whatever.

*Ministry of Health Circular No. 26/53, December, 1953—Welfare of Handicapped Persons. The Special Welfare Needs of Epileptics and Spastics.

There was little time for discussion after the four opening papers, which, as is usually the case, considerably exceeded their allotted time. This was a pity, especially as the subject of the meeting was of general medical interest. There might be something to be said for a compromise between this sort of meeting, which, valuable as it may be, is certainly not a discussion, and the sort of channelled and controlled—and sometimes artificial—discussion with which the B.B.C. has made us familiar.

LOCAL MEDICAL SOCIETIES

Liverpool Medical Institution

Speaking at a meeting on March 18, Sir Reginald Watson-Jones stressed the need for a clearer conception of what constituted a minor injury. Many finger injuries, hitherto regarded as minor, were in fact major and responsible for men being off work for long periods at a time. A simple strained ankle might turn out to have a recurrent subluxation associated with a displaced astragalus, and a badly handled shoulder dislocation might be the start of a recurrent dislocation. On the other hand, fracture-dislocation of the pelvis, commonly regarded as a major injury, usually gave rise to little trouble if properly managed. At the beginning of the meeting Dr. Henry G. Carlisle and Dr. G. F. Rawdon Smith were admitted, with acclamation, to life membership of the institution.

Preparations and Appliances

STORAGE CABINET FOR ENDOTRACHEAL TUBES

Dr. M. J. HARKER, consultant anaesthetist, Shrewsbury Group Hospital Management Committee, writes: I find the cabinet illustrated a very useful and time-saving adjunct to the anaesthetic department. It was devised by the theatre sister (Sister K. Wilks) and made by the carpenter (Mr. W. H. Edwards) at Copthorne Hospital, Shrewsbury. It is simple in construction, it facilitates the instant selection of any size or type of tube, and the tubes are kept at their correct curve by the kidney-shaped blocks. The cabinet fits conveniently under the ordinary dressing trolley, such as is used for the intravenous tray in the anaesthetic room. The top drawer, 8½ by 2½ in. (22.5 by 6.4 cm.), has a division in the centre and is used for airways and connexions. The second, third, and fourth drawers, of the same dimensions, have central kidney-shaped blocks ½ by 1½ by 2½ in. (1.9 by 3.8 by 6.4 cm.). There are two side pieces 8½ in. (21.6 cm.) long, to narrow the width of the drawer for the smaller tubes. The second drawer houses cuffed tubes, the third drawer nasal tubes, and the bottom drawer oral tubes.

There are two side pieces 8½ in. (21.6 cm.) long, to narrow the width of the drawer for the smaller tubes. The second drawer houses cuffed tubes, the third drawer nasal tubes, and the bottom drawer oral tubes.

Because of the present high cost of producing the Journal, and the great pressure on our space, correspondents are asked to keep their letters short.

Action of Chlorpromazine and Promethazine

SIR.—On April 2 a discussion took place at the Royal Society of Medicine on the action of chlorpromazine and promethazine. In practical anaesthesia these two substances are used together with pethidine. In the discussion it became clear that anaesthetists are not much interested in the fall of temperature which chlorpromazine produces, and that these substances are used together for their peculiar anaesthetic action.

Since from the pharmacological evidence there is not very much to choose between these substances so far as their central action is concerned, would it not be possible for observations to be made in patients using only one substance at a time? It would be of great value to know whether a dose of 200 mg. chlorpromazine given alone would have different effects from 200 mg. promethazine given alone, or from 200 mg. pethidine given alone. It would be important that the observations on the effect of these substances should be made by somebody who did not know which of the compounds had been administered, in order to exclude preconceptions in making the comparison.—I am, etc.,

Oxford.

J. H. BURN.

Hibernation Anaesthesia

SIR.—Drs. Angus Smith and J. G. Fairer (*Journal*, March 27, p. 759) suggest that the case of "prolonged hypotension following hibernation anaesthesia" described by us (*Journal*, March 13, p. 645) was in fact due to surgical shock, the result of inadequate anaesthesia. In reply we would like to make the following points.

(1) The patient was a small—120 lb. (54.4 kg.)—frail, elderly woman. In accordance with usual pharmacological practice we considered that a reduction in dosage, in relation to age and body weight, was indicated. (2) The dosage of the "potentiating mixture" given (chlorpromazine 12½ mg., promethazine 12½ mg., pethidine 25 mg.) produced the usual picture obtained after its exhibition in the doses recommended by Smith and Fairer—loss of consciousness, slight hypotension, initial rise in pulse rate, lack of response to painful stimuli, ease of intubation without muscle relaxants. (3) At no time during the operation were there any signs of inadequate anaesthesia. The blood pressure levelled off at 80/45 mm. Hg; the pulse rate remained steady at 120/minute (pre-operative level 100/minute); there were no voluntary movements, no sweating, and no lacrimation. The "aliquot mixture of nitrous oxide and oxygen" would appear to have been sufficient for adequate anaesthesia, its effect presumably being potentiated by the "lytic cocktail." The indications for supplementary doses of "lytic cocktail" are a rise in pulse rate and/or blood pressure, neither of which occurred during the operation on our case. (4) Our "hibernation anaesthetic" cases hitherto had awakened some 4–5 hours after the start of the hibernation, by which time the blood pressure was nearly at pre-operative levels. After the elapse of nearly four hours the case reported was still deeply unconscious and not reacting to deep painful stimulation. The usual picture of post-operative shock was absent (hypotension, hypothermia, clammy skin, cyanotic lips and nail-beds, rise in pulse rate, intense peripheral vasoconstriction). Although there was profound hypotension (50/20 mm. Hg) and hypothermia, the skin was quite dry, the lips and nail-beds were pink, the pulse rate was still 120/minute. We also feel that inadequate anaesthesia would have been accompanied by evidence of returning consciousness. (5) Chlorpromazine, according to Courvoisier *et al.*, diminishes, abolishes, or reverses the hypertensive effects of

an intravenous injection of adrenaline, but in the same doses and conditions only diminishes the hypertensive effects of noradrenaline and even in high doses does not reverse the hypertensive effects of noradrenaline. (In view of our experience with this case under discussion, one of us has given 0.05 mg. noradrenaline intravenously to a patient whose blood pressure was 70/40 mm. Hg (170/90 mm. Hg pre-operatively) 40 minutes after the exhibition of a mixture containing chlorpromazine 50 mg., promethazine 50 mg., pethidine 100 mg. The blood pressure was raised immediately to 130/70 mm. Hg.)

We feel satisfied that the case under discussion was not suffering from traumatic shock, but appeared to be suffering from a continuing effect of the modified dose of the "lytic cocktail." Although similar results have not occurred in our other cases and have not been reported elsewhere, we felt justified in describing our experience and the method used to produce a favourable outcome.—We are, etc.,

Carbon Dioxide Retention Simulating Curarization

SIR.—In your issue of March 6 (p. 565) Dr. C. V. Scurr recorded a case of "Carbon Dioxide Retention Simulating Curarization." In the *Journal* of April 3 (p. 820) Drs. T. C. Gray and E. S. N. Fenton report on a similar condition in one of their patients. To my mind, however, there is very little similarity between the two, and I do not think that the latter can be considered as offering confirmatory evidence of CO₂ retention as such.

In the case cited by Dr. Scurr, no periods of anoxia were recorded, and post-operatively "it was noted that such respiratory effort as was present was not marked by any urgency, neither was it accompanied by any tracheal tug, both of which features are usually present in cases of residual curarization." In Drs. Gray and Fenton's case, on the other hand, several periods of anoxia were admittedly experienced by the patient on each occasion, particularly on the second. Due to the pre-operative cardiac condition, it is more than likely that this anoxia was tolerated very poorly. At the conclusion of the second operation, "in view of the increasing cyanosis and distress, and loss of consciousness, an endotracheal tube was introduced." Surely this was gross anoxia. They then go on to state that the striking features of the patient on this occasion were "(1) inadequacy of the tidal exchange compared with the forceful chest movements and tracheal tug . . . , and (2) the bounding forceful pulse." Dr. Scurr attributes the features in (1) above to residual curarization, and not to CO₂ retention.

In view of the evidence, I venture to suggest that on both occasions Drs. Gray and Fenton's patient was suffering from the combined effects of O₂ lack and CO₂ excess—in other words, asphyxia. It is also very probable that there was some degree of residual curarization.—I am, etc.,

Beckenham.

P. M. F. MCGARRY.

Failed Forceps

SIR.—I was very interested to read Dr. R. Lisle Gadd's article on failed forceps (*Journal*, March 27, p. 735), which is a valuable contribution to the literature on one of the most serious complications that can befall a woman in labour. His article concludes that incomplete dilatation of the cervix (39%) is the main cause for failure, whereas in the Birmingham series occipito-posterior positions and deep transverse arrest of the head accounted for 56% of cases and incomplete dilatation of the cervix 20%.¹ Malposition of the foetal head was also 2½ times more common than undilated cervix in the Norwich series,² which has not been referred to by Dr. Gadd.

In the Manchester series only six out of 39 cases classified as incomplete cervical dilatation subsequently had a normal delivery, and only a further six had a low forceps delivery. This suggests that malposition of the foetal head, or some mechanical factor other than the failure of the cervix to dilate, was the main reason why the forceps failed. In Dr. Gadd's series incomplete cervical dilatation with occipito-posterior positions has been classified under the former category, whereas in my series and Mr. Law's we would have classified some of these cases under occipito-posterior positions or deep transverse arrest.

I have observed that in some cases of occipito-posterior position the anterior lip of the cervix becomes trapped between the head and the symphysis pubis, with the result that this cervical rim becomes oedematous and will never fully disappear unless the head is disimpacted and the cervix pushed up. This cervical lip, however, is no bar to a forceps delivery, provided manual rotation to occipito-anterior has been accomplished, and it is the malposition of the foetal head rather than the cervix that has led to the failed forceps.—I am, etc.,

Crewe.

Anaesthesia in Hospital Breech Delivery

SIR,—In his letter on the above subject (*Journal*, March 27, p. 758) Dr. D. C. Drutt asks for the reasons for advocating the use of the forceps on the aftercoming head. These reasons were very well stated by Baxter¹ a few years ago. In brief, his conclusions were that the maximum safe limit of traction on the shoulders is considerably less than the expulsive force of the uterus, so that, "when the patient is unable to expel the head by a spontaneous effort of normal magnitude, shoulder traction is unlikely to deliver a live infant." On the other hand, when forceps are used a very much greater traction is possible without any risk to the baby, provided that they are accurately applied to the sides of the aftercoming head. These views are based on good clinical and experimental evidence. There is also the less well-founded view that the blades of the forceps act as splints to the foetal head, and prevent dangerous fluctuations in shape and pressure at the moment of delivery.

The use of forceps on the aftercoming head is one of Smellie's greatest contributions to the art of obstetrics. His name is often erroneously associated with Mauriceau's technique of jaw flexion and shoulder traction, which was also the method used in this country by Giffard as early as 1725.² It is interesting to see how Smellie's teaching is receiving due recognition now after the lapse of two centuries, during which it was generally neglected.—I am, etc.,

Wivenhoe, Essex.

Considered Contraception

SIR,—May I be allowed to support Professor H. C. McLaren's letter on this subject (*Journal*, April 3, p. 817)? I would say that it is almost never justifiable to tell a patient that she must not have another pregnancy, and it should be done only when the adverse factor is permanent. In these circumstances it is my practice to offer bilateral partial salpingectomy as an alternative to contraceptive advice. The risk of abdominal operation is not unduly great.

As Professor McLaren says, the banning of further pregnancy to a young woman is a most serious matter, and advice on the subject should never be lightly given. Not only must her physical state be considered, but also her psyche. A woman who longs for children is often better undertaking a pregnancy at some extra risk rather than being condemned to perpetual sterility.—I am, etc.,

Leeds, 2.

ANDREW M. CLAYE.

Appointment with Fear

SIR,—Half the patients I have ever treated smoke like chimneys. Whatever else happens to them, they don't die of cancer of the mouth. What are we coming to? We mustn't smoke for fear of getting respiratory cancer of some sort. The stuff we inhale makes breathing a dangerous procedure. The poisons we consume in our food are sure to kill us soon, and of course we may even die in our sleep. In addition, the mental state induced by these hazards is sure to hasten the inevitable attack of coronary thrombosis or peptic ulcer. It seems that the way of living to a reasonable old age is to become a High Court judge, diet rigidly, give up smoking, and move to a rural area (there would also be less chance of getting run over on a farm).

Isn't it about time that we gave both our patients and ourselves a proper sense of proportion before we develop into a nation of anxious hypochondriacs? We haven't yet caught up on our American friends (if their magazine advertisements are anything to go by), but we'd better do something about it soon. Let us help our patients to live—and die—without the dread picture of disease for ever in their thoughts; and let us refrain from giving the lay press so much ammunition to use in their quasi-medical fear-stimulating extracts. Finally, the only cause of cancer of the mouth I have treated in 16 years of medical practice was in an old lady with no bad habits. She didn't even smoke.—I am, etc.,

London, E.9.

PAUL R. SAVILLE.

Abdominal Testicles and Fertility

SIR,—The gonadotrophic hormone in small boys causes precocious secondary sexual changes. Since the day 25 years ago when I was first shocked by the sight of a group of youngsters receiving this (as I think) unfortunate form of treatment, I have taught that it is unjustifiable except in the case of gross hypopituitarism—a subject for the endocrinologist.

This is only the expression of an opinion, but I agree with Dr. Nicholas S. Craig (*Journal*, March 20, p. 706), Denis Browne, Great Ormond Street, and the Boston Children's Hospital, or, if Dr. G. I. M. Swyer (*Journal*, April 3, p. 815) prefers it so, they agree with me. My reason for writing is to draw attention to the serious physical and psychological side effects apart from which the suggested and too often practised therapeutic test might be attractive.—I am, etc.,

Liverpool, 7.

CHARLES WELLS.

Fructose in Diabetes Mellitus

SIR,—In the *Journal* of February 27 (p. 510) you have published an annotation on "Fructose in Diabetes Mellitus." Since some of its implications might be misunderstood and lead to unnecessary and indeed dangerous experimentation, I would beg your permission to comment.

The annotation, as well as some of the original publications cited, clearly imply that most tissues of normal and diabetic animals can and do utilize significant amounts of fructose. By "utilize" I mean "metabolize in such a way as to derive some useful energy from it." It is, however, quite likely that in the mammalian organism, and in the presence of even small amounts of glucose, fructose is utilized almost exclusively by the liver and, to a lesser degree, by intestinal mucosa. Thus Bollman and Mann¹ have shown in 1931 that in the hepatectomized, eviscerated dog the intravenous administration of fructose results in little fructose disappearance, no slowing in the rate at which blood glucose decreases after hepatectomy, no slowing in the rate at which muscle glycogen decreases after hepatectomy, and no relief of hypoglycaemic convulsions. Gemmill² showed in 1941 that rat diaphragm cannot deposit glycogen when incubated with fructose, with or without the addition of insulin. This earlier evidence for lack of peripheral

fructose utilization has been recently confirmed conclusively by Wick and collaborators³ using fructose labelled with C¹⁴ in eviscerated rabbits.

The concept of fructose utilization by skeletal muscle has been fostered by the demonstration of muscle enzymes capable of phosphorylating and further metabolizing fructose.⁴ However, the primary product of fructose phosphorylation in both liver and muscle has been shown to be fructose-1-phosphate^{5,6,7}—that is, a metabolite which is not a regular by-product or intermediate of glycolysis. The further metabolism of fructose-1-phosphate has been shown to differ in liver and in muscle,^{8,9,10} and it might well be that in the intact muscle cell fructose-1-phosphate represents a metabolic dead end.

The presence of a normal fructose tolerance in the diabetic organism simply means that diabetic tissues utilize fructose as well (or as poorly) as normal tissues. Since in the normal neither brain cells nor muscle cells utilize a physiologically significant amount of fructose, there is no reason to believe that fructose utilization will be better in brain or muscle of the diabetic organism.

The statement that "fructose may prove to be a more useful sugar in conditions where glucose has a time-honoured place—for example, in the treatment of hypoglycaemia"—should be retracted. Hypoglycaemic convulsions occurred in the animals of Bullman and Mann as soon as blood glucose sank below the critical level, even though high blood fructose concentrations were maintained. It should be particularly kept in mind that most laboratory determinations of blood glucose also measure fructose, and that the danger of severe hypoglycaemia in the presence of what appears to be a normal or elevated "blood glucose"—that is, reducing sugar—determination is indeed a real one. The treatment of hypoglycaemia remains the time-honoured one: glucose.

In the treatment of diabetic acidosis it should be clearly understood that fructose administration in no way decreases the requirement for insulin. Fructose administration might, however, prove useful in diabetic acidosis for at least two reasons: (a) fructose represents a ready source of carbohydrate for the liver, and therefore one might expect a more rapid decrease in the excessive hepatic production of ketone bodies, (b) a larger proportion of fructose is almost immediately transformed into liver glycogen and other non-reducing metabolites (although a considerable portion, of course, is transformed into glucose); fructose might therefore be used to bring the tonicity of hypotonic salt solutions to normal, and thus facilitate their early administration without interfering quite as much as glucose with our ability to evaluate the adequacy of the blood sugar response to insulin. It remains to be seen, however, whether this will really prove of any practical value.—I am, etc.,

Boston, Mass.

Acholuric Jaundice

SIR,—I was most interested in the article by Drs. J. L. Emery and D. W. Lemmon (*Journal*, March 27, p. 737) on "Crises in Congenital Spherocytic Anaemia (Acholuric Jaundice)." I have been following the case of acholuric jaundice in a medical man, in which, when he was a student, the condition used to remain quiescent until a spell of hard physical or mental activity. The condition would invariably appear a week or so before he sat for an examination, when he would develop a pale yellow, earthy colour. Cessation of work used to lead to regression of these symptoms, which would recur at the next period of mental stress. Haematological examination revealed the typical findings of acholuric jaundice.

He has since had splenectomy, since when there has been a clinical cure, and no amount of mental or physical work produces any jaundice whatever.—I am, etc.,

London, S.W.3.

DAVID THOMAS.

Advice on Weight-lifting

SIR,—Dr. M. E. M. Herford (*Journal*, March 20, p. 703) is right to stress the importance of showing men how to lift without damaging the back. The prophylaxis of lumbar disk lesions begins, however, not after the injury, but before.

All men doing heavy work should have the mechanics of the lumbar joints explained to them and be taught how to avoid the initial damage, no less than a recurrence. He states that hospitals do not, in his experience, give this tuition. At the Department of Physical Medicine at St. Thomas's Hospital, a demonstration of the various ways of maintaining the lordosis during different types of work has been given by our physiotherapists in every relevant case for the past ten years. The first industrial body to illustrate the modern view on the prophylaxis of lumbar disk lesions¹ appears to have been the Workmen's Compensation Board of British Columbia, whose original poster is reproduced herewith.—I am, etc.,

London, W.1.

Chronic Pyelonephritis in Children

SIR,—In the past urinary infections in childhood have been treated much too lightly, and, as Drs. J. M. Stansfeld and J. K. G. Webb have shown (*Journal*, March 13, p. 616), for much too short a period. I am not convinced, however, that prolonged therapy, even using the broad-spectrum antibiotics, will prove successful, nor do I accept the arguments they use to explain why short courses of treatment so often fail.

Shortly after the war I studied a series of children of all ages who had had a proved urinary infection. The records are no longer readily available, but I recall that they comprised about 80 cases, of which over 70 were girls and almost every one had had at least two attacks. All the boys had demonstrable deformities in the renal tract. About eight of the girls, all with normal pyelograms, were liable to frequent recurrent attacks of urinary infection, and, at Dr. Charles F. Harris's suggestion, they were treated with prolonged courses of sulphonamides. The results were most disappointing and the treatment was eventually abandoned because so many of them developed staphylococcal infections whilst under treatment, whereas all the previous attacks had been due to *B. coli*. The new organism caused greater pain, dysuria, and fever, and was more difficult to eradicate than the old. Now that newer broad-spectrum antibiotics are available it is possible that prolonged therapy would be more efficacious, but clearly chloramphenicol would be too dangerous to use in this way; aureomycin might give rise to *B. pyocyaneus* infection in due course, and

hence terramycin would be the antibiotic of choice. No doubt Dr. Stanafeld is now using this drug, and his further experience will be awaited with interest.

The fact that the organism may change so readily with prolonged chemotherapy indicates a low resistance to infection in the renal tract and refutes the suggestion, made in the paper, that isolated foci of organisms, surviving in the kidney after the initial course of treatment, are responsible for the subsequent relapse.—I am, etc.,

Stock, Essex.

IAN G. WICKES.

Adolescence and the Family Doctor

SIR.—Everyone who is interested in the health of the adolescent will welcome your leading article (*Journal*, March 27, p. 748) broadening and summarizing what has been constructive in the recent discussions in the medical journals. The problems of youth are indeed "many-sided and compelling," yet it is only one side which is really stressed by you as well as by most other contemporary writers on the subject. The eventual adjustment and mental health of the adolescent is obviously now one of our principal concerns, and it seems generally agreed that at least some of these young people need help in tackling the emotional disturbances associated with growing up.

There are two considerations which arise from your wholly reasonable suggestion that "this is surely above all the sphere of the family doctor." One is concerned with the ascertainment of the mental health problems of adolescence, the other with the treatment of psychiatric problems by the family doctor. First, I would like to be convinced that even a good family doctor will encounter anything like all the mental health problems of his adolescent patients unless he seeks actively for them. I fancy that the problems of adjustment of the type which you mention are not, in fact, regarded as medical problems by these young people in the same way as a boil or a sprained ankle for which advice is sought in the doctor's surgery. Some support for this comes from a rough analysis of the medical problems discovered among the adolescents in a recent study of the health of a small random sample of families in a London practice. Only one in five of the few "mental health" problems of these adolescents reached medical care. Secondly, even if he does encounter this mental ill-health which exists in his practice, and in spite of the admirable work of Dr. Michael Balint (*Journal*, January 16, p. 115) and the recommendations of several learned medical bodies,¹⁻⁴ the modern doctor still knows little or nothing of the psychotherapy which we are told is so badly needed. He knows something perhaps of what has been called the "technique" of support and reassurance (most of which he has picked up by trial and error), but I doubt that this is enough to give more than very superficial help to the adolescent or anyone else who is in trouble.

If the evidence of need is good and the psychotherapists know what they are talking about, then there is an increasingly strong case for an expansion of teaching about the medical care of the minor psychiatric disorders of all ages, and particularly about the adjustment problems of adolescence.—I am, etc.,

Belfast.

Single Incision for Bilateral Orchidectomy

SIR.—With reference to the letter by Mr. W. Skyrme Rees (*Journal*, April 3, p. 815), many years ago I learned, I think from Charles Donald, that the right approach to the testis is through the scrotum, and many years' experience of operation for hydrocele has confirmed the wisdom of that advice. Nature pushed the testicles into the scrotum; why pull them out, trim or enucleate them, and then push them back again?

Oozing may follow operations on the testis. It is harmless if there is a scrotal incision, but leads to a troublesome haematoma if there is not. Both testicles can be approached through an incision in the median raphe, and the final result after healing is the only known example of scarless surgery, the only perfect cosmetic result where cosmesis is unimportant.—I am, etc.,

London, N.W.8.

HENEAGE OGILVIE.

Estimating Alcoholic Content of Body Fluids

SIR.—In the annotation on alcohol and road accidents (*Journal*, March 27, p. 749), I am surprised to read: "The more novel feature of the report is its discussion of estimating the alcoholic content of body fluids." This has been done for years in Sweden, and as long ago as 1936 I wrote an article on the subject which was published in your *Journal*.—I am, etc.,

Bristol.

Medical Treatment of Peptic Ulcer

SIR.—In a leading article (*Journal*, March 13, p. 632) the results of medical treatment of chronic ulcer of the stomach are estimated as follows: "On the evidence, therefore, it would seem that the value of any form of dieting or of any drugs other than alkalis (and these only for the relief of pain) must be considered unproved." For about 40 years I have been engaged in the diagnosis and treatment of chronic gastric ulcers, and on the basis of my experiences I can at almost all points accept the editorial point of view. All the medicinal experiments that have been made with a "rational and even causal" treatment of peptic ulcer, for instance—with "novoprotein," L-histidine hydrochloride ("larostidin"), or different hormones, or the Sippy or Roentgen treatment—have proved disappointing with regard to the lasting effects, and the latest ulcer drugs, hexamethonium ("vegolyse") and methantheline ("banthine"), seem to get the same fate. Only the treatment with large doses of bismuth forms an exception.

This treatment was originally indicated, though in a somewhat primitive form, by Kussmaul and Steiner (about 1890), and subsequently taken up by Hayem and other French clinicians; they used the drug either in the pure state or in the less expensive, but also doubtless less effective, mixture composed of equal parts of bismuth, kaolin, and talc (*pansement bismutique*). Partly owing to the unmethodical use of this drug, partly because of the absence of an actual scientific basis (especially of efficient follow-up), the bismuth treatment was gradually brought into discredit. In Germany it seems to have been abandoned about 1930, and in France there has been a rapid decline of bismuth therapy, the interest being chiefly centred on "pathogenic ulcer therapy." The treatment with large doses of bismuth appears to sink more and more into oblivion; it is not even mentioned in Bochar's impressive standard work *Gastroenterology*.¹

About 30 years ago I took up the treatment of chronic gastric ulcer with large doses of bismuth carbonate, and during the last 20 years I have used this form of treatment in all my ulcer patients on the following principles: 10 g. of bismuth subcarbonate three times daily for the first two months, twice daily for the next two months, and for the last two months once daily before the principal meal. As the action probably depends upon a protective treatment of the gastric ulcer, it is of the utmost importance that the bismuth should be given on an empty stomach, 10 to 15 minutes before the meals. The simultaneous dietetic treatment commenced with a light puréed diet, gradually progressing to a normal light diet in the course of four to six months.

In 1948² and 1950³ I published the results of an extensive research on this subject, based upon control examinations and follow-up of 400 patients with severe chronic ulcers, all with very pronounced roentgenologic changes, and in 60% with a duration of the disease of over five years. Apparently fresh ulcers with manifest bleeding were not included in this series of cases selected from a material of approximately 1,000 ulcer patients. In my 400 patients with gastric ulcer the immediate results were excellent, with rapid freedom from symptoms in the great majority (90%) of the cases, almost the same results ob-

tained in hospitalized patients (88%) and out-patients (83%) in six months. This observation is against the great importance which especially the psychosomatics attach to confinement to bed as an important sedative treatment in chronic peptic ulcer.

The permanent results—by far the most important point in estimating the efficiency of an ulcer treatment—are much better than could be expected: 41% of 400 patients were free from symptoms; these were cases of severe chronic ulcer, and the percentage is considerably higher than in the usual ulcer statistics. The freedom from symptoms applies to a great extent to the patients with the longest period of observation (10–16 years in 79 patients), where 31.6% were found to be free from symptoms, a lasting result which is far better than the usual one in medical treatment of gastric ulcer.

Practically similar results have been obtained by English authors, H. Avery⁴ and F. Croxon Deller⁵; the latter concluded from his investigations that "bismuth subcarbonate takes pride of place in the modern treatment of ulcerative conditions of the stomach and duodenum—it is a most valued therapeutic weapon."—I am, etc.,

Hellerup, Denmark.

Dyspareunia

SIR.—The cause of this condition, a frequent source of frustration and despair in the newly married, is as a rule anatomic or psychogenic. The textbooks recommend ointments, stretching, dilators, operation, etc., but within the orb of every practitioner is a treatment which I have on many occasions found easy and immediately successful.

With the buttock raised upon a sandbag the small area to be dealt with is cleansed with ether and then painted with iodine. Shaving is not necessary. Using a very fine needle a weal is raised 3 cm. from the vaginal margin by the injection of 0.5 ml. procaine at 4, 6, and 8 o'clock to the fourchette. Through each of the 3 weals 5 ml. of warm "proctocaine" is deeply injected. After waiting a few minutes the vagina can be ironed out quite painlessly with three fingers. Success is 100%. Occasionally in the nervous, anxious type of patient it is advisable to induce anaesthesia with thiopentone, 0.5 g.—I am, etc.,

London, W.1.

V. B. GREEN-ARMYTAGUE.

Infectious Mononucleosis

SIR.—Dr. S. Shubert, Captain J. G. Collee, and Dr. B. J. Smith (*Journal*, March 20, p. 671) make a stimulating contribution to the study of infectious mononucleosis (glandular fever).

It would seem necessary, however, to emphasize that the term "sporadic" applied to cases of glandular fever may give a misleading conception of the disease. The term serves a useful purpose in distinguishing a group of cases, collected from different sources, in which the antibody is, by selection, of unquestionable degree and quality. This type of case has, as a rule, been selected from hospital records and is nothing more than a caricature of the cases seen in an epidemic, in many of which antibodies are of borderline diagnostic significance and in others entirely absent. As Tidy¹ points out, the disease is of low infectivity, but "if two or three cases develop in a school or closed community, a high proportion of the occupants tend to become infected"; and again, "It is probable that the disease is infectious only in the early stages." By the time a single case is admitted to hospital cross-infection in a ward is rare. The following case, studied in an epidemic in 1952–3, illustrates these points.

An 18-year-old veterinary student, having spent a holiday at home where an epidemic of glandular fever was in progress, returned in good health to his studies at a university some 50 miles away. A week later he was off colour, and after a few days he reported sick with sore throat, frontal headache, and a stiff neck. He was admitted to hospital, where the diagnosis of angin-

ose glandular fever was confirmed, the heterophil antibodies reaching a dilution of 1/896 with positive absorption, and W.B.C. of 10,000 with 86% mononuclear cells. The staff, being unaware of the distant epidemic, took blood samples from the student's colleagues in a hostel, with entirely negative results. Thus an apparently "sporadic" case (and incidentally the most severe case in the epidemic) occurred in a town 50 miles away from the centre of the epidemic.

I maintain that so-called "sporadic" cases are merely the more severe forms which occur in any epidemic and indeed may be the only cases to be recognized in a mild epidemic. The difference lies in the degrees of infectivity, of symptomatology, of lymphocytosis, and of antibody formation. Glandular fever is primarily a disease of low infectivity, but widespread dissemination of infection is possible when other factors induce a hypersensitivity of a community to the cause. I hope to illustrate these points more fully at a later date.—I am, etc.,

Cupar, Fife.

DAVID W. W. HENDRY.

- ² *Lancet*, 1934, 2, 180.

SIR.—As one engaged in long-term investigation of infectious mononucleosis in a university population, may I make some comments related to the article by Dr. S. Shubert, Captain J. G. Collee, and Dr. B. J. Smith (*Journal*, March 20, p. 671)? The answer to their query "A Syndrome or a Disease?" is, I think, that the sporadic infectious mononucleosis is a syndrome and the epidemic glandular fever a disease. The suggested mechanism for the syndrome of lymphadenopathy, mononucleosis, and heterophil antibodies is that sensitization by a previous infection is required, whereon the "trigger action" is provided by reinfection at a suitable interval by the same or a closely allied organism. This agent may in many cases be that responsible for epidemic glandular fever, but it is likely that a heterogeneous group, viral, bacterial, and even protozoan, can produce similar results in a sensitized individual.

From experience of some 80 cases of infectious mononucleosis, I have seen several which could fit such a hypothesis, but in two instances there was a record of a recently previous blood examination. In both examples the first counts were done because of pharyngitis with enlargement of cervical lymph nodes suggesting mild infectious mononucleosis. In one patient the acute illness, with clear-cut mononucleosis and characteristic differential, occurred five months later, and in the other this took place after an interval of six weeks.

The serological tests seem an obstacle to the syndrome theory and have undoubtedly encouraged investigators to think in terms of a specific infective aetiology, but there is another viewpoint. At a conference of the British Student Health Officers' Association (Glasgow, July 6, 1953) I presented a progress report in which I claimed to have found a high correlation between the abnormal mononuclear count and the sheep cell agglutination titre of the serum from the same sample taken at or about maximum mononucleosis. This correlation was sufficiently high for the prediction of the agglutination titre, in the absence of Forsman antibody, with a reasonable degree of accuracy, the reciprocal of the titre being about one-tenth of the number of abnormal cells per cubic millimetre.

It seems that the antibody is simply a response to the presence of a special type of abnormal cell (of which a detailed account is in course of preparation). This possibility occurred to Paul and Bunnell¹ when they made their original contribution to the serology of infectious mononucleosis, and, if it can be established as a firm conclusion, the balance tips in favour of the syndrome concept, although the possibility that these cells produce or carry antibody specific for an unknown infective agent still remains. I am indebted to Collee, Shubert, and Smith for mention of Warren's paper, which I regret to say had escaped my notice. Warren² states that a positive Paul-Bunnell reaction only occurs when the curious lymphocytes of infectious mononucleosis form a large proportion of the differential count, an observation with which my own findings are in full accord.

Finally, I wish to underline the views of your contributors on the unsatisfactory nature of the simple agglutination reaction usually named the Paul-Bunnell test. There are at least 16 published articles representing over 100

cases where this test has been positive, even in titre as high as 1 in 2,560, in conditions other than infectious mononucleosis or serum disease. One wonders how many other strange cases, in which the former diagnosis has been made, properly belong to the same group.—I am, etc.,

Birmingham.

Metabolic Stimulating Effect of Salicylate

SIR.—Dr. J. B. Cochran's paper "Further Observations on the Metabolic Stimulating Effect of Salicylate" (*Journal*, March 27, p. 733) is of interest in relation to a series of experiments on the "Effect of Certain Hydroxybenzoic Acids on the Oxygen Consumption of Wistar Rats" which I have recently reported.¹ To summarize the relevant data I found that salicylate had a stimulating effect, meta-hydroxybenzoic acid a depressant effect, and amongst the compounds which were inactive were para-hydroxybenzoic acid and 2:6 dihydroxybenzoic acid (γ resorcylic acid).

The results with the latter compound are of particular interest, since it has been reported² that γ resorcylic acid was beneficial in doses lower than those of salicylate necessary to achieve comparable clinical results. It would seem, therefore, important to know whether further experience with this drug has supported the original claims and, if so, has Dr. Cochran observed any metabolic stimulating effect in the human? If the original clinical claims are supported and the compound has no effect on the oxygen consumption of patients, then this metabolic effect would appear irrelevant to the treatment of rheumatic fever. If, on the other hand, the drug has not proved successful, then the rationale for introducing the drug, the ability of the anion to chelate, would seem to be fallacious.

It seems possible that the metabolic stimulating effect of salicylate has its origin in an uncoupling of oxidative phosphorylation similar to that which has been demonstrated in the case of dinitrophenols and related compounds.³ Whether this is of any significance in elucidating the mode of action of salicylate in rheumatic fever must remain problematical. However, it is intended that the effect of salicylate on oxidative phosphorylation shall be studied elsewhere.—I am, etc.,

Long-acting Penicillin on Haemolytic Streptococci

SIR.—It may be of interest to note the effect of a long-acting penicillin on the course of an epidemic of haemolytic streptococci, Type "A," in a residential school of 137 boys of 8 to 13 years of age. A nose and throat infection started at the end of January, and by February 9 28 boys were in the sick rooms with pyrexia and "positive" nose and/or throat swabs, and 12 others were either away from school or isolated but not diagnosed. On February 10 all the remaining boys and all of the staff had nose and throat swabs taken; 31 of these were "positive"—all boys—giving a carrier rate of nearly one in three of the remaining boys. It seemed likely that the school would shortly have to close down.

During the following three days, February 11 to 13, all of these boys and 16 adult staff were given a single intramuscular injection of 2 ml. of benzathine penicillin ("penidural") L.A. Throat and nose swabs taken five days and ten days or more later were "negative" in all except one boy, which was returned as "small numbers." There have been no further cases up to date. Reactions occurred in 17 boys within 24 to 48 hours of injection, 7 having pyrexia of 99° to 102° F. (37.2° to 38.9° C.), 8 nausea or vomiting, and 7 local induration or stiffness. Most of the 16 adults were very stiff, 5 felt "sick and miserable," and 3 had

pyrexia. It seems probable that reactions are more likely to occur in those who are up and about. The cessation of the epidemic was more sudden and complete than had been hoped for. Whether this wholesale injection of infected and non-infected members of a community is more or less likely to produce insensitive strains of streptococci, I should like to hear argued.—I am, etc.,

Colwyn Bay.

HERBERT LORD.

Bovine Tuberculosis

SIR.—We wish to clarify a point arising out of our report on bovine tuberculosis (*Journal*, February 13, p. 372), which is the subject of a letter to you by Drs. T. R. Maurice and Hugh Ellis (*Journal*, March 13, p. 646). In our report we employed the words "accredited tuberculin-tested herds" to convey the sense of officially recognized herds containing no reactors. Our choice of words was unfortunate, in that it permitted confusion to arise with the special designation accredited.

We do not believe the milk from such accredited herds to be safe, as in fact the herd responsible for our investigation carried this designation. We do, however, consider milk from herds of non-reactors—that is, carrying special designation tuberculin-tested—or pasteurized milk to represent a reasonable universal level of safety, and certainly to be more reliable than assuming consumers will always boil milk prior to use.—We are, etc.,

Leicester.

R. W. KIND.
M. C. BROUGH.

Appendicitis in the Course of Measles

SIR.—Dr. W. H. Galloway's series (*Journal*, December 26, 1953, p. 1412) may appear apparently impressive, but only two of the seven operations seem justifiable to me on closer scrutiny of the case reports as submitted in the paper. The conclusion that the author derives from the series—namely, that symptoms of appendicitis during the course of measles warrant immediate operation—should not, I think, go unchallenged. I, with my limited experience in India, consider it my duty, in the cause of prevention of unnecessary appendicectomies, to raise my pen against it. Appendicular syndrome is fairly common in measles, and conservatism has proved successful in every case (about 15 in number) I have encountered so far. I do not deny the possibility of a fortuitous association of acute appendicitis with an attack of measles, and under these circumstances the case should be treated surgically on its merits. But such a coincidence is very rare and does not warrant the sweeping rule that a patient with measles showing appendicular syndrome should be operated on. On the other hand, my rule in practice has been that before diagnosing "surgical" appendicitis in a child, look in the mouth for Koplik's spots, and at the throat for congestion. If they are there, it is probably the "medical" appendicular syndrome not requiring a surgical intervention.

It does not mean thereby that the case should not be observed for acute surgical developments. As soon as there appears unequivocal evidence for the latter, surgical help should be called in. I may mention here some of the distinguishing features of the "medical" appendicular syndrome in measles: (1) associated flushed face, suffused eyes, and catarrh of the upper respiratory tract; (2) Koplik's spots on the buccal mucous membrane; (3) there is often leucopenia—occasionally there may be leucocytosis if the lungs show some inflammatory condition; (4) vomiting is often absent; (5) bowels tend to be normal or loose, but not constipated; (6) abdominal reflex on the right lower quadrant is often present; (7) the pain is more colicky in nature; and (8) comparatively little rigidity is present.

I have noticed a similar syndrome appearing in generalized urticaria when mucous membrane is probably involved as in measles. There also it is seen to respond to expectant line of treatment.—I am, etc.,

Poona City, India.

P. L. DESHMUKH.

Dental Anaesthetics

SIR.—Dr. H. Newton-Andrews made a valuable contribution when he reported in the *Journal* (March 13, p. 641) the astonishing fact that he had seen sparks when the dentist's forceps slipped during the extraction of a tooth. I was therefore grateful to Dr. H. J. V. Morton when he suggested to me that he would, if I wished, investigate experimentally this unforeseen danger. Mr. Morton's experiments have already shown that sparks, visible in the dark, may quite easily be struck with certain dental forceps from extracted teeth, whether dry or wet and whether filled or unfilled. This observation has been confirmed by Mr. J. D. Robson, the dental surgeon at Salisbury with whom for some years I have been investigating the use of cyclopropane anaesthesia for extraction work. Dr. Morton has also shown in three patients that when anaesthesia was induced with a 50% mixture of cyclopropane and oxygen in the manner I have advocated¹ a sample of expired gases, even up to the sixth exhalation after withdrawing the anaesthetic, could be ignited by an electric spark.

Perhaps it is luck that in more than 2,000 administrations of cyclopropane for the extraction of more than 5,000 teeth I have had no mishap; or perhaps it is because the energy of these incandescent particles is not quite sufficient to detonate the explosive mixture. However that may be, it is now abundantly clear that this form of anaesthesia for extraction of teeth must at present be considered dangerous and abandoned until the matter has been more fully investigated.—I am, etc.,

London, S.E.1.

J. G. BOURNE.

POINTS FROM LETTERS

Ulcerative Colitis

Mr. C. HORVITZ (London, S.W.1) writes: I was interested to read what Sir Robert Hutchison had to say about the operation of colectomy as performed by the late Sir Arbuthnot Lane (*Journal*, February 20, p. 454). I recall a certain occasion in my student days at Guy's Hospital on ward round with Lane. When confronted with a man who had a painful swollen wrist, he examined it for a few seconds, and then remarked to the class: "A clear case of auto-intoxication. We will remove his colon."

Smoking and Lung Cancer

Dr. G. G. SHERRIFF (London, W.8) writes: Is there necessarily any discrepancy between the fact that cancer of the lung increases with smoking or with life in towns, and the fact that it may occur in non-smokers? After all, smoking is an intensified and localized form of atmospheric pollution. One basic factor, then, would appear to be atmospheric pollution of various degrees and kinds.

Broken Milk-bottles

Dr. T. D. S. HOLLIDAY (Chester) writes: The danger of the dropped milk-bottle and its maiming effect on the hands, abdomen, and other parts of small children must be familiar to most doctors. The annual incidence of milk-bottle injuries in this country is probably considerable. Daily I view the quota of bottles huddled on the stone step with dread and my children with suspicion. Is it not possible for a better material to be used than glass? Would not waxed paper cartons be lighter and easier to transport, as well as safer than these slippery, dangerous bottles?

Telephone Manners

Dr. H. A. CONDON (Bromley, Kent) writes: I write to draw attention to a form of discourteous behaviour widely prevalent among hospital staff, both medical and administrative. I refer to the practice when making a telephone call of asking a secretary or the switchboard to find the desired person. The unfortunate recipient, on answering, is then kept waiting either while a search is made for the caller or until the caller is free to come to the telephone. This is no new problem—for example, it has been condemned by Hardy-Roberts (*Lancet*, 1951, 1, 1119) in an admirable lecture. However, the exercise of a little thought would soon abolish what is a most irritating practice.

Obituary

THOMAS CARNWATH, D.S.O., D.Sc., M.B., D.P.H.

Dr. Thomas Carnwath, who retired from the post of deputy chief medical officer to the Ministry of Health in 1940, died at his home at Whitehead, Northern Ireland, on April 2, after a long illness. He was 75 years of age.

Thomas Carnwath was born on April 7, 1878, the son of Mr. J. Carnwath, of Tyrone. From Foyle College, Londonderry, he went on to study medicine at Queen's University, Belfast, where he won a number of exhibitions and scholarships, and graduated M.B., B.Ch. with honours in 1903.

After holding an appointment as demonstrator of anatomy at his own university he continued his postgraduate studies at Berlin University and at Hamburg, where he was an assistant in the Institute of Hygiene. He also held a post in Berlin as an assistant in the Imperial Board of Health. On his return to Britain he took the Cambridge D.P.H. in 1906, and

was then appointed assistant medical officer of health of Manchester, and later deputy medical officer of health. He then joined the staff of the Local Government Board as a medical inspector, and about this time he was appointed lecturer in public health at St. Thomas's Hospital. On the outbreak of the first world war he joined the R.A.M.C., and was for a time attached to the Honourable Artillery Company. He was mentioned in dispatches, and in 1918 was awarded the D.S.O. By the time he returned to civilian life the Ministry of Health had taken the place of the Local Government Board, and Carnwath immediately became busily engaged in the many medical activities of the Ministry. In 1929 he was promoted to senior medical officer, and in 1935 he became deputy chief medical officer. At the Annual Meeting of the B.M.A. in 1934 he was president of the Public Health Section, and three years later president of the Section of Medical Sociology. In 1935 he was awarded the honorary degree of D.Sc. by Queen's University. After his retirement in 1940 he went to live in Northern Ireland, where, among other activities, he helped to carry out an investigation of the public health services of Belfast.

Apart from the numerous official reports of which he was the author, Dr. Carnwath, during the early stage of his career, had written a number of papers on public health subjects, some of which were published in German medical journals. He was an examiner at the Universities of London, Manchester, Birmingham, and Belfast, and a member of the Board of Studies in Hygiene and Public Health of the University of London and of the Senate of Queen's University, Belfast. In addition, he served on the Army Hygiene Advisory Committee and the National Radium Commission.

[Elliott & Fry, Ltd., London]

Dr. Carnwath married Margaret Ethel, only child of the late Andrew M'Kee, of Belfast, who survives him together with two sons.

We are indebted to Sir ARTHUR MACNALT for the following appreciation: May I be allowed to pay a tribute to my friend and former colleague, Thomas Carnwath? After a distinguished career at the Queen's University, Belfast, postgraduate study in Germany, and as deputy medical officer of health at Manchester, he became a medical inspector at the Local Government Board. It was a most interesting time, for the health services—tuberculosis, maternity and child welfare, and venereal diseases—were being planned and organized under the direction of Sir Arthur Newsholme. Then the first world war broke out, and Carnwath immediately joined the R.A.M.C.(T.F.). He came back to us in 1918 with a D.S.O. and resumed work in public health under his immediate chief, Sir George Buchanan. International health work, the Radium Commission, with many other activities, fully occupied him at the Ministry of Health. In each and all of them he did excellent though often inconspicuous work, and I was both honoured and pleased that he became Deputy Chief Medical Officer when I was appointed Chief Medical Officer of the Ministry in 1935. Those were strenuous days, for war threatened, and we had much to do in preparing for it. We were often working at the office until midnight. Carnwath had a serious illness just before the outbreak of war, and, though for a time he struggled gallantly on, the Ministry lost his valuable services early in 1940. In retirement his health improved, and he rendered services to Northern Ireland as an elder statesman of public health.

At the Ministry we liked Carnwath not only for his great abilities, but for his invariable kindness, goodness of heart, wit, and humour. The sympathy of his many friends goes out to Mrs. Carnwath and their two sons.

Medical Notes in Parliament

HOSPITAL DOCTORS' PAY

Mr. JACK BROWNE (Govan, Con.) asked the Minister of Health on April 8 whether the Medical Whitley Council had yet reached agreement on the pay of hospital medical staff. Mr. IAIN MACLEOD replied that an agreement had just been reached. He then gave the details issued by Committee "B" of the Medical Whitley Council and published in the *Supplement* of April 10 (p. 145). After saying that details of the new arrangements were being worked out by the two sides of Committee "B," the Minister added that he and the Secretary of State for Scotland had told the committee that they were prepared to approve the agreement. Its cost would be about £3,250,000 in a full year.

Consultants' Expenses

Mr. A. A. H. MARLOWE (Hove, Con.) asked the Chancellor of the Exchequer what consultations had taken place between the Treasury and the Ministry of Health with regard to the expenses of hospital consultants employed in the Health Service which were not deductible for income-tax purposes; whether he was aware that consultants incurred many expenses for which they could make no income tax rebate claim on Schedule E assessments; and whether he would introduce legislation to remedy this hardship.

Mr. J. A. BOYD-CARPENTER, the Financial Secretary, replied on April 8 that hospital consultants were, like other employees, assessable under Schedule E, and the same rules with respect to expenses applied to them as to other taxpayers so assessed. He saw no reason to propose legislation giving them preferential treatment. The general question of what expenses were admissible to such taxpayers was within the terms of reference of the royal commission.

Mr. MARLOWE said there was a conflict between the appointing authorities, who would not appoint a consultant

unless he had a motor-car, telephone, and secretary, and the Revenue authorities, who would not allow these expenses. A consultant therefore had necessarily to incur expenses which he could not deduct for tax purposes. Mr. BOYD-CARPENTER said the broad question was within the reference to the royal commission. He could not see any justification for treating these persons for tax purposes differently from other taxpayers.

Mr. H. M. KING (Southampton, Lab.) urged that consultants were not treated the same as general practitioners for this purpose. Would the Financial Secretary try to make an adjustment as between them? Mr. BOYD-CARPENTER said that sort of question was for the Minister of Health. He was only concerned with administration of the tax law. Mr. MARLOWE gave notice of his intention to raise the matter again.

Transfers to Part-time Service

Mr. KENNETH ROBINSON (St. Pancras, North, Lab.) was informed by Miss PAT HORNSBY-SMITH, Parliamentary Secretary to the Ministry of Health; that in 1951 the number of consultants employed by regional boards who transferred from whole-time to part-time service was 42, in 1952 it was 61, and in 1953 it was 46.

Defects of Welfare Services

The subject of debate in the House of Lords on April 7 was a resolution laying the blame for many of the failures in the welfare and health services on imperfect co-ordination between the various authorities concerned, and declaring that greater local discretion, financial and administrative, would result in better service at less cost.

Lord SALTOUN, introducing it, emphasized that he was not seeking to attack individuals but to correct the system. In the past three years there had been a trend towards crystallization in the various services, and the marking of boundaries between the various branches of what should be a common service. The motto should not be "Trespassers will be prosecuted" or "Over to you." But so many different authorities were concerned that some sort of co-ordination was difficult, and complete harmony at all times little short of a miracle. He suggested that a small committee should examine the services to find out how better co-ordination could be achieved, and to make a quick report.

Lord MATHERS suggested the possibility of a closer integration of the specialist and general-practitioner services by a closer linking of the functions of executive councils with the regional hospital boards. He was critical of the way in which many senior members of hospital staffs, he said, concentrated their work into the early part of the day; this might even involve duplication of staff to meet peak demands, while later in the day theatres might be empty and unused.

Lord Beveridge's Criticisms

Lord BEVERIDGE deplored the failure to establish health centres—there were three mentioned in the Ministry of Health report for 1952, and one or two others had come along since. The institution of health centres was proposed long before 1946, in an interim report of the B.M.A. Planning Commission, which set out a detailed scheme. Health, and the proper provision for it, would become soon even more important than houses. He pressed the Government to get "this dream, and main intention of the 1946 Act, put into reality. He criticized as inappropriate to a Health Service the Treasury rule of annual budgets, which meant hasty spending towards the end of a year, or the return of unexpended resources; and, going further, questioned whether a Minister and a Civil Service department was the right organ for running this national industry to secure for the people the means to health.

The EARL OF CRANBROOK, a regional hospital board chairman, said the machine could be made to work, by co-operation at every level. The members of various bodies were all drawn from people with an interest in local administration; many people sat on more than one body, and so secured a good deal of integration of policy.

Lord AMULREE said there were probably enough hospital beds for the sick if proper use was made of them. In 1948 a committee called together by the B.M.A. issued a very good report,¹ propounding practical and economical means, but nothing had been heard of it since. What was needed was free exchange between welfare institutions and the hospitals. The encouragement of domiciliary services for the benefit of the infirm and the frail was very important. According to the census figures, in 1901 the total number of people in the medical and auxiliary services was about 3,000 per million of the population. In 1951 it had risen to nearly 10,000 per million. That was rather alarming, because it showed that the supply was going to dry up.

Lord CALVERLEY said that the kingpin of the Health Service was the general practitioner. He was only heard of when he had made a mistake.

Desire for Improvements

Lord MANCROFT, a Lord-in-Waiting, was prepared to accept the spirit of the motion, but not the letter. There was no official façade and satisfaction about the services, he said, but a constant desire on the part of the Government for improvements. Co-ordination of the different parts of these services was one of the greatest single problems of the Health Service, but it was only emphasized and not created by the Service itself. Co-operation eventually rested on human relationships and personalities rather than on drastic reorganizations. Health centres were expensive to build, and had not been as popular either with patients or with doctors as had been expected. An alternative that presented itself was the establishment by doctors of group practices. This development was supported by the Minister, and was being encouraged by the offer of interest-free loans to doctors to acquire or convert buildings to establish a group practice. His general answer to the debate, however, rested on the fact that most of the subjects it covered were within the terms of reference of the Guillebaud and Phillips committees investigating the Health Service, and half-way conjectures from him would not be helpful. The motion was withdrawn.

College of Physiotherapy

Miss PAT HORNSBY-SMITH, Parliamentary Secretary, Ministry of Health, stated on April 8 in answer to Mr. F. J. ERROLL (Altrincham and Sale, Con.) that the Minister of Health would not give recognition to the British College of Physiotherapy under the terms of the N.H.S. (Medical Auxiliaries) Regulations, 1954.

Welfare Foods

Mr. JOHN RODGERS (Sevenoaks, Con.) asked the Minister of Food on April 6 what arrangements would be made for the local distribution of welfare foods, other than liquid milk, when the local offices of his department were closed later in the year. Major G. LLOYD GEORGE stated that the local health authorities had been invited to take over responsibility for these arrangements as part of their duty under the National Health Service Acts to provide for the care of expectant and nursing mothers and young children. The associations of authorities covering England and Wales had already agreed to do so.

Power Station Flue Gases

Mr. SOMERVILLE HASTINGS (Barking, Lab.) asked the Minister of Fuel and Power on April 5 whether, in view of the limited possibilities of existing processes for ridding the flue gases of power stations of harmful sulphur oxides, he would arrange for investigation and research into the matter. Mr. GEOFFREY LLOYD answered that it was already the subject of continuous research. Mr. HASTINGS pressed for special attention to the matter, saying that the present methods required large quantities of water, and the River

Thames would be saturated with the effluent of calcium sulphate when only two of the power stations on its banks were in use. Mr. LLOYD agreed that the limit had been reached with this effluent, and said that work was in progress on a new process involving the use of gas works liquor, but it was in an experimental stage.

Mr. HASTINGS also questioned the Minister about the additional amount of sulphur oxides that would be discharged from the proposed extension to the Bankside power station, and what methods were proposed for eliminating them from the flue gases. Mr. LLOYD told him that a steady decrease in fuel consumption was expected from now onwards, and the discharge of sulphur oxides would therefore be reduced. The new part of the station would disperse its oxides at high temperature and great velocity through chimneys 375 ft. high.

Gas Workers' Risks

Mr. GEOFFREY LLOYD, Minister of Fuel and Power, informed Dr. BARNET STROSS (Stoke-on-Trent, Central, Lab.) that the West Midland Gas Board employed three full-time and a number of part-time medical officers. The question of x-ray examinations of the employees, and at what intervals, was part of the board's day-to-day administration on which he was asking the chairman to write to Dr. Stross.

Dr. STROSS asked the Minister to bear in mind the work of the Medical Research Council on the specific risks which gas workers had to undergo, especially in cancer of the lung. Would he see that as far as possible all gas boards provided ample medical services for their workers? Mr. LLOYD replied that he had brought the matter to the attention of the gas boards, and impressed on them the importance of medical services.

Average Cost of Prescriptions

In reply to Mr. VAUGHAN-MORGAN (Reigate, Con.), on April 8 Miss PAT HORNSBY-SMITH gave the following Table showing the average cost per prescription in England and Wales for each month since June, 1952, and for the comparable period before June, 1953.

June, 1950, to February, 1952				June, 1952, to February, 1954			
1950		d.		1952		d.

Estimates obtained from sample

£5,000 Then and Now

Mr. C. OSBORNE (Louth, Con.) asked the Chancellor of the Exchequer on April 6 the net income of a married man with two children in 1935 who received a gross income of £5,000 a year; what it would be to-day; and what it would amount to to-day allowing for the depreciation in the value of the £ between 1935 and to-day. Mr. J. A. BOYD-CARPENTER, Financial Secretary to the Treasury, replied that a gross earned income of £5,000, in the case of a married man with two children, produced a net income, after deduction of tax, of £3,687 in 1935-6 and £2,689 in 1953-4. The latter amount was equivalent in purchasing power to about £1,090 in 1935-6.

¹Supplement, August 7, 1948, p. 71.

Medico-Legal

SPINAL ANAESTHETICS APPEALS FAIL

The Court of Appeal on April 8 dismissed the appeals of two men who became paralysed below the waist after they had been given spinal anaesthetics (nupercaine) contaminated with phenol antiseptic in 1947. Mr. C. H. Roe, aged 51, and Mr. Albert Woolley, aged 62, had claimed damages from the Ministry of Health and Dr. J. Malcolm Graham, the anaesthetist. Mr. Justice McNair, who had dismissed the actions, holding that the hospital theatre staff and the doctor were not negligent, found that the nupercaine had been contaminated by phenol getting into ampoules.¹ General damages had been provisionally assessed at £15,000 for Mr. Roe and £10,000 for Mr. Woolley.

Lord Justice Somervell said that the question was whether the percolation of phenol solution into ampoules was caused by the negligence of the defendants or either of them. Dr. Graham, who appreciated the possibility of cracks in ampoules, said that he examined each one carefully and he did not believe that he could have missed a crack. The judge accepted his evidence. The finding that the hospital authorities and Dr. Graham were not negligent was justified. The fact that something went wrong was not proof of negligence. There were obvious risks in surgical operations.

Lord Justice Denning said that no one could be unmoved by the disaster of these two men. The facts called for an explanation by the hospital authorities and Dr. Graham, and they had given one. They had spared no trouble or expense to seek out the cause of the disaster. There was a danger that ampoules might become cracked, and the cracks might be so fine that they could not be detected by ordinary inspection. The carbolic disinfectant in which the ampoules were kept would then seep through the cracks into the nupercaine, and no one would realize that it had taken place. That was the explanation of the disaster, and the question was whether any of the staff were negligent. Medical science had conferred great benefits on mankind, but those benefits were attended by considerable risks. Every surgical operation was attended by risks. Dr. Graham sought to escape the danger of infection by disinfecting the ampoule. In escaping that known danger he unfortunately ran into another danger. He did not know that there could be undetectable cracks, but it was not negligent for him not to know it at that time. "We must not look at this 1947 accident with 1954 spectacles," said his lordship. "The judge acquitted Dr. Graham of negligence, and we should uphold his decision." Never again, it was to be hoped, would such a thing happen. It was the extraordinary accident to these two men which first disclosed the danger. Nowadays it would be negligence not to realize the danger, but it was not then. These two men had suffered such terrible consequences that there was a natural feeling that they should be compensated, but we should be doing a disservice to the community if we were to impose liability on hospitals and doctors for everything that happened to go wrong. "Doctors would be led to think more of their own safety," he continued, "than of the good of their patients. Initiative would be stifled and confidence shaken. A proper sense of proportion requires us to have regard to the conditions in which hospitals and doctors have to work. We must insist on due care for the patient at every point, but we must not condemn as negligence that which is only a misadventure."

Lord Justice Morris also agreed that the appeals failed. No order was made as to costs. Leave to appeal to the House of Lords was refused.

The Medical Defence Union instructed Messrs. Hempsons to act for Dr. Graham.

¹British Medical Journal, November 21, 1953, p. 1165.

LACK OF HOSPITAL-G.P. LIAISON

A report has been published of an inquiry into the unsuccessful attempts of a general practitioner to gain admission to hospital for a patient dying of haemorrhage. Failure to secure admission was due to a number of circumstances, reports the investigating committee, which had been appointed by the Birmingham Regional Hospital Board. Its findings were as follows.

First, the general practitioner should have used the bed bureau. If he had, admission would have been obtained. Secondly, Wolverhampton Hospital Management Committee failed to communicate the proper arrangements to the medical staff, and the house-physicians did not know that refusal to admit could be decided only by the senior resident officer or the consultant on call. Thirdly, no real effort was made to impress upon two hospitals the seriousness of the case. The committee states that liaison between the hospital group and the general-practitioner service needs to be improved. Among the administrative recommendations to ensure that such a case shall not recur the committee recommends that refusal to admit to hospital shall not be based on lack of beds: extra beds must be put up.

Vital Statistics

Infectious Diseases

The largest increases in the notifications of infectious diseases in England and Wales during the week ending March 27 were 210 for scarlet fever, from 1,282 to 1,492, and 191 for dysentery, from 1,124 to 1,315, and the only large decrease was 258 for measles, from 2,325 to 2,067.

A small rise in the incidence of scarlet fever occurred in every region. The largest rise was 53 in London, from 41 to 94. 2,553 cases of whooping-cough, 10 more than in the previous week, were notified, and the largest fluctuations in the local returns were increases of 37 in Norfolk, from 39 to 76, 37 in Warwickshire, from 116 to 153, and 30 in Kent, from 120 to 150, and decreases of 39 in Cornwall, from 68 to 29, and 36 in Yorkshire West Riding, from 179 to 143. The chief variations in the trends of measles were an increase of 95 in Staffordshire, from 169 to 264, and decreases of 70 in Cheshire, from 160 to 90, and 42 in Norfolk, from 467 to 425. 14 cases of diphtheria, 4 fewer than in the preceding week, were notified.

The number of notifications of paratyphoid fever decreased by 25, from 45 to 20. This fall was contributed by Wales, where the notifications declined from 44 to 17. 24 cases of acute poliomyelitis were notified during the week. These were 2 more for paralytic and 3 more for non-paralytic cases than in the preceding week. The only administrative areas with 2 cases were Gloucestershire, Bristol C.B., and Staffordshire, Cannock U.D.

For the fourth consecutive week the number of notifications of dysentery has exceeded 1,000. The largest returns during the week were Lancashire 229 (Salford C.B. 50, Bolton C.B. 45, Eccles M.B. 18, Preston C.B. 15, Manchester C.B. 14, Southport C.B. 14, Ormskirk U.D. 14, Liverpool C.B. 11), London 194 (Islington 65, Lewisham 31, Shore-ditch 19, Stepney 11, Finsbury 10), Yorkshire West Riding 159 (Bradford C.B. 48, Keighley M.B. 29, Leeds C.B. 28, Dewsbury C.B. 24), Middlesex 101 (Southall M.B. 21, Hornsey M.B. 19, Enfield U.D. 16, Willesden M.B. 11), Leicestershire 100 (Leicester C.B. 100), Essex 58 (Romford U.D. 16, West Ham C.B. 10), Kent 54 (Sevenoaks R.D. 24), Devonshire 53 (Exeter C.B. 28, Great Torrington M.B. 17), Norfolk 45 (Norwich C.B. 45), Surrey 43 (Epsom and Ewell M.B. 21, Carshalton U.D. 15), Nottinghamshire 42 (Nottingham C.B. 23, Beeston and Stapleford U.D. 18), Warwickshire 39 (Birmingham C.B. 34), Staffordshire 35 (Cannock U.D. 21), and Berkshire 24 (Maidenhead M.B. 20).

In Scotland the number of notifications of dysentery increased from 276 to 366.

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of certain diseases notified weekly in England and Wales. Highest and lowest figures reported in each week during the nine years 1945-53 are shown thus -----, the figures for 1954 thus ————. Except for the curves showing notifications in 1954, the graphs were prepared at the Department of Medical Statistics and Epidemiology, London School of Hygiene and Tropical Medicine.

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending March 27 (No. 12) and corresponding week 1953.

Figures of cases are for the countries shown and London administrative county. Figures of deaths and births are for the 160 great towns in England and Wales (London included), London administrative county, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available. The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

CASES in Countries and London	1954					1953				
	Eng. & Wales	London	Scot.	N. Ire.	Eire	Eng. & Wales	London	Scot.	N. Ire.	Eire

Medical News

British Pharmaceutical Industry.—The annual dinner of the Association of British Pharmaceutical Industry was held on April 7, the president, Mr. C. L. Saul, being in the chair. In proposing the toast, "The Pharmaceutical Industry," Miss Pat Hornsby-Smith, M.P., Parliamentary Secretary, Ministry of Health, said that in the field of British enterprise it was a great industry. "You command a high standard for your products and show the world—particularly in those of your companies that have vast research enterprises besides their manufacturing processes—that you have a standard in which we in the Ministry of Health share your pride." Their keenest competitor in the world markets, Miss Hornsby-Smith continued, was a rehabilitated Germany "working like a beaver." The Ministry was grateful to the industry for the unflinching co-operation it had given in dealing with inquiries as to cost and calls for economy. The prescription side of the N.H.S. bill was about £35m. out of a total of £400m., the biggest single item being £280m. for the hospital service. The general practitioner had the last word in saying what should go on the prescription, and could make the biggest single contribution to economy, "because you in your industry merely provide the goods which he is responsible for ordering." Miss Hornsby-Smith said she thought that "such abuse and extravagance as there is lies not in the highly expensive drugs which are vital in particular and limited cases, but in the overprescribing of the small common articles—the cotton-wool, the lint, and the like." Referring to inquiries into costings and price, Miss Hornsby-Smith said that if the State was to fulfil its obligation to the public and the taxpayer they had to be able to assure the Public Accounts Committee "that we as a Ministry were satisfied that the prices charged in whatever sphere of your industry were right, proper, and justified." Mr. Saul proposed the health of the guests, to which Mr. A. E. W. Thomas, the editor of *The Listener*, made a most happy and witty response.

Food Production in East Africa.—A most successful three-day conference on the "Medical, Agricultural, and Veterinary Aspects of Food Production in East Africa" was recently held at Makerere College Medical School, Uganda, under the presidency of Sir Bernard Keen, F.R.S. The conference was organized by the East African Advisory Committee on Medical Research, and attended by doctors and experts on agriculture and local custom. Speaking in his opening address on the future of the Colonial Territories, the Governor of Uganda, Sir Andrew Cohen, stated his belief that their standard of living would be determined by no one more than those engaged in research. "We can no longer rely," he said, "on hit-and-miss methods and *ad hoc* solutions." During the discussions the medical workers pointed to the widespread existence of calorie and protein deficiency, particularly in the weanling child. A great increase in food production was needed—quantity not quality. In their answer the agriculturists emphasized the great inefficiency in the use of existing resources and the vast scope for improved production by relatively simple methods. One of the crucial questions was the shortage of man-power. There was evidence that East Africa was underpopulated, and only the best land was being used. Industrialization was in danger of preceding the agrarian revolution which alone could sustain it. Among the visitors from Britain to the conference were Professor A. C. Frazer (Birmingham), Professor P. C. C. Garnham (London School of Tropical Medicine), and Dr. R. Lewthwaite (Colonial Office).

Hostel for the Borderline Case.—On March 30 Sir Henry Cohen and the Bishop of Liverpool, Dr. Clifford Martin, opened an experimental hostel at Sefton Drive, Liverpool. The hostel, which is directly administered by the Liverpool

Personal Service Society, provides accommodation for 38 patients. The Liverpool Regional Hospital Board has entered into contractual arrangements for the use of 18 of the beds for patients who are transferred from hospital while still requiring medical and nursing care but who are as yet not fit for discharge to their own homes. The remaining 20 beds are available to the local health authority for patients who are aged and frail but who do not require medical and nursing care. The hostel is experimental in nature, and it is hoped that experience of its use will do much to answer many of the questions about those borderline cases which are neither fully the responsibility of the hospital service nor yet fit enough to be cared for in the type of hostel provided by the local health authority under Part III of the National Assistance Act.

Henry Simpson Newland Prize in Surgery.—The first award of this triennial prize to commemorate the services of Sir Henry Newland to the medical profession, particularly in Australia, will be made in 1955. The prize, offered by the Federal Council of the B.M.A. in Australia, will consist of £100 and a medal. It will be given for the best essay on "The Influence upon Surgical Practice of Irradiation and Endocrine Therapy." Essays, typewritten or printed in English, must be based on personal observation and experience, and not exceed 50,000 words in length. The prize essay will be submitted to the editor of the *Medical Journal of Australia*. The competition is open to any graduate of a medical school within the British Commonwealth. The closing date for the receipt of essays is May 20, 1955. Further information may be obtained from the general secretary of the Federal Council, 135 Macquarie Street, Sydney, Australia.

Hunterian Society Essays.—Dr. J. Lipsey, of Littlehampton, Sussex, has been awarded the Hunterian Society's Gold Medal for his essay in last year's competition. The subject was "The Management of Peptic Ulceration in General Practice." A *proxime accessit* award was made to Dr. B. C. Zoob, of Battersea. The subject for this year's essay is "Management of the Climacteric in General Practice." The competition is open to all general practitioners, and the closing date for entries is December 31. Further details may be obtained from the honorary secretary, Mr. Alec W. Badenoch, 110, Harley Street, London, W.1.

Nuffield Grant to Walter and Eliza Hall Institute.—The Nuffield Foundation has given £12,000 to the Walter and Eliza Hall Institute in Melbourne, Australia, for research into inherited elements in the more common human diseases. The gift is an outcome of discussions between the director of the Institute, Sir MacFarlane Burnet, F.R.S., and representatives of the Foundation.

Overseas Plastic Surgeons in Britain.—Twenty plastic surgeons coming from Austria, Belgium, Denmark, Egypt, Finland, France, Germany, Italy, and Portugal have just completed a two weeks' course at the Plastic Surgery and Jaw Injuries Centre of the Queen Victoria Hospital, East Grinstead. The course was directed by Sir Archibald McIndoe and arranged by the British Council.

William Hyde Award.—Miss P. C. Colson has recently received the William Hyde Award for 1952. Miss Colson is general secretary of the Central Council of Physical Recreation. The award is made by the Research Board for the Correlation of Medical Science and Physical Education, and is valued at £300.

Dr. F. E. Camps has been appointed to the part-time university readership in forensic medicine tenable at the London Hospital Medical School.

Dr. G. E. Francis has been appointed to the university readership in biochemistry tenable at St. Bartholomew's Hospital Medical School, London.

COMING EVENTS

Professor Henry K. Beecher, of Harvard, will deliver the MacArthur Postgraduate Lecture in the Surgery Lecture Theatre, University New Buildings, Teviot Place, Edinburgh, on May 5 at 5 p.m. His subject will be "Resuscitation and Other Early Care of the Severely Wounded Man."

Professor Gerhard Domagk will deliver the Cameron Prize Lecture in the Anatomy Lecture Theatre, University New Buildings, Teviot Place, Edinburgh, on May 6 at 5 p.m. His subject will be "The Development of Chemotherapy in Tuberculosis."

St. John Ambulance Brigade: Surgeons' Weekend Conference.—A conference and dinner for surgeons of all ranks, nursing officers, and non-medical officers nominated by their surgeons will be held at the Cairn Hotel, Harrogate, from April 23 to 25. Further information from the Department of the Surgeon-in-Chief of the Brigade, 8, Grosvenor Crescent, London, S.W.1.

Renal Association.—The annual general meeting will be held at the Ciba Foundation, 41, Portland Place, London, W.1, on May 28 at 4.30 p.m. Mr. I. H. Griffiths will speak on "Renal Arteriography," and Dr. Robert Gaunt on "Studies on the Experimental 'Eclampsia-like' Syndrome."

SOCIETIES AND LECTURES

A fee is charged or a ticket is required for attending lectures marked ●. Applications should be made first to the institution concerned.

Tuesday, April 20

SOCIETY FOR THE STUDY OF ADDICTION.—At 11, Chandos Street, W., 8 p.m., 70th annual meeting. Mr. Derek Curtis-Bennett, Q.C.: Alcoholism and the Law.

Wednesday, April 21

OXFORD UNIVERSITY.—At Department of Human Anatomy, 2.15 p.m., demonstration by Professor P. Stohr (University of Bonn): Morphology and Pathology of the Vegetative Nervous System.

ROYAL EYE HOSPITAL.—5.30 p.m., Mr. L. H. Savin: Ophthalmic Neurology (3).

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE.—3.30 p.m., Dr. C. Worster-Drought: Speech Disorders in Children of School Age.

Thursday, April 22

CHADWICK TRUST.—At 26, Portland Place, W., 5.30 p.m., Dr. C. Banning (Netherlands): Ante-Natal, Natal, and Post-Natal Care in the Netherlands.

MIDDLESEX COUNTY MEDICAL SOCIETY.—At Chase Farm Hospital, Enfield, 3.15 p.m., clinical meeting. Members of Enfield and Potters Bar and North Middlesex Divisions, B.M.A., are invited.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—5 p.m., Hunterian Lecture by Professor D. J. Browne: Principle of Controlled Movement in Orthopaedics.

ROYAL EYE HOSPITAL.—5.15 p.m., Dr. T. H. Whittington: Myopia, and the Care and Treatment of the Myopic Patient.

ST. ANDREWS UNIVERSITY.—At Physiology Department, Dundee, 5 p.m., Mr. J. Bruce: Surgery of the Small Intestine.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.—5 p.m., neurology demonstration by Dr. D. J. Williams.

Friday, April 23

OSTER CLUB OF LONDON.—At 11, Chandos Street, W., 7.45 p.m., Marie Stopes, Ph.D.: History of Contraception.

Saturday, April 24

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.—At Middlesex Hospital, 2.30 p.m., clinical meeting in Radiotherapy Department.

BIRTHS, MARRIAGES, AND DEATHS

BIRTHS

Harper.—On April 3, 1954, to Dr. Marita Harper (formerly Shattock), wife of Dr. Eric Harper, of Swindon, Wilts, a son.

DEATHS

Duncan.—On March 25, 1954, at the Chelsea Nursing Home, Gisborne, New Zealand, Robert Reid Duncan, M.B., Ch.B., D.P.H., formerly of Altrincham, Cheshire, aged 71.

Ham.—On March 28, 1954, Bertie Burnett Ham, M.D., D.P.H., formerly of Australia, aged 86.

Jameson.—On March 31, 1954, at his home, Romeland Cottage, St. Albans, Hertis, Harold Parnell Jameson, M.D., M.R.C.P.

Levy.—On March 31, 1954, at his home, The Heights, Marlow, Bucks, Alfred Goodman Levy, M.D., M.R.C.P., aged 87.

McMinn.—On March 31, 1954, at 47, Eaton Place, Brighton, Sussex, Robert Martin McMinn, M.B., Ch.B.

Mitchell.—On March 27, 1954, at Stowmarket, James Robertson Mitchell, M.C., M.B., Ch.B., D.P.H., of Dunallan, Combs Lanc, Stowmarket, Suffolk.

Moreton.—On March 31, 1954, at 24, Edensor Road, Eastbourne, Sussex, Reginald Moreton, M.R.C.S., L.R.C.P., aged 81.

Morrin.—On March 22, 1954, at 14, Fitzwilliam Place, Dublin, Eileen Morrin (formerly Dowling), M.B., Ch.B., wife of Francis J. Morrin, M.Ch.

Any Questions?

Correspondents should give their names and addresses (not for publication) and include all relevant details in their questions, which should be typed. We publish here a selection of those questions and answers which seem to be of general interest.

Encephalitis after Immunization

Q.—How great is the risk of encephalitis following immunization procedures against whooping-cough and diphtheria? Does the risk increase with age, and is it increased if a combined vaccine is given?

A.—There is no evidence of the occurrence of encephalitis following immunization with diphtheria prophylactic. American workers have reported cases of encephalopathy following injections of pertussis vaccine, but it is very difficult from a collection of case records to estimate what are the chances of developing such a syndrome after pertussis vaccination. It is noteworthy that in Byers and Moll's series¹ twice as many of the cases followed attacks of whooping-cough as followed the prophylactic vaccination. The risk in this country must be extremely small, as, despite the many thousands of young children who have received inoculations of pertussis vaccine in the past few years, recorded cases of post-inoculation encephalopathy have been very rare.²

Since most inoculations against pertussis are given in the early years of life it is impossible to say if the risk is greater with older children, although it may be that injections of vaccine in older children will activate a latent infection with a virus that has an affinity for the central nervous system—for example, mumps or herpes virus. There is no evidence that the risk would be greater with a combined prophylactic like pertussis vaccine and diphtheria toxoid, although the apparently greater risk of post-inoculation poliomyelitis following alum-containing combined prophylactics should be kept in mind. It is inadvisable to give pertussis vaccine alone or combined to a child with a history of recent convulsions or within three weeks of vaccination against small-pox.

Spots Before the Eyes

Q.—What are the causes of "spots before the eyes"? What are their significance and treatment?

A.—"Spots before the eyes" without any detectable particles moving about inside the eye can occasionally occur in patients suffering from derangement of the vessels which supply the occipital cortex. Such derangement is usually associated with cardiovascular disease elsewhere in the body, and it is unlikely that spasm can account for it in the absence of obliterative changes. A disordered liver, which is commonly blamed by the lay public, may also account for a few cases; but these "spots" are nearly always due to the presence of mobile opacities in the vitreous, and are essentially harmless. Indeed, many patients learn to ignore them when once they are assured that the spots are not of sinister import. Sometimes they are particularly obtrusive when a patient gets up after a long rest, as we can readily appreciate by a simple analogy. If a tumbler of lemon squash stands for a few hours, most of the flakes will settle to the bottom, but rotation or agitation of the vessel will spread these opaque particles, making the contents turbid.

Vitreous opacities are particularly common in myopes, and in all old people, but they are often found on routine examination of patients who had not noticed them. One important cause is choroido-retinitis, in which a shower of inflammatory particles will be launched into the vitreous.

Retinal detachment is another possibility to be borne in mind, but in this condition the patient will probably also complain of a shimmering film seen by the affected eye. Vitreous particles may also be derived from large retinal haemorrhages and intraocular foreign bodies.

There is no ocular treatment for "spots before the eyes" as such. When they are due to constitutional disturbance, treatment on general lines must be given. When the "spots" are due to intraocular disease—for example, retinal detachment—the causative lesion should be attacked. When they are harmless no treatment can disperse them, and the custom of piously prescribing potassium iodide as a remedy is quite useless. "Spots before the eyes," in the absence of general illness, demand a careful eye examination. If no abnormal signs are present, other than mobile vitreous opacities, the patient should be reassured.

Diseases Spread by Breast Milk

Q.—What diseases of the mother are likely to be communicated to the infant via her milk?

A.—The answer to this question is quite simple: no diseases are known to be transmitted to the infant via breast milk.

Certain possibilities may be considered, but these are more academic than practical. Staphylococci from a breast abscess might enter the milk, and could infect the child, and for this reason it is wiser to discard or boil milk expressed from an inflamed breast. It is not thought possible for bacteria in the systemic circulation to pass the cell barriers and enter the milk, but it is possible that viruses of small molecular size could do so. There is no evidence that this happens in man. It has been shown that, in specially bred strains of mice, cancer of the breast is transmitted in the breast milk, but nothing of this sort is known in man or other animals. Syphilis might be acquired from the nipple by an infant not infected before birth.

Thrush is frequently acquired from the mother's nipple, not from the milk.

Circumcision in Infancy

Q.—What are the indications for and against circumcision in the normal healthy baby?

A.—There are no contraindications to circumcision in earliest infancy. Later, haemophilia is an obvious contraindication.

The indications may be considered under three headings: religious, parental insistence, and paediatric. The first two do not call for any discussion. The third is rare. A preputial orifice so small that micturition is difficult, a long redundant prepuce with repeated ulceration at the tip, or one which is associated with recurring balanitis, and paraphimosis may be regarded as the chief indications. The subject has been well discussed by Gairdner.¹

Repeated X-ray Treatment for Cheilopompholyx

Q.—Is there any danger in repeating x-ray treatment of cheilopompholyx in a case which has already relapsed twice?

A.—Superficial x-ray therapy should be prescribed only by a dermatologist who knows what treatment the patient has previously received. Using unfiltered, fractional dosage—as should be employed—safety depends upon the actual dosage and the spacing of treatments. There is strong evidence to support the view that a total dosage exceeding 1,500 to 2,000 r units should not be given to any one area of skin. In some sites—for example, vulva and perineum—a total dosage of 1,000 to 1,500 r units should probably not be exceeded and such dosage is usually spaced over many years.

Arachnodactyly and Wedge-shaped Vertebrae

Q.—Is anything known of the inheritance of congenital wedge-shaped vertebrae? I know a father and daughter who both suffer from this condition, associated with mild arachnodactyly. It would be helpful to me to know whether the daughter's children are likely to develop the same condition.

A.—Arachnodactyly is due to a dominant gene, though there may sometimes be skipping of generations. Sporadic cases also occur; they may be due to dominant mutations. In about half the cases abnormalities of the vertebral column are also present. Very little is known about the genetics of wedge-shaped vertebrae, except that several instances in a family have been reported. As both the father and daughter are affected it is likely that a dominant gene is involved; if so, there is one chance in two that any child will receive it. It may be, however, that owing to possible skipping of generations the chance that any child will actually be affected is somewhat less.

NOTES AND COMMENTS

Male and Female Symbols.—Dr. E. J. THOMSON (Grimsby) writes: Your paragraph on the origin of ♂ and ♀ ("Any Questions?" March 6, p. 596) is obviously no more than a précis of your meditations on the matter, but it does include statements that read like facts, and some of them are fallacious. A less educated—and I refrain from "sophisticated"—eye would see at once that the symbols are simply primitive drawings of male and female genital parts. They were probably stereotyped, and their significance established, long before they were applied to Mars and Venus, and, on this basis, their use in alchemy becomes logical: the hard metal—the spear—is male, and the soft one—the pot—female.

The use of a distinctive part to represent the whole is common in all early art forms, and the gross exaggeration of sexual parts in Palaeolithic statues suggests that inscriptions of that period might yet be found to show just such hieroglyphs as these. This would put the date of origin nearer 10,000 than 2,000 B.C.

OUR EXPERT writes: I do not quite understand Dr. Thomson's difficulties. I am ready to take his word that the symbols ♂ and ♀ were used to indicate the genitals before they were used to designate the planets Mars and Venus, though I know of no evidence for this. As regards his second paragraph there must be a misunderstanding. An inscription must be "something written." Not only is there no evidence of writing among men of Palaeolithic culture, but the evidence that we have of their achievements suggests that the conception of writing had not dawned upon them. The earliest efforts that can be reasonably regarded as approaching writing are of the second half of the fourth millennium B.C. and are the work of men of Neolithic culture. This is long after 10,000 B.C. But, leaving the meaning of "inscription" aside, I know of no Palaeolithic painting or carvings of these signs, nor do I see any clear resemblance to ♀ in the exaggeration of the female genitalia in certain Palaeolithic figures. On the other hand, a resemblance of ♂ to the male genitalia may well satisfy those with the eye of faith so inclined, but I should like to have evidence from Palaeolithic paintings that it does so represent them.

Correction.—The leading article on remuneration of consultants (*Journal*, April 10, p. 860) should have read that the weighting allowed to part-time consultants and S.H.M.O.s is to be reduced from one and a quarter sessions to three-quarter sessions, not from one and three-quarter sessions to three-quarter sessions, as stated.

RADIOTHERAPY IN ITS RELATION TO DERMATOLOGY*

BY

B. W. WINDEYER, F.R.C.S., D.M.R.E., F.F.R.

Professor of Radiology, University of London

The art and science of radiotherapy has been closely associated with dermatology ever since the first attempts at treatment with x rays were made within a few months of Röntgen's epoch-making discovery in November, 1895. It was the evidence of erythema of the skin, of dermatitis, and of necrotic ulceration, produced accidentally on the exposed hands and faces of enthusiastic workers or during prolonged demonstrations of the properties of the new-found rays, that gave the first indication of a biological reaction. Similarly the biological action of radium was discovered by the recognition of radium-produced dermatitis by Walkoff in 1900, and by the famous Becquerel burn in 1901 (Becquerel and Curie, 1901). Becquerel carried some radium in his waistcoat pocket and subsequently developed a painful ulcer on his chest wall.

Since those early days radiotherapy, by the use either of x rays or of the radiations from radioactive substances—in particular radium and radon and more recently some radioactive isotopes—has been used with benefit in a great number and variety of dermatological conditions. It has brought to dermatological practice an important method of treatment. Indeed, it is probably no exaggeration to say that for many dermatologists radiotherapy has been their most important single therapeutic agent. At the same time it must not be forgotten that radiotherapy has also brought to dermatology some new and difficult problems in the form of pathological conditions which are among the most distressing and tragic, and the most resistant to treatment which can occur.

In the content of this lecture it is not possible to describe all the dermatological conditions for which radiotherapy may be of value, but some discussion of the main groups and the underlying principles may be of interest.

In dermatological practice the effect which is required by radiotherapy is usually one which is limited to the skin and immediate subcutaneous tissues. It is therefore desirable to use a type of radiation which is soft and absorbed in the surface layers and does not penetrate deeply into the body. This is obtained by x rays of low voltage or by the beta rays from radium or other radioactive substances. There is no necessity, and it is undesirable, to use more penetrating radiation such as is useful for more deeply seated neoplasms, except in the case of some of the more infiltrating malignant skin tumours. What is commonly known as superficial x-ray therapy—that is, x rays generated at a tension of not more than 100 kV, and lightly filtered radium plates which allow a high proportion of the beta rays to emerge, have been the main methods of radiotherapy for skin diseases. In more recent years some beta-

emitting isotope such as P³² or strontium⁹⁰ has been used as a substitute for radium with certain advantages.

Action of Radiation in Dermatology

The use of radiotherapy in dermatology may be grouped into three main types of technique, each used for the treatment of distinct and different groups of disease with different dosage levels and with the object of producing different biological effects.

1. *Multiple Small Doses.*—A technique of multiple small doses is used for the treatment of inflammatory conditions and of many dermatoses. The size of each dose is often less and usually not more than 100 r—about a quarter of that which would produce a visible erythema—and the intervals between each dose are usually of about a week. It may be repeated four or five times in a course of treatment, but the repetitions must be strictly limited, as even with such small doses harmful sequelae will occur after prolonged or multiple courses of treatment. From the earliest days of x-ray therapy it became known that many inflammatory conditions, both acute and chronic, would regress and subside after such small doses of radiation, but although much work has been done and many facts have been accumulated the true nature of the action of radiation in effecting such results is not known. Theories have been advanced that the action is primarily on the blood vessels, causing dilatation and diapedesis, or that there is a destructive effect on the most sensitive cells, the lymphocytes, which are accumulated in the tissues irradiated, with the liberation of antibodies, or a destructive effect on developing fibroblasts. Whatever the exact mechanism may be there is some definite reaction produced, without any clinical erythema, which promotes the regression of these pathological processes. Similar techniques are used in the treatment of some haemangiomas in children and for keloids.

2. *Single Dose.*—A single-dose technique is used to produce temporary epilation in cases in which there is infection deep in the hair follicles. The dose given is one which will produce a mild erythema—that is, between 400 and 500 r with this quality of radiation—and it acts by causing damage to the sensitive cells lining the hair follicles. The hair falls out, leaving the follicles open and amenable to the application of fungicidal or bactericidal agents. The follicles regenerate after such dosage and the hair grows again.

3. In the treatment of malignant disease higher dosage is given, and it may be close to the maximum that the normal tissues will tolerate without irreparable damage. The whole basis of the radiotherapy of malignant tumours is that there is a difference between the radio-sensitivity of many malignant growths and the normal tissues in which they grow. Such malignant lesions of the skin can be destroyed by doses which are not

*Chadwick Trust Malcolm Morris Memorial Lecture given at St. Mary's Hospital, London, W.2, on December 3, 1953.

sufficient to cause permanent irreparable damage to the skin and subcutaneous tissues. In most cases, however, the dose necessary will cause a marked inflammatory reaction, with subsequent dryness and permanent depilation. The biological reactions involved in the destruction of the tumour cells are of a complicated nature and involve alterations in the molecular structure of the intracellular protoplasm.

A single-dose technique may be used in the treatment of some superficial malignant tumours of limited extent and known radiosensitivity. This is convenient in such cases because it allows the treatment to be completed without numerous attendances. In larger and more infiltrating lesions a safer result with less damage to normal tissues is obtained by spreading the total dose out over a more prolonged period of time. This may be achieved by using a fractionated technique—that is, the total dose is spread over a period of some days or even weeks, and a daily treatment is given, delivering a predetermined fraction of the total on each occasion. When radium is used the same type of effect may be obtained by continuous irradiation with a small quantity of radium, spread over a period of days.

Inflammations and Dermatoses

Before the days of chemotherapy, x rays were used to treat pyogenic infections such as boils and carbuncles, with marked improvement as regards the relief of pain and induration. There is more rapid subsidence and the inflammatory process becomes more circumscribed. Erysipelas also was treated as a routine in some institutions. These are matters of historical interest now, but there is still a useful field for radiotherapy in the treatment of chronic paronychia, which may be resistant even to modern chemotherapy and which can be healed in the great majority of cases by doses of the order of 100 r or less, repeated at weekly intervals for four or five doses.

A variety of the more chronic types of dermatosis are treated in the same way. Patches of neurodermatitis respond well to the same order of dosage, and chronic eczema with lichenification, resistant to other methods of treatment, usually heals after three or four exposures.

X-ray treatment is of real value in many cases of chronic acne vulgaris with induration of the subcutaneous tissues. There is more doubt about its value in acne rosacea, but I believe that here too it has an important place in the skin manifestations, and certainly it is at present the most valuable method of treatment available to promote healing of the corneal infiltrations and to alleviate the distressing symptoms of pain and photophobia.

Lupus Vulgaris.—The value of x-ray therapy in lupus vulgaris has been the subject of considerable discussion. There is no doubt that many cases have healed after repeated doses of the order of 100 r at weekly intervals. In the course of years many patients have received gross overdosage, with the development of telangiectasis, excessive fibrosis, and subsequent carcinomatous degeneration, and there has been a tendency to consider that carcinoma developing on lupus is always the result of the x-ray treatment. There are, however, examples of lupus carcinoma when no x-ray treatment has been given. The excessive scarring occurring in this disease is likely to give rise to carcinoma in the same way as carcinoma may arise in any other scar tissue, particularly the extensive scars from burns. Fortunately there seems to be good reason to expect that newer methods of treatment will be more efficacious and may make x-ray treatment unnecessary in this disease.

Psoriasis.—This was one of the first conditions to be treated by x rays. The lesions, whether on the skin or on the nails, respond well to small doses in most cases, but unfortunately they recur with almost unfailing regularity. The unfortunate patient then, not unnaturally, again seeks

the remedy which has been so successful, and the process is repeated. There have been many instances in which excessive radiation has been given, perhaps by the accumulation of dose over a period of years by a succession of practitioners, with resultant sclerosis and telangiectasis and ultimately the development of malignant disease. It has been truly said, and it particularly applies to x-ray therapy, that volumes have been written not only about the cures for psoriasis but about the cures for the conditions produced by the cures for psoriasis. Of course, it is not always radiotherapy which causes cancer in psoriasis. There are cases of development of malignant disease in the absence of any irradiation, but I believe that psoriasis should be subjected to radiotherapy only in exceptional cases, when patches resistant to other forms of treatment are causing distressing symptoms, or for involvement of the nails.

Pruritus.—The same arguments apply to the treatment of pruritus. In many instances x-ray therapy will immediately cause relief of symptoms, but only too often the condition recurs, and then recourse is had again to the miracle treatment. The dangers of accumulation of dose are enhanced by the fact that the perineum and perianal regions are parts of the body naturally soft and moist, which are particularly sensitive to irradiation, and do not tolerate heavy dosage. It is difficult for the patient to realize the dangers of this apparently simple and rapid method of alleviating his discomfort, and he may go off to another unsuspecting practitioner when the original one refuses further treatment. There have been many real tragedies with extensive necrosis due to such treatment, and I consider that pruritus also should be treated by radiotherapy only in exceptional circumstances when there is a real dermatitis with lichenification, and after due warning to the patient.

Angiomata

The mixed capillary cavernous type of haemangioma, the so-called strawberry naevus, is often treated by irradiation, and the results of such treatment are almost universally satisfactory. These lesions are present at birth or appear shortly afterwards. They may grow with considerable rapidity during the first year of life, causing great alarm to the mother or they may show little progress, becoming actually larger but with an increase in size only proportional to the growth of the child. In some cases there may be no increase in size, and they may begin to regress and disappear completely within a few months without any treatment.

There is a tendency for all of them to regress within a few years, and it is doubtful if any but a small proportion would remain until adult life even without any treatment. There is no doubt that radiotherapy will make them disappear more quickly and more completely, and, apart from the general desirability of curing the deformity as quickly as possible, there are some cases in which treatment is urgently required. An angioma on the lip may interfere with sucking, or one on the eyelid may interfere with the function of the eye. Others may ulcerate and, if situated in or near the napkin area, may become infected.

Two or three suberythematous doses of superficial x rays or applications of beta-ray radium plates will ensure gradual regression, and in most cases this will continue until there is no sign of the lesion and the overlying skin will gradually attain practically normal texture. Complete regression with this form of treatment may take a year or two, but it is preferable to any attempt to cause rapid disappearance with larger doses, as they may cause atrophy and scarring of the skin. There have been instances where such larger dosage has been responsible for severe deformity by interference with the growth of a limb or the proper development of the bones of the face or orbit. More deeply seated cavernous haemangioma may be effectively treated by the implantation of radon seeds with appropriately small dosage, which should be kept to 1,200 r as a maximum.

The use of radiotherapy in these lesions, if properly controlled with suitably small dosage, is in every way preferable

to treatment by carbon dioxide snow, which in most cases leaves an unsightly scar.

The central vein angioma, or spider naevus, is unsuitable for radiotherapy; and the capillary haemangioma, or port-wine stain, commonly occurring on the face and sometimes of considerable extent, also does not respond to this form of treatment. In order to obtain any improvement in the discoloration by the use of x rays or radium it is necessary to give such dosage that there will be some permanent damage to the texture of the skin. The cosmetic result is usually worse than if no treatment had been given except to cover it with make-up, and there is the real danger of severe scarring, necrosis, and even cancer formation in later years.

Thorium X has been used for the treatment of these stains, being contained in a solution which is painted on the surface of the lesion with the object of making use of its alpha rays with their limited power of penetration. Some dermatologists with experience of hundreds of cases so treated consider that a worthwhile improvement can be obtained, but I have not been able to convince myself of any appreciable effect.

Keloid

In the treatment of keloids and hypertrophic scars radiotherapy has an important part to play. When the keloidal scar is recent and still vascular and has not become organized into solid fibrous tissue, marked improvement can be obtained by the application of x rays or of radium two or three times at intervals of a month or six weeks. Each individual dose should be less than that which would cause an erythema, and care must be taken that the total dose is not excessive. There is subjective improvement with lessening of itching, tenderness, and pain, and the scar becomes paler, flatter, softer, and more pliable, so that there is an improvement in the amount of contracture that may be present. If the keloid is old, hard, and avascular it will not respond to radiotherapy. In such cases it should be removed surgically where possible, and the recent scar treated by radiotherapy to prevent recurrence of keloid. X rays are often used as a pre- or post-operative measure to prevent the development of thick and unsightly scars when surgical operations are undertaken in sites where a good cosmetic effect is essential.

Temporary Depilation

Ringworm of the scalp in children was first treated by Freund in 1897. Its success depends on complete temporary epilation of the affected area, which in fact means complete temporary epilation of the whole scalp. In the first years of radiotherapy there were many failures and accidents in the treatment of these children. Insufficient dosage at any point might mean that areas of infected hair remained on the scalp and the whole scalp became reinfected when the new hair grew again. There were cases of permanent epilation and of necrosis of the skin through overdosage, either in large patches or in strips between adjacent x-ray fields. There were also many successful cases. One of my colleagues had his scalp depilated for ringworm by Sir Malcolm Morris about 50 years ago. He has still an excellent head of hair.

In 1907 Kienböck described a method of giving irradiation to the scalp using five points of application. In 1909 Adamson, a British radiologist, described some modifications to this method, and ever since that time the Kienböck-Adamson technique has remained the most frequently used standard technique for irradiating the scalp in cases of ringworm. A four-field method is advocated by Shanks (1931) as a saving in time, but whichever is used the results, in careful hands, are now uniformly good. Ringworm of the scalp has been stamped out except for sporadic cases, and any real complications and sequelae from the treatment are of the greatest rarity.

Sometimes straight hair may grow back in curls after epilation and—much more serious—curly hair may turn straight. This fact has, however, its compensations. It is a well-known result among the coloured population of Washington, D.C., in the United States, and many mothers

will apply irritants to their children's scalps so that they will simulate ringworm, be treated by epilation, and run a chance of getting straight hair.

Temporary epilation may also be necessary for the cure of resistant cases of sycosis barbae.

Malignant Disease

In the treatment of malignant disease of the skin radiotherapy has a role of great importance. In some cases it is the method of choice and should be used as the sole treatment. In some cases it is better to use a combination of radiotherapy and surgery and in others surgical excision alone should be employed.

The choice of method of treatment, the technique, and the dosage will be decided according to the clinical and histological features of each individual case. Radiotherapy may be given by x rays generated at high or low voltage, by surface application of radium, by radium needle implantation, by telradium, or by some radioactive isotope used in any of these ways as a substitute for radium. A single dose, a continuous application, or a fractionated course of treatment may be the technique chosen.

Whatever it may be, it is essential for the curative treatment of malignant disease of the skin, as in cancer of other organs, to give the chosen form of radiotherapy as a single planned course of treatment. There is no place in the attempted cure of cancer for the multiple-small-dose technique. After possible initial regression the tumour becomes progressively more resistant and cannot then be cured even by more adequate dosage.

A second principle is that if failure has occurred after such a planned course of radiotherapy, a second attempt at treatment is unlikely to be successful and runs a risk of producing necrosis. Surgical ablation should then be carried out in the majority of cases, even though it may mean considerable disfigurement by sacrifice of tissue. In some cases of marginal recurrence outside the previously treated area a further course of radiotherapy may be successful, and may be undertaken without serious risk.

Rodent Ulcer

In small and superficial rodent ulcers there is little to choose between the curative results of radiotherapy and surgical excision. Radiotherapy may be chosen because of the better cosmetic effect in some situation, particularly in extensive lesions in which excision would entail a graft to cover the defect.

In superficial cicatrizing growths, which are often of considerable extent before the diagnosis is made, surgery may be impossible or may be practicable only at the expense of great deformity. Radiotherapy may be successful in such cases with only minimal resultant scarring. In some cases in which the eyelids or the conjunctiva is extensively involved the use of a combination of radiotherapy with surgery may be desirable. Preliminary irradiation may allow the surgical excision to be limited to a simple excision of the eyeball, instead of a wide exenteration of the orbit. Earlier, more limited lesions of the eyelids may be treated by irradiation with little scarring or deformity, and without damage to the eye if a contact shield is placed between the lids and the globe or if the beam of radiation can be directed away from the eye by displacing the eyelid during the treatment.

Squamous-cell Carcinoma

Squamous-cell carcinoma of the skin responds as well to radiotherapy as does basal-cell carcinoma. The percentage of cures is lower because the lesions are in general more extensive when they come for treatment, and because a proportion arise in scar tissue with poor blood supply. There are also a number of failures due to the development of glandular metastases. As a general rule involvement of bone or cartilage by direct extension of malignant disease means that the growth is less likely to be cured by irradiation and more likely to undergo necrosis. Careful technique with radiation of hard quality will, however, provide some

successes in these cases, and it is worth while attempting radiotherapy in the first place in cases such as those of the pinna of the ear, where subsequent surgical excision will not have been made more difficult or more extensive if recurrence or necrosis results.

Malignant tumours on the limbs are difficult to treat by irradiation owing to the likelihood of necrosis of underlying bone and tendons. Squamous-cell carcinoma of the lower limb which sometimes arises on the site of long-standing varicose ulceration is often extensive and infiltrating. It is usually best treated by amputation. In the upper limb, however, every effort should be made to conserve the functions of the hand, and success may be achieved even in lesions of great extent by surface application of radium on a moulded appliance over a period of not less than two or three weeks.

Epithelioma of Lip

Epithelioma of the lip may come within the province of the dermatologist. Here too the choice between radiotherapy and surgery must be carefully decided for each individual case. Radiotherapy may be chosen, particularly in growths extending along the lip margin, on account of the excellent cosmetic results. Surgery should be chosen in cases of recurrence after radiotherapy and in advanced cases with deep extension and involvement of bone. Surgery may be necessary for repair of the tissue defect where radiotherapy has successfully dealt with an ulcerating type of lesion.

In tropical and subtropical countries such as Australia or South Africa, where European populations have continuous exposure to hot sunlight, there is a much higher proportion of skin malignant disease than in this country. Radiotherapy is of enormous benefit, and is widely used for the treatment of multiple lesions, either hyperkeratoses which would progress to the development of cancer, or frankly cancerous lesions. There is a place for surgery too in the treatment of these patients with a multiplicity of lesions and the certainty that more will develop. The cosmetic results must be of minor importance, and anyway, in a dry and keratotic skin, the scars of multiple small incisions may not be more unsightly than those of multiple treatments by irradiation. Surgery is generally preferable to irradiation for malignant growths occurring on the trunk. The type of rodent ulcer is often the intradermal and superficial cicatrizing variety; when treated by irradiation they usually leave thin atrophic scars which are easily damaged if rubbed by clothing; the cosmetic effect is not important, and surgical excision is often quicker and easier for the patient than a fractionated course or prolonged continuous applications of radiotherapy.

Although successful results may be anticipated from adequate surgery or adequate radiotherapy of rodent ulcer and squamous cancer of the skin, even early growths which are superficial and apparently innocuous in appearance, if not adequately treated, will recur and they will infiltrate widely, causing destruction of underlying tissues and ultimately the death of the patient. There are also some few of them, with no obvious difference in their clinical appearance, which appear from the onset to be much less amenable to treatment and which, despite wide excision or apparently suitable radiotherapeutic technique, develop rapid and widespread recurrence.

Naevocarcinoma

Malignant melanoma, or naevocarcinoma, is one of the most rapidly developing and deadly forms of malignant disease. It is usually considered to be the supreme example of a radioresistant tumour for which surgery is the sole appropriate treatment. Recent observations have shown that some of these tumours are radiosensitive and that it is advisable to give wide and intense post-operative irradiation after surgical excision.

Reticuloses

The diffuse group of diseases affecting the reticulo-endothelial system, which includes mycosis fungoides, Hodgkin's disease, reticulum-cell sarcoma, lymphosarcoma, and the

leukaemias, have dermatological manifestations, sometimes as the first presenting feature. Radiotherapy is of great value in the treatment of many of these eruptions as well as in the more deeply seated lesions in glands, viscera, and skeleton. They often are very radiosensitive and disappear rapidly with small dosage, but unfortunately they are not permanently arrested, and widespread recurrence almost invariably leads to a fatal termination.

Local Reactions

Often there is misconception about the type of local reaction which occurs after irradiation for the treatment of malignant disease. It may be necessary to give the maximum dose which the normal tissues will tolerate, and this may produce a moist desquamative reaction of the epidermis. It is less frequently seen nowadays, and is avoided whenever possible. It will heal rapidly in 10 to 14 days, leaving a dry, rather inelastic, and hairless skin with some pigmentation, and in individual cases there may be later development of telangiectases. This is the maximum therapeutic reaction which should be produced on the skin and should not be confused with an area of necrosis, the x-ray or radium burn, which is a deeper ulceration involving the dermis or deeper tissues.

Necrosis

Necrosis is the most serious complication of irradiation. It may occur as an immediate sequel to treatment with high dosage, in the form of early or acute necrosis. In such cases, following an early developing erythema which becomes a deep purplish colour, with some oedema of the affected part, the ulceration may extend rapidly, and is associated with severe pain. There is little tendency to heal, because of lack of blood supply, due to endarteritis of the vessels in the affected area. There is always marked secondary infection.

Acute necrosis occurs as the result of some error or accident in technique such as the use of the wrong filter, the overlapping of adjacent fields of irradiation, or some miscalculation or error in measurement of the time for delivering a prescribed dose. It may also occur as the result of lack of appreciation in the prescription of treatment of the dose which some particular area will tolerate. There are individual variations in resistance according to age and certain pathological states: infected tissues necrose more readily; certain parts of the body are more sensitive than others, particularly if bone is close underlying the skin or there is a deficiency of blood supply; the previous application of local irritants may increase sensitivity; and, in particular, previous irradiation renders the tissues more liable to necrosis.

Necrosis may occur when a deliberate risk has had to be taken and heavy dosage has had to be used as the only possible chance of curing the disease. Although necrotic ulceration is often thought to be a sign of inaccurate treatment it is inevitable that occasional instances should occur in the treatment of large numbers of cases of cancer. It may sometimes be the price that has to be paid for the cure of the disease. Necrosis should never occur, and the risk should not be run, when dealing with non-malignant conditions which can be treated by other means.

Necrotic ulceration may occur as a late phenomenon. An area which has been heavily irradiated has some deficiency of blood supply due to increased fibrosis and sclerosis of the blood vessels. Such a volume of tissue may not withstand the effects of trauma occurring at a later date and may break down with the development of ulceration similar to that of acute necrosis. For example, after the treatment of a malignant tumour of the skin excessive exposure to the sun or to frost-bite may precipitate necrosis even many years later. Heavily irradiated bone and cartilage are particularly liable to late necrosis, and the precipitating cause may be some accidental blow or even a local infection of minor degree. Necrosis of the jaw may occur following dental extraction even five and ten years after heavy irradiation for cancer of the tongue or mouth.

Carcinogenesis

Repeated small and suberythematous doses, each of which has no apparent clinical effect, may cause irreparable damage to the skin. The effects come on gradually and may not be seen until years after the irradiation. There is dryness of the skin due to destruction of sweat and sebaceous glands, permanent depilation, and loss of elasticity due to fibrosis of the dermis. There is also a diminution in subcutaneous tissue, and the skin develops a drawn, shiny parchment-like appearance, sometimes with the development of disfiguring telangiectasis. This stage will go on to the development of hyperkeratoses and papillomata; if occurring on the hands, cracks and fissures will occur around the nails, which become ridged and brittle. Eventually cancer will develop with induration of the base of the hyperkeratoses, or by extension of ulceration from the unhealed fissures. This is the type of reaction and sequence of events which occurred in the pioneer radiologists.

In 1904, nearly 20 years before the formation of the British X-ray and Radium Protection Committee, which led the way in setting up safe working conditions, Dr. Cecil Lyster, medical officer in charge of the electric department of the Middlesex Hospital, discussed the loss of sensation in his own fingers after repeated daily exposure, and stated: "It was not until after three months' constant exposure that I noticed my nails were becoming hard and dry with a tendency to split. The hair came off the back of my hands and I soon found the skin, where most exposed to the rays, became dry and scaly." He then used a pair of wash-leather gloves painted with white lead, and his hands improved. His account goes on to describe the ulceration which developed on the back of his fingers following the exposure of his ungloved hand for 20 minutes to x rays in May, 1903. His hands healed on that occasion, but unfortunately he developed cancer of the hands and died 17 years later. He was one of that gallant and unfortunately numerous band of x-ray martyrs who died as the result of changes induced by overexposure to radiation. There were other pioneers, and among them dermatologists, who suffered from the general effects of irradiation and succumbed from aplastic anaemia.

Discrimination in Use of Radiotherapy

These local and general reactions and sequelae, occurring sometimes 10 and 20 years after multiple treatments or frequent exposures, have drawn attention to the urgent necessity for discrimination in the choice of the condition for which radiotherapy should be used. I consider that as a principle it should not be used in any non-malignant condition for which a simpler and safer method of treatment will give equal chances of success.

Warts.—The place of radiotherapy in the treatment of warts is a question on which there is by no means general agreement. Many of them will disappear after adequate irradiation, but in most instances single warts of long standing, particularly those around and under the finger-nails, need a dose to the small area involved which is sufficient to produce a sharp erythema and perhaps desquamation. Warts on the plantar surface of the foot are a special problem; they can frequently be treated with complete success by a single dose of x rays or a single treatment by radium. This is particularly true of the infective plantar warts of children. The sole of the foot, in common with the palms of the hands and the perineum, is one of the most dangerous areas to irradiate. It is very liable to trauma, and necrosis may occur after heavy dosage. Sometimes warts have failed to disappear or have recurred and have been given a further dose, perhaps by another practitioner. In some cases callosities caused by faulty weight distribution have been treated as plantar warts and have inevitably recurred. Whatever the reasons, there have been numerous cases of severe and crippling necrosis following the treatment of warts, and I consider that, even though the majority can be treated easily and successfully without accident, it is wiser to withhold

irradiation and to treat them all by safer methods such as surgical excision.

Cosmetic Treatments.—The use of radiotherapy for cosmetic reasons such as the removal of superfluous hair should be condemned, as it has been the cause of many real tragedies. Permanent depilation cannot be attained without running the risk of later skin changes, with much disfigurement and subsequent cancer formation. The permanent reduction in secretion of sweat can also be attained only with great risk, and hyperidrosis should be treated by irradiation only in exceptional cases. The risks inherent in the treatment of pruritus and psoriasis have already been discussed.

The type of skin cancer which occurs as the result of irradiation is usually squamous-cell epithelioma, but rodent ulcers have occurred and sarcoma has also been described.

Radiotherapist and Dermatologist

The advent of the radiotherapist has created some problems and some difficulties in deciding the exact place of the dermatologist and of the radiotherapist in the radiotherapy of dermatological conditions. These problems must be solved, and are being solved, by mutual good will and understanding, because both have some essential contribution to make. X-ray therapy is for many dermatologists such an important part of their work that they have installed their own x-ray therapy plants as a necessary adjunct to their dermatological practices. They have become accustomed to treating their patients with standardized techniques and have largely eliminated the dangers and accidents by using very small doses, which are all that is necessary for the majority of patients they treat. Naturally such experienced dermatologists consider that there is no necessity for the help of the radiotherapist and that they can be self-sufficient. On the other hand, there is a tendency for the radiotherapist to consider that all cases of malignant disease of the skin should undoubtedly be treated by him and should be in his sole care.

I do not think that these arrangements are satisfactory and in the best interests of the patient. Radiotherapy of all conditions is best conducted, and the best results will be obtained, if there is constant and close collaboration between the radiotherapist and his colleagues in other clinical specialties. In dermatological radiotherapy, collaboration between dermatologist and radiotherapist will bring the best results so far as the patient is concerned.

Apart from such technical questions as ensuring accuracy by proper calibration and measurement of dose, of ensuring homogeneity of irradiation over the field irradiated, and apart from questions of protection of patient and personnel and adequate maintenance of plant, the radiotherapist can bring his experience in the irradiation of other conditions. The use of this knowledge, added to the specialized clinical experience of the dermatologist, is most likely to ensure progress in this branch of therapy.

Such collaboration is also essential in the development of the proper use to be made of new methods of irradiation and new technical possibilities that are now available. The whole field of use of radioactive isotopes must be explored. Many of these are suitable for dermatological use, with greater convenience and safety than the established methods of irradiation, and can provide a variety of new techniques. There is also an urgent need for more knowledge of the biological effects produced by radiation in many of the conditions which are treated.

The period of 30 years since the death of Sir Malcolm Morris has seen many changes and much progress in radiotherapy in relation to dermatology. We are now in a period of intense activity and discovery, but there is still much to be done.

TREATMENT OF ACUTE GASTRO-DUODENAL HAEMORRHAGE WITH PARTICULAR REFERENCE TO QUANTITATIVE BLOOD REPLACEMENT

BY

F. W. GUNZ, M.D., Ph.D., M.R.C.P.
HaematologistI. D. GEBBIE, M.B., F.R.C.S., F.R.A.C.S.
Assistant Surgeon

AND

R. C. S. DICK, M.R.C.P., M.R.A.C.P.
Assistant Physician

Christchurch Hospital, Christchurch, New Zealand

During the year beginning in May, 1952, we treated patients with acute gastro-duodenal haemorrhage by a method incorporating the following principal features: (1) initial treatment by conservative measures; (2) early estimation, by means of a blood-volume determination, of the amount of blood lost; (3) quantitative replacement of the blood lost; (4) repetition of the blood-volume estimation to determine if haemorrhage has ceased or has recommenced; (5) early surgical intervention in cases of haemorrhage continuing or recurring in spite of conservative treatment.

We have been impressed with the increased saving in life since the inception of this therapeutic regime, and, while our own trial continues, publication of clinical detailed results obtained to date seems to be warranted.

The treatment of acute gastro-duodenal haemorrhage is still controversial. Agreement is lacking on such points as the diet to be given, the quantity of blood to be administered and the rate of transfusion, and the indications for emergency surgical operations.

It is difficult to compare the results furnished by various means of treatment, because of fundamental differences in the material reported on by the authors. Such differences are particularly noteworthy in the age and social grouping of patients studied and in the average severity of the haemorrhage: whereas some authors include all cases of bleeding in their series, others select only those of "severe" or "massive" haemorrhage; and the criteria by which the assessment of the severity is made vary widely.

One further source of differences among the various published accounts is worthy of emphasis. While some report "personal" series treated by outstanding specialists in this field, others summarize work carried out at general hospitals by heterogeneous medical groups without special facilities for selection or segregation of patients. The treatment described in this paper was carried out by a staff of general physicians and surgeons of varying experience, and the results represent the work of some 15 individuals. We believe that a similar scheme could readily be organized at any well-equipped general hospital.

Definition.—The term "gastro-duodenal haemorrhage" as used here denotes bleeding arising from intrinsic lesions of the stomach or duodenum. It excludes bleeding from oesophageal varices. "Acute" means bleeding at or shortly before the first examination.

Principles of Treatment

At Christchurch Hospital, at the present time, all patients stated to be suffering from acute gastro-duodenal bleeding are initially admitted to a surgical ward and seen by the surgeon dealing with acute cases. A physician is always on call, particularly when a patient's suitability for operation is being considered. Emphasis is laid on conservative treatment in the early stages, and adequate blood transfusion is regarded as its most important part. Only when this is seen to have failed to arrest the bleeding, or in cases of recurrent haemorrhage, is surgical intervention considered. We believe that non-arrest of bleeding should be diagnosed within 48 hours of admission and that the decision to operate should be made during that period.

Blood Transfusion

The purpose of blood transfusion is twofold: to relieve shock and other symptoms resulting directly from loss of blood and to raise the patient's haemoglobin concentration to a level permitting adequate oxygenation of vital organs, such as the heart, liver, kidneys, and brain, and giving the best possible chance to the surgeon if he should be forced to intervene. It is widely recognized that emergency surgery carried out on anaemic patients is beset with a high and possibly prohibitive mortality, especially if the anaemia is of any length of standing. Prevention and rectification of anaemia seem to us to be the most important single aim in the initial treatment of acute gastro-duodenal haemorrhage, and we believe that, whenever there is evidence that blood has been lost, the extent of the loss should be ascertained and the deficit made good as rapidly as possible.

It was pointed out by Bennett *et al.* (1938) that in the early stages of most cases of acute haemorrhage an examination of the peripheral blood alone can give no valid information about the amount of blood lost, because cells and plasma are lost in equal proportion, and anaemia cannot be diagnosed until the plasma volume is restored by means of haemodilution. This classical paper has not received the attention it merits, and the severity of haemorrhage is still estimated by most investigators in terms of the haemoglobin level or red-cell count. Thus Crohn (1953) defines "massive" haemorrhage as that which is accompanied by shock and a lowering of the red-cell count to 3,000,000 or less per c.mm. or the haemoglobin level to 7.5 g. or less per 100 ml. In our series, following the advice of Bennett *et al.*, we have estimated the blood loss by means of a determination of the blood volume, and have used the figures so obtained for prescribing the quantity of blood to be transfused, the aim being restoration of the total red-cell mass to the figure calculated to be normal for each patient.

Other Therapeutic Measures

The diet is regulated according to individual requirements. Although we do not regard initial starvation as desirable we have found that many patients suffering from considerable degrees of gastro-duodenal haemorrhage tolerate early feeding badly and prefer to take only sips of fluid, at least during the first 12 hours. We give a semi-liquid gastric diet as soon as patients can take it comfortably. Nothing seems to be gained by forcing patients to eat or drink in the intervals between haematemeses.

Colloidal antacids have generally been given from an early stage, especially where pain persisted.

Sedation seems an important aspect of treatment, and includes not only drugs (we prefer not to use morphine in patients who are vomiting) but also liberal reassurance by the attending practitioner. When apprehensive patients are suddenly translated to an unfamiliar environment and then subjected to a series of investigations, which though necessary are puzzling to them, brief explanations and friendly reassurance can do much to ensure the success of treatment.

Surgery

During recent years it has become evident that in certain cases haemorrhage from the stomach or duodenum will not

subside under conservative treatment, however long continued, and that surgical removal or obliteration of the bleeding lesion is necessary. Two courses are open to the surgeon: either to operate on all except mild cases of haemorrhage (Finsterer, 1939; Stewart *et al.*, 1950) or to attempt to select those patients in whom conservative treatment is likely to be unsuccessful. We have adopted the second course, subjecting to emergency surgical treatment two classes of patients: (1) Those who in spite of conservative treatment, including adequate blood transfusion, showed evidence of bleeding at the end of 48 hours' observation in hospital—the operation, preceded by appropriate measures of resuscitation, being performed as soon as such a diagnosis had been made. (2) Those who, following cessation of the original haemorrhage, showed evidence of recurrent bleeding while still in hospital.

The operation of choice was partial gastrectomy, but in one case this was not thought to be feasible because of the patient's poor condition, and a local repair was done.

Technique of Blood-volume Estimation

We have used exclusively Gregersen's (1944) Evans blue method for determining the plasma volume (V_p), and have found it convenient and accurate enough for emergency use. Only slight modifications in Gregersen's technique have been necessary in our series. Thus the chromogenicity of the dye used by us was so high that the recommended injection of 25 mg. could sometimes not be repeated within 48 hours without producing a rather alarming slaty-grey staining of the patient's skin and mucosae. For this reason we injected the full dose only in exceptionally large patients, while in those of small and medium stature we gave 15 to 20 mg. on each occasion. Calibration standards were prepared from dye diluted solely with plasma. We have now performed well over 300 blood-volume estimations with this dye and have noted no sign of toxicity in any patient.

In the calculation of the total blood volume (V_b) and the total red-cell mass (V_c) we have made use of the venous haematocrit reading, multiplying it by a factor of 0.96 to correct for trapped plasma. We realize that an error was thereby introduced, as the total body haematocrit reading is lower than that of the venous haematocrit, and that the correction factor 0.86 would have given a more accurate result (Mollison, 1951). For the purpose of computing the amount of blood to be transfused the calculated V_c was compared with the "ideal" V_c . The latter was obtained by multiplying the patient's "ideal" weight (from Life Tables, using the patient's height and age) by the figure 36 ml. per kg. body weight. The work of Reeve and Veall (1949) has indicated that 30 ml. of red cells per kg. is a better estimate of the "ideal" V_c . The second error thus introduced into our calculations acted in the opposite direction to the first and partly cancelled it. We have calculated that by using the older figures mentioned we overestimated blood losses by from $\frac{1}{2}$ to $1\frac{1}{2}$ pints (284 to 850 ml.) per patient, according to the severity of the haemorrhage. This error does not appear to invalidate the results of our investigations, which were carried out under emergency conditions and not intended to supply fundamental data. When successive blood-volume estimations were compared for the purpose of establishing the presence or absence of continued bleeding the errors mentioned above did not influence our calculations, as we were comparing two sets of figures both obtained with the use of the same factors.

Using the Evans blue technique in non-bleeding patients, we have found successive estimations of the V_p to agree to within 5%, as claimed by Gregersen. Great care in injecting the dye, in removing samples of blood, and in estimating dye concentrations (using a Coleman spectrophotometer at a wavelength of 625 m μ) was, however, necessary to obtain such results, and all these operations were carried out by experienced senior laboratory staff. As few of our patients were able to take much food at the time of our examinations we have had little trouble with turbid plasma samples. Difficulties occasionally arose in estimating the

height and weight of gravely ill patients, and in some cases we found it inadvisable to use the "ideal" weight for calculating the "ideal" V_c owing either to the presence of gross obesity or to malnutrition. In these cases we used a figure lying between the actual and the "ideal" weight.

Technique of Transfusion

All patients were transfused by means of the continuous-drip method with either stored whole blood or packed red cells. The normal rate of transfusion was one pint (570 ml.) in four hours. This rate was generally exceeded for the first one or two bottles of blood in the more severe cases of haemorrhage; when active bleeding was obviously proceeding, and particularly when patients were being prepared for emergency operations, blood was often given at very rapid rates and sometimes simultaneously into two veins.

As already stated, our aim was to restore the total V_c to the "ideal" by means of transfusion. For this purpose we assumed a pint bottle of stored blood to contain 200 to 220 ml. of red cells. If, therefore, we found a deficit of 1,000 ml. in the V_c we would give four to five bottles of whole blood. Packed red cells were often given when a patient's V_p was found to be large compared with his V_c , and especially when heart failure was present. In a few cases incipient congestive heart failure with a large V_p appeared to make it advisable to leave the patients with a blood volume of only about 80% of the calculated normal.

Material

During the year since the adoption of this therapeutic regime we treated 88 cases of acute gastro-duodenal haemorrhage: males, 69 (78%); female, 19 (22%). Five of these were admitted twice during the year, so that the series comprises 93 separate admissions. In addition several other patients were on admission thought to be suffering from haematemesis or melaena, but were on investigation found to have lost only insignificant amounts of blood. We decided to exclude these from our series. Table I shows the age

TABLE I

Age Incidence among 93 admissions (88 patients):			
0-29 years	2	60-69 years	24

Over 50 years	74 (78.5%)		
" 60 "	59 (63.5%)		
" 70 "	35 (37.7%)		

incidence among our patients. It will be seen that the great majority were middle-aged or elderly. This is in contrast to many other published accounts in which acute gastro-duodenal haemorrhage appeared to be most common among the younger age groups. As has been found by others, men were more commonly affected than women, although their preponderance was unusually heavy in our material.

Diagnosis

The diagnoses made in our 88 patients were as follows: gastric ulcer, 29 (male 25, female 4); duodenal ulcer, 26 (male 19, female 7); stomal ulcer, 2; probably peptic ulcer, 4; ulcer not visualized, 20; hiatus hernia, 2; gastritis, 3; carcinoma of stomach, 2. A definite diagnosis is indicated only when it was proved radiographically, at gastroscopy, operation, or necropsy. The group of four patients classed as cases of "probable peptic ulcer" had ulcers proved on previous occasions, but no ulcer was found during the current admission. Patients listed under the heading "ulcer not visualized" had strong histories pointing to peptic ulceration, but no actual lesion could be demonstrated. The policy at our hospital has so far been to wait at least one week after presumptive cessation of the haemorrhage before undertaking radiological or gastroscopic studies. Inevitably some of the more acute ulcers must have healed in the intervening period and their visualization thus became

impossible. A few emergency radiological examinations were carried out immediately before operation. In two cases no lesions were found at operation, but after gastrectomy bleeding ceased. It is probable that in at least one of these a high gastric ulcer was left behind.

Results

Table II shows the reduction in the red-cell mass found in those patients who had not been transfused at the time when their blood volume was first estimated, and in another six

who had recurrent haemorrhages after their first transfusion. Following the suggestion of Bennett *et al.*, we have arranged these individuals into three groups according to the magnitude of the blood loss. The "mild" group, with a reduction of up to 19% in their V_C , comprised 6% of the total; the "moderate" group, with a reduction of 20 to 49% in the V_C , 36%; and the "severe" group 58%. The last-named group lost more than 50% of their V_C . If a reduction in the V_C of 40% or more had been taken as implying "severe" or "massive" haemorrhage, as was done by Stewart *et al.* (1950), 78% of our patients would have fallen into this class.

The quantity of blood given is indicated in Table III. It will be seen that only about 25% had small transfusions of up to 4 pints (2.3 litres), while over 20% had more than

Average: 7.9 pints (4.49 l.)			

10 pints (5.7 litres) each. The average, 7.9 pints (4.49 litres) per patient, is among the highest reported. It equals that used by Stewart *et al.* in their patients undergoing emergency surgical treatment.

In the great majority of our patients the initial treatment was solely by medical means (Table IV). Only 14% had

emergency surgical operations. "Interval" gastrectomies were carried out in another 17 patients (18%) after cessation of the bleeding. One-third of all individuals therefore underwent operations either during or after the haemorrhage.

Among 93 admissions there were seven deaths, making a mortality rate of 7.5% (Table V). One further patient died from a cerebral haemorrhage ten days after cessation of

TABLE V.—Mortality

	Survivals	Deaths	Mortality
Medical treatment	75	5	6.6%
Surgical treatment	11	2	15.4%
Total	86	7	7.5%

a bout of melaena. As he had advanced arterial disease with hypertension and a history of a previous cerebral accident, we believe that his death was coincidental with the condition for which he was admitted and that he should not be

included in our list of deaths from the effect of acute gastro-duodenal haemorrhage. With medical treatment alone the mortality was 6.6%, while among the 13 patients treated surgically two died (15.4%). If the patient treated by cauterization of the bleeding vessel who succumbed to a recurrent haemorrhage is omitted from the "surgical" group, the mortality among the 12 patients treated by emergency partial gastrectomy was 8.3%.

Particulars of the fatal cases are given in Table VI. Their average age was 65.4 years and did not differ significantly from that for the whole series. Several of them had serious

TABLE VI.—Particulars of Fatal Cases

Age	Sex	Diagnosis	Operation	Complications	Cause of Death	Death avoidable

62	M	Gastric ulcer	—	Perforation of gastric ulcer	Shock and haemorrhage	?

complicating diseases and were obviously poor surgical risks. Nevertheless we feel that at least three might have been saved by more rapid transfusion followed by operation. Only one patient, a 45-year-old Maori woman with gross abdominal and general tuberculosis in addition to an enormous gastric ulcer, appears in retrospect to have been doomed, whatever the treatment.

The following three cases are quoted to illustrate some of the details of our methods of diagnosing and treating acute gastro-duodenal haemorrhage.

Case 77

A man aged 37 was admitted eight hours after having vomited a small quantity of brownish fluid; he felt faint. He had had a similar episode nine years previously, when a diagnosis of duodenal ulcer was made. On examination he was a rather pale young man but not in distress. His pulse rate was 100; blood pressure 170/110; haemoglobin, 14 g. per 100 ml. Within two hours of admission the blood volume was found to be: V_B 62% of normal, V_P 68%, V_C 55%, indicating a deficit of 6 to 7 pints (3.4 to 4 litres) of blood (see Fig. 1). As this was an early case in the series

FIG. 1.—Case 77; blood-volume estimations.

and the patient's condition seemed to be good, no action was taken at this stage, but the blood volume estimation was repeated three days later. During this time there had been no further vomiting, the bowels had not moved, and the patient felt moderately well. The haemoglobin had fallen to 8.5 g. per 100 ml. The second estimation showed V_B 60%, V_P 84%, and V_C 33%, suggesting a further loss of about 3 pints (1.7 litres) of blood, with partial restoration of the plasma volume. Transfusion was now started, a total of 7 pints (4 litres) of whole blood being given. Further estimations demonstrated that the gain in V_C equalled the quantity of red cells administered, and this was evidence that bleeding had ceased. Large stools containing altered blood were passed from the fifth day onward. Radiography later demonstrated considerable deformity of the duodenal cap. The patient also suffered from advanced essential hypertension.

Comment.—This case history demonstrates an instance of an almost silent haemorrhage from a duodenal ulcer. On admission the patient's condition was good and his haemoglobin level normal. Yet a blood-volume estimation revealed a very considerable red-cell deficit. It was later possible to show by the same means first a further haemorrhage and then its arrest, all before there had been any overt signs of bleeding. When melaena occurred it was proved not to indicate renewed bleeding.

Case 53

A man aged 67 was admitted four days after a fainting spell. There was no vomiting or melaena. He had had abdominal pain for two and a half years. During a recent cholecystectomy for the relief of this pain a mass was discovered on the posterior surface of the stomach and interpreted as a probable penetrating gastric ulcer. Soon after admission the patient passed a large melaena and collapsed. His blood pressure was 90/55; haemoglobin, 8 g. per 100 ml. Blood-volume estimation showed V_B 73% of normal, V_P 98%, V_C 42% (Fig. 2), indicating a total deficit of about 6 pints (3.4 litres) of blood. A transfusion was started, with improvement of his condition. A second blood-volume estimation 36 hours later showed V_B 97%, V_P 105%, V_C 80%, and no significant difference between the quantity of blood administered and retained. It was concluded that bleeding had then been arrested.

FIG. 2.—Case 53; blood-volume estimations.

Twenty-four hours later the patient collapsed again and passed another stool containing much blood. Blood-volume estimation showed V_B 53%, V_P 64%, V_C 40%. Emergency operation was decided upon, and was carried out after the transfusion of 6 pints (3.4 litres) of blood in three hours. At operation the splenic artery was found eroded by a large gastric ulcer adherent to the pancreas. The artery was tied and subtotal gastrectomy with splenectomy was performed, the ulcer being oversewn. The patient recovered. A total of 23 pints (13 litres) of blood had been given.

Comment.—The interest of this case lies in the use of blood-volume estimations to show a temporary arrest of bleeding and also the extent of both the primary and the recurrent haemorrhage. The blood volume was initially almost completely replaced by means of transfusion, and we believe that this enabled the patient to withstand the effects of the grave recurrent haemorrhage and to be prepared for a major emergency operation, which was successful.

Case 39

A man aged 47 was admitted with a history of severe upper abdominal pain for the past four days, black stools for two days, and vomiting of bright blood shortly before

FIG. 3.—Case 39; blood-volume estimations.

arrival in the ward. He had had indigestion for seven to eight years, and asthma for the same period. He was shocked, sweating, and orthopnoeic. His blood pressure was 78/50. His chest was emphysematous, and there were marked movements of the accessory respiratory muscles. Blood-volume estimation showed V_B 65% of normal, V_P 70%, V_C 58% (Fig. 3), with an estimated deficit of 3½ pints (2 litres) of blood. Overnight he was given 3 pints (1.7 litres) of blood with clinical improvement, but a second blood-volume estimation, which showed V_B 71%, V_P 89%, V_C 49%, suggested a further loss of about 4 pints (2.3 litres) of blood when the transfused blood was taken into account. Further transfusions were given, his condition remaining poor mainly because of severe asthma. The next day there was great improvement and the blood volume was substantially normal. It was concluded that bleeding had now ceased, and the patient continued to make progress. Daily haemoglobin estimations showed a steady level, but six days later it was noted that it had dropped by 6 g. per 100 ml. in 24 hours. The patient looked a little pale, but his clinical condition was excellent and there had been no overt bleeding. An emergency operation was now carried out following the rapid transfusion of 4 pints (2.3 litres) of blood. Two large gastric ulcers were discovered—one with a large actively bleeding artery in its floor. After a partial gastrectomy the patient recovered. A total of 15 pints (8.5 litres) of blood had been given.

Comment.—This patient, in addition to bleeding from gastric ulcers, was suffering from severe chronic asthma and emphysema, and his condition during the first two days was extremely poor and probably precluded surgery. By means of repeated blood-volume estimations it was possible to show arrest of the bleeding within 48 hours of admission. Adequate blood transfusion restored his blood volume to normal and so improved his clinical condition that gastrectomy could be safely undertaken a week later, when haemorrhage recurred.

Discussion

The scheme of treatment here described was introduced in an effort to improve our results, which we had judged to be unsatisfactory. There were two fundamental considerations which led us to its adoption:

(1) It appeared improbable that we should be able to gauge the extent and duration of bleeding by the means usually employed—namely, an analysis of the clinical features plus estimations of the haemoglobin content of the peripheral blood. We therefore tested the possibility of using blood-volume estimations.

(2) We regarded prompt replacement of the lost blood as the single most important measure in conservative treatment, and also as an indispensable preliminary to surgery. The usually quoted indications for transfusion did not appear precise enough; it seemed logical, once the extent of the blood loss had been determined, to replace it as completely as possible and thereby to give the patient an optimum chance of healing his ulcer and of withstanding further bleeding, should that occur.

Below we examine the validity of these two considerations in the light of our findings.

The results of the initial blood-volume estimations are shown in Fig. 4, where the V_C on the abscissa is charted against the initial haemoglobin concentration. Only those

FIG. 4.—Results of initial blood-volume estimations.

patients who had not been previously transfused are included. It will be seen that, as might be expected, there is a general positive correlation between the two levels; however, more significantly, there are numerous striking exceptions in which a high initial haemoglobin concentration is paired with a low V_C . The findings reproduced in Fig. 4 are summarized in Table VII. In column 4 of this we also give the amount of blood calculated to be necessary to raise the initial V_C to normal in all patients in the various groups of severity. For instance, among the seven patients with initial haemoglobin concentrations of 4 to 5.9 g. per 100 ml. the initial V_C was 23 to 44% of normal, and 7 to 11 bottles of blood would have been required in individual cases to bring the V_C to the calculated normal. Again there is a general correlation between the initial haemoglobin level and the average amount of blood required. But the departures from the average become more and more marked as the initial haemo-

TABLE VII.—Correlation Between Initial Haemoglobin Level and Red-cell Mass (63 Admissions Previously Untreated)

Initial Hb (g. per 100 ml.)	No. of Patients in each Group	Initial red-cell Mass (% of Normal)	No. of Bottles of Blood required to raise Red-cell Mass to 100%
2-4	1	17	7-11
4-5.9	7	23-44	6-10
6-7.9	15	25-61	2-8
8-9.9	16	31-88	1-5.9
10-11.9	14	30-87	2.5-9.5
12+	10	43-81	

globin level rises. Thus among the 10 patients with levels exceeding 12 g. per 100 ml. the initial V_C varied from 43 to 81% of normal and the quantity of blood required to raise it to normal from 2.5 to 9.5 bottles.

We believe that these figures show vividly the difficulty of gauging the severity of bleeding from haemoglobin estimations. Whereas the lower levels generally give a good indication, the higher ones often do not: the reason is that the high haemoglobin levels tend to be found soon after an acute haemorrhage and before there has been time for haemodilution to occur. At that time there is no possibility of knowing the eventual haemoglobin level or how soon it will be reached. Consequently it is impossible to estimate the quantity of blood which it will be necessary to give.

The problem of establishing continuance or cessation of bleeding in some cases is too well known to need elaboration; yet on its solution depends the treatment to be given. By means of repeated blood-volume estimations we have often been able to come to a definite decision, and to distinguish between the two causes of a falling haemoglobin level—haemodilution and continued bleeding. In this connexion the limits of accuracy of our method must be taken into account: before it was possible to diagnose further loss of blood the difference in successive estimations must exceed the experimental error. We have taken deficits in excess of 200 ml. of red cells as positive evidence of bleeding. There have been only a few cases in which interpretation of the findings was doubtful.

The indications and purpose of blood transfusion in acute gastro-duodenal haemorrhage vary with the views of different authors writing on the subject: "the presence of sweating or restlessness; anaemic pallor, as shown in the palms of the hands and in the conjunctivae; or a haemoglobin level of 60% or under are our indications for immediate transfusion" (Ogilvie *et al.*, 1952); "the object [of transfusion] was to make the patient fit enough to stand a possible recurrence of haemorrhage or an emergency operation" (Ferguson and Wyman, 1951); "give [blood] at an estimated hydrated 3,000,000 [R.B.C. per c.mm.] and stop at 4,000,000" (Rosssett and Stephenson, 1952); "transfusion in every case" (Alsbrook *et al.*, 1952); "early transfusion with the aim of raising the red-cell count to 3,500,000 per c.mm." (Gott *et al.*, 1952). These few excerpts from recent papers show the wide divergence of opinion which still exists. In most of the older publications transfusion was the exception rather than the rule.

We regard transfusions as being of prophylactic as well as of immediate therapeutic value. When symptoms and signs of shock are present transfusion is obviously a matter of urgency; but people may lose large amounts of blood without accompanying shock, and the fallacy of judging the size of the loss from haemoglobin estimations has already been pointed out. Such patients may readily develop severe shock if further bleeding takes place, and their resuscitation at that stage may be a problem of the greatest difficulty, while emergency surgery may then be impossible. Moreover, a mild or moderate haemorrhage may progress to a severe one. Further, it is well recognized that the presence of anaemia impairs the action of organs like the heart, liver, and kidneys, and probably also the chances of healing at the ulcer site. It is likely that patients over 50 are progressively less tolerant of anaemia, and that this accounts for the rising mortality in the older age groups. Nearly 80% of

our patients were over 50. These arguments have persuaded us to transfuse every case of acute gastro-duodenal haemorrhage and to attempt to replace completely all the red cells which have been lost.

Many observers have in the past stated their fear lest transfusion may cause renewed bleeding once it has been arrested. Like other recent authors, we have found no evidence of this happening in our patients. It is probably of some importance to give the blood slowly so as to increase the blood volume and raise the blood pressure gradually, but this should not preclude rapid administration where there are signs of shock or the patient has to be prepared for emergency surgery. It is likely that prolonged hypotension contributes significantly to the fatal outcome in some cases, and slow transfusion may not be adequate to raise a dangerously low blood pressure to a safe level.

The transfusions given by us were generally large and often massive. The danger of overtransfusion has been widely discussed, and in our patients we have watched carefully for any signs which might have indicated it. It is gratifying that with one exception these have been completely absent. The exception was a man of 84 who died several days after arrest of bleeding from a chronic duodenal ulcer and after transfusion of 7 pints (4 litres) of whole blood. At necropsy moderate pulmonary oedema was present; possibly this was partly caused by the transfusion and might have been avoided if packed red cells had been given instead of whole blood. This patient was, however, extremely senile, and death did not occur during or soon after transfusion; nor were any signs of respiratory distress noted at any stage. For these reasons the significance of the transfusion causing death was doubtful. This fatality occurred early in our series, and since then we have often given packed red cells instead of whole blood, especially when the history of bleeding extended over several days and when the plasma volume was in the vicinity of normal. It should also be mentioned that severe haemorrhage in elderly patients sometimes causes signs of acute coronary insufficiency with or without congestive heart failure, and that in this series there were several instances—at least three with actual myocardial infarction. All of these were greatly benefited by adequate transfusions, and the signs of failure disappeared as a result.

Downie's (1952) suggestion that administration of large quantities of stored blood might interfere with wound-healing if surgery became necessary has not been borne out by our experience. It is improbable that the requirements of these patients could be met entirely from fresh as opposed to stored blood, however adequate the resources of the transfusion service.

It is not our purpose to discuss the still controversial question of the place of emergency operations in the treatment of acute gastro-duodenal haemorrhage. With the indications previously quoted such operations were performed in 14% of our patients. Mainly through lack of sufficiently vigorous resuscitation, it was impossible to make fit for surgery several other patients who might have profited from it and who died in its absence. We believe that 15 to 20% of the members of a series composed like ours will probably need to be operated on in the acute stage. Our mortality rate of 8.3% in 12 partial gastrectomies—several of which were performed on patients with serious complicating diseases—seems encouraging, and to bear out the statement made by Amendola (1952) that emergency subtotal gastrectomy if performed early may be done without significantly greater risk than the elective procedure. We are prepared to believe that our total mortality rate could have been lowered if we had followed the policy of Stewart *et al.* (1950), who perform emergency gastrectomy on all patients who have had a blood loss in excess of 40% of their V_C . This would have involved operations on nearly 80% of our patients, or about 75 emergency gastrectomies in one year. Emergency surgery on this scale would appear to demand very special facilities, which unfortunately do not at present exist at our hospital.

Comparison with a Control Series

We mentioned above the difficulty of comparing the results yielded by different methods of treatment of acute gastro-duodenal haemorrhage. Nevertheless some standard of comparison is necessary in order to assess the success of any therapeutic regime. For this reason we have analysed a second unselected series of 93 patients with acute gastro-duodenal haemorrhage who were treated at Christchurch Hospital during the eighteen months immediately preceding the introduction of the new regime.

This control series consisted of 68 men and 25 women, with an average age of 59 years; 71% were over 50 and 47% over 60 years. This series was therefore slightly younger than the experimental series. In 86 patients (92.5%) treatment was medical and in 7 (7.5%) by means of emergency surgery. The amount of blood given to these patients varied from 0 to 21 pints (11.9 litres), with an average of 2½ pints (1.4 litres). Half the patients received no transfusions. The distribution of diagnoses was very nearly the same in both series. The mortality rate among the controls was 17.2% (16 cases), with an average age of 64 years. One of the deaths followed emergency surgery.

The experimental and the control series appear comparable as regards age and sex distribution and diagnosis. It is difficult to compare the severity of bleeding as no blood-volume estimations were done on the controls. From a scrutiny of the clinical records it appears, however, that no gross difference existed, and such differences were not in any case likely to be important in what amounts to the two halves of one continuous list of 186 admissions. The two series differ, however, greatly in the quantity of blood which was given to individual patients. Whereas an average of 7.9 pints (4.5 litres) was transfused in the experimental series, the controls received only 2½ pints (1.4 litres), and 50%, among them three fatal cases, were not transfused at all. Five other fatal cases received fewer than 4 pints (2.3 litres) each. The percentage of emergency operations performed on the controls was about half that in the experimental series. We believe that these differences in treatment were probably largely responsible for the reduced mortality rate in the experimental series (7.5% as against 17.2%). This reduction of over 50% in the total mortality is statistically significant ($\chi^2=4.02$; $P<0.05>0.02$).

When comparing our results with those reported in the literature we can take into account only those series which resemble ours in age distribution and severity of bleeding. After a careful search we have found only one report which fulfils these conditions. Tanner (1951) includes in his "Period No. 5" a total of 74 patients 55% of whom were aged over 60 and 34% over 70; 18% of these had emergency operations. The total mortality was 13.5%. In Avery Jones's (1947) series of 411 cases the total mortality was 7.8%. The average age was, however, distinctly lower (33% over 60), although at the time of publication this appeared to be the oldest known series. It was interesting that among Avery Jones's patients 12% of those between 60 and 69 and 21% of those aged 70 and over died. The comparable figures for the present experimental series are 8.3% and 8.6% respectively. We may therefore conclude that our results compare favourably with those of other authors who were working with material similar to that encountered by us. It may also be tentatively concluded that increasing age among patients suffering from acute gastro-duodenal haemorrhage does not necessarily lead to a rapidly increasing mortality rate, provided that the criteria of severity and the methods of treatment are equally applied in all age groups. Of these methods the most important would appear to be early adequate blood transfusion together with emergency surgical operation in suitably chosen cases.

Summary

A method of treating patients with acute gastro-duodenal haemorrhage is described. Its most impor-

tant features are early complete replacement of the lost blood in all patients, and emergency surgical operation in selected cases.

Employment of this method led to a halving of the mortality rate at Christchurch Hospital.

The results in a series of 93 admissions compare favourably with those reported in the literature.

We acknowledge with gratitude the help of Mr. J. T. Murray, hospital biochemist, who standardized and supervised the blood-volume estimations and made many important contributions to our work; and of Drs. A. F. Burry and A. V. Kurta, who assisted throughout the course of these investigations. The following surgeons and physicians were in charge of the patients included in the experimental series: M. H. Aiken, L. A. Bennett, W. H. Bremner, P. W. Cotter, W. M. Cotter, J. K. Davidson, H. E. H. Deaham, D. McK. Dickson, M. K. Gray, J. F. Landroth, D. G. Radcliffe, and W. L. F. Utley. Without their help and co-operation this work could not have been undertaken.

ARSENAMIDE TREATMENT OF FILARIASIS DUE TO *W. BANCROFTI* AND *A. PERSTANS*

BY

JAMES A. McFADZEAN, M.B.

AND

F. HAWKING, D.M., M.R.C.P., D.T.M.

Medical Research Council Laboratories, Gambia, British West Africa

Arsenamide is a trivalent arsenical, and has the formula: $(\text{COOHCH}_2)_3\text{As} \begin{array}{c} \diagup \diagdown \\ \diagdown \diagup \end{array} \text{CO.NH}_2$. It was first employed in the treatment of *Wuchereria bancrofti* infections by Thetford *et al.* (1948), when they reported the treatment of six cases. Since then the compound has been used by various other workers as summarized in the discussion below. This paper describes the results obtained in the arsenamide treatment of 37 cases of filariasis in Gambia, British West Africa, and the action of suramin in two trypanosomiasis patients whose blood contained *bancrofti* microfilariae.

Methods.—Four groups of cases were investigated: (1) Two cases of yaws were treated under close observation in the ward as a preliminary test for tolerance. (2) Eleven cases of filariasis were treated in the ward under similar close observation. (3) Twenty-one cases were treated in a village; among these there was one fatality due to acute hepatic necrosis. (4) Five cases were treated in the ward with low doses and special

precautions against toxic effects. For the present work the drug was supplied in 5-ml. ampoules of 2.5% buffered solution.

Group 1. Two Cases of Yaws

Case 1.—A man aged 46 complained of pain all over the body. He weighed 60 kg. He was given one intravenous injection of 5 ml. arsenamide, followed the next day by one injection of 7.5 ml. and then 10 ml. daily for 10 days (2 mg./kg. arsenamide, 3 mg./kg., and then 4 mg./kg.). He vomited after the fifth and sixth injections; occasionally a trace of albumin was found in the urine. During treatment he lost 3 kg. in weight, which he subsequently regained. His previous symptoms cleared up.

Case 2.—A man aged 25 had ulcers on the legs and on an arm. He weighed 66 kg. He was given the same injections as in Case 1 (1.9 mg./kg. arsenamide, 2.8 mg./kg., and then 3.8 mg./kg.). He did not vomit at all, but lost 2 kg. in weight, which was regained; occasionally a faint trace of albumin was found in the urine. The ulcers cleared up rapidly.

These cases suggested that 10 ml. of the solution (approximately 4 mg./kg.) daily would be tolerated. The dose level which was adopted for the trial against *W. bancrofti* was half this—namely, 5 ml. (about 2 mg./kg.) daily for 12 days.

Group 2. Cases of Filariasis Treated in Hospital

Eleven cases were treated in the research ward at Fajara. On admission the patients were examined clinically for any contraindication to treatment; and then two or three days were allowed to elapse so that the microfilaria cycle could settle after the change in habits. At 10 p.m. on the evening before the injections of the drug were to begin, two lots of 20 c.mm. blood were taken from the finger-tip and spread on a slide for enumeration of microfilariae in the usual way. Throughout the trial all the slides were examined and the microfilariae enumerated by one of us (J. A. McF.). All subsequent measured quantities of blood in the cases treated in the ward were taken within a few minutes of 10 p.m. Conditions were further standardized by all the injections being given in most cases within a few minutes of 10 a.m. The urines from these cases were examined daily for albumin, each patient was weighed daily, and a watch was kept for any signs of toxicity of the drug, particularly vomiting.

Results

Table I records the microfilariae counts of the 11 patients treated in the ward. Four to five days after the first injection the total number of *bancrofti* microfilariae had decreased by 22%; at nine days it had decreased by 86%; and at 12 days the total reduction was 98%. Subsequently, only occasional microfilariae were found in the blood of these patients. Finally, when the last blood samples were taken (at six months) all the patients were free from microfilariae except for one who still had two microfilariae per 40 c.mm., and one who still had one microfilaria per 40 c.mm. (at three months).

In eight of the patients *perstans* microfilariae were also present initially; 70–200 days after treatment their total numbers were reduced by 70%, and in four the blood became negative.

Toxic Features

Vomiting.—Three patients vomited occasionally. One other patient (Case 10) vomited a quarter to three hours after each injection; she was receiving the largest dose per kg. of body weight, and treatment was stopped.

Headache (4 cases).—This is difficult to assess, as it is a common complaint among Africans.

Signs of Death of Adult Worms or Allergic Reactions.—Two patients had pyrexia. One other patient developed enlarged tender glands in the axilla and one developed a tender epididymis.

Loss of Weight (1 case).—This was the patient (Case 10) who vomited considerably.

TABLE I.—Treatment of 11 Cases of *Bancroftian Filariasis* (Group 2) in Hospital by Arsenamide, 125 mg. Daily

Case No.	Age	Weight (kg.)	No. of Injections	Bancrofti Microfilariae per 40 c.mm. (<i>M. perstans</i> in parentheses)							
				Start	Day 4-5	9	12	26	40-60	70-100	200-250
